Despite the advent of percutaneous coronary intervention (PCI), CABG remains one of the most commonly performed surgical procedures in the United States. The main indications for CABG are based on high-risk anatomical features and include significant left main disease or its equivalent (i.e., concomitant proximal LAD and proximal left circumflex artery stenosis), multivessel coronary artery disease that involve the proximal LAD, and triple vessel disease (Eagle et al., 2004). Studies have also demonstrated that patients with left ventricular dysfunction, and especially those with significant amount of viable myocardium on noninvasive imaging, may derive greater benefit from surgical revascularization. In these selected patient populations, CABG has been shown to markedly improve survival compared with medical therapy (Yusuf et al., 1994). However, there are also significant risks associated with CABG. Registries maintained by the Society of Thoracic Surgeons have consistently shown operative mortality of 2–3%. In addition, there are other known perioperative complications, including myocardial infarction, stroke, renal failure, bleeding, and wound infections. Various scoring systems have been derived to predict the risk of these perioperative events and to aid in informed decision making for individual patients. The careful consideration of the benefits and risks of surgery is especially important for those patients with a high-risk profile, such as the frail elderly or those with many comorbidities (Eagle et al., 2004).

There has also been ongoing debate on whether a subset of patients with surgical disease may be treated with PCI rather than CABG. For instance, recent registries have suggested that in patients with uncomplicated left main disease, PCI may yield comparable rates of major adverse cardiovascular events as CABG (Seung et al., 2008). The landmark Synergy between PCI with Taxus and Cardiac Surgery (SYNTAX) trial published in 2009 randomized patients with three-vessel or left main coronary artery disease to PCI or CABG and showed that while patients who underwent PCI had higher rate of repeat revascularization, the rates of death and myocardial infarction were similar between the two arms. In particular, for patients with less complicated lesions, the choice of revascularization strategy did not lead to a significant difference in outcomes (Serruys et al., 2009). On the other hand, new surgical techniques such as off-pump CABG or minimally invasive CABG with hybrid PCI may also significantly alter the risk-benefit balance. With these advances, it is likely that the optimal strategy for revascularization will continue to evolve in the coming years and become increasingly individualized.

Definition

Although no standard definition exists, the term coronary event is used in clinical research to refer to adverse events caused by disease processes affecting the coronary arteries. These may include what are termed "hard" events such as deaths that are attributed to coronary artery disease and nonfatal myocardial infarctions, but also occasionally "soft" events such as angina or revascularizations for worsening coronary artery stenosis. Because coronary event is often such a composite of clinical events of varying significance, there remains considerable debate on what should constitute the most appropriate component endpoints and how to define them, with the recognition that these choices may significantly influence the results and impact of clinical trials and other studies (Kip, Hollabaugh, Marroquin, & Williams, 2008). To address this, guidelines such as the 2001 ACC Clinical Data Standards and the 2007 Joint ESC/ACCF/AHA/WHF Task Force for the Redefinition of Myocardial Infarction Expert Consensus Document have been released to standardize the definitions of the most important clinical events such as cardiovascular death and myocardial infarction.

Definition

Coronary heart disease (CHD) is a condition in which the arteries that supply the cardiac muscle,

the coronary arteries, develop reduced luminal size due to the presence of atherosclerosis.

Description

Coronary heart disease (CHD) is a condition in which the arteries that supply the cardiac muscle, the coronary arteries, develop reduced luminal size due to the presence of atherosclerosis (Antman, Selwyn, Braunwald, & Loscalzo, 2008). Atherosclerosis is a progressive condition that starts as fatty streaks and may result in plaque development and ultimately in flow-limiting narrowing or occlusion of coronary arteries. The clinical manifestations of CHD include conditions such as angina, myocardial infarction, and heart failure. Angina, or chest discomfort, develops due to an imbalance between myocardial oxygen demand and the available blood supply. In myocardial infarction, plaque rupture and clot formation at the site of rupture result in occlusion of the artery and loss of blood flow to the heart muscle.

CHD is the major cause of one-third of all deaths in individuals older than 35, and one-half of all middle-aged men and one-third of middle-aged women in the United States will develop CHD (Lloyd-Jones, Larson, Beiser, & Levy, 1999). The Framingham Heart Study, a prospective cohort study of 5,209 individuals that began in 1948 and has continued to collect information and add participants, has defined many of the risk factors for atherosclerotic disease through epidemiologic techniques. Risk factors for coronary heart disease include other medical conditions such as hypertension, diabetes mellitus, and dyslipidemia, as well as behavioral factors such as cigarette smoking (Lloyd-Jones et al., 2010).

Atherosclerotic plaques associated with myocardial infarction are known to have certain features that increase the propensity to develop rupture and clot (Antman et al., 2008). Postmortem studies from cases of sudden death associated with CHD have revealed plaques with thin fibrous caps, relatively large lipid cores, and a high content of a particular type of inflammatory cell, macrophages. It is thought that rupture or erosion of the thin fibrous cap results in activation of the clotting cascade and development of occlusive clot.

Treatment of individuals with coronary heart disease involves primary or secondary prevention of myocardial infarction and heart failure (Antman et al., 2008). Medications such as aspirin and clopidogrel prevent clot formation, beta blockers reduce myocardial workload, and statin medications reduce cholesterol and stabilize coronary plaques. Angiotensin-converting enzyme (ACE) inhibitors reduce blood pressure and resistance in the small arteries and have been shown to prevent cardiac events particularly in patients who have developed left ventricular dysfunction.

Nonpharmacologic treatment of CHD includes percutaneous coronary intervention (PCI), a procedure that involves dilatation of the coronary artery lumen with a balloon and usually followed by implant of a coronary stent (Antman et al., 2008). PCI has been shown to reduce cardiac events in patients who present with myocardial infarction or angina at rest. In some patients with severe CHD involving all three main coronary vessels, particularly in the setting of diabetes or reduced ventricular function, coronary artery bypass graft surgery is a better treatment option.

In terms of behavioral interventions for prevention of CHD, regular aerobic exercise has been associated with improvement in multiple coronary artery disease risk factors, including blood pressure, serum cholesterol, glucose intolerance, and body mass index (Thompson et al., 2007). In addition, healthy dietary patterns have been associated with improved cardiac mortality, as well as lower blood pressure and serum cholesterol (Appel et al. 1997, 2005; Knoops et al., 2004). The 2006 dietary guidelines of the American Heart Association have emphasized maintaining a healthy dietary pattern over a focus on specific nutrients (Lichtenstein et al., 2006). Generally, the recommendations encourage consumption of a variety of fruits, vegetables, and grain products; fat-free dairy products; legumes; poultry; lean meats; and fish, preferably oily fish, at least twice a week. A meta-analysis of 38 randomized controlled trials conducted by the Cochrane Collaboration found that dietary advice reduced low-density lipoprotein cholesterol and blood pressure (Brunner,

Rees, Ward, Burke, & Thorogood, 2007). However, the largest randomized trial to date of a dietary intervention to reduce cardiovascular risk, the Women's Health Initiative Dietary Modification Trial, found no effect on cardiovascular events of group and individual sessions to reduce total fat intake and increase intake of vegetables, fruits, and grains, among 48,835 postmenopausal women (Howard et al., 2006).

A substantial literature has developed documenting the link between psychosocial factors and coronary heart disease, including depression, anger, and anxiety (Albus, 2010). A meta-analysis of 11 prospective cohort studies of healthy individuals estimated a relative risk of 1.64 for adverse cardiac events, including myocardial infarction (MI) and cardiac death, associated with depression (Rugulies, 2002).

Coronary Vasoconstriction

Leah Rosenberg
Department of Medicine, School of Medicine, Duke University, Durham, NC, USA

Definition

Coronary vasoconstriction is the process by which vessels of the heart reduce their overall diameter. This functional capacity is mediated

by a variety of intrinsic and extrinsic stimuli, and may be pathologic and life-threatening.

Description

There are a variety of means by which the arterial and venous flow of the heart are affected by the overall circulating volume in the body. One crucial effector is the sympathetic nervous system, upregulated or suppressed in different situations. The sympathetic nervous system involves the secretion of the hormones epinephrine and norepinephrine from the adrenal medulla. Other important endogenous mediators include endothelin-1, serotonin, thromboxane, and prostaglandins (Rose & Post, 2010).

Coronary Vasoconstriction in Acute Coronary Syndromes and Variant (Prinzmetal's) Angina

Acute coronary syndromes, a term encompassing unstable angina and myocardial infarction, are brought about by a variety of pathophysiological changes that include coronary vasoconstriction. Myocardial infarctions are clinical sequelae of plaque disruption and clot formation over the plaque. Other elements involve platelet activation, dysregulation of the coagulation system, imbalance of myocardial oxygen demand, and finally plaque rupture resulting in vessel occlusion and cell death (Gelfland, Gelfland, & Cannon, 2009). Coronary vasoconstriction, induced by local and circulating levels of vasoconstrictors, also contributes to ischemia or infarction.

Prinzmetal's angina is another clinical syndrome that involves coronary vasoconstriction without plaque disruption. Also referred to as variant angina, Prinzmetal's angina is primarily caused by vasospasm without plaque disruption and thrombus formation. While many Prinzmetal's patients also have atherosclerotic lesions, the clinical presentation and electrocardiogram changes are caused by functional narrowing from coronary vasoconstriction.

Coronary vasoconstriction is the central mechanism of myocardial infarction caused by cocaine. As an analogue of sympathetic outflow, cocaine that is smoked, injected, or inhaled may cause of type of transient vascular obstruction that can lead to myocardial infarction and result in death of the myocardium.

Corticotropin-Releasing Hormone (CRH)

Jennifer Heaney

Definition

Corticotropin-releasing hormone (CRH) or corticotropin-releasing factor is a hormone that is secreted by the hypothalamus. It is one of the

hypophysiotropic hormones, a group of hormones produced by the hypothalamus that affect the anterior pituitary gland; CRH stimulates the secretion of adrenocorticotropic hormone (ACTH) from the anterior pituitary. CRH plays a key role in the endocrine response to stress as it is involved in one of the initial stages of activation of the hypothalamic-pituitary-adrenal axis (HPA axis) (Martin, Reichlin, & Brown, 1977).

CRH is not only produced in response to stress but exhibits a circadian rhythm of secretion across a 24-h period as a result of input from the central nervous system (Martin et al., 1977). Consequently, hormones that are produced in response to CRH, ACTH and cortisol, also demonstrate a circadian pattern of secretion (Greenspan & Forsham, 1983).

Cortisol

Tobias Stalder and Clemens Kirschbaum
Chair of Biopsychology, Technische Universität Dresden, Dresden, Saxony, Germany

Definition

Cortisol (or "hydrocortisone") is a steroid hormone which is essential for life. It is produced in the adrenal cortex and is predominantly regulated by the neuroendocrine hypothalamus-pituitary-adrenal (HPA) axis. Cortisol fulfills vital functions in the regulation of various homeostatic processes and is particularly well known for its role in the body's response to physical and psychological stress. These characteristics combined with its high potency and multitude of physiological effects make cortisol a hormone of prime interest for research in the area of behavioral medicine.

Description

Biosynthesis and Basic Characteristics

Cortisol is mainly synthesized and secreted from the *zona fasciculata* of the adrenal cortex. In addition, it is also produced in smaller amounts in other tissues, including hair follicle cells, the placenta, and the brain (Ito et al., 2005). The main precursor for the production of cortisol is cholesterol from which it is derived via two alternative paths involving several intermediate metabolic steps. As most other hormones, cortisol is secreted in a pulsatile fashion with marked circadian rhythmicity and a mean production ranging from 8 to 25 mg/24 h (mean production: ~13 mg/24 h). Due to its relatively small size (molecular weight: 362.5 Da) and its lipophilic nature, cortisol is able to freely diffuse in and out of target cells.

Cortisol in Blood

Following its synthesis in the adrenal cortex, cortisol is secreted into the blood stream where most of it binds to transport proteins. Approximately 70% of cortisol molecules are bound to cortisol-binding globulin (CBG or transcortin) via high-affinity receptors. A further 15–20% of cortisol is bound to lower-affinity receptors of albumin while an additional 5% is also bound to erythrocytes. Hence, only about 5–10% of cortisol circulates as an unbound or "free" hormone in the blood. Following the free hormone hypothesis (Mendel, 1989), only this unbound fraction of cortisol can enter target cells and is thus biologically active while the larger part of bound cortisol serves as an inactive reservoir. It is assumed that mechanisms influencing the level of circulating transport proteins play an important role in regulating the functional potency of the cortisol signal. Estimates of the biological half-life ($T_{1/2}$)

of unbound cortisol in blood range from 60 to 115 min. The bioavailability of cortisol is thus relatively long compared to other hormones, such as epinephrine or β-endorphin, which show a $T_{1/2}$ in the range of seconds to a few minutes.

Physiological Actions

Mechanisms of Signal Transduction

Cortisol binds to two main types of receptors, the mineralocorticoid (MR) and glucocorticoid receptors (GR). The two receptor types differ with regard to their affinity for cortisol with MRs showing a 6–10 times higher affinity than GRs. As a result, about 90% of MRs are occupied throughout the day, while higher GR occupancy is only reached at times of peak cortisol secretion or during stress responses. Besides their affinity for cortisol, MRs and GRs also differ in terms of their distribution pattern with cortisol-responsive MRs being predominantly located in the kidneys and limbic structures of the brain, while GRs are expressed widely throughout the brain as well as in peripheral tissues (De Kloet, Joëls, & Holsboer, 2005).

The "classical" mechanism of cortisol action comprises its genomic effects. Unbound cortisol is able to freely diffuse into the cells of the body where it binds to high-affinity receptors in the cytoplasm. While unoccupied receptors are guarded by heat-shock-proteins (HSP), cortisol binding releases the HSP which enables the cortisol-receptor complex to enter the cell nucleus. Here it binds to specific sites of the deoxyribonucleic acid (DNA) and acts as a transcription factor to alter the cell's protein biosynthesis. Subsequently, the cortisol-receptor complex is transported back into the cytoplasm. Here it disintegrates and the cortisol molecule, which may have been structurally altered, exits the cell into the extracellular space.

While the time course of genomic effects of cortisol is relatively slow ranging from several minutes to hours, cortisol also affects cell function via faster non-genomic mechanisms. These mechanisms influence a wide range of intracellular processes and are of importance across many peripheral as well as central structures. Targets of non-genomic cortisol action might include lipids and proteins in the cell membrane and cytoplasm as well as membrane MR and GR.

Tissue effects of cortisol are markedly influenced by enzymatic action within target cells. Here, two variants of the enzyme 11β-hydroxysteroid dehydrogenase (11β-HSD) are of particular importance. 11β-HSD type 1, which predominates in adipose and hepatic tissues, converts inactive cortisone to active cortisol and thus has an amplifying effect on local cortisol action. On the other hand, 11β-HSD type 2 is primarily found in the kidneys and placenta where it converts cortisol to its inactive metabolite cortisone.

Effects of Cortisol

Cortisol has a wide range of effects on target tissues throughout the body. Indeed, cortisol is so essential that humans cannot survive removal of the adrenal glands unless glucocorticoid replacement is provided. The effects of cortisol are often permissive rather than direct, which means that it frequently does not initiate an action but provides an environment for the action to take place. Importantly, while being adaptive at normal concentrations of cortisol, many of its actions can have deleterious effects at aberrant concentrations. Both excessive levels and underproduction of cortisol have been implicated in the etiology of various diseases (Chrousos, 2009).

Effects on Carbohydrate and Lipid Metabolism

Cortisol is the primary glucocorticoid in humans, which hints to the fact that one of its pivotal functions lies in facilitating the mobilization of energy resources. It enhances gluconeogenesis in the liver and reduces glucose uptake into muscle and adipose tissue, which increases the amount of glucose available for the body. Cortisol also crucially augments the conversion of protein to glycogen and thus helps to maintain hepatic glycogen stores on which other hormones, like glucagon, can subsequently act to increase glucose levels. Cortisol also increases the breakdown of proteins stored in muscle, bone, and connective tissue and inhibits protein synthesis in non-hepatic tissues which increases the

amount of protein available for gluconeogenesis. Importantly, while this catabolic action is physiologically beneficial at adequate concentrations of cortisol, at excessive levels, it results in the depletion of protein stores which can manifest in symptoms such as thinning of the skin, reduced muscle mass, or osteoporosis.

Besides aiding proteolysis, cortisol is also assumed to facilitate the mobilization of free fatty acids from fat depots which further supports gluconeogenesis. However, cortisol may also have stimulatory effects on appetite and calorie intake and leads to enhanced fat deposition in abdominal and facial areas. Under conditions of chronically elevated cortisol secretion, e.g., in Cushing's syndrome, this leads to a characteristic pattern of central adiposity, as well as fat depositions in the face ("moon face") and at the neck ("buffalo hump").

Effects on Electrolyte Metabolism

The effects of cortisol on sodium and water retention are considerably weaker than those of aldosterone, the primary mineralocorticoid hormone in humans. However, this lack in potency is outweighed by the approximately 200-fold higher concentrations of cortisol compared to aldosterone which indicates that cortisol also plays an important role electrolyte metabolism.

Immunological Effects

Cortisol is the most potent endogenous immunosuppressive substance with strong anti-inflammatory effects. Virtually all steps involved in the local inflammatory response to injury, e.g., dilation of capillaries or tissue swelling, are inhibited by cortisol. It also decreases leukocyte recruitment and effectiveness at the site of inflammation. These effects of cortisol have long been recognized and used in anti-inflammatory drug treatments. Cortisol also profoundly suppresses the immune response to antigens, e.g., by reducing the number and activity of thymus-derived lymphocytes (T-cells). In addition, cortisol inhibits other components of the immune response such as cytokine synthesis, proliferation and differentiation of monocytes as well as activity of macrophages and natural killer cell.

Effects on Brain and Cognition

Cortisol is able to enter the brain where it affects a wide range of neuronal processes and cognitive functions. Cortisol exerts these actions both via the slower genomic pathways as well as via fast non-genomic effects which directly affect the responsivity of neuronal networks. Via these pathways, cortisol interacts with the neurotransmitter systems (including noradrenergic, serotonergic, dopaminergic and cholinergic, and GABAergic neurotransmission) as well as with neuropeptidergic systems, e.g., oxytocin and arginine vasopressin.

One of the best described effects of cortisol on cognitive functions is an enhancing influence on the encoding and consolidation of emotionally relevant information under arousing conditions (de Quervain et al., 2009). However, while cortisol may enhance memory consolidation, acutely elevated cortisol levels are also associated with impaired memory retrieval, particularly of declarative memory, as well as with compromised working memory function. Despite the involvement of other brain regions (e.g., hippocampus and medial prefrontal cortex), close reciprocal interactions between cortisol and noradrenergic neurotransmission in the basolateral nucleus of the amygdala are assumed to be of particular importance for the modulation of these effects on memory. Besides effects on memory, a stimulatory influence of cortisol on psychological arousal has also been reported. Similarly, cortisol can lead to increased amplitude and decreased latency of EEG event-related potentials and heightened EEG frequency.

In addition to these actions under normal functioning, pharmacological administration of high doses of glucocorticoids has been associated with profound psychoactive effects (Lupien, Maheu, Tu, Fiocco, & Schramek, 2007). These include the experience of psychiatric symptoms, such as depression, mania, and psychotic episodes, often collectively referred to as "steroid psychosis." Interestingly, during the initial phase of treatment, elevations of mood and euphoria are often seen while dysphoric mood states and depression predominate with prolonged treatment. This is in line with the fact that Cushing's syndrome,

i.e., chronic endogenous hypercortisolemia, is also frequently associated with depression and/or other psychiatric symptoms which usually subside with successful treatment. Importantly, chronic exposure to excessive amounts of cortisol has also been associated with hippocampal atrophy and cell death as well as with deficits in hippocampus-dependent cognitive functioning. This effect might play a particular role with regard to the cognitive decline often seen with older age.

Regulation

Overview

The synthesis and secretion of cortisol from the adrenal cortex is predominantly controlled by the neuroendocrine HPA axis, a signaling cascade involving the release of corticotropin-releasing hormone (CRH) and adrenocorticotropin hormone (ACTH) as well as numerous other substances, specifically neuropeptides. Both the activity of the HPA axis as well as the secretion of cortisol occur in a pulsatile fashion with approximately 12–18 ultradian pulses per 24-h span. The concentration of circulating cortisol is determined by the frequency and amplitude of individual pulses. The release of cortisol via the HPA axis is under tight negative feedback control, with cortisol inhibiting its own secretion by downregulating levels of CRH and ACTH.

Besides regulation via the HPA axis, there is also considerable evidence that levels of ACTH and cortisol can dissociate under various conditions, suggesting additional extra-pituitary regulatory mechanisms. Here, sympathetic innervations of the adrenal gland via the splanchnic nerve are likely to be of special importance. This pathway is assumed to particularly modulate cortisol secretion by altering adrenal sensitivity to ACTH and is likely to involve both intra-adrenal paracrine interactions as well as direct splanchnic innervation of the adrenal cortex (Bornstein, Engeland, Ehrhart-Bornstein, & Herman, 2008).

Basal Secretion

The secretion of cortisol is subject to considerable circadian variation: Following a circadian nadir during the early night, cortisol levels show a strong increase during the second half of sleep. Upon morning awakening, an additional rise in cortisol levels for approximately 30–40 min post-awakening is seen (the "cortisol awakening response," CAR; Fries, Dettenborn, & Kirschbaum, 2009) which results in circadian peak levels being reached. Subsequently, cortisol levels show a gradual decline over the remainder of the day until they again reach nadir levels during the first half of sleep.

Response to Physiological and Psychological Stress

A prominent feature of cortisol secretion is its marked increase in response to both physiological as well as psychological stress. With regard to the former, cortisol responses have been shown following intense exercise or hard physical work. For a significant cortisol response to occur under these conditions, exercise has to be highly intense or sustained with a maximum oxygen uptake (VO_{2max}) over 70%. The cortisol response to exercise shows no habituation after repeated exposure. In addition to exercise and intense physical work, a range of other physical conditions have been shown to result in cortisol responses, e.g., pain and physical trauma, hypoglycemia, hypoxemia, increased insulin levels, or consumption of a protein-rich meal.

It is now well established that cortisol secretion also responds strongly to psychologically challenging conditions. The magnitude of this response is dependent on both, external factors and characteristics of the individual. Situations containing both uncontrollable and social-evaluative elements tend to result in the largest cortisol responses (Dickerson & Kemeny, 2004). A wide range of psychological factors (e.g., appraisal of the situation, personality traits, coping and attributional style, perceived social support, or adverse early life experiences) as well as physiological predispositions (sex, age, or genetic factors) have been shown to influence the magnitude of the cortisol stress response (Foley & Kirschbaum, 2010). In contrast to the response to physiological challenge, the cortisol response to psychological stress shows

considerable habituation following repeated exposure to the same stress-eliciting situation.

Measurement

Modern laboratory methods allow for rapid and economic cortisol determination in different matrices. Most frequently, cortisol levels are measured in blood, saliva, or urine samples which usually provide information on cortisol production and levels over relatively short time intervals (minutes to days). A recent addition to this methodology is the measurement of cortisol concentrations in hair which is assumed to provide an index of integrated cortisol secretion over prolonged periods of up to several months.

Blood Plasma or Serum

The assessment of cortisol in blood (both plasma and serum) reflects acutely circulating concentrations and thus provides a valuable approach for assessing momentary cortisol levels or dynamic changes in cortisol secretion. Importantly, the assessment of total cortisol in blood comprises both bound and unbound cortisol and their separation can be time consuming and thus expensive. Consequently, blood assessments are not best suited for assessing the bioavailable fraction of cortisol. In addition, blood sampling bears a minor risk of infection and through its invasive nature may itself trigger an acute cortisol stress response.

Saliva

As with cortisol assessments in blood, salivary measurements also reflect acutely circulating cortisol levels. However, as only unbound cortisol can passively diffuse into saliva, salivary cortisol levels only represent the free, biologically active fraction. Importantly, the level of salivary cortisol is unrelated to salivary flow rate and shows only a minimal time lag of 1–2 min to plasma cortisol levels. In addition, saliva sampling is an unintrusive and generally well-accepted method which may easily be carried out under ambulatory conditions. Salivary cortisol assessments are thus increasingly used as the method of choice to determine acute levels of biologically active cortisol in human research (Kirschbaum & Hellhammer, 1994).

A potential limitation relating to both blood and salivary assessments of cortisol is that single spot samples only reflect cortisol secretion during the acute sampling situation. Since many situational variables are known to influence cortisol secretion (see above), drawing conclusions regarding overall functional cortisol status from such "spot data" can be misleading.

Urine

A considerable amount of circulating cortisol is metabolized and excreted into urine. The assessment of urinary cortisol metabolites thus provides a measure of cumulative cortisol secretion over the time period during which urine samples were collected. By using an extended collection period of, e.g., 24 h, the respective results are less influenced by momentary fluctuations in cortisol levels but integrate overall secretory patterns over the sampling period.

Hair

The examination of endogenous cortisol concentrations in human hair has recently been introduced as a new measure of steroid hormone determination. As it is assumed that cortisol is incorporated into the hair shaft during hair growth, the examination of cortisol levels in a specific hair segment is believed to provide a retrospective index of cumulative cortisol secretion over the period during which the respective hair segment has grown. Given a hair growth rate of approximately 1 cm/month, the examination of a 3 cm hair segment should allow the assessment of cumulative cortisol levels over a 3 months period. This largely extended window of examination combined with the possibility of a *retrospective* assessment highlights the potential of hair cortisol analysis as an important future research tool (Stalder & Kirschbaum, in press).

Definition

Cost-effectiveness is concerned with improving the performance of a health care system by ensuring the resources available to a health care system are used in their most productive way. This can only be achieved through careful consideration of the full consequences and opportunity costs of introducing a new health care program in the context or setting in which it is to be introduced. Appropriate evaluation methods must be

employed to accommodate this information and avoid simplifying assumptions that threaten the evaluation's validity.

Description

Economic evaluation has been defined as "ensuring that the value of what is gained from an activity outweighs the value of what has to be sacrificed" (Wiliams 1983). Hence, economic evaluation reflects the fundamental principles of economics that (1) resources are scarce, (2) choices are made between alternative uses of resources, and (3) a particular deployment of resources involves forgoing the benefits generated from alternative deployments of the same resources. Hence, it requires consideration of both outcome measurement and opportunity cost. Cost-Effectiveness Analysis (CEA) is the most common methodology of economic evaluation in health care, aimed at informing decision-makers faced with constrained resources. For a particular level of health care resources, which need not be the current level, the challenge is to choose from among all possible health care programs the combination of programs that maximizes total health benefits produce.

The theoretical basis for CEA derives from a decision-maker with a fixed budget choosing between many possible programs based on a comparison of the difference in effects between a program under consideration and the current way of serving the same patient population (incremental effects), and the difference in costs between the two programs (incremental costs). Where incremental costs and incremental effects have different signs, the solution is trivial, for example, the new program costs more (i.e., reduces resources available for other unrelated programs) and produces less effects than the current program. Similarly with negative incremental costs and positive incremental effects, a "win-win," no substantial reflection is required. In most cases, however, a new intervention involves incremental effects and incremental costs with the same sign, for example, the intervention is more effective but costs more than the existing intervention. To provide the greater effects of the new treatment, the number of other unrelated treatments must be reduced to release resources to support the additional costs of the new treatment. Here the decision-maker looks to the economist for "inputs" to the decision-making process – in particular decision rules for CEA.

The Decision Rules of CEA

The traditional analytical tool of CEA is the incremental cost-effectiveness ratio (ICER), the incremental cost of the new program divided by the incremental effects of the new program. Maximum health gain from available resources is produced under the following decision rules:

The league table rule: Select programs in ascending order of ICER (i.e., project with lowest ICER first) until available resources are exhausted.

T*he threshold ICER rule*: Select programs with ICER less than or equal to λ, the shadow price of the budget.

Because ICERs have not been estimated for all programs currently delivered in health care systems, comprehensive league tables are not available and the league table rule cannot be followed. The threshold rule has provided the basis for economic evaluation guidelines in many jurisdictions. In each case the use of CEA is linked to addressing the problem of maximizing health improvements from available resources.

This solution is based on assumptions of perfect divisibility and constant returns to scale in all programs. Yet, such conditions do not hold generally in health care decision-making. One cannot divide up an investment to fit whatever budgetary amount is available. A manager must purchase an entire Magnetic Resonance Imaging (MRI) machine, it is not divisible, it is all or nothing. Apart from such physical constraints on divisibility, some programs may not be divisible because of political or ethical constraints. It is ethically problematic to offer vaccination to only 50% of children. Increasing investment in a particular program may not produce

proportionally equal increases in outcomes as program coverage expands from highest need/most severe patients to lesser need/severity groups. So the additional outcomes produced from investing resources in a program may diminish with the scale of the program. Even if the program under evaluation does exhibit constant returns to scale the opportunity, cost of the program is likely to have non-constant returns in the sense that increased resource requirements for the new program mean the decision-maker has to "dig deeper" into his existing budget to fund it. After resources from the least productive current program have been exhausted he must look to other more productive programs meaning that the marginal opportunity cost of the program increases with size.

Because decision-makers are faced with choices between programs of different sizes, and the opportunity costs of programs depend crucially on program size, the different programs are not directly comparable. The ICER is the *average cost per Quality Adjusted Life Year (QALY)* or the inverse of the average rate of return on additional investments required by a program. Comparisons of ICERs across programs ignore problems introduced by the different sizes of programs. They do not compare like with like. Moreover, decision-makers cannot purchase individual units of QALYs. Each program produces a "package" of QALYs, and the average price per QALY may differ by program size. Consequently the ICER threshold decision-rule is not sufficient to maximize health effects from available resources. There is no theoretical justification for asserting that the strategy with the lowest cost-effectiveness ratio is the most desirable one.

To adopt the threshold ICER approach in the absence of the theoretical assumptions requires an unspecified supply of resources with constant marginal opportunity cost. Anything further from the reality of decision-making is hard to imagine.

Even if the assumptions are accepted for the purposes of the theoretical model, the problem of determining a threshold remains. Under the model, the threshold is given by the opportunity cost of the marginal program funded from available resources. This is determined by constructing the ICER league table, but requires information on the incremental costs and effects of *all* possible programs. Hence, the threshold value required to make decisions that produce the maximization of health gains from available resources cannot be determined even if the theoretical assumptions hold.

Extending Economic Evaluation to Identify Efficiency Improvements

For an intervention to represent an efficient use of resources the additional effects it generates must exceed the effects forgone from the most productive alternative use of the same resources. Hence, efficiency cannot be established only by reference to the resources required and outcomes produced by a particular intervention. Information on alternative uses of those resources is also needed and so efficiency is context-specific. Even where incremental costs and effects of an intervention are identical in different settings, it does not mean the efficiency of that intervention is the same in all settings.

If economics is to inform decision-makers about the efficiency of investments, traditional approaches to CEA and the use of ICERs are insufficient. Mathematical approaches to constrained maximization, such as integer programming (IP), solve the decision-maker's problem and are the only universal approach to ranking programs according to efficiency under a resource constraint. The key requirement of the IP approach is that the specification of the problem (i.e., objective function and constraints) must accurately reflect the decision-maker's problem setting.

The substantial data requirements of the IP approach, specifically the incremental costs and effects of all programs together with the resources available for investment, may be difficult to satisfy. However, these requirements reflect the complex nature of the decision-maker's problem.

An alternative practical approach is available (Birch & Gafni 1992; Gafni & Birch 1993) which

satisfies a modified objective of an unambiguous increase in health improvements from available resources (i.e., an objective of improving, as opposed to maximizing, efficiency). This requires that the health improvements of the proposed program be compared with the health improvements produced by that combination of programs that have to be given up to generate sufficient funds for the proposed program. Only where the health improvements of the proposed program exceed the health improvements of the combination of programs to be given up does the new technology represent an improvement in the efficiency of resource utilization. The approach does not rely on an arbitrarily determined threshold value to ascertain the efficiency of the program, nor is it dependent on unrealistic assumptions about perfect divisibility and constant returns to scale. Instead, the source of additional resource requirements is identified and the implications of canceling programs to generate these resources form part of the analysis. Iterative application of this efficiency-improving approach would eventually lead to efficiency maximization as opportunities to further improve efficiency are exhausted.

Concern with maximizing health improvements from available resources may be just one of several objectives that decision-makers face. For example, political considerations associated with providing equal access to services and providing greater priority to health improvements of specific population groups may be important goals. However, the presence of multiple objectives and constraints does not reduce the importance of adopting a constrained maximization model as the basis for analysis. It remains important that whatever goals are identified, these must be pursued efficiently in order to avoid wasting resources. The explicit identification of each objective and constraint enables the full range of policy concerns to be incorporated systematically into the analysis. Hence, the complex objectives faced by decision-makers, far from limiting the role of economic analysis, represent precisely the challenges that the economic model of constrained maximization is intended to accommodate.

Cost-Minimization Analysis

Definition

This term refers to an economic evaluation tool. Cost-minimization analysis is mostly applied in the health sector and is a method used to measure and compare the costs of different medical interventions. The principal limitations of this cost evaluation method are that it can only be used to compare treatments that provide the same benefits or effectiveness (identical outcomes, e.g., therapeutic effects); moreover, costs need to be determined accurately. In this way, a decision maker can choose the treatment with the lowest total cost. The assessment of costs is performed by identifying the study's perspective, all the resources used, and quantifying them into physical units. The most common perspectives are societal perspective (includes all costs incurred by health care services, social services, patients, and society in general) and third-party payer perspective (includes the costs incurred by an insurance company, a government, etc.). In order to quantify the resources used, a physical unit is defined, such as the number of hospital days, the time that a nurse spends with a patient, number of doctors' visits, etc. Once the units are defined and quantified, they are translated to costs by multiplying the unit costs by the number of units used.

The use of this tool is rather limited as it is difficult to demonstrate that the efficacy of two or more interventions is equivalent. A common application of cost-minimization analysis is the comparison of generic drugs in order to achieve market approval. Some experts consider that cost-minimization analysis is no longer useful (Briggs & O'Brien, 2001) and, furthermore, that other economic evaluation methods such as cost-utility, cost-benefit, and cost-effectiveness analyses are more comprehensive, given that they allow for the comparison of interventions with different effectiveness outcomes and the incorporation of uncertainty.

Definition

Couple-focused therapy (CFT) is a psychological therapy with the focus of attention on the relationship between two individuals rather than on one individual. The aim of CFT is to enable a better level of functioning in couples – married or unmarried – who are experiencing distress in their relationship. Couples may seek CFT for a variety of reasons, such as distress in terms of finances, sexuality, communication, infidelity, or individual psychopathology as well as physical health problems with an impact for the couple. Consequently, CFT will differ according to the respective relationship problems. Moreover, couple interventions may also vary based on the phase of the relationship during which they occur: Whereas primary prevention programs or couple education (e.g., the Prevention and Relationship Enhancement Program, PREP, from Howard Markman) might be offered for prevention of future distress relatively early in the relationship, CFT is usually called for when severe problems are present.

In general, the first step of CFT is to identify the areas of dissatisfaction in the relationship, and to implement a treatment plan to which both partners are willing to agree. Based on this treatment plan, therapy sessions will differ according to the chosen model or the philosophy behind the therapy. In the following, some of the best-known approaches will be briefly characterized.

Behavior-Focused Therapy

Traditionally, behavior-focused therapy is based on the idea that both partners (possibly involuntarily) tend to reward and punish specific behaviors during the development of their relationship. Consequently, this behavior exchange is an important treatment focus (e.g., by providing encouragement of positive behavior) in behavioral couple therapy.

Cognitive-Behavioral Therapy

With its roots in behavioral therapy, cognitive-behavioral CFT has enriched the focus on behavior with the perspective on couples' beliefs regarding the relationship. Therapists aim at questioning and modulating presumptions about the positive (or more often negative) motives of each partner and thereby try to prevent negative behavior.

Psychoanalytical Therapy

Psychoanalytical CFT attempts to discover early developmental conflicts in relation to the present interpersonal interactions within the couple. In this approach, couples are thought to be able to improve their relationship through a better understanding of how early parent-child interactions might influence later behavior in adulthood.

Emotion-Focused Therapy

As indicated by the name, the main emphasis in emotion-focused CFT is on the identification and expression of emotional needs in the couple relationship. In particular, the expressions of underlying feelings are supposed to change the perception of the partner and motivate behavior change.

Integrative Therapy

In a number of more recent approaches, researchers have combined a variety of treatment strategies within a consistent theoretical framework, resulting in integrated treatment models (among others the Enhanced Cognitive-Behavioral Couple Therapy by Epstein and Baucom (2003), or the Integrative Behavioral Couple Therapy by Jacobson and Christensen (1998); also see Snyder (1999), Snyder, Castellani, and Whisman (2006)).

CFT programs are broadly evaluated treatment options with effect sizes in the range of $d = 0.72$ for communication and relationship satisfaction, whereas in comparison typically no changes in marital quality in untreated couples are observed (Baucom, Hahlweg, & Kuschel, 2003). However, it should be noted that CFT is no guarantee that the relationship will improve, and there are couples who might benefit more from ending their relationship than from continuing it. This makes the overall evaluation of CFT a challenging topic in behavioral medicine (cf., Christensen, Baucom, Vu, & Stanton, 2005).

Definition

A co-worker is a person who a worker works with, in their role as worker. Co-workers can share their knowledge and expertise when others are faced with problems or novel situations; this can be especially useful when alternative solutions are not readily accessible. The co-worker relationship can also have effects on workplace dynamics, individual stress level, and relationships. Positive relationships between co-workers can be seen as supportive and beneficial in dealing with day-to-day problems and strains arising from employment (Deery, Iverson, & Walsh, 2010), and positive relationships can increase job satisfaction, job involvement, and organizational commitment (Dur & Sol, 2008). This supportive relationship may be more likely to occur in interactionally intense and high stress settings and can help one cope with high job demands. The pace and intensity for the work can be regulated through collaboration between co-workers, and workplace norms are often established through co-worker interaction and collaboration (Deery et al., 2010).

Co-worker relationships can be influenced by a variety of personality traits. Matching co-workers into groups based on these personality traits can lead to strong group cohesion and can create an effective team (Tett & Murphy, 2002). Additionally, supportive and positive co-workers can promote an environment where new ideas are easily and comfortably discussed, which also has positive impacts on the group (Joiner, 2007). Conversely, a mismatch of personality traits can have negative impacts on group dynamics (Tett & Murphy, 2002).

C-Reactive Protein (CRP)

Acute phase proteins; Inflammatory markers

Definition

C-reactive protein (CRP) is an important protein of the acute-phase response, which is a nonspecific physiological and biochemical response to infection, inflammation, and tissue damage. Increases in CRP are found during infection, chronic inflammatory diseases, and following a myocardial infarction. Strenuous exercise and psychological stress can also induce increases in CRP, albeit to a lesser extent compared to the physiologically more traumatic events described above. Therefore, levels of CRP can be reflective of both acute and chronic inflammation (Gabay & Kushner, 1999).

The CRP molecule consists of five calcium-binding nonglycosylated protomers in a pentameric symmetry. CRP is mainly produced by hepatocytes, even though other sources have also been reported. The production is stimulated by cytokines, which are released under the influence of the macrophages and monocytes at the site of the inflammation. Interleukin (IL)-6 has been shown to be most important for CRP production, but other cytokines, such as IL-1, tumor necrosis factor-alpha, interferon gamma, as well as glucocorticoids, can also play a role. Interestingly, specific combinations of these factors can both enhance as well as inhibit CRP production (Gabay & Kushner, 1999; Pepys & Hirschfield, 2003).

The function of CRP is to restore normal structure and function of the tissue that has been affected. CRP recognizes and mediates the elimination of pathogens through activation of the complement system (Gabay & Kushner, 1999; Pepys & Hirschfield, 2003). Even though the aim of the initial increase in CRP is to combat infection and acute inflammation, chronically raised levels have been associated with negative effects for health. Particular attention has been paid to the association between high levels of CRP and increased risk for atherosclerosis and cardiac events; high levels of CRP have been implicated in the pathogenesis, progression, and complications of atherosclerotic plaques (Ridker, 2004).

CRP can be readily assessed in serum using commercially available (high-sensitivity) assays. As the clearance rate of CRP remains stable, the increases in serologically determined CRP are indicative of CRP production. Following the stimulus, it takes on approximately 6 h until an increase is detectable in the serum. The half-life of CRP is less than 24 h.

Crohn's Disease (CD)

Synonyms

English: Regional enteritis
Latin: Enteritis regionalis Crohn; Enterocolitis regionalis; Ileitis terminalis; Morbus Crohn (MC)

Definition

Crohn's disease is a chronic inflammatory disorder which can affect the entire gastrointestinal (GI) tract. It is most commonly located in the terminal ileum and the proximal colon but may involve any part of the GI tract. Its incidence in middle Europe is around 1.5–8.5% and its prevalence around 0,036%. The inflammations generally appear in outlined sections, affect all laminae of the intestinal wall, and cause abscesses and fistulae. Key symptoms are persistent diarrhea, abdominal pain, fever, weight loss, and rectal bleeding. The course of the disease can be described with recurrent relapses and symptom-free intervals, both of which vary in length and strength.

Description

In genetically susceptible individuals impaired and inappropriate immune responses to microbial antigens of commensal microorganisms are discussed for pathogenesis. Data on expression suggest that macrophages and epithelial cells could be the locus of the primary pathophysiological defect and that T-cell activation might be a secondary effect inducing chronification of the inflammation, presumably as a backup mechanism to insufficient innate immunity. Genetic predisposition, ethnicity, smoking behavior, nutrition habits, and enhanced drug intake are discussed as further risk or modulating factors. No causal therapy is currently available for Crohn's disease.

Though not curable, glucocorticoids, aminosalicylates, antibiotics, immunomodulatory substances, enteral (specific diets) or parenteral feeding (under avoidance of the digestive tract), and surgical procedures can alleviate symptoms' severity (Akobeng & Thomas, 2007; Butterworth, Thomas, & Akobeng, 2008). Ninety percent of the patients concerned have to undergo surgery at least once in their lifetime, and 20% of operated patients will undergo further surgery within the next 5 years.

Due to a lack of well-designed randomized controlled trials in the field of behavioral medicine, only insufficient evidence is available so far to make firm conclusions about the efficacy of different psychotherapeutic treatment options for induction of remission in Crohn's disease. Neither any specific personality traits nor any family structures in correlation with the occurrence of Crohn's disease have hitherto been clearly identified. Although a causal relationship with critical life events and/or stress has not been established so far, Crohn's disease creates an immense burden on patients and is a critical strain on patients and relatives. Consequently, psychological changes (including higher values of depression, anxiety, and/or emotional instability) are very often observed. From the point of view of behavioral medicine, a behavioral therapy is thus as reasonable as for any other severe chronic disease for which no cure exists. Besides psychotherapy (behavioral, conflict-oriented, psychodynamic, or supportive), relaxation techniques (progressive muscle relaxation, autogenic training) as well as stress management training can be useful in conjunction with standard medical interventions. Such interventions do often not directly affect the course

of the disease, but patients' mental condition and illness-related quality of life improve.

Generally, a positive course of the disease mainly depends on the patients' compliance. Active coping strategies and a problem solution orientation were identified as best predictors for a shorter duration of inflammations and longer relapse-free episodes. The following coping strategies were mostly beneficial in the management of the disease: "accurately adhere to medical advice," "be trustful in medical practitioners," "seek for further information," "actively cope with problems," and "encourage yourself." The probability of actually receiving an adequate medicinal therapy is enhanced with greater compliance. If the relationship between the physician and patient is disturbed or if the patient has no adequate coping strategies, the additional use of psychological interventions should be recommended with higher priority. Especially with phobic reactions after diarrhea, comorbidity with depression and/or anxiety, or other acute psychological conflicts, a supportive psychological therapy should be initiated. Besides solving acute conflicts, general aims of such interventions should lie in an enhancement of the relaxation ability and strengthening of individual coping strategies.

Crossover Design

Synonyms

Repeated measures design

Definition

Subjects in a crossover design study are assigned to receive two or more treatments in a particular sequence. Imagine a study in which some subjects receive Treatment A on a given day (the first period) and a week later receive Treatment B (the second period). Others subjects (usually close to an equal number) would receive Treatment B first and then, 1 week later, receive Treatment A. Such a study would be described as having a two-period, two-treatment, two-sequence crossover design. Crossover designs can involve various numbers of treatments, sequences, and periods. In these designs, individual subjects are randomized to treatment sequences (as opposed to treatment groups as occurs in parallel groups study designs).

The primary advantage of the crossover design is that each subject serves as his or her own control, providing data in each treatment arm of the study. The design also has some disadvantages, one of which can be difficulty in interpreting the results. Since all subjects receive more than one treatment there can be a carryover effect from one or more early periods to subsequent periods, leading to a biased estimate of the treatment effect(s) of interest.

Cross-Sectional Study

J. Rick Turner
Cardiovascular Safety, Quintiles, Durham, NC, USA

Definition

A cross-sectional study describes a group of subjects at one particular point in time (Campbell, Machin, & Walters, 2007).

All study designs and methodologies have advantages and disadvantages. The randomized controlled trial, which is placed at the top of the Hierarchy of Evidence by some researchers and therefore is considered a very strong source of evidence, has some disadvantages: They are lengthy, expensive, and may be limited in how well results from them can be generalized to the treatment's effect in the general population in real-world clinical circumstances.

The cross-sectional study is usually comparatively quick and easy to conduct. Examples of its implementation include the use of an interview survey and conducting a mass screening program. Additional advantages are that many risk factors can be studies at the same time, and that they are suitable for studying rare diseases. Disadvantages include the following:

- Only one disease outcome can be studied at once.
- Temporal relationships can be difficult to identify. Since the survey provides a snapshot of information at one time, it is not possible to address the issue of which item of interest that is currently present may have caused (influenced) another item that is also currently present.
- The selection of control subjects can be problematic.
- From a statistical perspective, only relative risk can be obtained.
- Focusing on the subjects, lack of recall and recall bias can be of concern.
- Data derived from these studies cannot meaningfully be used to test the effectiveness of an intervention, i.e., they are not good for answering research questions. Nonetheless, they may be useful for generating hypotheses (asking questions) that can subsequently be further investigated in randomized controlled trials.

Cultural and Ethnic Differences

Definition

The recognition of culture and its components as a complex and fluid process, rather than a static construct, is critical to attempts to understand the cultural influences on health and health behavior; culture cannot be reduced to a single variable or construct.

Twelve features are essential to an understanding of a culture: history, social status, points

of interaction within and between social groups, value orientations, verbal and nonverbal language and communication processes, family life processes, healing beliefs and practices, religion and religious practices, art and other forms of expression, dietary preferences and practices, recreational forms, and manner and style of dress (Hogan-Garcia, 2003). The subjective components of culture, such as beliefs, values, and explanatory cognitive frameworks, are communicated both verbally and nonverbally; the objective component of culture consists of rules relating to individual and group behavior (Hogan-Garcia, 2003). Culture is constructed by and exists and operates at the levels of the individual and the group and changes over time (Nagel, 1994). Individuals who ascribe to a particular culture share an identity and a framework for understanding the world.

Too often, culture is erroneously assumed to be synonymous with ethnicity. However, ethnicity and culture represent quite different concepts. Ethnicity is a function of both one's self-identification and the identification by others of membership in a specific group based on specific characteristics, such as biological characteristics, nationality, language, and/or religion (Yinger, 1994); it is a function of both cultural history and psychological identity (Melville, 1988). Like culture, one's ethnic identity may change due to changes in one's self-perception and the social context in which one lives. Additionally, individuals may claim membership in various cultures and/or ethnicities simultaneously, and may prioritize these memberships differently depending on any variety of circumstances. As an example, an individual may simultaneously consider herself Polish, Russian, Christian, nondenominational, female, and American.

The concept of ethnicity has also been used confused in the literature with the concept of race. Like ethnicity, the concept of race has been used to explain perceived differences in appearance and behavior across individuals and groups, based on the erroneous assumption that each race is associated with distinct, fixed physical and behavioral characteristics. However, the definition of race, the classification of individuals by race, and the meaning or significance associated with a particular designation have varied over time, place, and purpose of designation, both in the United States and elsewhere (Loue, 2006). Additionally, shifting perceptions of self-identity and self-worth may also influence how an individual self-designates at any particular time and place. Unfortunately, epidemiological literature has frequently confused ethnicity and culture and race by equating ethnicity with country of origin and/or skin color and culture with ethnicity or race, based upon the assumption that any observed differences seen between groups are the result of true and fixed genetic or cultural differences between the groups (Karlsen, 2004).

Additionally, reference to a particular culture, ethnicity, or race assumes and implies homogeneity within the classification being used. However, within every group, differences exist with respect to socioeconomic status, religion, age, understandings of health and illness, educational and employment opportunities, social status and power, and access to services. It is important to recognize that although classifications based on culture and ethnicity may be useful as a shorthand, they are not unitary constructs. A full understanding of the mechanisms that may underlie health disparities requires a more in-depth understanding that is possible only through the examination of the relevant constitutive elements.

The politics of HIV/AIDS illustrates the confusion that often surrounds culture, ethnicity, and race. The human immunodeficiency virus (HIV), the causative agent of AIDS, is transmitted through the exchange of various bodily fluids, such as semen, vaginal fluid, breast milk, and blood. Approximately 1 year after the identification of the first observed cases of the disease, the Centers for Disease Control and Prevention (CDC) labeled Haitians a "risk group," meaning that anyone who was Haitian was believed to be at increased risk of contracting and transmitting the virus by virtue of their group membership, rather than as a function of their individual behaviors (Schiller, Crystal, & Lewellen, 1994). Here, individuals' ethnicity and race were presumed to be congruent with culture and "culture"

was presumed to be a factor in disease transmission. Ironically, this categorization of all Haitians as a risk group reflects US biomedical culture with respect to its understanding at the time of disease process and the meanings of culture, ethnicity, and race.

Description

Culture influences almost every aspect of illness, including how an illness is identified, defined, and made meaningful; the timing and onset of the illness; the symptomatology; the course and outcome of the illness; how individuals, families, providers, and others respond to an experience of the illness; and how individuals seek, utilize, and respond to treatment (Kleinman, 1988). It is beyond the scope of this entry to review the role of culture in each of these aspects across all diseases. Instead, the role of culture as it relates to disease diagnosis, symptomatology, and treatment is examined in the context of several chronic diseases.

As an example, the prevalence of bipolar disorder appears to vary across cultures. Bipolar disorder is a serious, chronic mental illness characterized by manic and depressive episodes (Type I) or hypomanic episodes and major depressive recurrences (Type II). The disorder is associated with impairments in the quality of life, increased rates of suicide, and high financial costs. However, the prevalence of bipolar disorder varies across countries. The consumption of omega-3 fatty acids found in seafood appears to serve a protective effect for individuals who consume large quantities of seafood over their lives, suggesting that nutritional habits play a role in the development of the disease (Noaghiul & Hibbeln, 2003).

Cultural aspects are also implicated in the symptomatology and management of bipolar disorder. The manic phase of bipolar disorder is characterized by an "excessive involvement in activities," that often assumes the form of sexual indiscretions and buying sprees. However, how this excessive involvement manifests may have to be reformulated so as to be consistent with the cultural context in which the individual lives. Clinicians who are unfamiliar with the client's culture may erroneously interpret the client's behavior as symptomatic of bipolar disorder when it is not, or may erroneously ascribe behavior to cultural influences when the behavior actually indicates the presence of bipolar disorder. Similar diagnostic errors have been noted in the context of schizophrenia. The overdiagnosis of schizophrenia among African Americans has been attributed in part to providers' lack of cultural understanding and their consequent misinterpretation of cultural mistrust as paranoia and miscommunications between the provider and the patient. Too, clinicians unfamiliar with the client's culture may be more likely to prescribe or to refrain from prescribing particular pharmacologic treatments based on misunderstandings of the client's behavior.

Culture also plays a role in the prevalence, experience, and course of epilepsy. Epilepsy is a brain disorder that is characterized by a predisposition to generate seizures, with neurobiological, cognitive, psychological, and social consequences. Research findings indicate that the prevalence of the disorder is higher in developing countries compared to more developed countries (Mac et al., 2007). In some cultures and religious groups, such as some Asian Indian and Muslim communities, consanguineous marriages, that is, between blood relatives such as first cousins, is customary. Parental consanguinity had been found to be associated with an increased risk of certain forms of epilepsy. It is important to recognize, however, that not all Asian Indian and Muslims enter into consanguineous marriages and some individuals who are neither Asian Indian nor Muslim may do so.

Individuals may search for an explanation for their seizures, which are often unpredictable and may be uncontrollable. Explanatory models of epilepsy differ across cultures. Individuals from Western developed nations are more likely to ascribe to a biomedical model of the disease, whereas individuals of other cultural backgrounds may attribute the cause of epilepsy to witchcraft, divine punishment, bad luck, or supernatural forces (Allotey & Reidpath, 2007; Mac et al., 2007). The existence of such vast

differences in beliefs regarding the causation of the illness between a patient and a provider may seriously impede communication and adversely affect their ability to work together to control the seizures (Reynolds, 2000). The beliefs that individuals hold regarding their illness also have implications for their willingness to adhere to prescribed treatment, the extent to which they utilize alternative treatments, and their daily functioning. Individuals who believe that their illness lasts only as long as their seizure lasts may refuse to take medication on an ongoing basis, resulting in an inability to control the seizures. Alternative treatments, such as smoke inhalation, herbal preparations, and dietary treatments, may be sought; some of these may be toxic, leading to additional illness. Daily functioning may be limited, not because of the effects of the epilepsy itself, but because individuals and even their health care providers may believe that individuals with epilepsy must restrict their activities, including the avoidance of sun exposure, strenuous exercise, and the obligations demanded by regular employment (Allotey & Reidpath, 2007; Mac et al., 2007). The belief that epilepsy is a contagious disease, common in many countries, may cause people to avoid touching an individual who is experiencing a seizure, even though some forms of help might reduce the likelihood of injury to the individual experiencing the seizure (Mac et al., 2007).

Type 2 diabetes mellitus, which is increasing in prevalence worldwide, results from an interaction between genetic, environmental, and behavioral factors. Numerous studies have reported differences in the prevalence of type 2 diabetes across various ethnic groups. For example, South Asian migrants have been found to have a higher prevalence of type 2 diabetes compared to Westerners; African Americans have been reported to have a higher prevalence compared to Whites (Hussain, Claussen, Ramachandran, & Williams, 2007). These distinctions, which presume a nonexistent homogeneity within the named groups and heterogeneity across groups, can only serve as a foundation for additional study. One must search further for the underlying explanations for these observed differences.

Obesity and physical inactivity have been implicated as factors in the development of type 2 diabetes (Hussain et al., 2007). Accordingly, cultural factors that encourage or promote overeating and a sedentary lifestyle and/or constrain efforts to eat healthily and exercise more may play a role in the development of the disease and its progression. Diet and exercise must both be managed by individuals within the context of their everyday lives and their interactions with others. Standards of modesty in dress may diminish individuals' opportunities to engage in vigorous exercise, attempts to participate in religious fasting rituals may predispose individuals to hypoglycemia, and the consumption of traditional foods, such as those prepared with butter or that are fried, may thwart attempts at weight reduction. Additionally, the standard for what constitutes an ideal body or weight varies across cultures. In some contexts, obesity may signify privilege and affluence, an announcement to the larger world that the individual is able to afford the more costly "status" foods such as meat, butter, and sweets. The ability to refrain from physical exertion, such as that associated with exercise, may also signal higher social and financial status. Individuals' self-identities may be intimately linked to their adherence to specified behavioral norms; their participation in social, religious, and/or other activities; and their relationships with others. Consequently, clinicians' efforts to persuade their patients to modify behaviors may be perceived by the patient not as a necessary change in lifestyle to prevent disease and improve health, but rather as a potential loss of one's identity, status, and membership in a particular group.

In some instances, individuals' interpretations of their symptoms may impede their receipt of potentially helpful treatments. As an example, the term "ataque de nervios," literally an attack of nerves, is utilized by many Puerto Ricans to refer to their response to a specific traumatic event, such as a death in the family or betrayal by one's spouse. (Ataque de nervios is often referred to in the psychiatric literature as a culture-bound syndrome.) That response may include fainting, dizziness, shortness of breath,

weakness, and/or chest pain. The individual may experience feelings of sadness and depression, nervousness and insecurity, or irritability and anger. The experience of an ataque communicates to others in a culturally and socially acceptable manner one's feeling that the world has gone out of control.

An ataque may occur in the absence of any pathology, but in some circumstances may be indicative of an underlying anxiety, affective, or panic disorder. Individuals suffering from ataques may dismiss out of hand the possibility that such experiences suggest an underlying disorder for which they might seek treatment. However, the converse is also true: Clinicians who are unfamiliar with the cultural meaning of ataques may misinterpret the patient's experiences as indicative of pathology when they represent instead a time-limited, culturally sanctioned response to trauma.

As an example of how cultural *change* can impact the diagnosis, prevalence, and treatment of a disease or disorder, consider how understandings of homosexuality have varied over the last 40 years. Once considered a mental illness, individuals who were diagnosed as homosexual were subjected to therapeutic interventions to transform their sexual orientations. Cultural change both within the medical profession and within the larger society in the United States provided the impetus to declassify homosexuality per se as a mental illness requiring treatment. The prevalence of the "illness," the "course of illness," and the "prognosis" were thus dependent on whether the underlying orientation was to be considered an illness at all. Similarly, cultural *change* at a societal level has transformed our understanding of alcohol abuse from that of a moral defect, to an individual medical problem, to a public health issue; our perception of partner violence as a legitimate response to a partner's failure to fulfill role obligations, to a medical diagnosis of the battered partner as a masochist, to a public health and criminal justice issue. Once treated through prayer, alcohol abuse is now seen as amenable to counseling, pharmacologic treatments, and, under some circumstances, legal intervention. Similarly, remedies for partner violence have broadened to include counseling for both the batterer and the battered. Our perception of disease necessarily impacts our prevalence estimates, how the affected individual interprets his or her experience, the course of the individual's illness, and how we as individuals, clinicians, and a society respond to the individual in the context of that experience.

Implications

Much emphasis has been placed on clinicians' need to develop cultural competence in order to better communicate with and counsel their patients. However, all too often, efforts to inculcate cultural competence reduce culture to a laundry list of characteristics attributed to a particular group, characteristics that are presumed to be true of all members of that named group and to exist across time and place. Such efforts fail to recognize the fluid nature of culture at the individual and group levels, the complexity of culture, the heterogeneity that exists within larger groups, and the similarities that exist across groups.

A focus on the development of cultural humility, rather than cultural competence, is more likely to lead to improved communication between providers and their patients, between researchers and their research participants, and across diverse communities. In contrast to cultural competence, which focuses on substantive issues and may lead to both stereotyping and a false sense of security derived from "knowing," cultural humility focuses on process as a key element, requiring that the individual remain open to continual learning, engage in continual self-reflection and self-critique, and attempt to equalize the power imbalances that are inherent in the provider-patient or researcher-participant relationship (Tervalon & Murray-Garcia, 1998). Improved communication and understanding across cultural differences may ultimately lead to improved health for individuals and communities and a reduction in health disparities.

Definition

Cultural competence is defined as a set of congruent behaviors, attitudes, and policies that come together in a system, agency, or among professionals to facilitate effective work in cross-cultural situations (Cross et al., 1989). Linguistic competence is an important component of cultural competency because language is a key aspect of culture.

"Culture" is defined as an integrated pattern of learned human behaviors (e.g., styles of communication, customs) and beliefs (e.g., views on roles and relationships) shared among groups (Robins, Fantone, Hermann, Alexander, & Zweifler, 1998; Donini-Lenhoff & Hendrick, 2000). The word "competence" implies having the capacity to function effectively with a cultural group (Cross, Bazron, Dennis, & Isaacs, 1989).

Description

A key reason for cultural competence in health services administration and public health is to deliver the highest quality of care to all patients, regardless of race or ethnicity, cultural or religious background, or English proficiency (Betancourt, Green, & Carrillo, 2002). Another important reason for delivering culturally competent care is to reduce and eliminate health disparities in health status of diverse people and to enhance the quality of services and health outcomes. Racial and ethnic minorities are more likely to die from many life-threatening diseases compared to members of the majority group. One likely contributor to the disparities in health outcomes and mortality is biased care stemming from conscious or unconscious racial stereotypes (LaVeist, 2002).

Cross et al. (1989) proposed a Cultural Competence Continuum Framework that ranges from "cultural destructiveness" where health services can create harm to "cultural proficiency" where health care services are responsive to the health beliefs, practices, and cultural and linguistic needs of diverse cultural groups. Descriptions of each of the levels in the continuum follow:

- Cultural destructiveness refers to attitudes, practices, and policies within an organization or system that are harmful to a cultural group. This level represents a lack of understanding and unwillingness to learn about other cultures.
- Cultural incapacity involves the lack of capacity to respond to the needs of a cultural group. These practices may consist of disproportionately allocating resources that may ultimately benefit one group at the expense of another.
- Cultural blindness consists of considering all people or groups the same, without acknowledging cultural nuances. This can lead to forced assimilation to institutional attitudes that may blame members of cultural groups for their circumstances.
- Cultural pre-competence involves a commitment to social and civil justice. In this level, it is recognized that continuous expansion of cultural knowledge and resources to address the needs of cultural groups are needed.
- Cultural competence consists of ensuring that the needs of the cultural group are met by the practitioners and health service organizations. It involves being aware of and recognizing group differences and having insight into one's cultural values. In this level, organizations and public health practitioners are able to operate effectively in different cultural contexts.
- Cultural proficiency is a more advanced standard than cultural competence and incorporates all of the concepts of cultural competence, but a higher level of awareness, knowledge, and skills. Culturally proficient practitioners and organizations strive to be innovative and creative in developing and implementing interventions and evaluation tools.

The Cultural Competence Framework involves five essential elements that help health care organizations and public health practitioners change from not understanding the importance of cultural competence to practicing it. These components include: (1) developing a regard for diversity or demonstrating an awareness and commitment to learning about cultural differences; (2) conducting cultural self-assessment or encouraging organizations to take this process into account; (3) understanding the dynamics inherent when cultures interact; (4) accessing cultural knowledge or demonstrating a commitment to integrating lessons learned into the health care delivery skills; and (5) adapting to diversity or developing strategies that translate cultural competency into system change and clinical practice.

Culturally competent care would involve changing from a "one size fits all" model of care to a model in which care is responsive to different cultural communities. Organizations can aim to achieve cultural competence by assuring diversity among board members, staff, and providers, enhancing data collection, providing effective and translation services, and incorporating cultural competence skill development and education. An organization can identify their level of cultural competence through the use of measures that assess cultural attitudes, practices, structures, and policies of programs. Acquiring these data

can help determine areas of weakness to inform the training needed to strengthen cultural and linguistic competency.

Definition

Culture: Culture is a complex system that includes beliefs and values that are socially transmitted within groups who have similar backgrounds and experiences. Culture is often used to refer to individuals from the same racial and ethnic group, but culture is distinct from one's race or ethnicity. Cultural beliefs and values create motivational force, or provide the underlying rationale or impetus to behave, think, and feel in a certain way. Most empirical research has focused on understanding the association between health behaviors and cultural beliefs and values related to religion and spirituality, temporal orientation, and collectivism and individualism (Kagawa-Singer, Dadia, Yu, & Surbone, 2010).

Religion and spirituality: Spirituality and religion are related but distinct factors that have been shown to influence conceptualizations about diseases. Spirituality is defined as having a personal relationship with a higher power and faith, and may be a process used to find meaning in one's life, while religion is defined as a set of practices and beliefs (e.g., dogma, doctrines) that are shared by a community or group. Religion can be thought of as behavioral manifestations of one's spirituality (Taylor, 2001).

Temporal orientation: Temporal orientation is defined as one's cognitive focus of their behaviors, thoughts, and affect in terms of past, present, or future domains. Individuals may think, feel, or act based on perceived consequences that are immediate (present orientation), will happen in the future (future orientation), or has happened in the past (past orientation) (Nuttin, 1985).

Individualism and collectivism: Individualism and collectivism are beliefs and values related to social processes and interactions. Individualism is characterized by placing greater value on personal autonomy, responsibility, and freedom of choice whereas collectivism is characterized by values that include group responsibility and decision making and maintaining harmonious relationships with others (Triandis, McCusker, & Hui, 1990).

Description

Association Between Cultural Factors, Health Behaviors, and Racial and Ethnic Background

By the year 2050, it is estimated that the racial and ethnic composition of the USA will change dramatically and groups that are currently minorities will make up the majority of the US population. In anticipation of this, and the poorer health outcomes that these groups continue to experience, efforts are focusing on developing more effective strategies for health promotion and disease prevention by addressing cultural beliefs and values related to health behaviors. Cultural factors are now being addressed as part of health behavior interventions based on studies which have shown that these factors are associated with health behaviors. Racial and ethnic group differences in cultural beliefs and values also provide support for addressing these factors as part of health promotion and disease prevention efforts. These findings are summarized in the sections below (Smedley, Stith, Nelson, & Institute of Medicine (U.S.), 2003).

Temporal Orientation. As described above, temporal orientation is defined as one's cognitive focus of their behaviors, thoughts, and affect in terms of past, present, or future domains. Studies have shown that future temporal orientation promotes greater psychological well-being, avoidance of risky health behaviors, and adherence to preventive health behaviors and beliefs, whereas present temporal orientation is associated with reduced adherence. There are also racial differences in temporal orientation. For example, Brown and Segal found that African Americans reported greater levels of present temporal orientation related to hypertension management compared to whites. Individuals with higher levels of present temporal orientation reported lower perceptions of susceptibility to adverse effects of uncontrolled disease, perceived fewer benefits of hypertension medication, and reported greater perceptions of burden from the negative aspects of medication. Similar results were reported in a qualitative study of perceptions of cervical cancer screening in Hispanic women. Women in this study reported that reasons for not obtaining screening as recommended included beliefs that less emphasis is placed on screening to prevent future health outcomes because the future cannot be changed or guaranteed. In a community-based sample of African American women, present time orientation was associated with never having a mammogram, but women who had greater levels of future temporal orientation were most likely to participate in genetic counseling for BRCA1 and BRCA2 mutations and receive test results. Greater levels of future temporal orientation were also associated with uptake of genetic counseling for BRCA1 and BRCA2 mutations in samples that consisted mostly of white women (Brown & Segal, 1996; Boyer, Williams, Callister, & Marshall, 2000).

Religion and Spirituality. Religion and spirituality have been examined extensively as predictors of health behaviors and beliefs. For instance, explanatory models for cancer among African American and Hispanic women include the belief that cancer is due to God's will. Other work has shown that religious and spiritual beliefs influence decisions about seeking treatment for breast cancer symptoms and other health behaviors. Lannin and colleagues found that religious and spiritual beliefs, such as prayer about cancer can lead to healing, were associated with a greater delay in seeking treatment for breast cancer symptoms. African American women were significantly more likely than white women to endorse these beliefs. Similar findings have been reported for Hispanics; faith in God was influential in determining the length of time between symptom recognition and seeking care in Hispanic men and women. Studies have also shown that religion and spirituality are important coping resources following breast cancer diagnosis in African American, Hispanic, and white women; however, the importance of these needs may differ depending on one's racial or ethnic background. For example, while 25% of white cancer patients reported five or more spiritual needs following their cancer diagnosis, significantly more African American (41%) and Hispanic (61%) women reported five or more spiritual needs. African American women were significantly more likely than white women to use

God as a source of support following diagnosis. African American prostate cancer survivors also reported significantly greater levels of religiosity compared to white prostate cancer survivors. African American men have also been shown to be significantly more likely than white men to report that faith contributes to good health and faith in God played a role in health-seeking behaviors among Hispanic men. Other work has shown that while religion is very important to the majority of adults diagnosed with disease and one third of healthy adults pray for health conditions, African American men and women were significantly more likely than white men and women to be willing to allocate time with health care providers to discuss spiritual issues rather than health care concerns (Lannin et al., 1998; Moadel et al., 1999; Kub et al., 2003).

Collectivism and Individualism. Individualism and collectivism may also contribute to health behaviors and beliefs, but less empirical data are available on these associations. But studies have examined the relationship between constructs that are similar to individualism and collectivism. Communalism, for example, is defined as having greater recognition of the interdependence of people, particularly family members and familism is defined as having a stronger identification with and attachment to family members. Prior studies have shown that communalism is associated with collectivism and African Americans and Hispanics have been shown to have greater endorsement of collectivism (e.g., interdependence, group responsibility) and familism compared to whites. Other work has shown that greater levels of social integration and the size of one's social network were associated with adherence to breast and cervical cancer screening among Mexican, Cuban, and Central American women. Thompson and colleagues found that African American women who declined to participate in genetic counseling and testing for inherited breast cancer risk reported significantly greater concerns about the impact of testing on family members compared to women who participated in counseling and testing. Further, in a national sample of African American, white, and Hispanic adults, greater levels of individualism were associated with an increased likelihood of eating the recommended number of servings of fruits (Boykin, Jagers, Ellison, & Albury, 1997; Sabogal, Marin, & Perez-Stable, 1987).

Measurement of Cultural Factors

Although cultural beliefs and values are socially transmitted and shared among individuals with similar racial backgrounds and experiences, these factors are most often measured as an individual difference characteristic using self-report measures. Research is now being conducted to develop instruments that measure cultural beliefs and values within specific situational contexts.

Integration of Cultural Factors into Health Promotion and Disease Prevention

Cultural tailoring is an approach that has been used to promote adherence to a wide range of health behaviors that include cancer screening, HIV risk reduction, and informed decision making about genetic testing for inherited disease risk. The premise of cultural tailoring is that information and messages that are customized to one's culturally based beliefs and values will be more effective than generic approaches because they address issues and ways of thinking and coping that are most salient to an individual. Culturally tailored interventions have had mixed results. For instance, Halbert and colleagues developed and evaluated a culturally tailored genetic counseling (CTGC) protocol for African American women as part of a randomized trial. The CTGC protocol included standardized probes to elicit discussion about cultural factors that have been shown to influence decisions about genetic counseling among African American women (e.g., spiritual and religious beliefs, communalism). For example, women were asked what aspects of their spiritual and religious beliefs influence their decision to have genetic testing to facilitate discussion about the role of these factors in decision making about genetic testing for BRCA1/2 mutations. Women who received CTGC reported greater levels of satisfaction compared to those who received standard genetic counseling (SGC), but there were no differences in uptake of BRCA1/2 test results between

women who were randomized to CTGC and SGC. Further, women randomized to CTGC and SGC did not differ in terms of psychological outcomes such as changes in risk perception and cancer worry compared to decliners. In other research, Kreuter and colleagues found that African American women liked culturally relevant health education materials that addressed fruit and vegetable intake and mammography using four cultural constructs (religiosity, racial pride, collectivism, and time orientation) better than materials that were tailored to behavioral constructs. However, women who received both types of education materials (behavioral and culturally relevant materials) were most likely to obtain a mammogram and had greater increases in fruit and vegetable consumption compared to women who received culturally relevant materials, those tailored to behavioral constructs only, and women in the control condition (Kreuter et al., 2005; Kalichman, Kelly, Hunter, Murphy, & Tyler, 1993; Halbert, Kessler, Troxel, Stopfer, & Domchek, 2010).

These findings raise questions about how to develop interventions that are effective in terms of addressing cultural beliefs and values and promoting health behavior change. One issue may be that previous culturally tailored interventions have been based on conceptualizations of cultural factors that are not specific to different health promotion and prevention behaviors. Studies have shown that different cultural values are elicited depending on situational characteristics and context; but existing instruments that measure cultural factors do not relate specifically to different health behaviors (e.g., medication adherence, avoidance of risk factors, early detection) that define the spectrum of health promotion and disease prevention and, therefore, may be less sensitive for interventions studies that aim to address these factors.

Conclusions

Cultural beliefs and values are important to a wide range of health promotion and disease prevention efforts. Empirical evidence is emerging on how to address these factors as part of health behavior interventions.

Definition

Cystic fibrosis (CF), a genetic recessive illness, occurs in 1 of 3,500 live births each year in the United States and currently affects approximately 30,000 people, predominantly Caucasians (Cystic Fibrosis Foundation [CFF], 2008). In 1962, average life expectancy was 10 years of age; however, the current life expectancy of a person with CF is approximately 37 (CFF, 2009). More than 46% of people registered with the CF Foundation are adults. Adults with CF now participate in many developmentally-appropriate aspects of life which were previously rare for this population, including completing high school (92%), working part- or full-time (48%), and marrying or living with a partner (38%; CFF, 2008). As people with CF are living longer, there is a need for effective transition from pediatric to adult health care.

CF is caused by a single genetic defect. There are over 1,500 known mutation variations with the most common defect being the Delta F508 mutation (Farrell et al., 2008). In 1989, this defect

was identified on chromosome 7 (Riordan et al., 1989). When working properly, the cystic fibrosis transmembrane conductance regulator gene produces a protein which transports chloride and sodium across cells, particularly in submucosal glands. In CF, this abnormal electrolyte transport results in the production of thick, sticky mucus, affecting the pulmonary, gastrointestinal, pancreatic, and reproductive systems (Welsh & Smith, 1995). Cycles of infection and inflammation result in significant lung damage. Approximately 90% of patients with CF experience pancreatic insufficiency, resulting in difficulty absorbing fats and proteins which leads to undernutrition. Some patients develop CF-related diabetes, liver damage, and bone disease. About 98% of men are infertile due to the absence, malformation, or blockage of the vas deferens. Women have better reproductive capabilities, though conception is often difficult due to excessive cervical mucus.

Diagnostic criteria for CF include both clinical features and laboratory results (Farrell et al., 2008). Laboratory tests include newborn screening (occurring in all 50 states since 2010), quantification of sweat chloride, and genetic testing. Median age of diagnosis is 6 months of age (CFF, 2008), with approximately 70% of children diagnosed before 1 year of age (Walters & Mehta, 2007). A very vigorous treatment regimen is instituted at the time of diagnosis. Some 90% of morbidity and mortality is due to progressive lung disease. Lung function, as measured by percent predicted of forced expiratory volume in one second, slowly declines over time, at a rate of approximately 1–2% each year (Rosenthal, 2007). Given the multiple systems affected by CF, treatments typically include antibiotics (oral, nebulized, and intravenous), enzyme replacement therapy, airway clearance, nebulized bronchodilators, nebulized mucolytic agents, and aggressive nutritional therapies, ranging from increasing caloric intake to enteral nutritional feedings (Eiser, Zoritch, Hiller, Havermans, & Billig, 1995; Orenstein, 1997). The medical regimen is extremely complex and time consuming, which results in significant challenges for adherence.

The Cystic Fibrosis Foundation (CFF) was established in 1955 (CFF, 2008); this organization accredits the more than 115 care centers, manages a patient registry, develops evidence-based practice guidelines, and provides funding for research. The CFF Therapeutics Pipeline includes 33 interventions at various stages of development, including medications to treat symptoms, potentiators and correctors to address the basic defect, and gene therapy to prevent disease.

Chemokines; Interleukins; Lymphokines; Monokines

Definition

1. Low molecular weight proteins that stimulate or inhibit the differentiation, proliferation, or function of immune cells.
2. Small cell-signaling protein molecules that are secreted by numerous cells of the body in order to affect the behavior of other cells that bear receptors for them.
3. Extensively involved in intercellular communication.

Description

Cytokines are small cell-signaling protein molecules weighing approximately 25 kDa. Based on their presumed function, cell of secretion, and target of action, cytokines were previously referred to as lymphokines, interleukins (IL), and chemokines. These terms were generally used in an attempt to develop a standardized nomenclature for molecules that were secreted by and which acted on cells of the body. However, due to an ever-increasing number of cytokines with diverse origins, structures, and effects being discovered, these terms are now considered to be obsolete. Although the IL designation is still used, it is anticipated that a nomenclature based on cytokine structures will eventually become established.

Cytokines and their receptors are categorized according to two major structural families:

- *The hematopoietin family*:
  - Includes growth hormones
  - Includes many IL implicated in both innate and adaptive immunity
- *The TNF family*:
  - Also functional in both innate and adaptive immunity
  - Includes many members that are membrane bound

Both major structural families of cytokines are thought to play an active role in local and systemic effects that contribute toward innate and adaptive immunity.

The effect of a particular cytokine on a given cell depends on the cytokine, its extracellular abundance, the presence and quantity of the complementary receptor on the cell surface, and downstream signals activated by receptor binding (the last two factors may vary by cell type). When a cytokine binds to a receptor, a signal is transmitted into the cell which activates particular genes and, in turn, alters the activity of the cell. Once activated, these cells are capable of producing other cytokines. Each individual cytokine can have several different functions depending on which cell(s) it binds to.

Cytokines are strongly involved in regulating immune function. For example, in lymphocyte activation, both T and B cells critically depend on receiving signals delivered by specific cytokines that bind to receptors on their cell membranes. Likewise, cytokines are influential in promoting or inhibiting local and systemic inflammation.

Considering cytokines are multifunctional, it remains complex to simplify these molecules in order to give a precise account. This is due to:

1. The redundant (sharing the same properties) effect of cytokines
2. Multifunctional properties of cytokines (pleiotropy)

3. Several cells may be capable of producing the same cytokine
4. The ability of cytokines to act synergistically or antagonistically with each other

Therefore, it is easier to imagine that these important protein molecules work in a network to promote or inhibit the interaction of the immune system with other physiological systems, by which they remain mutually dependent on each other.

Daily Stress

Synonyms

Daily hassles; Everyday problems

Definition

Daily stress is defined as mundane hassles, strains, or annoyances associated with routine daily activities and transactions of everyday life. Daily stress is relatively minor, but has the potential to disrupt the flow of everyday life and add to overall levels of stress.

Daily stress can be both anticipated and unanticipated. Anticipated daily stressors include, for example, driving in rush hour traffic on the way home from work, paying bills, working long hours, job performance evaluations, or taking children to after-school activities. Unanticipated stressors may include arguments with spouse, car trouble, getting stuck in long lines at the grocery store, getting sick, losing one's keys, or inconveniences due to weather.

Description

Daily stressors are not inherently stressful events, but they are events that people might appraise as stressful. The experience of feeling stressed depends on what events one notices and how one appraises or interprets these events, which is referred to as the "primary appraisal." Events that are stressful for one person may be routine for another. For example, one may see an upcoming job interview as an exciting opportunity. Others may view it as terrifying. Theoretically, the person then engages in a "secondary appraisal" to determine the adequacy of personal and social resources for dealing with the stressor.

Daily stress is different from major life stressors such as getting married, death of a loved one, or

M.D. Gellman & J.R. Turner (eds.), *Encyclopedia of Behavioral Medicine*,
DOI 10.1007/978-1-4419-1005-9,

divorce. Unlike life events that call for people to make adjustments to their lives, daily hassles are part of everyday life. Daily stress is more frequent and continuous form of stress than less frequent events that constitute major life stressors. Because of its frequency it may be a more important determinant of stress than major life stressors.

Daily stress and minor hassles have been found to be important forms of stress. Research indicates that routine hassles may have significant harmful effects on mental and physical health (i.e., declines in physical health such as headaches or backaches or worsening of symptoms in those already suffering from illness). Minor hassles can produce stress and aggravate physical and psychological health in several ways. First, the effect of minor stressors can be cumulative. Each hassle may be relatively unimportant in itself, but after a day filled with minor hassles, the effects add up. The cumulative impact of small stressors may wear down an individual until the person eventually feels overwhelmed, drained, grumpy, or stressed out. The aggregate effects of everyday hassles have the potential to compromise well-being or predispose an individual to become ill. Second, daily stress can contribute to the stress produced by major life stressors and influence the relationship between major life events and illness. That is, daily stress can contribute to the stress produced by major life events. If a major life event is experienced at a time when minor life events are also high in number, the stress may be greater than it would otherwise be. Alternatively, major life events, either positive or negative, can also affect distress by increasing the number of daily hassles they create.

Data

J. Rick Turner
Cardiovascular Safety, Quintiles, Durham, NC, USA

Synonyms

Numerical information; Numerical representation of (biological, psychological, behavioral) information

Definition

Data is a plural construct indicating more than one piece of numerical information. The singular form of the term is datum. Statistical analysis (certainly of the type useful in the discipline of behavioral medicine) almost always uses more than one piece of numerical information, and the term datum does not occur again in any other methodology entry in this encyclopedia.

Description

Accordingly, plural words are used in conjunction with the word data: "the data are, the data were, these data, the data show, etc." If you are uncertain as to how to construct a phrase including the word data, replace the word data in your mind with the word results. While the terms data and results are not truly synonymous, the word results is also a plural construct. This strategy will

therefore likely help you express a phrase including the word data correctly.

Data can generally be classified into one of the following scales of measurement: nominal, ordinal, and ratio. Nominal scales involve names of characteristics. Common examples from behavioral medicine include sex (male and female subjects in a research study) and race or ethnicity. An ordinal scale is defined as one in which an ordering of values can be assigned. Age of study subjects categorized as less than 25 years of age, 25–30 years of age, and 31 years of age and older is one example. Data measured on a ratio scale can be manipulated in certain ways not possible with the previous scales. For example, someone weighing 220 pounds (lbs) can be said to weigh twice as much as another subject weighing 110 lbs. The same applies for height and age. The feature of the ratio scale that makes such comparisons possible is that the value of zero on the scale represents a true zero – a weight of zero and a height of zero (no matter what the unit of measurement) means that there is no weight or height, respectively.

You may have noticed what appears to be an initial contradiction in the previous paragraph: Age is discussed in both the ordinal scale and the ratio scale discussions. The reason for this apparent paradox is that data can be measured (recorded) on one scale but reported on another. Imagine that 100 subjects participate in a research study, and each of their ages is recorded in years and months. Then, for various reasons, the subjects are each placed into one of three ordinal categories: those aged less than 25 years of age, 25–30 years of age, and 31 years of age and older. This is perfectly acceptable, but any statistical analysis performed would have to take into account the scale on which the data are reported: Different analyses are appropriate for different kinds of data.

It is also of interest to note that, while it may be convenient to report the subjects' ages in this ordinal fashion, a certain degree of precision in the information is lost. For example, two subjects aged 26 and 29 years, respectively, would both be placed in the middle category. Therefore, although they provide different raw data (their age in years and months) they contribute equally to the total number of subjects in that category.

Database Development and Management

J. Rick Turner
Cardiovascular Safety, Quintiles, Durham, NC, USA

Definition

The goal of experimental methodology and operational execution in behavioral medicine research, like all research, is to provide optimum quality data for subsequent statistical analysis and interpretation. These data need to be stored and managed. Databases facilitate such storage and management. Data management is therefore an important intermediary between data acquisition and data analysis.

Description

Analysis of data collected in behavioral medicine clinical trials is typically conducted using files of data contained in a database. It is of critical importance that the data collected from all sources are accurately captured in the database. A brief list of such data includes: subject identifiers (rather than their names); age, sex, height, and weight; questionnaire data concerning a multitude of topics; and physiological measurements made before, during, and possibly after the treatment period(s).

A data management plan for a clinical trial is written along with the study protocol and possibly a statistical analysis plan before the study

commences (statistical details can also be included in the study protocol). The data management plan identifies the documentation that will be produced as a result of all of the data collected during the conduct of the trial. This plan covers items such as:

- The form(s) on which raw (source) data will be recorded.
- Entering data.
- Cleaning the data.
- Creating data reports.
- Transferring data.
- Quality assurance processes.

The quality assurance (QA) component is vital. While differing definitions of quality activities can be found, Prokscha (2007) defined quality assurance (QA) as a process involving the prevention, detection, and correction of errors or problems, and quality control (QC) as a check of the process. The data stored in the database need to be complete and accurate. Processes that check data and correct them where necessary (i.e., make a change to the database) need to be formalized, and all corrections documented in an audit trail such that a later audit can reveal exactly how the final database was created. That is, following initial data entry, the audit trail will record "who, what, when, why" information for all changes subsequently made.

Having collected optimal quality data, first-rate data management is also critical. Many data that are collected can now be fed directly from the measuring instrument to computer databases, thereby avoiding the potential of human data entry error. However, this is not universally true. Therefore, careful strategies have been developed to scrutinize data as they are entered. The double-entry method requires that each data set is entered twice (usually by different operators) and that these entries are compared by a computer for any discrepancies. This method operates on the premise that two identical errors are probabilistically very unlikely, and that every time the two entries match the data are correct. In contrast, dissimilar entries are identified, the source data located, and the correct data point entry confirmed.

To facilitate the eventual statistical analysis of the enormous amount of data acquired during a clinical trial, recording and maintaining them is extremely important. Database development, implementation, and maintenance therefore require attention. The goals of a database are to store data in a manner that facilitates prompt retrieval while not diminishing their security or integrity.

There are several types of database models. Clinical research typically utilizes one of two types, the flat file database or the relational database. Each has its advantages and disadvantages, and these will be considered by data managers before they decide which type to employ. The flat file database model is simple but restrictive, and it becomes less easy to use as the amount of data stored increases. This model can also lead to data redundancy (the same information, e.g., a subject's birth date, being entered multiple times) and consequently to potential errors. This model works well for relatively small databases.

Relational databases are more flexible, but they can be complex, and careful initial work is needed. This work involves initial logical modeling of the database. The defining feature of a relational database is that data are stored in tables, and these tables can be related to each other. This reduces data redundancy. Subject identifiers in one table, for example, can be related to their heights in another table, their baseline blood pressure in another table, and so on, thereby eliminating the need to store identifiers with each individual set of measurements. Since these databases can contain huge amounts of tables, use of one of several commercially available relational database management systems is typical.

Death Anxiety

Chad Barrett
Department of Psychology, University of Colorado Denver, Denver, CO, USA

Synonyms

Fear of Death; Thanatophobia

Definition

Death anxiety refers the fear of and anxiety related to the anticipation, and awareness, of dying, death, and nonexistence. It typically includes emotional, cognitive, and motivational components that vary according to a person's stage of development and sociocultural life experiences (Lehto & Stein, 2009). Death anxiety is associated with fundamental brain structures that regulate fight-or-flight responses and record emotionally charged explicit and implicit memories (Panksepp, 2004). Cognitive dimensions of death anxiety can include an awareness of the salience of death and a variety of beliefs, attitudes, images, and thoughts concerning death, dying, and what happens after death (Lehto & Stein, 2009). Death anxiety can be experienced consciously or unconsciously; it can motivate individuals to ameliorate their death anxiety through distraction (Greenberg, Pyszczynski, Solomon, Simon, & Breus, 1994), attempts to enhance self-esteem (Bassett, 2007), or by pursuing positive life changes (Tedeschi & Calhoun, 2004). Individuals experiences of death anxiety can be influenced by their developmental stage. Young adults are mostly concerned about dying too soon, and adult parents are mostly concerned about the effect of their possible death on other family members. Elderly adults are often more concerned with becoming a burden on others, dying alone, or dying among strangers (Kastenbaum, 2000). Sociocultural influences can also shape the cognitive, experiential, and emotional components of death anxiety (Kübler-Ross, 2002; Lehto & Stein, 2009).

Description

Most people report some fear of death, but only a few people report high levels of death anxiety (Kastenbaum, 2000). According to Noyes et al. (2000), only 3.8% of respondents indicated that they were much more nervous than most people about death or dying, and 9.8% indicated they were somewhat more nervous than most people. Stressful experiences can often increase a person's level of death anxiety, (e.g., life-threatening encounters, tragedies, disasters, health problems, illness, or death of a friend or family member, etc.) (Kastenbaum). A meta-analysis of research on death attitudes among older adults indicated that health problems were associated with elevated levels of death anxiety (Fortner & Neimeyer, 1999). In a later review of the literature on death attitudes, Neimeyer, Wittkowski, and Moser (2004) noted that the relationship between death anxiety and health problems is sometimes equivocal. While many studies found positive associations between health problems and death anxiety, others found no significant relationship. Neimeyer et al. discussed more sophisticated studies and that such conflicting findings may be the result of moderator variables such as social support, coping styles, and religious beliefs. Increased social support, approach- and acceptance-based coping strategies, intrinsic religiosity, and beliefs in a positive afterlife are typically associated with less death anxiety.

Definition

Death within 1 h of the onset of acute symptoms.

Description

Sudden cardiac death (SCD) is an important public health problem, with an annual incidence estimated between 180,000 and 250,000 cases in the United States. The working definition of SCD is death within 1 h of the onset of symptoms, in the absence of preceding evidence of severe pump failure. In prior decades, the majority of SCD cases have been estimated to occur due to rapid cardiac arrhythmia, specifically ventricular tachycardia (VT) and ventricular fibrillation (VF). More recent data indicate that VT/VF is the presenting rhythm in SCD about 30–40% of the time. SCD may also occur due to life-threatening slow heart rhythms (bradycardia) or due to other causes such as massive pulmonary embolism or intracranial hemorrhage (Hinkle & Thaler, 1982; Lloyd-Jones et al., 2010).

In prospective cohort studies, women have a lower incidence of sudden death than men. Coronary artery disease (CAD) is the most common finding in SCD and is discovered in as many as 80% of SCD cases. However, among the large population of patients with coronary artery disease, the absolute risk of SCD is still low. In addition, a substantial proportion of SCDs occur in the absence of known prior heart disease.

Clinical risk factors for SCD have been developed, and the most reliable of which is reduced left ventricular ejection fraction by cardiac imaging such as echocardiogram. However, the prevailing clinical indicators of risk are still limited in their specificity, and identification of individuals at high risk remains a major challenge (Chugh et al., 2008).

Two major mechanisms have been implicated in SCD in the setting of CAD. First, acute plaque rupture may lead to coronary artery occlusion, inadequate blood flow to cardiac muscle (ischemia), and subsequent VT and VF. Another potential mechanism related to CAD results from the presence of myocardial scar from a prior myocardial infarction. With this myocardial substrate, heterogeneity in depolarization and conduction can allow for the development of reentry, in which a tachycardia circuit develops and which manifests as VT that can eventually degenerate to VF. Other underlying cardiac abnormalities can also predispose to SCD. For instance, cardiomyopathies due to causes other than CAD (e.g., alcohol, long-standing hypertension, sarcoidosis) are also associated with SCD. In addition, primary electrical abnormalities, such as inherited ion channel disorders, are relatively rare but potent causes of sustained ventricular arrhythmia in the absence of structural heart disease (Virmani, Burke, & Farb, 2001).

The major treatment against SCD is a preventive therapy, the implantable cardioverter-defibrillator. Randomized controlled trials of primary prevention ICD therapy have demonstrated survival benefit in patients with left ventricular ejection fraction <0.36 and with symptoms of congestive heart failure (Bardy et al., 2005; Moss et al., 2002).

A number of studies have noted an association between psychosocial factors, in particular depression, and SCD. For instance, Empana et al. examined data from enrollees of a health maintenance organization in Washington state, in a case control study involving 2,228 out-of-hospital cardiac arrests. Cases of out-of-hospital cardiac arrest ($n = 2,228$) among patients aged 40–79 years were identified from emergency medical service incident reports, and their ambulatory medical records were examined for the existence of depression. Compared with nondepressed subjects, the adjusted odds ratio of cardiac arrest was increased in less severely depressed subjects (OR 1.30, 95% CI 1.04–1.63) and further increased in severely depressed (OR 1.77, 95% CI 1.28–2.45) (Empana et al., 2006). In a cohort analysis involving 915 individuals aged 70 years or older in northern Finland, Luukinen et al. found that depression was associated with increased risk of sudden death (HR 2.74, 95% CI 1.37–5.50), whereas the risk of non-sudden death was not significantly increased. (Luukinen, Laippala, & Huikuri, 2003) In the Nurses' Health Study of 63,000 female nurses without known cardiovascular disease at study outset, cohort analyses indicated a significant association between depression and SCD in multivariable models that included hypertension, diabetes, and hypercholesterolemia (HR 2.33, 95% CI 1.47–3.70). The relationship of depression at study outset to subsequent SCD appeared to be related to a specific association with antidepressant use (Whang et al., 2009). A separate cohort analysis of the Nurses' Health Study included 72,359 women with no history of cardiovascular disease or cancer in 1988 and used the Crown-Crisp Index to assess phobic anxiety. During 12 years of follow-up, women who scored 4 or greater on the CCI were at higher risk of SCD (HR 1.59, 95% CI 0.97–2.60). After adjustment for possible intermediaries (hypertension, diabetes, and elevated cholesterol), a trend toward increased risk persisted for SCD ($P = 0.06$) (Albert, Chae, Rexrode, Manson, & Kawachi, 2005).

Definition

Defensiveness is defined as a coping strategy that is characterized by a general orientation away from threatening self-relevant information and a denial or minimization of negative affects such as distress, anxiety, or anger.

Description

Defensiveness is characterized by a general orientation away from threatening self-relevant information and a denial or minimization of negative affects such as distress, anxiety, or anger (Weinberger, Schwartz, & Davidson, 1979). Self-relevant information that is perceived as being inconsistent with personal goals and beliefs is likely to trigger defensive coping reactions (Croyle, Sun, & Hart, 1997). Defensiveness appears to occur normatively in response to self-relevant health risk information, but also to vary across individuals as a more enduring orientation to coping with distress. There is much conceptual overlap between defensiveness, repressive coping, avoidant coping, and denial in the literature, in that each share a core coping process of minimizing, denying, or repressing distress, negative affect, or distressing information to serve emotion regulation goals (Myers, 2010).

Defensiveness has been most frequently assessed through the use of measures of self-reported defensiveness (Weinberger et al., 1979), such as the Marlowe-Crowne Social Desirability Scale (MCSD; Crowne & Marlowe, 1960). Those who score high on social desirability are thought to minimize, deny, or repress negative emotions such as anxiety and anger, reflecting a defensive or self-deceptive orientation to the self that involves avoidance of distress-arousing thoughts. Measures of self-reported trait anxiety are also frequently used in conjunction with the MCSD to identify those who minimize or deny negative affects and who score high on defensiveness to capture a true defensive or, interchangeably, repressive coping group (Myers, 2010; Weinberger et al., 1979). Those who have a defensive or repressive coping style are less likely to report negative affect, distress, somatic symptoms, and chronic stress across a variety of tasks, experimental conditions, and self-report measures. Although defensive/repressive copers deny distress in response to stressful experimental conditions, physiological indicators of distress are often observed.

Defensiveness occurs rather frequently in the population. It has been estimated that 10–20% of the general population, 30–50% of those with particular chronic illnesses, and up to 50% of the elderly use defensive or repressive coping strategies (see Myers, 2010 for a review). In the context of behavioral medicine, defensiveness appears to prompt cognitive, behavioral, and physiological variations, which may have important implications for health. Specifically, the current literature suggests that:

1. Defensiveness is associated with information processing variations that occur normatively in response to self-relevant health threat information.
2. Defensiveness may have direct effects on physiological functioning.
3. Defensiveness is associated with greater morbidity and mortality in a number of chronic illnesses and disease states.

Defensive Cognitive Processing

Defensiveness influences the way that information is processed when threatening self-relevant information is perceived. Defensive cognitive processing variations appear to occur normatively in response to perceiving personally threatening health risk information. Defensive denial processes tend to appear early in the health-threat appraisal process and tend to diminish over time. They are less extreme when individuals are aware of direct actions to eliminate the threat, and are less common when positive states and experiences (e.g., positive mood, optimism, self-affirmation) are bolstered prior to threat perception, or when active coping alternatives are available and reasonable to execute. Defensive cognitive processing variations such as (a) minimization of the seriousness of health threats, (b) self-serving prevalence estimates,

(c) tendencies to denigrate the accuracy or validity of an undesirable test result, and (d) biased processing of health risk information occur frequently in response to perceived health-threat information. These normative defensive processes may play an important role in regulating emotional distress in the short term so that rational health-protective actions can be identified, enacted, and maintained (Croyle et al., 1997; Wiebe & Korbel, 2003).

Physiological Effects of Defensiveness

An emerging literature has identified links between a generalized defensive or repressive coping style and physiological variations in responding which may have direct impacts on health (see Myers, 2010 for a review). It has been hypothesized that the effort required to repress, minimize, or deny negative thoughts and emotions characteristic of defensive coping may result in heightened autonomic reactivity and may impact cardiovascular arousal. Defensiveness has been associated with increased cardiovascular reactivity to stress via increased sympathetic demand when defensive processes are initiated and maintained. Homeostatic changes in baseline cardiovascular functioning are thought to occur over time in response to increased sympathetic reactivity. Cardiovascular disease risk may be increased in defensives through a physiological mechanism of increased stress reactivity, possibly triggering changes in vascular functions or structure that may alter resting blood pressure levels.

Increased Prevalence of Morbidity and Mortality among Defensive Copers

There is an extensive body of literature that links trait-like defensive and repressive coping with poor physical health (see Myers et al., 2007 for a comprehensive review). Repressive/defensive coping appears to both contribute to poor health and disease progression, and to also be used more frequently among those with chronic illnesses. There is a fairly extensive literature linking repressive coping with increased risk for mortality in coronary heart disease (CHD) and myocardial infarction (MI). Repressive coping is associated with a twofold increased risk of death, MI, and other cardiac events. In addition, heightened levels of defensiveness are associated with hypertension, high blood pressure, as well as high lipid and glucose levels. For example, high scores on the MCSD have been associated with elevated blood pressure and heart rate reactivity. Additional support for the association between defensiveness and elevated blood pressure in the general population was found in Jorgensen, Johnson, Kolodziej, and Schreer (1996) meta-analysis. Further, a meta-analysis by Mund and Mitte (2011) suggested that repressive copers are at greater risk of developing cancer and coronary heart disease.

Degenerative Diseases: Disc or Spine

Daniel Gorrin
Department of Physical Therapy, University of Delaware, Newark, DE, USA

Definition

The intervertebral disc is a structure located between adjacent vertebral bodies that functions primarily as a shock absorber. The disc is comprised of a fibrocartilaginous outer layer called the annulus fibrosus and a gelatinous inner layer called the nucleus pulposus (made up of collagen fibrils embedded within a water/mucopolysaccharide mix). The disc is connected to the cartilaginous end plates located on the cranial and caudal aspects of the vertebral bodies. The end plates assist in providing the disc with nutrients.

Degenerative disc disease is a potential cause of back pain marked by an atraumatic, gradual onset of symptoms. Due to its primary function as a shock absorber, the disc is subject to significant "wear and tear" during the course of a lifetime. As the patient increases in age, the disc may undergo a degenerative process in which water is lost from the nucleus pulposus and replaced with fibrocartilage. Systemic, cellular, and biochemical changes related to aging may also contribute to degeneration of the disc. Pain resulting from degenerative disc disease is thought to be caused by a combination of irritation of the disc's nociceptive fibers and inflammatory products found within the damaged disc.

The degenerative process can also affect the outer layer of the disc, the annulus fibrosis, which could increase the risk of a herniation of the nucleus pulposus. Tears in the annulus or degeneration of the annulus can limit the structure's ability to contain the gel-like nucleus. Release of the nucleus can cause impingement and irritation of the surrounding spinal nerve roots or even the spinal cord itself. This condition (commonly referred to as a "bulging" or "herniated" disc) can result in localized pain at the site of the herniation or pain in the areas supplied by the nerve (radiculopathy).

Patients who experience degenerative disc disease or a disc herniation are likely to regain full function with non-operative treatment. Physical therapy interventions including mobilization, manipulation, traction, core stabilization exercises, electrical stimulation, and biofeedback are used in treatment of these conditions. Appropriate pharmacological intervention, nerve root injections, and epidural injections can also help provide pain relief. Operative treatment may be indicated if the patient presents with severe neurological deficits or receives no benefit from conservative treatment.

Chronic inflammatory polyarthritis; RA

Definition

Rheumatoid arthritis (RA) is a chronic inflammatory condition that affects the synovium of joints in the body. While the exact cause of RA is unknown, it is considered to be an autoimmune condition, in which the body attacks its own healthy cells. In a normal, healthy joint, the synovial membrane provides synovial fluid that functions to reduce friction and lubricate the joint surfaces and to provide nutrients to the cartilage. With RA, the synovial membrane becomes inflamed and thickens, forming a pannus. A pannus is an accumulation of tissue that ultimately causes damage to structures in the joint capsule, such as the cartilage, subchondral bone, and even ligaments.

RA presents with periods of both exacerbation and remission. The typical signs and symptoms of RA include pain, morning stiffness, swelling, and decreased mobility of the affected joints. Normally, multiple joints are affected in a symmetric pattern, with both sides of the body being affected. The small joints of the hands and feet are the most common joints to be affected, as well as the cervical spine. As the condition progresses, laxity in the ligaments supporting the joint may develop, causing joint deformities or dislocations.

RA's symptoms are not only musculoskeletal, but the condition can also affect the cardiovascular, renal, and pulmonary systems that may also present in this condition, including fatigue, loss of appetite, and decreased endurance. In some patients, firm skin nodules may form in areas such as the elbows or fingers. It usually presents between the ages of 20–50 years old, and females are more affected.

Although there is no cure for RA, there are pharmacotherapy treatment options that target the pain and inflammation with hopes of slowing the progressive of the disease. The use of medications includes analgesics, nonsteroidal anti-inflammatory drugs (NSAIDs), corticosteroids, disease-modifying antirheumatic drugs (DMARDS), and biologic response modifiers (BMRs). Physical therapy is also a critical component in the management of RA. During periods of an active flare, joint protection and rest are the most important. Exercise, though, should still be a component of treatment, organized into short bouts with frequent rest periods to limit fatigue. In order to prevent deformations and maintain adequate range of motion, it is very important that patients consistently change positions of the affected joints. If swelling is not present, it is also recommended that light stretching be done.

Because the manifestations of RA are irreversible, management and treatment of RA is a lifelong process. It is essential for patients to work closely with their health care providers in order to establish an individualized treatment plan in order to maintain as much functional independence as possible.

Degrees of Freedom

J. Rick Turner
Cardiovascular Safety, Quintiles, Durham, NC, USA

Definition

Degrees of freedom may be defined as the number of squares of deviations from the mean minus the number of independent linear restrictions placed upon the quantities involves. For n numbers there are n squares of deviations from the mean, of which only $(n - 1)$ are independent. That is, when $(n - 1)$ are specified, the nth is also specified.

Description

This is the most esoteric definition in the Methodology category of entries, and please do not be concerned if it sounds a little hard to digest. The following scenario will make it much clearer.

Suppose you are asked a question: "Choose any five numbers that add up to 100." How much choice do you actually have? A few moments' thought will reveal that you only have four choices. You can choose any four numbers you wish, but having done so, you have no choice about the fifth. Whatever the sum of the four numbers you have chosen, only one number will take you from there to 100, and hence you have no choice.

Now consider this issue in a slightly different way, but one that is precisely equivalent: "Choose any five numbers that have a mean of 20." This is an equivalent task since any five numbers that have a mean of 20 will add up to 100. Therefore, once again, there are only four choices: These four choices precisely determine the value that must be chosen as the fifth. Hence, in a group of scores with a fixed mean, there is one less degree of freedom than the total number of scores. This explanation ties in to the information provided in the entry titled "▶ Variance," in which the calculation of variance from a term called "the sum of squares" is described: Variance is obtained by dividing the sum of squares by the degrees of freedom.

A word of further explanation is in order here. While the term $(n - 1)$ is used by the majority of statisticians, it is possible that you might on occasion see the term n used as the denominator instead of $(n - 1)$ when calculating variance. The mathematical reasoning behind the statement that $(n - 1)$ is the better choice is beyond the scope of this encyclopedia's discussions. Nonetheless, a simple explanation makes the point.

Whenever a single research study is conducted, a sample of study participants is chosen from the population of all individuals who could theoretically have participated as subjects. The data collected from the subjects who did participate facilitate the precise calculation of the variance in the characteristic of interest to the researchers (reduction in blood pressure, reduction in an assessment of depression, etc.). However, this precisely calculated value is not of primary interest. What is of most interest is an estimate of the variance that would be seen in the general population of individuals who may be exposed to the intervention of interest if the study reveals that the intervention is both safe and also of therapeutic benefit. That is, the goal is to use statistical methodology to estimate in an optimum manner how well the results of a single experimental study will generalize to the general population of patients should the intervention become widely used. The best estimate of the population variance is generated by the use of $(n - 1)$ as the degrees of freedom, that is, as the denominator when the sum of squares is divided by the degrees of freedom.

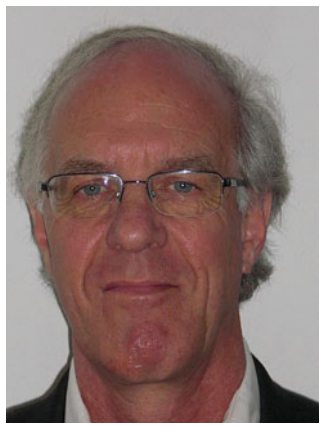
Biographical Information



Joost Dekker was born in Doetinchem, the Netherlands, on June 23, 1951. He received a BSc in chemistry (Utrecht, 1973, cum laude) and MSc in psychology (Utrecht, 1980). He obtained his PhD in 1988 (Utrecht, cum laude). He is a licensed health psychologist. He was senior researcher at the WHO Collaborating Center on Quality of Life in Relation to Health Care, Amsterdam (1987–1988), and senior researcher and subsequently head of the research department at the Netherlands Institute of Primary Health Care, Utrecht (1988–2001). He was also director of the Institute of Health and Welfare Studies, Amsterdam (2001–2007).

Dekker is currently Professor of Allied Health Care at the Department of Psychiatry and the Department of Rehabilitation Medicine, VU University Medical Center, Amsterdam, the Netherlands (1997–present). He is chair of the research track Soma & Psyche in the Mental Health research program, EMGO Institute for Health and Care Research, and leader of the Quality of Life research program, Cancer Center Amsterdam. He is "dosent" of Psychological Aspects of Rehabilitation at the Faculty of Sports and Health Sciences, University of Jyväskylä, Finland.

Dekker's research concerns behavioral factors in somatic disease, in the clinical epidemiological tradition. He focuses on musculoskeletal disorders, neurological disorders, and – recently – cancer. He has obtained grants from numerous agencies, including the Ministry of Health, Netherlands Organization for Health Research and Development, and NGOs. He is (co)author of more than 225 international peer-reviewed scientific publications, more than 80 national peer-reviewed scientific publications, and more than 90 scientific publications in books, reports, and other journals. He served as editor in chief (2007–2011) and associate editor (1993–2006) of the International Journal of Behavioral Medicine. He performs editorial services for a wide range of scientific journals and has supervised 21 successfully defended PhD theses.

Dekker is president elect of the International Society of Behavioral Medicine (2010–2012) and will serve as president from 2012 to 2014. Other positions in ISBM include member of the Board (2007–present), member of the Governing Council (1994–2006), chair of the Strategic Planning Committee (2004–2006), chair of the Nominations Committee (2006), and co-chair (1996–1998) and chair (1998–2002) of the Education and Training Committee. He is involved in other international and national boards and committees. Examples include the Society of Behavioral Medicine, the Cochrane Collaboration, Netherlands Health Council, Netherlands Health Research Council, Netherlands Behavioral Medicine Federation, and Royal Netherlands Society of Physiotherapy. He has contributed to the organization of numerous international and national conferences.

Major Accomplishments

Dekker developed the theory on behavioral and neuromuscular factors in activity limitations in

osteoarthritis. The theory provides an integrated model of how behavioral factors (negative affect and avoidance of activities) and neuromuscular factors (muscle weakness, poor proprioception, and laxity of joints) interact, resulting in activity limitations in this clinical condition. Empirical support for the theory has been obtained in cross-sectional and longitudinal research (Dekker, Tola, Aufdemkampe, & Winckers, 1993; van der Esch, Steultjens, Knol, Dinant, & Dekker, 2006; van der Esch et al., 2007; Steultjens, Dekker, & Bijlsma, 2002).This theory was used to develop therapeutic approaches aimed at improved performance of activities in osteoarthritis. Examples include "behavioral graded activity" and "stability training." These therapeutic approaches have been and are being evaluated in randomized clinical trials, which are providing evidence in support of these approaches (Pisters, Veenhof, Schellevis, de Bakker, & Dekker, 2010; Veenhof et al., 2006).

He contributes to the integration of psychology and rehabilitation (including rehabilitation medicine, physiotherapy, and occupational therapy). This integrated approach results in novel theories and innovative treatments. The previously mentioned research on activity limitations in osteoarthritis illustrates the integration of psychology and rehabilitation. Other examples include the development of therapeutic approaches for neurological patients, specifically stroke patients with apraxia (Donkervoort, Dekker, Stehman-Saris, & Deelman, 2001; Donkervoort, Dekker, & Deelman, 2006; van Heugten et al., 1998) and patients with dementia (Graff et al., 2006).

Dekker also contributes to the scientific foundation of rehabilitation medicine, physiotherapy, and occupational therapy. This work concerns the application of the International Classification of Functioning in these disciplines (Dekker, 1995), summarizing the evidence in support of exercise therapy in a wide range of disorders (Baar, Assendelft, Dekker, Oostendorp, & Bijlsma, 1999; Smidt et al., 2005), assessing prognostic factors for quality of life (Braamse et al., 2011; van der Waal, Terwee, van der Windt, Bouter, & Dekker, 2005), summarizing the evidence in support of occupational therapy in numerous disorders (Steultjens, Dekker, Bouter, Leemrijse, & van den Ende, 2005), assessing the impact of comorbidity on pain and activity limitations (van Dijk et al., 2010), and contributing to the development of measurement instruments and clinimetrics (Dekker, Dallmeijer, & Lankhorst, 2005).

He strongly supports the implementation of his research into clinical practice. This has resulted in the foundation of an outpatient clinic for advanced rehabilitation in osteoarthritis, the development and implementation of a national consensus on the treatment of osteoarthritis (van den Ende et al., 2010), and the implementation of screening and treatment for psychological distress in patients with multiple sclerosis and cancer.

In the role of editor in chief, Dekker contributed to the definition of the profile of the International Journal of Behavioral Medicine (Dekker, 2007). *IJBM* has been defined as an interdisciplinary journal, publishing research on factors relevant to health and illness. The scope of *IJBM* extends from biobehavioral mechanisms, clinical studies on diagnosis, treatment, and rehabilitation to research on public health, including health promotion and prevention. *IJBM* is an international journal: manuscripts originate from all over the world, addressing issues related to both local and global health.

Definition

Dementia is a disorder characterized by a progressive decline in intellectual function or behavior severe enough to cause impairment in social and occupational functioning.

Description

The term dementia is derived from the Latin words de ("without") and mens ("the mind"). The most widely used criterion for diagnosing dementia is the DSM-IV, which defines dementia as a disorder characterized by progressive decline in intellectual function or behavior severe enough to cause impairment in social and occupational functioning. Memory loss is the hallmark feature as well as impairment in one or more cognitive abilities, including language, reasoning, executive function, praxis, and visuospatial skills.

The DSM-V, which is expected to be published in 2012, has adopted the term "Neurocognitive Disorders" and further subdivided it into "Major" and "Minor" to replace the DSM-IV classification of "Delirium, Dementia, and Amnestic and Other Cognitive Disorders."

There are four dementia syndromes that account for approximately 90% of cases. They are Alzheimer's disease, vascular dementia, dementia with Lewy bodies, and frontotemporal dementia.

Alzheimer's disease: Alzheimer's disease (AD) is the most common dementia accounting for 50% of all cases. The major pathology is an abnormal extracellular accumulation of beta-amyloid peptide and intracellular accumulation of tau protein. Beta-amyloid is believed to be the main component of senile plaques (SPs) and tau is involved in the development of neurofibrillary tangles (NFT). Neuropathological examination of AD brains reveals that most cases of AD have a combination of NFT and SP. The NFTs initially appear in the hippocampus and entorhinal cortex and then extend to the neocortex. SPs tend to be seen more in the association cortex. Memory changes have been correlated with hippocampal and entorhinal pathology whereas more global cognitive decline is seen with neocortical involvement. AD onset is typically insidious, often taking years before the correct diagnosis is made. The first clinical criteria based on consensus were published in l983, referred to as the NINCDS-ADRDA. The advancement in MR imaging, PET imaging, CSF assays, and other biomarkers have shown that the older criteria are no longer well suited to diagnose AD and newer guidelines for all-cause dementia and AD dementia, which is further subdivided into amnestic and non-amnestic presentations, have recently been published (Dubois et al., 2007).

Cardinal features of the disease are progressive decline in mental status functions, including memory loss, and one or more cognitive impairments involving language, executive, visuospatial/perceptual dysfunction, apraxia, and agnosia. The cognitive deficits seen in AD are progressive and interfere with activities of daily living (ADL). The average time course for AD is between 8 and 12 years after diagnosis, but it can last as long as 20. It is now accepted that there is a prodromal phase in which individuals exhibit mild cognitive impairment, also referred to as MCI, before reaching the threshold for early dementia (Peterson, 2000).

There are three stages of AD. In mild AD, individuals typically present with problems recalling recent events with relative sparing of older memories. Other frequent cognitive problems include difficulty in solving problems and carrying out complex multi-step tasks, making sound decisions, planning difficulties, and problems in holding information in mind. Changes in personality are also common, with irritability and apathy among the most frequent complaints voiced by caregivers. Individuals in the early stages of AD may also exhibit empty speech, problems finding words, and have difficulty expressing their ideas. In the midstage or moderate AD, individuals become more confused and their memory loss is more pervasive. They may have difficulty retrieving older memories such as their address, school they attended, or names of relatives. Assistance with basic ADLs such as grooming, toileting, and other self-care activities may be necessary. Personality changes are more pervasive and it is not unusual for caregivers to report aggression and paranoia. In the late or severe stage of AD, afflicted individuals have lost the ability to communicate beyond occasional words or phrases and require full time assistance for all self-care activities. At this stage, motor symptoms are common as well as loss of bowel, bladder, and swallowing abilities. Most AD patients die of complications of chronic illness (pneumonia).

Vascular dementia: It is estimated that nearly two thirds of individuals who experience a stroke will have some degree of cognitive impairment, with roughly a third exhibiting frank dementia (Selnes & Vinters, 2006). Cognitive impairment resulting from vascular factors has been termed, "vascular cognitive impairment" or VCI. Various components of the "metabolic syndrome," a term that refers to a cluster of cardiovascular risk factors, including diabetes, hypertension, hyperlipidemia, hypertriglycemia, and impaired glucose tolerance, have been linked to age-related cognitive decline. Postmortem studies have revealed that VCI can also coexist with AD pathology, and those with both pathologies show a greater degree of cognitive impairment (REF). Since many of the vascular risk factors can be modified following changes in one's lifestyle (diet, exercise, not smoking, etc.) and medication, it may be possible to improve or even decrease the incidence of VCI with the appropriate intervention (Gorelick et al., 2011).

Dementia with Lewy bodies: Dementia with Lewy bodies (DLB), also known as Lewy body dementia, Lewy body disease, and cortical Lewy body disease, is the second most common dementia after Alzheimer's disease. DLB can present as a movement disorder resembling Parkinson's disease with cognitive changes or with memory and dysexecutive changes suggestive of Alzheimer's disease with visual hallucinations and/or delusions. Other presenting features of DLB include fluctuating levels of attention, characterized by drowsiness, starring off, lethargy, a history of falling, sleep-related disturbances, and autonomic dysregulation involving body temperature, blood pressure, urinary difficulties, constipation, and swallowing difficulties. Risk factors are age (>60 years), gender (male), and family history.

Frontal temporal dementia: Frontal temporal dementia (FTD) is a category of conditions involving atrophy and neuronal loss of the frontal and temporal lobes, resulting in prominent language impairment and behavioral decline. It is the most prevalent dementia among younger individuals. It is estimated that between 20% and 50% of individuals with dementia under 65 years of age have FTD (REF). Three FTD syndromes have been proposed: behavioral variant, semantic dementia, and progressive nonfluent aphasia. In the behavioral variant, neuropsychiatric features, characterized by emotional dysregulation, are prominent early in the disease. Social inappropriateness, lack of insight, apathy, disinhibition, and diminished activity are frequent as well as more extreme behaviors including poor hygiene, hyperorality, shoplifting, and other impulse control problems. This variant is often misdiagnosed as depression due to the apathetic behavioral style. Frank psychosis is unusual but seen most often among individuals with Alzheimer's disease (Cardarelli, Kertesz, & Knebl, 2010; Neary et al., 1998). In semantic dementia, patients present with fluent speech that is devoid of meaning and may contain

semantic paraphasias. The central feature is language output characterized by the use of words that approximate the intended word, such as "thing to eat with" for knife or "clothes" for skirt. In addition, this variant is also associated with associative agnosia, or the inability to recognize and assign meaning to objects and facial recognition deficits, including well-known figures such as celebrities (Cardarelli et al., 2010; Neary et al., 1998). The third variant, progressive nonfluent aphasia, is characterized by speech that is agrammatical, nonfluent, stuttering or halting, and effortful. Word retrieval difficulties or frank anomia are common with phonemic paraphasias such as saying "dat" for cat or "drother" for mother. Other impairments include difficulties with comprehension, reading, and repetition. Median survival for FTD is comparable to AD, approximately 9 years. Since there is no treatment for FTD, intervention is at the level of establishing behavioral management strategies for issues related to behavioral conduct and psychological counseling for caregivers and family members (Cardarelli et al., 2010; Neary et al., 1998).

Other Dementias

Treatable Dementia

There are a number of treatable dementias. The most common are those resulting from metabolic disorders such as a vitamin B-12 deficiency, normal pressure hydrocephalus, chronic substance abuse, subdural hematoma following trauma and hypothyroidism. For this reason, it is important to first rule out the treatable dementias with the help of a careful medical work-up, blood tests, and neuroimaging.

Rapidly Progressive Dementia (RPD)

There is a group of dementing conditions that develop subacutely and involve rapid decline of cognitive, behavioral, and motor function. A variety of etiologies can lead to RPD including neurodegenerative, toxic-metabolic, neoplastic, infectious, and inflammatory conditions (Geschwind, Shu, Harman, Sejvar, & Miller, 2008; Rosenbloom & Alireza, 2011).

The most widely studied RPD subgroup is the prion disease Creutzfeldt-Jakob disease or CJD. The sporadic form of CJD (sCJD) typically presents with mental status alterations characterized by dementia and/or psychiatric changes accompanied by cerebellar and extrapyramidal symptoms. sCJD onset is usually between 50 and 70 years and is equally prevalent in males and females, with a short median survival of 5 months. Of note, psychiatric complaints and behavioral symptoms such as depression, malaise and marked anxiety can precede the dementia and movement disorder. The EEG in the later stages of the disease has a distinctive diagnostic pattern of periodic sharp waves. The other form, referred to as variant CJD (vCJD), is rarer and can affect either young or older adults. Mean age of onset is 29 years and typically presents as a psychiatric disturbance lasting 6 or more months before other symptoms begin. Although the classic EEG pattern described above for sCJD is not typically present, the diagnostic feature of vCJD is the pulvinar sign on MRI (Geschwind et al., 2008).

Assessment of Dementia

The diagnosis of dementia should be ascertained through a combination of careful history taking, an interview with the patient and an informant, and neuropsychological testing performed by a qualified professional. The type of cognitive battery used to assess dementia will depend on several factors, including the time allotted for assessment, the willingness of the patient to participate in the testing process, and clinician availability.

Assessment of dementia requires an understanding of the normative aging process, brain anatomy and neural circuitry, and neuropathology. The mental status evaluation should focus on three components: cognition, personality/mood, and behavioral function. The type of examination can vary from bedside screening to a comprehensive evaluation.

The most widely known measure is the Mini-Mental State Examination (MMSE), a short screening instrument developed in the l970s to assess cognition in the elderly. It is untimed,

consists of 11 questions and a total possible score of 30 points. Originally designed for psychogeriatric patients (Rosenbloom & Alireza, 2011), this measure has been used to assess mental status in a wide variety of neurologic and general medical disorders as a dementia screen, not as a diagnostic tool. Its purpose is threefold: to screen for cognitive impairment, to assess severity of impairment, and to monitor change over time with repeated assessments.

There are many advantages of the MMSE, some of which include the ease of administration, the availability of international translations, the use of cutoff scores that make inter-study comparisons easier, and the availability of norms for age and education. However, there are several drawbacks to the MMSE (Nieuwenhuis-Mark, 2010). One criticism of this screening instrument is that it relies heavily on intact verbal skills, a problem for those with limited language ability or with a low educational level. Also there is a lack of consensus as to which cutoff score is best to use and whether the norms have been collected on representative samples. Although the MMSE has wide international use and has been translated into many different languages, there are questions as to whether the translations are really comparable to the original test due to the fact some of the items may not be relevant in other cultures (e.g., reciting "no, ifs, ands, and buts"). The most serious criticism is that the MMSE was developed as a cognitive screen, but it is widely used as a diagnostic tool and has been shown to be insensitive in discriminating between age-related cognitive change, mild cognitive impairment, and early dementia (Mitchell, 2009).

Ideally, bedside examinations and screening measures should be supplemented with more comprehensive testing using standardized neuropsychological measures with known reliability and sensitivity for detecting cognitive impairment. A qualified neuropsychologist will select measures designed to assess specific cognitive abilities including general intelligence, language abilities (e.g., verbal fluency, word retrieval, comprehension), conceptual reasoning and abstraction, perception, spatial cognition (visuoconstructive graphomotor and assembling abilities), attention and memory (working memory, verbal and nonverbal immediate and delayed recall), motor speed and the executive functions (e.g., skills involved in planning, organization, set shifting, goal setting, and problem solving). Additional questionnaires are frequently included to assess a patient's emotional status, in particular symptoms of anxiety and depression. A major goal of the neuropsychological evaluation is to identify a specific pattern of cognitive change associated with a particular dementia. Another goal is to provide a baseline from which to compare future evaluations. A third goal is to identify cognitive strengths and weaknesses that can be used to address treatment and management issues.

Prevention of Dementia

There is compelling evidence from basic and clinical research that aerobic exercise may be neuroprotective. Transgenic mouse models, epidemiologic, biomarker, and prospective clinical studies have linked exercise with improved cognition and provided evidence that physical activity directly modulates known risk factors associated with dementia, including obesity, vascular disease, hypertension, diabetes, inflammation, and cardiovascular disease. The mechanism by which increased physical activity improves cognition is not known. It has been proposed that physical exercise may reduce beta-amyloid deposits in the brain, increase synaptogenesis and plasticity, boost endorphins and growth factors, or increase brain perfusion (Savica & Peterson, 2011).

Education and intellectual stimulation have also been credited with having a neuroprotective role against dementia and cognitive decline (Stern, 2002). Numerous observational studies have shown a strong and positive association between higher intellectual activities and reduced cognitive decline. A lower educational level is associated with a 30% increased risk of having AD. It is possible that higher education is a proxy for higher SES which confers an advantage in terms of overall health, lifestyle, and reduced stress.

More recent studies have provided preliminary evidence showing that cognitive training, i.e., mental exercises to improve memory, reasoning, and processing, may improve cognition and instrumental activities of daily living. Preliminary evidence has shown in animals that increased mental activity is linked to increased brain volume (Willis et al., 2006).

Diet: Although it has long been held that diet is linked to cognition, the evidence remains controversial. Most attention has centered on the Mediterranean diet, one which is high in vegetables and non-saturated fat, and linked to a lower risk of cognitive decline. It is argued the diet is high in antioxidants and its relationship to reducing oxidative stress is the key factor responsible for improved cognition (Savica & Peterson, 2011).

Social Networks: There are several studies suggesting that social connectivity, as defined by participation in social activities and maintaining interpersonal relationships, may be protective against cognitive decline. Conversely, social disengagement, loneliness, and not living with a partner have been found to be linked to AD, although this association did not apply to those who were divorced or widowed (Seeman, Lusignolo, Albert, & Berkman, 2001). A valid criticism of these studies is that it is difficult to know whether reduced social connectivity is a risk factor or an actual symptom of AD, given that social withdrawal is a feature of early dementia.

Subject characteristics

Definition

Demography can be defined as the statistical science focusing upon the distribution, density, vital statistics, and various other defining characteristics of human populations. Demographics therefore include characteristics such as sex, age, race/ethnicity, height, weight, and socioeconomic class.

When reporting a research study, it is necessary to provide a summary of the relevant demographic characteristics of the subjects who participated in the study. Ultimately, the goal of a clinical study is not to provide precise information for that particular subject sample but to collect information that generalizes to the population from whom that particular sample was chosen. Therefore, a given subject sample needs to reflect that population adequately for such generalization to be meaningful.

Not all demographic information is always of relevance. In some studies, perhaps a clinical trial of a new drug, it may not be necessary to report the socioeconomic status of the study participating in the study. If there is no biologically plausible reason to think that individuals from different socioeconomic strata would respond differently to the drug, it is not necessary to report this information. In contrast, sex and age may be considered to be of considerable relevance if there are biologically plausible reasons to think that these factors may influence drug responses.

Denial

Synonyms

Coping strategies; Defense mechanism

Definition

The psychological concept of denial refers to a cognitive and emotional coping strategy involving the negation of a fact or reality. In the context of health psychology, denial refers to the negation of a health problem, effecting either oneself or someone else. Individuals experiencing denial refuse to believe facts that are difficult to face, such as being diagnosed with a terminal or chronic illness. Denial is a common and normal process; it can be either protective or harmful in managing a health problem, depending on the extent of the denial and how it impacts individuals' decision making. For instance, denial has been identified as a useful and necessary first step in the process of coping with a terminal or life-threatening illness to allow individuals to adjust

to the situation. However, denial can become a problem when it persists and prevents individuals from actively coping with the truth and/or receiving necessary care and treatment for their illnesses. Family members or friends of an individual diagnosed with an illness may also engage in denial; they may cope with the experience of learning their loved one is ill by rejecting the idea. If their denial persists as well, they may advise their loved one to not seek treatment or reject the truth regarding what is happening to their loved one.

Description

Denial as a psychological process has a long history, originating with Sigmund Freud's theory of defense mechanisms. Freud conceptualized defense mechanisms as strategizes utilized by individuals to protect themselves from difficult memories by distorting them or making them inaccessible to consciousness; denial was one such strategy. Over time, theorists have identified different types of denial that an individual may experience or engage.

Defensive Denial

Defensive (or pathogenic) denial is a specific form of denial in which individuals use defensive processes to manage their emotional responses and allow for appropriate decisions regarding health threats. This is a dynamic process that accommodates new information and can be distinguished from other forms of denial that ignore reality. Defensive denial minimizes threats but is responsive to reality and information regarding the situation. It may lead to the minimization of health threats, protective social comparisons that minimize the individuals' risks, or questioning the validity of health threat information. It is unclear how defensive denial impacts behavior, although it has been suggested that it may decrease negative affect and thus allow individuals to engage in protective health behaviors (Wiebe & Korbel, 2003). However, if a person experiencing pathogenic denial is not exposed to information regarding the seriousness of the situation, he/she may not recognize the truth of his/her situation (Janis, 1983).

Malignant Denial

Malignant (or pathological) denial is a maladaptive form of denial that prevents individuals from receiving necessary treatment for their conditions. What makes this form of denial malignant is the impact it has on health-care decisions: individuals will ignore doctors and refuse treatment. For instance, individuals suffering from psychological conditions, such as substance abuse and eating disorders, often deny they have a problem and refuse help or treatment. Individuals with infectious diseases who are experiencing malignant denial may engage in behaviors that put others at risk of becoming infected as well (Kalichman, 2009). Thus, this form of denial is a serious concern as it can negatively impact both an individual's own and others' health.

Denial versus Avoidance

Denial must be distinguished from avoidance. Avoidance refers to individuals' refraining from reminders of the truth, although they are cognitively aware of the facts, whereas denial suggests that individuals have refused to accept the facts. Thus, an avoidant individual may recognize he/she is ill but refrain from going to the doctor for treatment, while an individual in denial would refuse to see the doctor because he/she would not acknowledge he/she had an illness. Although these concepts are often confused and the terms used interchangeably, they are conceptually distinct.

Definition

Problematic use of drugs altering behavior and psychological function is categorized in terms of patterns and consequences of use. The common worldwide codification of these disorders is found in International Statistical Classification of Diseases and Related Health Problems 10 (ICD-10), which refers to these disorders as *Mental and behavioral disorders due to psychoactive substance use*. The generic ICD-10 definition is: "*a wide variety of disorders that differ in severity and clinical form but that are all attributable to the use of one or more psychoactive substances, which may or may not have been medically prescribed*." The American Psychiatric Association codification of these disorders is found in the Diagnostic and Statistical Manual – Fourth Edition (DSM-IV), which uses the diagnostic label of *Substance-Related Disorders*. The generic DSM-IV definition is: "*The Substance-Related Disorders include disorders related to the taking of a drug of abuse (including alcohol), to the side effects of a medication, and to toxin exposure*." While "dependence" historically has had a precise scientific definition, common use is often confused with "abuse," "addiction," and other terms.

Description

Determinants of Dependence

Problematic use of drugs altering behavior and psychological function ("psychoactive drugs") is determined by circumstances of use, route of administration, dose, and drug or medication. Direct biological and behavioral effects of a chemical or drug determine the likelihood of drug taking. The "abuse liability" or "abuse potential" is determined with standardized preclinical/animal laboratory procedures. In these experiments, the test drug is made available through an intravenous line, as a liquid for oral consumption, or on occasion as vapor or smoke. The animal has the opportunity to press a lever or engage in some other response producing drug delivery. The rate of responding and frequency of drug delivery are compared to the vehicle, or solution without drug (placebo). If the drug is "self-administered" at higher rates than vehicle, it is deemed to have "rewarding" or reinforcing effects that will sustain drug seeking and drug taking.

Within a series of similar drugs (e.g., stimulants, anxiolytics) the relative reinforcing effect can be established as a hierarchy from least to most reinforcing. In turn, this is characterized as relative abuse liability. Generally, though not always, the animal self-administration patterns predict the likelihood of human self-administration. In these experiments, food and water may be concurrently or sequentially available for comparison to drug intake or to determine the effect of drug on other behaviors. Numerous comparisons can be made, and other paradigms implemented, to further characterize the properties and behavioral consequences of drug self-administration. In animals, the core

biological effects of the agents are examined and in humans a variety of self-report descriptive measures, such as "liking," "willingness to take again," and "unpleasant effects" are also determined. Arguably, it is the balance of *immediate* pleasurable to unpleasant effects that determine possible persistent use. Untoward effects that follow excessive use, for example, "hangovers" are not necessarily deterrents to resumption of drinking alcohol. Ultimately, when use persists and dependence emerges, a variety of untoward outcomes occur. Continued use in patterns that produce hazardous and debilitating outcomes (biological, behavioral, social) are key features in determination of dependence.

Within drug self-administration studies, whether with nonhuman animals or humans, dose-ranging studies are conducted with, for example, "low," "medium," and "high" doses, again with comparison to placebo. The result is often, though not always an inverted U-shaped curve with lower doses consumed less than intermediate doses, while very high unit doses may generate less drug taking (due to increasing adverse effects or satiating doses achieved with less output). In some instances, for example, sedatives, the medication itself may impair ability to continue self-administration. Other experimental strategies determine whether changes in intake are due to incapacitating effects of the drug, titration to seek optimal effect, adverse effects at a particular dose, or other factors. While the interactions may be complex, dose is an important factor in self-administration and establishing drug dependence.

The route of administration (intravenous, inhalation, insulfflation, oral) may alter the likelihood of drug dependence. More rapid onset is typically observed with intravenous and inhalation routes and it is generally thought that this may increase the probability of persistent use. However, individual preferences or dislikes may intervene; for example, many people are unwilling to use injection paraphernalia. Still, while IV heroin use produces a singular and pronounced effect, orally ingested opioids for nontherapeutic purposes can also produce profound dependence. Most agents with moderate to high abuse potential can be expected to be associated with dependence in some people, regardless of route, when used outside of therapeutic regimens.

Other factors important to use and ultimately dependence may include drug availability and social circumstances. Social factors are commonly important in initial use even though later use may be solitary. The relative ease of obtaining a drug makes initial exposure and frequent use more likely for those individuals who are responsive to the effects. Still, most individuals exposed to drugs do not proceed to a level of use that can be categorized as dependence. Knowing who will, or will not proceed to dependence, that is, who is vulnerable to effects of a particular drug and likely to engage in persistent use is a matter of considerable interest.

Behavioral/Psychological and Physical Dependence

The various diagnostic and scientific schemata may differentiate or emphasize two aspects of dependence that are commonly inseparable: behavioral or psychological dependence and physical dependence. As drug action and determinants of persistent use have been more effectively delineated, these distinctions may be less useful but are separable in some circumstances.

Drug dependence typically refers to persistent use despite problems across the spectrum of personal and social activities as well as biological/medical and psychological harm. In current terminology, dependence refers to patterns of behavior that precede, are concurrent with, and follow use. Drug seeking (soliciting/purchasing drugs from others) can be elaborate and time consuming. The behavior of drug taking, legal or illegal, is typically characterized by ritualized events.

These behaviors may be socially accepted as well as being behaviorally and psychologically relatively benign, for example, persistent coffee/caffeinated beverage consumption at moderate doses. Caffeine, most commonly through coffee or carbonated beverage consumption, is thought to be the most widely used drug in

the world. In this example, two prominent ritualized patterns exist. One entails the legal purchase of beans or ground coffee, special home apparatus for grinding and preparing coffee along with the spectrum of containers from which it is consumed. A second pattern that has evolved in recent decades stems from the long-standing practice of coffee with meals or in coffee shops. Now, the elaborate rituals are well represented by Starbucks, Caribou, and other chains as well as myriad local purveyors. The user determines size (volume), dose (singles, doubles, triples), dairy product additions ranging from skimmed milk to heavy cream, additional additives be they spices or liqueur flavorings. The use, dose, drug-taking style, may differ from person to person and time to time for the particular person. Persistent caffeine use has clear biological and psychological effects and cessation of use leads to an array of symptoms.

Heroin use likewise entails procedures and rituals: mixing, drawing drug into a syringe, tying off an extremity to gain access to a vein and injection. Use by smoking or insufflation is also accompanied by a systematized approach to self-administration. These events may be solitary or in groups. The consequences of drug administration are then experienced. Heroin or other persistent opioid use for nontherapeutic purposes often follows a course of increasing dosing as tolerance emerges to the euphoriant effects, increase in associated illegal contacts during drug seeking, increasing cost, and deterioration of social circumstances. Tolerance is not consistent across all effects. Thus, diminished euphoriant effect leading to higher dosing with opioids is not matched by tolerance to respiratory depressant effects and death may ensue. In the case of potent stimulants, cardiovascular excitation/dysfunction or seizures occur as doses increase despite reduction in perceived euphoriant effects. These patterns of use in the face of untoward consequences are emblematic of dependence.

The behaviors immediately following drug use are dependent on the characteristics of the agent. Sedating drugs produce feelings of euphoria or pleasure, varying levels of lethargy and somnolence to virtual unconsciousness, and at the extreme, death, usually from respiratory depression. Stimulant-type drugs generate patterns of energized behavior ranging from active euphoria and self-confidence to highly stereotypic behaviors, hallucinations, and psychosis, and at the extreme, death due to cardiovascular accident or collapse.

Dependence may also refer to a biological state, historically referred to in pharmacology as "addiction" or more recently as "physical dependence," in which a distinctive profile and sequence of symptoms emerges when use is discontinued. The constellation of symptoms observed on abrupt discontinuation in the presence of physical dependence is referred to as a "withdrawal syndrome" (composed of withdrawal signs and symptoms). The consistency of such patterns is most evident for drugs with sedative-like properties such as opiates (e.g., heroin), benzodiazepines (e.g., diazepam), barbiturates (e.g., pentobarbital), and alcohol. These symptoms are typically the reverse of those associated with high-dose drug use; for example, with opioids, behavioral activation, increases in respiration, and increased gastrointestinal activity over baseline emerge. Direct physical symptoms dissipate over days but behavioral and biological symptoms that have been conditioned by repeated pairings of drug self-administration and previously neutral environmental stimuli may persist for months. They may be elicited by environmental circumstances in which drug use or withdrawal symptoms previously occurred. In the case of stimulants, behavioral malaise, impairment in performance, diminution of blood pressure, and other symptoms are common. For the licit drug caffeine, the most pronounced withdrawal symptoms are headache, inattention and associated performance deficits, and fatigue. The constellation of symptoms is often a determinant of reemergent drug seeking and drug taking, or in treatment jargon, "relapse."

As noted, in special circumstances, the components of dependence may be separable. This is informative with respect to the contribution of environmental circumstances, behavioral

consequences, and biological underpinnings. These separable determinants can be examined in the laboratory, for example, by comparing the behavior of animals that have learned to self-administer drugs to those that have passively received the drugs. Comparable instances exist in humans. Remarkable resilience and persistence of behavior emerges for individuals using psychoactive drugs to excess, be the drug stimulant or sedative like. However, patients receiving high doses of intravenous opioids in hospital settings for pain, invariably have a pattern of biological adaptations characteristic of dependence that dictate physiological sequelae to abrupt cessation of dosing will occur. Thus, for example, the constipation associated with high-dose opioid use is followed by increased gastrointestinal motility. Still, it is extraordinarily uncommon on recovery and discharge from the hospital for these patients to engage in the patterns of drug seeking and drug taking that are evident in individuals whose use was established through illicit acquisition and seeking euphoriant effects. Similarly, patients treated with methadone or buprenorphine for previous heroin dependence, are, on one hand physically dependent and tolerant to many opioid effects at a stable dose, but unlikely to seek and use illicit opioids. In other circumstances, for example, treatment of attention deficit-hyperactivity disorder, drugs with some dependence liability are used effectively for treatment and diminish the likelihood of illicit drug use and abuse; thus treating one disorder diminishes a range of problems, including propensity to illicit drug use. These examples point to the importance of a range of environmental and behavioral factors contributing to substance use disorders.

Acquisition, Maintenance, and Elimination of Drug Dependence

In the laboratory, nonhuman subjects (e.g., rodents, primates) generally self-administer, or will work to obtain, the same agents that are taken by humans in both laboratory and natural settings. Conversely, discovery of a drug used for euphoriant purposes in human populations, can generally be translated into animal paradigms with evidence of self-administration. There are some exceptions and special cases; for example, nonhuman organisms rarely self-administer hallucinogens, but for a variety of pharmacological and social reasons, these are not self-administered by humans in the same way as, for example, heroin. Persistent harmful heroin, cocaine, alcohol, or other drug use is clearly distinctively different from either therapeutic drug use or even "controlled" licit or illicit drug use.

Acquisition of drug taking is essentially a social and cultural phenomenon. For legal psychoactive drugs (e.g., alcohol), society sets relatively clear rules and norms generally with a view to harm reduction and control. Most people conform to the accepted social and legal constraints while some go on to dependence. For illegal drug use, the social group sets the norms. Both entail socially driven exposure.

Stable use of legal drugs may differ considerably within and across drugs. Caffeinated beverages may be consumed consistently throughout the day with late day cessation to permit undisrupted sleep. Historically, nicotine/cigarettes were consumed in virtually all social and nonsocial environments during the "maintenance phase." Here the change in social norms over many decades has resulted in limited venues for use, dramatic increases in prices, and remarkable reductions in use across the population in some countries, while unfettered use is permitted and maintained in other countries, thus pointing to the importance of social determinants in use and maintenance. Illegality of a drug sets maximum constraints on some aspects of use that must be circumvented but also establishes a separate market beyond regulatory control. Even with the alternative social constraints, not all individuals who use, be it stimulants (e.g., cocaine), opioids (e.g., heroin), or marijuana, go on to dependence.

Some of the factors that contribute to increased reinforcing effectiveness when a drug is self-administered (immediacy of effect, genetic makeup) have been considered. Yet the factors leading to transition from casual, stable, or infrequent use of a drug, legal or illegal, to

persistent, compulsive-like use by any given individual is not well understood.

Elimination of drug use and termination of self-administration and dependence can be studied in the animal laboratory and some findings are translatable to the human case. In the human natural environment, elimination or cessation may result from a variety of self-imposed regimens or externally applied circumstances. Severe dependence typically requires a course of specific treatment for the substance use disorder(s). For drugs that produce profound withdrawal syndromes, for example, alcohol, the first phase may require intensive medical management. However, this is distinct from the typically required course of treatment involving cognitive behavior therapy, substantial social and behavioral adjustments, and possibly maintenance medications.

Definition

The measurement of depression is a process conducted by clinicians and researchers for the purpose of (1) identifying people who may require treatment for depression, (2) identifying people who meet specific diagnostic criteria for

depression, and (3) quantifying the severity of depressive symptomatology.

Description

Depression is defined by a cluster of behaviors and symptoms that have both mental and physical manifestations and affect a wide range of functionality. Specific criteria for depression include experiencing persistent depressed mood or loss of interest or pleasure in most things along with at least four out of the following additional markers: sleep disturbance, feelings of worthlessness or guilt, appetite or weight changes, concentration problems, decreased energy, psychomotor retardation or agitation, and suicidality. Depression is ideally diagnosed through a face-to-face interview with a trained mental health professional based on the current versions of the Diagnostic and Statistical Manual of Mental Disorders (DSM) or the International Classification of Disease (ICD) criteria. It is also important to note that symptoms that do not meet criteria can be impairing and thus may be important to measure as well. As such, depression can be measured both categorically (i.e., meeting diagnostic criteria or not) and continuously (i.e., symptom severity). Depression measurement can be broken down into three distinct functions: screening, diagnosis, and quantification of symptoms. Instrument choice should be made according to these functions, in addition to what population is being assessed, what specific hypotheses are being tested, and if there is a desire to compare the results to other research findings.

Screening instruments are designed to capture anyone who could potentially meet diagnostic criteria for depression and should be referred for further evaluation. They can additionally be used to estimate the prevalence of possible depression in a given setting. They typically do not require a lot of time, have empirically supported cutoff criteria, and can be self-administered or administered by a nonclinician. As screening instruments are unable to diagnosis depression on their own, further assessment by a clinician is needed to establish a diagnosis.

Diagnosis of depression is typically done through a face-to-face interview with a trained clinician. Sometimes, as is typical in medical settings, this occurs only with those patients who have been screened as possibly depressed with the final diagnosis confirmed by a clinician. In research settings, the gold standard for depression diagnosis is a standardized diagnostic interview, such as the Structured Clinical Interview (SCID) or the Composite International Diagnostic Interview (CIDI). Structured diagnostic interviews can take over an hour depending on the patient and are typically administered by a clinician who has also been shown to reliably distinguish cases from among multiple participants. It is important to note that diagnostic interviews are meant to categorize individuals as diagnosed or not but will not capture people who fall just below the criteria, yet are still impaired.

Symptom rating scales offer a continuous assessment of depression severity. They are typically brief, can be self-administered or administered by a nonclinician, and may include a cutoff for screening purposes. They are particularly useful in monitoring changes in depression symptoms over time, and thus can be used in both clinical and research settings to evaluate treatment effects. Although many symptom rating scales have established clinical significance or severity cutoff values, they are unable to diagnose depression on their own; thus, assessment by a clinician or a structured diagnostic interview is needed for diagnosis.

There are multiple things to consider when making a depression measurement choice. First, depression and depressive symptoms can co-occur with or result from a variety of physical conditions such as hypothyroidism, cancer, diabetes, HIV/AIDS, heart disease, medication side effects, substance withdrawal, and other illnesses. Therefore, evaluating for additional medical issues can be important in the assessment of depression. Second, practical considerations should be taken into account, including the length, whether it assesses specific aspects of depression (i.e., measurement of suicidality and somatic symptoms separately), reading level, response formats, need for training to administer,

Note: Some measures come in more than one version with varying lengths and differences in administration

and whether it can be used to assess treatment response and severity of depression along with being able to diagnose. Finally, the Depression Task Force for the DSM-V is considering changing the criteria for depression to include a specification of the severity of depression, using the Patient Health Questionnaire (PHQ-9) or the Clinical Global Impressions (CGI) scale. This forthcoming change in criteria may influence the choice to include the PHQ-9 or CGI in the measurement of depression before measures are adapted to the new criteria.

Below we have provided Table 1 with the twenty-two most commonly used and validated measures of depression. For each measure, we indicate the number of items, type of measure (i.e., screening, diagnostic, and/or symptom rating scale), who can administer the measure (i.e., clinician, interviewer, self), whether it has any established cutoffs for severity or clinical significance, whether the scale or one of the subscales assesses depression specifically – as opposed to general psychological distress or mental illness, and the timeframe the assessment covers.

Diagnostic features of depression

Definition

Major depressive disorder (MDD) criteria requires five or more diagnostic features, with either (1) depressed mood or (2) anhedonia being present during the same 2 week period and a change in previous daily functioning.

Diagnostic features include (1) depressed mood (feeling sad or empty); (2) markedly diminished interest or pleasure in almost all activities (anhedonia); (3) weight loss or weight gain (at least 5% body weight change in a month), increased or decreased appetite; (4) insomnia or hypersomnia; (5) feelings of restlessness or feeling slowed down (psychomotor agitation or retardation); (6) fatigue, loss of energy; (7) feelings of worthlessness, excessive or inappropriate guilt; (8) diminished ability to think or concentrate, indecisiveness; and (9) recurring thoughts of death and/or suicide.

Dysthymic disorder or a chronic depressive disorder requires depressed mood, for more days than not, over a period of 2 years, and two or more of the diagnostic features previously mentioned. During the 2-year period, symptoms of depressed mood and the minimum of two diagnostic features are to have never remitted for more than 2 months at a time.

Diagnostic features include (1) poor appetite or overeating, (2) insomnia or hypersomnia, (3) low energy or fatigue, (4) low self-esteem, (5) poor concentration or difficulty making decisions, and (6) feelings of hopelessness.

- Depression symptoms must cause clinically significant distress or interfere with daily functioning (i.e., social, occupational) or daily tasks.
- Depression symptoms are not due to a general medical condition or due to the direct physiological effects of a substance.
- Depression symptoms are not better accounted for by bereavement.

Description

Symptoms of depression can be categorized by a marked change in a person's (1) physical well-being, evidenced by changes in sleep and eating

behaviors; (2) emotional well-being, such as feelings of sadness and/or hopelessness; and (3) thoughts. For example, negative thought patterns. Hallmark symptoms of depression are loss of interest in activities (anhedonia) and a depressed mood (melancholia), as at least one of these symptoms are necessary for MDD diagnostic criteria. Depression symptoms can have catatonic features, melancholic features, atypical features, and postpartum onset.

Depression symptoms may present differently among children and adolescents. Some children may present with mood irritability or a failure to make expected weight gains. Diagnostic duration of symptoms for children and adolescents is typically at least 1 year.

Depression diagnosis is two times more likely among women than men. Women's increased likelihood for depression is found in the general population, across cultural groups and across demographic groups (Bromet et al., 2011). Although studies have not concluded that depression symptoms differ by gender (Kessler, McGonagle, Swartz, Blazer, & Nelson, 1993), some studies suggest men exhibit more externalizing symptoms of depression (angry outbursts, irritability, withdrawal, blunted affect, etc.) while comparatively, women have more melancholic symptoms of depression (sadness, guilt, etc.) (Hatzenbuehler, Hilt, & Nolen-Hoeksema, 2010).

Depressive symptoms are quite common in several biomedical health conditions and have been shown to predict worse prognosis in heart disease (Bush, 2002; Frasure-Smith & Lesperance, 2006), even if at low levels. Because depression is a heterogeneous construct with multidimensional characteristics, the cardiovascular literature has begun to identify depression symptom clusters that are associated with worse coronary heart disease outcome. For example, some authors have found somatic depressive symptoms to be associated with cardiac disease severity (de Jonge et al., 2006; Watkins et al., 2003). A recent study comparing cognitive affective symptoms to somatic affective depressive symptoms found that somatic affective symptoms predicted worse cardiovascular outcome while cognitive affective symptoms did not (Martens, Hoen, Mittelhaeuser, de Jonge, & Denollet, 2009). Somatic affective symptoms include sadness, dissatisfaction, pessimism, suicidal ideas, crying, work difficulty, insomnia, fatigability, loss of appetite, somatic preoccupation, and loss of libido.

Effective treatment methods of patients with depressive disorders

Description

There are several types of treatment for depression, and these are mainly somatotherapy and psychotherapy. Somatotherapy for depression usually includes pharmacotherapy and electroconvulsive therapy (ECT). In addition, other types of somatotherapy including transcranial magnetic stimulation (TMS) can be available now in several countries such as USA (Gelenberg, 2010).

With regard to pharmacotherapy, there are several different types of drugs, so-called antidepressants. Antidepressants include selective serotonin reuptake inhibitors (SSRI), serotonin noradrenaline reuptake inhibitors (SNRI), tricyclic antidepressants (TCA), tetracyclic antidepressants, monoamine oxidase inhibitors (MAOIs), and other types of antidepressant drugs (Gelenberg, 2010; Hales & Yudofsky, 2003; Sadock & Sadock, 2003). The effectiveness of these antidepressants is generally comparable between classes and within classes of medications. On the other hand, side effect profiles clearly differ among the different classes of antidepressants. Pharmacotherapy is most widely used for treatment of depression. Especially pharmacotherapy is recommended as an initial treatment choice for patients with mild to moderate major depressive disorder as defined by DSM-IV-TR. The choice of each antidepressant is usually determined by anticipated side effects and safety for the individual patient. In general, the SSRIs and other newer antidepressants are better tolerated and safer than either TCAs or the MAOIs, although many patients still benefit from older drugs including TCAs. During pharmacotherapy, patients should be carefully and regularly monitored to evaluate side effects. Overall, approximately two-thirds of the patients with major depression respond to an adequate trial of antidepressant medication. However, far few achieve full remission of symptoms.

ECT is recommended as a treatment of choice for patients with severe major depressive disorder and those with psychotic features. Other cases such as a suicidal patient with an urgent need for response can also be appropriate for ECT treatment. ECT has the highest response and remission rates among any antidepressant treatment. ECT is generally provided 2–3 times per week and total of 6–12 treatments. ECT is a safe treatment, and it is suggested that risks of morbidity and mortality do not exceed those associated with anesthesia alone. Side effects of ECT include short-time confusion, memory impairment, headache, muscle aches, and so on. ECT is the use of electrically induced repetitive firings of the neurons in the CNS. The mechanisms of action of ECT are complex and not completely understood.

TMS was approved for use in patients with major depressive disorder in USA. TMS uses a magnetic field to stimulate or inhibit cortical neurons. Because the area of cortex stimulated is related to placement of the coil on the skull, the coil is most often placed over the left dorsolateral prefrontal cortex for treatment of depression. There are few findings regarding long-term follow-up data of TMS treatment effect. So more longer-term data and further refinement of TMS are needed.

Regarding psychotherapy, cognitive-behavioral therapy (CBT) and interpersonal psychotherapy (IPT) are most well-known and proven psychotherapeutic approaches for patients with depressive

disorders (Gelenberg, 2010). CBT combines cognitive psychotherapy with behavioral therapy, including behavioral activation, and its goal is to reduce depressive symptoms by challenging and reversing irrational beliefs and distorted attitudes and encouraging patients to change their maladaptive preconceptions and behaviors in real life. On the other hand, IPT focus on interpersonal factors that may interact with the development of depressive disorders. The goal of IPT is to intervene by identifying the trigger of depression, facilitating mourning in the case of bereavement, promoting recognition of related affects, resolving role disputes and role transitions, and building social skills to improve relationships and to acquire needed social supports. Although these psychotherapies are recommended as an initial treatment choice for patients with mild to moderate major depressive disorder, these should be used in combination with pharmacotherapy for severe major depressive disorder.

Treatments of depression generally include several different steps, and these are acute phase treatment, continuous phase treatment, and maintenance phase treatment. Primary aims of the acute phase treatment are to improve symptoms of depression and achieve a full return to the patient's functioning. Continuous phase treatments are mainly provided to reduce the risk of relapse for a patient who has been successfully treated. Regarding patients who have had multiple major depressive episodes or who have chronic features, maintenance phase treatment should be considered in order to reduce the risk of a recurrent depressive episode.

Definition

Developmental disabilities (DD) is an umbrella term for a group of interrelated, chronic, nonprogressive, neurological, or brain-based disorders which are defined as "severe, life-long disabilities attributable to mental and/or physical impairments, manifested before age 22, that result in substantial limitations in three or more areas of major life activities: capacity for independent living, economic self-sufficiency, learning, mobility, receptive and expressive language, self-care, self-direction" (Administration on Developmental Disabilities, 2007). In the case of young children, DD is likely to result in significant limitations. Low IQ scores are typically associated with DD, and individuals with intellectual disabilities comprise the largest group considered to have DD (Larson et al., 2000), but other conditions may impose functional limitations on individuals whose intelligence is at or

above average. Sensory impairments are included only as occurring in combination with impairment in intellectual and adaptive functioning. The current conceptualization includes diagnostic classifications of intellectual disability (formerly mental retardation), autism spectrum disorders (ASD), cerebral palsy (CP), and specific syndromes whose behavioral phenotype includes limitations in intellectual and adaptive functioning (e.g., fragile X, trisomies, Prader-Willi, Smith-Magenis) but does not specify an etiology or medical diagnosis.

Description

Epidemiology

Researchers from the CDC estimate the prevalence of DD by tracking five conditions: intellectual disability (ID), autism spectrum disorders (ASD), cerebral palsy (CP), hearing loss, and vision impairment. The essential features of ASD are impaired reciprocal social interactions, delayed or unusual communication styles, and restricted or repetitive behavior patterns. ID is defined as a condition marked by an IQ < 70 with concurrent limitations in adaptive functioning, previously referred to as mental retardation. Cerebral palsy is defined as a group of nonprogressive, but often changing, motor impairment syndromes secondary to brain lesions/anomalies arising at any time during brain development or as a result of neonatal insult.

Developmental disabilities affect approximately 17% of children younger than 18 years of age in the USA (Bhasin, Brocksen, Avchen, & Van Naarden, 2006). In 2006–2008 nearly 10 million children aged 3–17 had a developmental disability on the basis of parent report (Boyle et al., 2011). The most recent CDC prevalence estimates of ASD are 1 in 88 children (Baio, 2012). Population-based estimates of functional limitations and health services utilization among children with DD were 4–32 times higher than for children without DD (Boulet, Boyle, & Schieve, 2009), while the cost to society of ASD alone is estimated to be $35–$90 billion annually (Ganz, 2007). The CDC estimates that the average lifetime cost associated with intellectual disability (IQ < 70) is approximately $1,014,000 per person (in 2003 dollars).

Etiology

The likelihood of identifying an underlying etiology increases with the degree of disability. Prenatal causes include *genetic abnormalities* including chromosomal abnormalities (e.g., trisomies, X-linked, microdeletions, and subtelomeric rearrangements), single gene disorders (e.g., X-linked recessive conditions), and multifactorial/polygenic conditions (e.g., spina bifida); *congenital infections* (e.g., rubella, syphilis); alcohol and other drug or teratogen exposure; and maternal disorders. Perinatal causes include *placental complications, preeclampsia/eclampsia, birth trauma/anoxia, complications of prematurity* (e.g., IVH), *infections* (e.g., bacterial meningitis), and *metabolic abnormalities*. Postnatal causes include *infections, trauma, environmental pollutants/neurotoxins, malnutrition*, and *inborn errors of metabolism* (e.g., PKU).

Genetic disorders now account for approximately 55% of moderate to severe ID (IQ < 50) and 10–15% of mild ID (IQ 50–70), and these percentages continue to increase with the use of new molecular techniques. More than 1,000 genetic disorders leading to developmental disabilities have been identified, many with active research programs (Tartaglia, Hansen, & Hagerman, 2007). Fragile X syndrome (FXS), the most common form of inherited ID, is caused by a mutation in a single gene (FMRP1) on the X chromosome, resulting from expansions of cytosine-guanine-guanine (CGG) repeats, which interferes with the normal transcription of a single protein (FMRP). Other disorders, such as Smith-Magenis or velocardiofacial syndrome (also known as 22q11.2 deletion syndrome), are microdeletion syndromes. Prader-Willi and Angelman syndromes are both the result of deletions on the same chromosome (15), but the expression is related to inheritance from either the father (Prader-Willi) or mother (Angelman). Still other disorders are characterized by the addition or absence of an entire chromosome (e.g., Down syndrome or trisomy 21; Klinefelter or

47, XXY; Turner or 45, X), leading to overexpression or imbalance of many genes and subsequent abnormalities.

Diagnosis

The American Academy of Pediatrics has recommended that developmental surveillance be incorporated into every well-child visit and that any concerns should be promptly addressed with standardized developmental screening tests (AAP, 2006). In addition, screening tests should be administered regularly at the 9-, 18-, and 24-month visits, including ASD specific measures. There is no universally accepted screening tool appropriate for all populations and all ages. However, accurate, cost-effective, and parent-friendly questionnaires are available for ages 1 month to 5 1/2 years in multiple languages (e.g., Ages and Stages Questionnaires, third Ed., Brookes Publishing). In addition, tools such as the M-CHAT and a follow-up interview used to screen for ASD are available, at no cost (www.firstsigns.com), covering a range of ages (e.g., 16–48 months) and in many languages. Once identified as being at risk, diagnostic developmental and medical evaluations should be pursued, typically involving pediatric subspecialists and using valid and reliable measures of cognition, adaptive behavior, communication, social, and neuropsychological functioning.

Intervention/Current Best Practices

Prevention has focused on *educational initiatives* to eliminate or minimize risk factors such as smoking and alcohol use during pregnancy or lead and mercury exposure as well as *medical initiatives* such prenatal screening and treatment for infectious disease (e.g., syphilis, CMV), genetic screening and counseling for carriers of genetic disorders, and the use of vaccines to prevent maternal or child infections (e.g., rubella, meningitis) (Brosco, Mattingly, & Sanders, 2006). In addition, early identification and treatment (e.g., newborn screening for genetic and metabolic disorders and fetal alcohol syndrome) have been successful in limiting the impact of severe developmental disabilities (Powell et al., 2010; Bertrand, 2009) and pilot programs using a variety of assays using urine or blood are under way (e.g., cytomegalovirus). Even late treatment has been successful in partially reversing the severe cognitive impact associated with metabolic disorders such as untreated PKU (Grosse, 2010).

Emerging areas of knowledge that influence practice include targeted pharmacological and evidence-based treatments for specific disorders such as fragile X and ASD, as well as a growing body of clinical guidelines specific to conditions in the pediatric age range. Evidence-based comprehensive treatment programs for young children with ASD emphasize behavioral- and/or development-based models. For example, the UCLA Young Autism Project, the Princeton Child Development Institute, and the Douglass Developmental Disabilities Center utilize traditional behavioral interventions(e.g., discrete trial training). The Learning Experiences and Alternative Program for Preschoolers and their Parents (LEAP) and the Walden Early Childhood Program utilize behavioral interventions in naturalistic settings and incidental teaching. Division TEACCH incorporates both behavioral and developmental approaches, while the Denver Early Start Model has a developmental orientation. In addition, care consideration guidelines are currently being developed for fragile X and other disorders having unique behavioral phenotypes (e.g., velocardiofacial, Smith-Magenis), and as understanding of the underlying mechanisms advances, targeted treatment studies are under way that may eventually reverse the neurodevelopmental abnormalities (e.g., medications that regulate the activity of the mGluR5 pathway in fragile X). At this time, best practice includes the need for intensive, multidisciplinary treatment programs for individuals with developmental disabilities and their families that focus on strengths and include medical, behavioral, educational, and therapeutic interventions.

Dexamethasone Suppression Test

Definition

Dexamethasone is a synthetic glucocorticoid and acts as a ligand of glucocorticoid receptors. The principle of the dexamethasone suppression test (DST) is based on this binding capability. Via receptor binding, dexamethasone exerts a negative feedback function on the hypothalamus-pituitary-adrenal (HPA) axis (de Kloet, Vreugdenhil, Oitzl, & Joels, 1998). The HPA axis is a hierarchical hormonal system encompassing the hypothalamus, the pituitary gland, and the adrenal cortex with their respective hormones CRH (corticotropin releasing hormone), ACTH (adrenocorticotropin hormone), and cortisol. Beside its role in stress regulation, the HPA axis is vital for supporting normal physiological functioning. Its functioning is controlled by several negative feedback loops. Generally, the DST is applied as a standard diagnostic tool to assess feedback sensitivity of the HPA axis in clinical settings (e.g., in major depression, posttraumatic stress disorder, etc.) as well as in psychoneuroendocrinological research (e.g., in stress research) (Bellingrath, Weigl, & Kudielka, 2008; Yehuda et al., 1993).

The dexamethasone suppression test normally consists of the oral intake of a single dose of dexamethasone (see below) which then leads to the suppression of ACTH at the level of the pituitary and subsequently to a reduced cortisol secretion from the adrenal cortex. Of course, dexamethasone can also be applied intravenously. In contrast to endogenous glucocorticoids like cortisol, dexamethasone primarily acts at the level of the pituitary (due to the blood-brain barrier). Selected doses of dexamethasone vary depending on the aim of the diagnostic test, the tested population, or the given research question. A typical dose to identify individuals with increased cortisol suppression after dexamethasone intake (indicating increased negative feedback sensitivity) is the application of 0.5 mg of dexamethasone. Oral intake normally takes place at 11 pm and cortisol measurements are repeatedly performed during the following morning or day to account for the normal circadian rhythm of cortisol (and ACTH) with highest levels in the morning and decreasing levels over the remainder of the day (except for stress-related superimposed hormone surges). After ingestion of a standard dose of 1 mg of dexamethasone, an almost complete suppression of the cortisol secretion in healthy individuals can be expected. That means, cortisol levels are typically suppressed to concentrations less than 5 μg/dl until the following afternoon after the intake of 1 mg dexamethasone the night before. However, in the normal population up to 10% non-suppressors can be identified. Fortunately, there are virtually no side effects reported for a single dexamethasone intake of 1–2 mg of dexamethasone. In different patient groups, either no cortisol suppression (e.g., in Cushing's disease) or cortisol super-suppression (e.g., in some patients suffering from posttraumatic stress disorder) can be observed. For the diagnosis of Cushing's disease, dexamethasone doses of up to 8 mg are applied. However, it is of note here that other tests need to complement a definite diagnosis of Cushing's disease.

In recent years, a much lower dexamethasone dosage of 0.25 mg was suggested (mainly for research purposes) to increase the sensitivity of the DST, called low-dose DST (Cole, Kim, Kalman, & Spencer, 2000; Yehuda, et al., 1993). This version of the test is advantageous if subtle differences are to be detected in HPA axis negative feedback sensitivity in apparently healthy individuals (Bellingrath et al., 2008). After intake of 0.25 mg of dexamethasone, endogenous cortisol concentrations of about 5 μg/dl can normally be expected.

One should be aware of the fact that an unequivocal interpretation of DST results should additionally account for the following two issues: Since the exact amount of circulating dexamethasone is dependent on metabolic functioning, bioavailability of dexamethasone should be controlled for, especially in certain patient groups with known metabolic dysfunctions. Furthermore, in order to rule out altered reactivity of the adrenal cortex to ACTH signals, one should want to additionally check the extent of ACTH suppression.

Finally, the DST can also be combined with other pharmacological provocation tests like the CRH stimulation tests (Heuser, Yassouridis, & Holsboer, 1994). Over the last decades, the combined Dex-CRH test applying a premedication of 1.5 mg dexamethasone the night before followed by a CRH application (e.g., 100 μg or 1 μg/kg body weight) the following afternoon proved its usefulness especially for the assessment of HPA axis feedback regulation in psychiatric disorders.

Diabesity in Children

Definition

The association of obesity and diabetes has been recently referred to as diabesity.

Description

In 2000, then Surgeon General David Satcher announced that the epidemic of obesity in the United States was increasingly affecting children and adolescents (Satcher, 2001). At the time of the surgeon general's announcement, approximately 16% of youth were categorized as being obese, defined as a body mass index (BMI) greater than the 95th percentile for age and gender. Overall, that same childhood obesity rate persists in the USA today; however, minority children have significantly higher rates. Data from the HEALTHY study in middle school–aged children showed that approximately 50% of sixth grade students in middle schools with a predominate minority population were overweight or obese (BMI $\geq$ 85th percentile for age and gender) (HEALTHY, HEALTHY Study Group, 2010).

Concomitant with the rise in childhood obesity is a corresponding increase in the incidence of the metabolic syndrome and type 2 diabetes in pediatric subjects. Before the 1990s, it was rare for most pediatric centers to have patients with

type 2 diabetes. By 1994, type 2 diabetes patients represented up to 16% of new cases of diabetes in children in urban areas, and by 1999, depending on geographic location, the range of percentage of new cases of type 2 was between 8% and 45% (HEALTHY, HEALTHY Study Group, 2010). The SEARCH study showed that after age 10 years, of all American Indian children who have diabetes, two thirds have type 2; of all Hispanic and African American children with diabetes, approximately a third have type 2; and only 8% of non-Hispanic White children affected with the disease have type 2 (SEARCH, 2006). Therefore, type 2 diabetes occurs mainly in ethnic minorities in the United States, as has been described in children in a number of countries throughout the world.

A period of prediabetes, defined as either elevated fasting glucose levels, impaired glucose tolerance, and/or elevated A1C (5.7– $<$ 6.4%), occurs before the development of frank type 2 diabetes. Type 2 diabetes in children and youth, as in adults, is caused by the combination of insulin resistance and relative B cell secretary failure. Plasma insulin concentrations appear normal or elevated, but there is a loss of first-phase insulin secretion that cannot compensate for underlying insulin resistance. There are a number of genetic and environmental risk factors for insulin resistance and limited B cell reserve, including ethnicity, obesity, sedentary behavior, family history of type 2 diabetes, puberty, high and low birth weight, and female gender. Family education level, SES, maternal diabetes or excessive weight gain, failure to breast feed, and exposure to an obesogenic environment are additional risk factors.

Type 2 diabetes in pediatric subjects has a variable presentation, although many children present with symptoms caused by elevated glucose. There is an associated increase in A1C $\geq$6.4% which can be used to make the diagnosis. Few pediatric subjects with type 2 diabetes can be treated with diet and exercise alone; therefore, pharmacologic therapy is most often required. Depending on initial glucose levels and the degree of symptoms caused by hyperglycemia, practitioners usually prescribe metformin for those subjects who are mildly affected, or subjects begin insulin therapy if they have more significant hyperglycemia. Relatively few pediatric subjects use other or combination therapy. Unfortunately, while they are undergoing the present pharmacologic regimens, many patients appear unable to achieve glycemic targets over the long term. Specific treatment algorithms for pediatric patients with type 2 diabetes that are aimed at achieving glycemic targets have not been investigated in youth. The ongoing Treatment Options for type 2 Diabetes in Adolescents and Youth (TODAY) trial, sponsored by the National Institutes of Health, has investigated best treatments for type 2 diabetes in pediatric subjects and will provide evidence for improving the outcome of pediatric type 2 diabetes.

The term diabesity was coined to raise awareness about the adverse health effects of obesity. Today, obesity and diabetes has become a healthcare crisis of epidemic proportions. It is a given that individuals and families must change their behavior if we are to reverse the present trends. But they cannot do it on their own. Reversing the trends will require the coordinated efforts from local, state, and national governments; public and private industries; community and religious organizations; schools; and the health-care system. Information must be provided, social norms must change, and, most importantly, an environment that supports healthy lifestyles must be created. Only then will the childhood diabesity epidemic be reversed.

Definition

Diabetes (mellitus) is defined as elevated blood glucose levels (hyperglycemia), which over time can lead to chronic microvascular complications such as diabetic retinopathy, nephropathy, and neuropathy. Diabetes is caused by deficiency in insulin production (type 1 diabetes), which in many cases can be accompanied by increased insulin demand, also known as insulin resistance (type 2 diabetes). Type 2 is the most common form of diabetes accounting for 85–90% of all cases. Diabetes can be diagnosed by way of a fasting plasma glucose ($\geq$126 mg/dl), an elevated HbA1c ($\geq$6.5%) or an oral glucose tolerance test (2-h postchallenge plasma glucose $\geq$200 mg/dl). Alternatively, someone presenting with symptoms of hyperglycemia, such as excessive thirst or urination, blurring of vision, or weight loss, combined with a random plasma glucose of $\geq$200 mg/dl, can also be diagnosed with diabetes.

Control of hyperglycemia is essential to reduce the risk of chronic microvascular complications associated with diabetes. This can be done through adopting healthy lifestyle and dietary habits, the use of oral medications to lower blood glucose, and/or the use of insulin replacement therapy. Diabetes is often a familial disease with genetic and environmental predisposing factors. First-degree relatives of individuals with diabetes have an approximate fivefold to tenfold increase in the risk of developing diabetes compared to the general population.

While diabetes mellitus ("sweet siphon") refers to the more common form of diabetes, characterized by hyperglycemia, diabetes insipidus ("bland or tasteless siphon") refers to an inability to retain free water due to deficiencies in the production or action of antidiuretic hormone (vasopressin).

Patient education; Self-management education

Definition

Diabetes education is the process of enabling patients with diabetes to gain knowledge, problem-solving skills, empowerment, and ability to manage their condition through the application of appropriate treatments and lifestyle intervention.

Description

Diabetes is a chronic condition whose management and control is highly dependent on both appropriate treatment prescriptions and patient implementation of those recommendations. Proper diabetes management requires a high degree of involvement on the part of the patient if it is to be successful. Education for patients with diabetes requires transfer of knowledge, as well as problem-solving skills, that incorporates the needs, goals, and experiences of patients with diabetes, with the ultimate objective of supporting "informed decision making, self-care behaviors, problem solving, and active collaboration with the health-care team." The implementation of appropriate treatment prescriptions and self-management behaviors needs to ultimately lead to improved clinical outcomes, health, and quality of life.

Diabetes self-management standards have been modified over the years to incorporate evidence-based recommendations. Guiding principles for these standards, which need to be adhered to by any entity seeking accreditation for their educational activities, dictate that diabetes education should improve clinical outcomes and quality of life, incorporate empowerment models, and individualize the educational approach to include behavioral and psychological strategies that are culturally and age appropriate. Group education, ongoing reassessment and education, and behavioral goal setting are critical elements to successful patient education programs. The American Diabetes Association has published specific standards for diabetes self-management education (DSME) that address several areas. DSME programs need a clear organizational structure, mission statement, and goals that are overseen by an advisory group, which include representatives from health professionals, patients, community, and other stakeholders. The DSME programs need to determine the specific educational needs of their target populations and identify appropriate resources to meet those needs; they must designate a professional coordinator to manage the program. Professional and experienced educators (nurse, dietitian, pharmacist, etc.) develop and implement educational interventions based on a curriculum that relies on current evidence and practice guidelines. Patients need to receive a documented individual assessment and education plan, with a personalized follow-up plan for ongoing education and support. Measurement of patient-defined goals forms the basis for patient reassessment and ongoing support and education. The DSME also needs to measure and document the effectiveness of the education process and use this opportunity for continuous quality improvement.

Diabetic foot care

Definition

Routine care of the feet for individuals who have diabetes, including inspection, skin and nail care, and prevention of injury.

Description

Diabetes may cause nerve damage that affects feeling in the feet. Diabetes may also reduce blood flow to the feet, making it harder to heal injuries or to resist infection.

Most people with diabetes can prevent serious foot problems by taking some simple actions. Routine foot care should include an annual foot exam by a healthcare provider, or more often if foot problems are present. The exam includes evaluation for injuries or breaks in the skin, nail problems, pain, sensitivity, or changes in foot shape or skin color. In some cases, healthcare providers may recommend specially fitted shoes.

Individuals with diabetes should inspect their feet every day, looking for red spots, cuts, swelling, or blisters. They should wash feet daily and apply moisturizing lotion to tops and bottoms of feet, but not between toes. Toenails should be trimmed straight across and filed if they can be easily seen and reached, otherwise a foot care specialist should trim nails. Shoes and socks should be worn at all times to prevent injury to the feet. Other self-care measures to prevent foot problems include keeping blood glucose levels controlled, not smoking, and avoiding sitting and crossing legs for prolonged periods. Increased activity may promote foot health along with other overall benefits to the cardiovascular system.

Type 2 diabetes prevention

Definition

There are several factors that increase a person's risk for developing type 2 diabetes mellitus. These include increased age, a family history of diabetes, race (persons of color having greater risk), obesity, body fat distribution, physical inactivity, and evidence of a metabolic defect as measured by either elevated fasting glucose, impaired glucose tolerance, or elevated glycosylated hemoglobin A1c. Because many of these risk factors are modifiable, notably obesity and activity patterns, it should be possible to reduce risk by interventions designed to help high risk persons reduce weight and increase their levels of physical activity. There is increasing evidence that this is indeed the case. In 1997, the Chinese first reported that lifestyle intervention in persons with impaired glucose tolerance (IGT) resulted in a significant reduction in the incidence of diabetes, with a 40% reduction occurring over a 6-year period (Pan et al., 1997). In 2001, the Finns reported that lifestyle intervention in persons with IGT resulted in a 58% reduction in 3-year diabetes incidence (Tuomilehto et al., 2001), and in 2002, the American Diabetes Prevention Program (DPP) study reported an identical 3-year reduction in diabetes incidence (Knowler et al., 2002). This entry focuses on the DPP.

Description

The DPP was a three-group randomized clinical trial that was conducted in 27 centers across the United States. The 3,234 subjects were all 25 years of age or older, had IGT, and a body mass index (BMI) of at least 24 kg/m^2. All ethnic groups were represented with 45% of the cohort being African American, Hispanic American, American Indian, or Asian/Pacific Islander. In addition, 68% of the cohort was women, 31% between the ages of 25–44, 49% between 45 and 59, and 20% 60 and above. Subjects were randomly assigned to a medication condition (using metformin), a medication placebo control condition, or a lifestyle intervention. The lifestyle

intervention was an intensive program with very specific goals: a minimum of 7% loss of body weight and maintenance of this weight loss through the course of the trial and a minimum of 150 min per week of physical activity with brisk walking being the standard.

The lifestyle intervention was a 16-session core curriculum implemented over 24 weeks to account for holidays and regionally defined special events. Each session was taught by a lifestyle coach who worked with the subject one on one. In addition, subjects had access to a dietitian, a behaviorist, and exercise physiologist if they so elected. Frequent contact with the lifestyle coach and support staff was the norm with most subjects following a weekly meeting schedule (The Diabetes Prevention Program (DPP) Research Group, 2002).

The intervention provided education and training in diet and exercise methods and behavior modification skills. Emphasis was placed on the use of self-monitoring techniques to assess dietary intake and diet composition, active problem solving to reduce the impact of personal and social cues to eat in ways counterproductive to achieving weight goals, and building self esteem, empowerment, and social support to reinforce lifestyle modifications. The intervention was individualized to address social and cultural factors that impact eating behavior, and a long-term maintenance program was introduced following the core curriculum.

The intervention was successful in reducing the risk for developing type 2 diabetes by 58%. Subjects in the lifestyle condition lost an average of 7 kg following the core curriculum and maintained a negative weight loss with an average loss of approximately 4 kg and 36 months postcore. In addition, 74% of the subjects in the lifestyle condition achieved the minimum study goal of 150 min of physical activity per week with the mean activity level at the end of the core curriculum being 224 min per week. Importantly, the intervention was effective for all participants, regardless of race, age, or gender.

As noted above, this is the same percentage of risk reduction obtained by the Finns. It is exceedingly rare in the annals of human clinical trials that two independent studies conducted on separate continents would report identical findings. A reasonable assumption is that the Finnish and American trials used identical lifestyle interventions (both were delivered to individual participants rather than in group sessions). However, they were quite different with the American trial being substantially more intensive. In the Finnish trial, each participant in the lifestyle intervention group had seven sessions with a nutritionist during the first year of the study and one session every 3 months thereafter (Tuomilehto et al., 2001).

It is tempting to conclude that the American approach to lifestyle intervention was less efficient than that used by the Finns, but there are differences between the Finnish and American participants worth noting. The mean body mass index (BMI; kg/m^2) in the Finnish sample was about 31, and in the American sample it was about 34, suggesting that the Americans were 9–10 kg heavier, on average, than the Finns. The DPP cohort was heterogeneous in terms of age and race/ethnicity whereas the Finns studied a fairly homogenous population. In addition, because of local environmental and cultural differences between Finland and the USA, it is likely there were fewer opportunities for physical activity for American participants than for Finns.

The prevention of type 2 diabetes is clearly a behavioral issue that involves implementing interventions designed to modify eating and physical activity behaviors. Future efforts need to consider how to translate efficacy studies such as those reviewed here into the broader public health. Such efforts need to involve behavioral scientists in the design of these interventions.

Diabetes: Psychosocial Factors

Maartje de Wit
Medical Psychology, VU University Medical Center, Amsterdam, North Holland, The Netherlands

Definition

Diabetes psychosocial factors are those factors associated with the psychological and social well-being of people with diabetes, as well as how those factors are related to diabetes-related self-management behaviors and glycemic control.

Description

The daily self-care of patients with diabetes mellitus type 1 or 2 is crucial for achieving blood glucose targets. Self-management is the foundation of diabetes treatment. A good understanding of the changes and challenges faced by people with diabetes is therefore essential in guiding these patients. We should remember that despite medication and improvements in administration systems, over one third of patients have long-term poorly controlled diabetes and thus a greatly increased risk of micro- and macro-vascular complications (Harris, 2000; Writing Team for the Diabetes Control and Complications Trial/Epidemiology of Diabetes Interventions and Complications Research Group, 2002). Psychological and social factors play an important role in the self-management of diabetes. This involves more than just knowledge of the patient. Research on self-care of diabetes patients shows that especially perceptions, attitudes, emotions, and social support are important in the process of behavior change.

Adaptation and Self-management

Diabetes is a chronic disease that puts specific demands on the daily life of patients. The most important task is keeping blood glucose values within normal limits in different situations. This requires the patient to be always aware of the effects of diet, physical activity, and glucose-lowering medication. Patients using insulin are advised to monitor their blood glucose levels frequently, to anticipate changing circumstances, and if necessary, to correct the glucose concentration in a timely manner. Fluctuations in blood glucose levels are often unavoidable. Low blood glucose (hypoglycemia) may seriously disrupt daily functioning and thus lead to frustration and anxiety in patients as well as in their family members.

Many patients with type 2 diabetes have, in addition to impaired glucose regulation, metabolic problems requiring a change of lifestyle and drug treatment. An increasing number of patients with type 2 diabetes need to take several oral medications each day, and many of them also need daily insulin injections. For many, this treatment appears a difficult task, which translates into poor treatment adherence. Diabetes is truly regarded as one of the most psychologically damaging chronic diseases with a high risk of "burnout."

After Diagnosis

The adjustment process starts with the diagnosis. In type 1 diabetes, the majority of cases are diagnosed early in childhood and impact the entire family. Understandably, the diagnosis causes strong feelings of fear and uncertainty. Most children and their parents appear to adjust quite well to the new situation after some time (Anderson,

2003). Successful adaptation depends on the family situation and the quality of care provided. Generally, during adolescence, a worsening of diabetes is seen. Increasing insulin resistance plays a role, but also the tendency of adolescents to diminish their attention to their diabetes and to take more risks. Conflicts may arise in the family, which in turn contribute to poorer adjustment of blood glucose of youths. However, young people with diabetes tend to rate their psychosocial well-being equal to that of their healthy peers (de Wit et al., 2007).

Diabetes mellitus type 2 is, in most cases, diagnosed in adulthood although in recent years the mean age at diagnosis has decreased. Research shows that when type 2 diabetes is diagnosed at an early stage, this causes little or no emotional reaction (Adriaanse & Snoek, 2006). This is presumably because a medical treatment is usually not an issue and initially "only" lifestyle changes of patients are requested. Longitudinal research has shown that the significance of diabetes and the psychological impact of this disease changes over time (Thoolen, de Ridder, Bensing, Gorter, & Rutten, 2006). It is therefore important not only to pay attention to adaptation problems soon after diagnosis, but also in the subsequent treatment process. In patients with type 1 or type 2 diabetes, possible health complications may occur that seriously complicate daily functioning and adversely affect quality of life.

Social Support

Social support is a complex construct, but generally is found to have positive effects on diabetes management. Research has demonstrated positive effects on adherence and control for both structural support (e.g., family, friends, co-workers, density of support networks) and functional support (e.g., diabetes-specific help, communication style, cohesiveness). Especially in adolescents, the importance of a supportive family has been shown. Open, empathic communication within families and continued parental involvement in diabetes care is important for achieving good adherence and glycemic outcomes (Anderson, 2003). Evaluation of interventions designed to enhance support, such as social skills training, and improved understanding about diabetes for families, has revealed positive effects on adherence and control. Several trials have demonstrated that group instruction to impart diabetes knowledge and coping skills produces better results than individualized instruction. Support provided through self-help groups or through a mentor (a well-adjusted patient) has been promoted but not researched in the context of diabetes.

Quality of Life

Diabetes, with daily requirements for self-monitoring and management in order to avoid the short-term consequences of hypoglycemia and the long-term complications associated with hyperglycemia, has a substantial impact on daily life. The demands of daily self-care can easily interfere with normal routines and friendships, thereby compromising emotional and social well-being. Attaining strict glycemic control as well as good quality of life (QoL) is a challenge for people with diabetes, their families, and health-care providers. This has led to considerable interest in diabetes-specific quality of life, assessed through a wide range of concerns including morale, well-being, depression, and role functioning. Studies looking into the relationship between diabetes control and QoL find low correlations, if any, although there is evidence to suggest that patients suffering from diabetes-related complications (neuropathy, retinopathy, nephropathy) on average report lower levels of QoL compared to patients without secondary complications (Snoek, 2000). In children, the relationship between glycemic control and QoL is complex and inconsistent across studies as well (Bryden et al., 2001; Hoey et al., 2001; de Wit et al., 2007).

Psychiatric Comorbidity

Diabetes has long been associated with the psychological constitution of patients. Their mental state was considered to be the cause of the disease or as a factor in diabetes regulation.

Indeed, a meta-analysis does show that depression increases the risk of developing type 2 diabetes by 30%, taking known risk factors into account (Knol et al., 2006). There is evidence that patients with poorly controlled type 1 diabetes, as measured by levels of glycosylated hemoglobin (HbA1c), can be distinguished psychologically as a group from patients with well-controlled diabetes on measures of depression and eating disorders. In patients with type 2 diabetes, there is also evidence of a relationship between depression and poorer glycemic control. There is increasing evidence that psychiatric comorbidity is more frequent in adults as well as adolescents with diabetes than in the general population (Anderson, Freedland, Clouse, & Lustman, 2001; Bryden et al., 2001), with adverse consequences for diabetes control. Below three major mental disorders that can complicate the treatment of diabetes are discussed.

Eating Disorders

Food and postponement of food are inextricably linked to a disturbance of blood glucose control in people with diabetes. Time to think about what you eat and when, can result in feelings of frustration and "binge eating," especially if the diet is restrictive. This may explain the increased prevalence of "binge eating disorder" in female patients with type 2 diabetes (Kenardy et al., 2001). In girls with type 1 diabetes, the prevalence of bulimia nervosa is elevated (Colton, Olmsted, Daneman, Rydall, & Rodin, 2004). Eating disorders almost always go along with an elevated HbA1c, frequent fluctuations in blood glucoses, and a greatly increased risk of early development of microvascular complications. Underdosing of insulin as a way to lose weight is not uncommon, particularly among adolescent girls. Among girls with type 1 diabetes, 10% admit to skipping some insulin injections, and 7.5% report injecting less insulin than is required in order to lose weight (Neumark-Sztainer et al., 2002). The treatment of severe eating disorders in diabetes is complex and requires a close collaboration between diabetes clinicians and professionals of clinics specialized in eating disorders.

Anxiety

Extreme anxiety may affect diabetes control, primarily by the disturbing effect of stress hormones, but also by avoidance behavior. One must be careful in giving alarming information like risk of diabetes-related health complications ("fear appeals") if one wants to encourage patients to improve self-management. Most diabetes patients are already concerned about the potential complications of their illness, and further increasing this fear probably does more harm than good. Two fears specific to patients with diabetes require special attention, namely, fear of injections and self-monitoring of blood glucose and fear of hypoglycemia. Although the prevalence of extreme anxiety for the injection of insulin and for self-monitoring of blood glucose is low among diabetic patients using insulin (0.3–1.0%), this fear may be accompanied by great distress and poor diabetes regulation. Moreover, 40% of patients with a phobic fear of injections also have a phobia of pricking the finger to obtain a blood sample. Data on the effects of psychological treatment for self-testing or injection fear are scarce. Both phobias are often associated with other psychiatric disorders, which makes these patients particularly vulnerable (Mollema, Snoek, Ader, Heine, & van der Ploeg, 2001).

Hypoglycemia remains the major side effect of intensive insulin therapy. Exact data are lacking, but a large proportion of patients using insulin have frequent worries about hypoglycemia. More uncommon is a phobic fear of hypoglycemia which can arise once a patient experienced a severe hypoglycemia with loss of consciousness. Patients with a compulsive or panic disorder can be extremely afraid of hypoglycemia without ever having had a real risk. A complicating factor is that anxious patients often do not know whether the symptoms of sweating, dizziness, and heart palpitations they are experiencing are due to dropping blood glucose levels or a panic attack. It is understandable that phobic patients may pursue "safe" blood glucose levels, which translates into a higher HbA1c. Patients with milder forms of fear benefit from hypoglycemia prevention training, which

aims to improve their symptom perception and better recognition of risk factors for hypoglycemia (Cox et al., 2001). Phobic patients and partners can benefit from cognitive behavioral therapy where they can learn to examine how realistic their views on hypoglycemia are and replace irrational thoughts with more adaptive cognitions.

Depression

Mood disorders are twice as common in patients with diabetes compared to the general population. The prevalence of moderate to severe depression among both type 1 and type 2 diabetes patients is estimated at 10–20% (Anderson et al., 2001). For adolescents with type 1 diabetes, the risk of depression is 2–3 times higher compared to their healthy peers (Hood et al., 2006). The relationship between diabetes and depression is not entirely clear. Probably biochemical and psychosocial factors play a role. Patients with depressive symptoms have poorer glycemic control and more complications and are more often hospitalized. Early recognition and treatment of depression in people with diabetes will probably result in major health benefits. Both psychological and pharmacological treatments of depression in diabetes patients are proven to be effective (Katon et al., 2004).

Sexual Problems

It is estimated that approximately 50% of men with a diabetes duration greater than 5 years have some degree of erectile dysfunction, with adverse effects on their perceived quality of life. It seems that these sexual problems are not often discussed with health-care professionals (De Berardis et al., 2002). Neuropathy and metabolic disorders are considered as the main causes of erectile dysfunction, but acute fluctuations in blood glucose and psychological factors may play a role as well. Drug treatment of erectile dysfunction, sometimes in combination with psychotherapy or marriage counseling, may be effective.

Less is known about sexual dysfunction in women with diabetes, but recent research among women with type 1 diabetes showed that they have more problems with sexual arousal and lubrication compared to healthy women. Sexual problems in female patients are often associated with depressive symptoms, making it difficult to determine cause and effect.

Conclusion

Successful management of diabetes requires considerable motivation and adaptability of the patient. Because people with diabetes are at increased risk for psychological problems that may complicate self-management behaviors, attention to the psychosocial functioning of patients is important in all phases of treatment. The fact that depression and other psychosocial problems are often not recognized and discussed calls for systematic monitoring of psychological well-being of diabetic patients as part of the regular appointments. Research into the effects in youth and adults with diabetes has shown that such an approach is feasible and that the well-being of patients and their satisfaction with care increase (Pouwer, Snoek, van der Ploeg, Ader, & Heine, 2001; de Wit et al., 2008). Nurses can play an important role in such approach. Additional psychological assessment and intervention can be provided as needed. Diabetes is a largely self-managed disease. Consequently, if the patient is unwilling or unable to self-manage his or her diabetes on a day-to-day basis, outcomes will be poor, regardless of how advanced the treatment technology is. Cognitive, emotional, behavioral, and social factors have a vital role in diabetes management, particularly because research has shown depression and other psychological problems are prevalent and negatively impact on well-being and metabolic outcomes. There is more to diabetes than glucose control; a biopsychosocial approach is required for optimal results. Motivational counseling and behavior change programs in type 2 diabetes have been shown to be effective in improving adherence and warrant further dissemination in primary and secondary care. In type 1 diabetes, adolescents are at increased risk of coping difficulties and poor diabetes outcomes, and warrant special attention. For all age groups, monitoring of

patients' emotional well-being as an integral part of routine diabetes care is recommended. Discussion of quality-of-life issues in the context of clinical diabetes care in itself promotes increased adherence and patient satisfaction, and has proven to increase recognition of signs of emotional problems and "diabetes burnout." Integrating psychology in diabetes management can help to effectively tailor care to the patient's individual needs and improve outcomes.

Definition

Diabetic neuropathy is nerve damage resulting from high blood sugar levels (hyperglycemia) and poor metabolic health in individuals with diabetes mellitus. Diabetic neuropathy can affect any number of organs or organ systems. Although it can develop after the initial diagnosis is made, it is commonly used as a symptom to diagnose diabetes in a patient. A significant percentage of patients have clinical evidence of nerve damage at the time of diagnosis, which suggests that even prediabetes can cause early diabetic neuropathy. In general, the more poorly controlled the diabetes, the more severe the diabetic neuropathy. Studies have shown that nerve conduction through the body slows significantly with each percent rise in glycosylated hemoglobin (HbA1c) values. The most commonly encountered forms of diabetic neuropathy include distal symmetric polyneuropathy, autonomic neuropathy, polyradiculopathy, and mononeuropathy.

Distal symmetric polyneuropathy is the most common type and is often synonymous with diabetic neuropathy. It is characterized by the symmetrical damage of sensory nerves that initially affects the lower extremities. The natural history of symmetric polyneuropathy illustrates the principle that the longest axons are affected first. Consequently, patients initially report symptoms in their toes and feet, which eventually progress to the classic bilateral "stocking and glove" numbness. Individuals with peripheral neuropathy can experience debilitating pain, tingling, and numbness in their hands and feet. Because many patients ultimately lose all sensation in their feet, they must be fitted with nonabrasive shoes and are taught to check their hands and feet daily for abrasions and injuries that can progress into limb and life-threatening ulcers.

Autonomic neuropathy includes a wide spectrum of symptoms that can affect multiple organ systems such as the cardiovascular, gastrointestinal, genitourinary, and even the neuroendocrine system. Its diagnosis can be difficult because of multiple organ involvement and insidious onset. Symptoms of cardiac neuropathy include exercise intolerance, resting tachycardia, and silent myocardial infarction. Neuropathic disease of the upper gastrointestinal tract can cause dysphagia, retrosternal pain, and "heartburn." More concerning is delayed stomach emptying which can cause nausea, vomiting, early satiety, prolonged fullness after eating and anorexia. When autonomic disease affects the lower gastrointestinal tract, patients present with severe constipation, diarrhea, and even bowel

incontinence. Neuropathy affecting the genitourinary system can cause bladder dysfunction, erectile dysfunction, and painful intercourse due to decreased vaginal lubrication. Less commonly, neuropathy can even cause hypoglycemia unawareness where patients become unable to perceive dangerously low blood sugar levels.

Diabetic polyradiculopathies refer to several types of asymmetric proximal nerve disease in the diabetic patient, the most common being diabetic amyotrophy and diabetic thoracic polyradiculopathy. Diabetic amyotrophy is the more common of the two and involves an acute onset of pain followed by weakness involving one proximal leg, with concurrent autonomic failure and weight loss. If the disease affects the contralateral leg, symptoms can occur immediately or much later after the initial episode. No treatments have been shown to be effective for diabetic amyotrophy. Thoracic polyradiculopathy, another type of diabetic polyradiculopathy, describes an injury of the high lumbar or thoracic-level nerve roots. These patients present with severe abdominal pain and have frequently undergone multiple studies to identify the cause of their symptoms.

Lastly, there are two types of diabetic mononeuropathy: cranial and peripheral. Cranial lesions commonly affect nerves surrounding the eye and typically result in unilateral eye symptoms including pain, drooping eyelid, and double vision. The most common peripheral lesions in diabetic patients are median nerve mononeuropathy at the wrist and common peroneal mononeuropathy near the ankle, both of which can result in pain, drooping, weakness, and decreased range of motion.

Improving the symptoms of diabetic neuropathy can be difficult; most efforts are made to prevent the onset and worsening of existing diabetic neuropathy. Treatment of diabetic neuropathy emphasizes tight blood sugar control, managing pain symptoms through pharmacotherapy (i.e., analgesics, certain antidepressants, steroids) and/or psychosocial interventions (e.g., meditation, relaxation training), and practicing diligent foot care (i.e., washing feet, inspecting for cuts, bruises, or blisters).

Successful diabetes management is associated with several behavioral and lifestyle factors, which have been shown to improve with psychosocial interventions such as motivational interviewing, health coaching, and cognitive behavioral therapy. Well-controlled diabetes is often the result of adherence to a healthy diet and exercise regimen, keeping track of carbohydrate intake, frequent and routine checks of blood sugar levels, taking required amounts of insulin, and discontinuing negative behaviors such as smoking or excessive drinking. Modification of these behaviors in children and adults has resulted in improvements in diabetes management, which can prevent or slow the development of diabetic neuropathy.

Definition

A diabetologist is a physician with expertise in diabetes care. The physician is often board certified in pediatric or adult endocrinology with special interest or extra training in diabetes care or research. However, diabetology is not a recognized medical specialty and has no formal training programs. Thus, any physician whose practice and/or research efforts are concentrated mainly in diabetes care may be considered a diabetologist/diabetes specialist.

The National Institute of Mental Health Diagnostic Interview Schedule was discussed in the Archives of General Psychiatry by Robbins, Helzer, Croughan, and Ratcliff (1981). The interview schedule allowed lay interviewers or clinicians to make psychiatric diagnoses according to *DSM-III* criteria, Feighner criteria, and Research Diagnostic Criteria. It was being used in a set of epidemiological studies sponsored by the National Institute of Mental Health Center for Epidemiological Studies. Its accuracy has been evaluated in a test-retest design comparing independent administrations by psychiatrists and lay interviewers to 216 subjects (inpatients, outpatients, ex-patients, and nonpatients).

The National Institute of Mental Health Diagnostic Interview Schedule for Children, Version 4 (NIMH DISC IV or "DISC") is a highly structured diagnostic interview used to assess psychiatric diagnoses of children and adolescents. The DISC was designed to be administered by interviewers with no formal clinical training following the rules and conventions outlined in the DISC training manual. The DISC questions elicit the diagnostic criteria specified in the *Diagnostic and Statistical Manual of Mental Disorders – Fourth Edition (DSM-IV)* and the WHO International Classification of Diseases, Version 10 (ICD-10).

The Generic or "12 month" DISC was used in NHANES. Seven of the 34 diagnostic assessments were included in NHANES over the 6-year

period that the DISC was administered: generalized anxiety disorder, panic disorder, eating disorder, elimination disorders, major depression/dysthymic disorder, attention deficit disorder/hyperactivity (ADD/ADHD), and conduct disorder. In each module, questions are asked about specific symptoms during the past year, and then follow-up questions in cases of positive endorsement. Two of the DISC modules in NHANES, eating disorder and major depression/dysthymic disorder, were comprised of two parallel interviews. A youth-informant interview (DISC-Y) administered in-person to children asked questions about themselves, and a parent-informant interview (DISC-P) administered by telephone to a parent or caretaker asked questions about their child. Only the DISC-Y was administered for generalized anxiety disorder and panic disorder, and only the DISC-P was administered for elimination disorder, ADD/ADHD, and conduct disorder. Depending on the module, responses and diagnostic scores derived from the interviews can be combined or examined separately.

Definition

Diaries are self-report instruments often used in behavioral medicine research to examine psychological processes (i.e., affect, social interaction, marital and family interactions, stress, physical symptoms, mental health, well being) within the natural context of everyday life. Diaries require study participants to keep track of cognitions, emotions, or behaviors in a log for a particular period of time and are designed to "capture life as it is lived" (Bolger, Davis, & Rafaeli, 2003).

Examples of diaries include paper and pencil diaries, augmented paper diaries (ancillary devices are programmed to prompt participants to respond at a particular time), and electronic diaries (i.e., palm pilots, PDAs). Diaries can be collected repeatedly over a number of days, once daily (daily diary), or even sampled several times during the day.

Advantages

One advantage of diary methods is that information is gathered in the context of the participant's everyday life, which may illicit behavior that is more representative than that observed in the laboratory setting. Secondly, diary methods reduce the likelihood of retrospection. That is, the time between an experience and the recounting of the experience by the participant is minimized. By asking the participants to record information when an event occurs or shortly thereafter, diaries also reduce biases related to recall (the greater the time between events and its recollection, the greater the potential for

distortion), recency effects (more recent events are more likely to influence judgments) and salience (moments of peak intensity or personal relevance influence judgments more than less salient experiences). Finally, diary studies eliminate the difficulty of summarizing multiple events.

Disadvantages

Despite the many advantages of diary methods, several disadvantages also exist. For example, diaries require experimenters to conduct training sessions to ensure that participants understand the diary protocol, which can be time consuming for the experimenter. Secondly, diaries can be onerous for participants. The burden of repeated queries and responses places substantial demands on the participant and requires a greater level of participant commitment compared to other types of research studies. Thirdly, the act of completing the diary may affect participants' responses or alter participants' understanding of a particular construct. For example, a more complex understanding of the surveyed topic may develop or the experience of the diary study may change participants' conceptualization of the topic to fit with those measured in the diary. Finally, participants may develop a habitual response style when making repeated diary entries, which may have negative consequences. For example, participants may skim over sections of a diary questionnaire that rarely apply to them, but inadvertently omit responses to these questions at relevant times.

Diathesis-Stress Model

Risk factors

Definition

Diathesis refers to a predisposition or vulnerability for the development of a pathological state. Diathesis-stress models argue that certain pathological states or diseases emerge from the combination of a predisposition with stressful events (Zuckerman, 1999). Most models specify that neither the diathesis nor stress alone is sufficient to produce the disorder. Instead, stress activates the diathesis, which then leads to the disorder. More broadly, diathesis-stress models are similar to the idea of risk-factors for stress-related diseases.

Description

History

Early diathesis-stress models primarily focused on psychiatric disorders such as schizophrenia, depression, and anxiety disorders, born out of the observation that these disorders tend to be inherited and yet also show a significant relationship to life stress (Zuckerman, 1999). These early diathesis-stress models identified fixed biological and/or hereditary factors as predispositions, and often argued for singular directionality, i.e., that the stress acted upon the diathesis. Later, the idea of diathesis was expanded to include physiological, behavioural and psychological diatheses, some of which may be acquired (Zuckerman). Broadening the scope of diatheses to include "non-biological" factors also resulted in a change in the presumed directionality, such that diatheses may influence the experience of stress.

Diatheses

Zuckerman (1999) has argued that diatheses are traits, and as such they not only should be present before the onset of the disorder but also should not change as the result of the disorder. Diatheses may be conceptualized as dichotomous, i.e., present or not. However, many diathesis-stress models suggest that the degree of diathesis present sets a threshold of vulnerability to stress. The greater the level of diathesis present, the less stress required to activate it and create the pathological state (Zuckerman). Some diathesis-stress theories, such as Fowles (1992) theory of schizophrenia, argue that stress may not be necessary for the disorder to develop. If the level of diathesis is high enough, the threshold is met and, even in the absence of stress, the disorder will develop (Zuckerman, 1999).

The Role of Stress

One important issue for diathesis-stress models is the potential confounding of stress with the diathesis. For example, if a personality trait, such as neuroticism, is identified as a diathesis for a disorder, such as anxiety, then the issue becomes whether the diathesis is reacting to stress or is the cause of stress. Therefore, many diathesis-stress models define stress in terms of external events rather than defining stress as subjectively reported reactions to events (Monroe & Simons, 1991). Further, identifying genetic, biological, and/or physiological diatheses, rather than psychological ones, also serves to avoid the problem of confounding (Zuckerman, 1999). Also, diathesis-stress models often assume that the stress must occur in close temporal proximity to the onset of the disorder (Zuckerman, 1999). Some stress-diathesis models suggest that not only do diatheses differ by disorder but also by the type of stress necessary to activate a specific diathesis. For example, for major depressive disorder, stressors that involve loss of one's social structure (e.g., job loss, divorce, death of a loved

one) have been identified as those that combine with diatheses to produce the disorder (Monroe & Simons, 1991).

Specifying Diathesis-Stress Models

Conceptualizations of diatheses and stressors that are binary (present or not) lead to relatively simple models. If both the diathesis and stress are present, the disorder will occur, but if one or both are absent, the disorder should not occur. However, most research on diathesis-stress models suggests that neither diatheses nor stress are dichotomous. Some models have suggested that diatheses are categorical, such as evidence suggesting that allelic variation in the 5-HTT-linked polymorphic region (5-HTTLPR) of the serotonin-transporter gene serves as a diathesis for anxiety-related disorders (Lesch et al., 1996). However, these models do not consider the polygenic nature of most disorders and they are likely artificially categorizing dimensional variability in gene expression (Zuckerman, 1999). Further, stress is often scaled in terms of the severity of individual stressors (i.e., traumatic stress producing posttraumatic stress disorder; PTSD) or in the total number of stressors (i.e., more instances of loss associated with higher rates of depression). Continuous diatheses and stressors lead to more complex models. Models may specify additive effects, such that more stress is required to bring about the disorder in someone with less of the diathesis than in someone with a greater degree of the diathesis. Interactive models may suggest that if the diathesis is absent, no amount of stress may bring about the disorder, but once present, the diathesis can vary in its loading, thus requiring different amounts of stress to bring about the disorder. Thus, important questions to consider when developing diathesis stress models involve the nature of the diathesis (categorical, continuous, continuous only if present), the diathesis threshold necessary for the disorder to emerge, the type (e.g., loss, fear) and nature (categorical or continuous) of the stress necessary to activate the diathesis, the nature of the effects of each (additive, interactive), and whether the diathesis and stress are independent of one another or correlated.

Current State of Stress-Diathesis Models

Recently, the basic diathesis-stress model has been expanded to include predispositions that protect individuals from developing stress-related disorders, or resilience (Belsky & Pluess, 2009). Instead of focusing on why some people fall victim to disorders in the face of stress, resilience research focuses on why some people seem resistant to a disorder, even in the face of extreme stress. However, resilience is not the opposite of diathesis, but instead, individuals may differ in their overall plasticity to both negative (i.e., stress) and positive (i.e., supportive) environmental influences (Belsky & Pluess, 2009).

Biographical Information

Joel Dimsdale was born in Sioux City, Iowa, in 1947, and obtained his BA degree in biology from Carleton College. He then attended Stanford University, where he obtained an MA degree in Sociology and an MD degree. He obtained his psychiatric training at Massachusetts General Hospital and then completed a fellowship in psychobiology at the New England Regional Primate Center. He was on the faculty of Harvard Medical School from 1976 until 1985, when he moved to University of California, San Diego (UCSD).

Dimsdale is distinguished professor emeritus and Research Professor in the department of psychiatry at UCSD. His clinical subspecialty is consultation psychiatry. He is an active investigator, a former career awardee of the American Heart Association, and is past-president of the Academy of Behavioral Medicine Research, the American Psychosomatic Society, and the Society of Behavioral Medicine. He is on numerous editorial boards, is editor-in-chief emeritus of

Psychosomatic Medicine, and is a previous guest editor of *Circulation*. He has been a consultant to the President's Commission on Mental Health, the Institute of Medicine, and is a long-time reviewer for NIH. He consults to the National Academy of Sciences regarding behavioral issues in space. He is a member of the DSM V taskforce and chairs the workgroup studying somatic symptom disorders. Dimsdale is the former chair of the UCSD Academic Senate and currently chairs the Systemwide University of California Faculty Welfare Committee.

Dimsdale is an active teacher who supervises CL psychiatry. He mentors trainees and junior faculty members from psychiatry, psychology, pulmonary medicine, nephrology, anesthesiology, and surgery. Dimsdale directs UCSD's K12 training grant for fostering the careers of outstanding young clinical faculty.

Dimsdale's major research interests include sympathetic nervous system physiology as it relates to stress, blood pressure, and sleep; cultural factors in illness; and quality of life. He is the author of more than 500 publications as well as the editor of four books.

Major Accomplishments

Dimsdale has been an active investigator who has mentored generations of medical students, residents, psychology students, and post docs. He has been repeatedly tapped for leadership positions in national organizations, on medical journals, and in university governance.

Activity limitations; Impairment; Participation restrictions

Definition

The World Health Organization views disability not as a property of an individual person but as an interaction between features of a person's body and their social and physical environment. Disability can exist at the level of impairments (to body structures and functions), activity limitations, and/or participation restrictions. Impairments are defined as a significant deviation or loss in body functions or structures. Activity limitations are difficulties a person has in performing activities; an activity is the execution of a task or action. Participation restrictions are problems a person experiences in involvement in life situations; participation is involvement in life situations.

Governments also define disability within antidiscrimination legislation and to provide access to government support and services. For example, in the United Kingdom, the Equality Act (2010) considers a person to have a disability if they have a physical or mental impairment that has a substantial and long-term adverse effect on their ability to perform normal day-to-day activities.

Description

The World Health Organization estimates that, worldwide, 650 million people live with disabilities of various types. It is expected that this figure will continue to rise as the world's population ages and the prevalence of chronic illness increases. The management of disability is complex and typically involves multidisciplinary teams and input from multiple services. As a consequence, the management of disability will benefit from the use of theoretical frameworks that are able to accommodate such multidisciplinary ways of working.

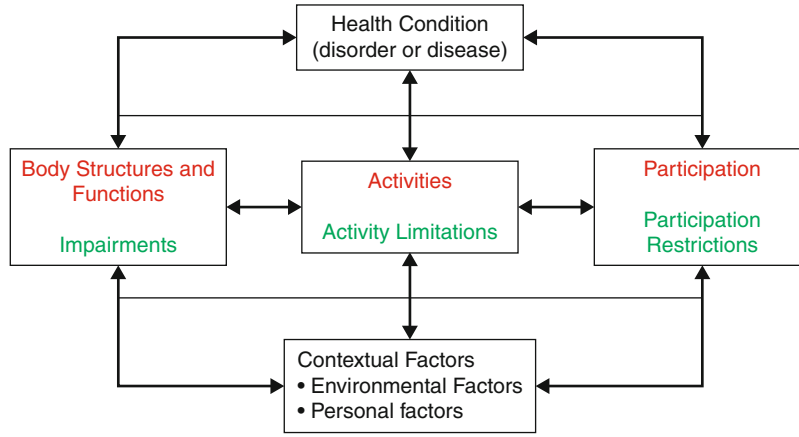
Conceptualizing Disability

The World Health Organization's International Classification of Functioning, Disability and Health (ICF) provides such an integrative framework (WHO, 2001). A summary schematic of the ICF is shown in Fig. 1.

The WHO designed the ICF as a classification system for health and health-related states. However, the ICF can also operate as a complex model of health and disability. The ICF identifies three health components, namely, body structures and functions, activities and participation, and their corollaries of impairment, activity limitations, and participation restrictions (see the "Definition" tab for a description of each component).

The ICF has several features of particular relevance to behavioral medicine (Dixon & Johnston, 2010).

First, the relationships between the components are reciprocal. This means that impairments can cause activity limitations but also that activity limitations can cause impairments. For example, osteoarthritis is a health condition in which the structure of the hip joint is impaired; this impairment is experienced as joint stiffness and pain (impairments). A person with osteoarthritis of the hip might, as a result of such impairments,



Disability, Fig. 1 Summary schematic of the ICF

experience difficulties getting up and down stairs and walking (activity limitations), and these activity limitations might restrict their ability to use buses or trains, which might reduce their ability to visit the cinema in town (participation restrictions). However, reduced walking might also cause further impairments in the structure and function of the hip joint, as muscle strength weakens with reduced use. Thus, within the ICF, reductions in impairment can be achieved through interventions that target activity limitations and vice versa. This makes the ICF suitable for use by multidisciplinary teams typically required for the effective management of the consequences of chronic illness. For example, medical doctors can intervene surgically or pharmacologically; allied health professionals can intervene with a range of therapies, for example, physiotherapy and speech and language therapy; social services can intervene with adjustments to the home environment, for example, provision of ramp access to the home, an electric wheelchair, and other assistive devices.

Second, the role of the environment and personal factors in disability is recognized by the contextual factors component of the ICF. These contextual factors enable other disciplines to contribute to our understanding of disability. The ICF provides a detailed description of the environmental factors, which include assistive products and technologies, the natural and man-made environment, social services, systems, and policies. These environmental factors enable diverse disciplines, such as architecture and town planning, to contribute to achieving reductions in disability. The personal factors component is less well described by the ICF; however, personal factors have been operationalized in the form of individual cognitions and emotions. Inclusion of the personal factors component and the observation that activity limitations and participation restrictions are behavior(s) enables psychology to inform our understanding of disability. Psychology can be defined as the scientific study of behavior, and as such, models of behavior and behavior change can be used to understand the factors that influence disability. Further, the inclusion of behavioral models of disability delivers the evidence base on how to intervene to change behavior (Bandura, 1969; Michie et al., 2009), which enables reductions in disability to be achieved, again without the need to reduce chronic impairments.

A behavioral approach to disability conceptualizes disability as behavior, which is influenced by the same psychological processes that affect any other type of behavior. As a consequence, an individual with a health condition will be motivated to engage in an activity or participate in a social situation because it achieves the things they like, because they believe other people would like them to do so, and because they believe they are able to do so. The behavioral approach can be used to explain, in part, the so-called disability paradox. The disability paradox is the observation that two people, living in

identical social and environmental situations, experience different levels of disability, i.e., people with severe impairments might report lower than expected levels of disability, whereas an individual with mild impairment might experience higher than expected levels of disability. This observed discordance between impairments and activity limitations and participation restrictions may, in part, be explained by differences in cognitions, emotions, or coping strategies. The behavioral approach, in particular, should not be used to "blame" people with disabilities for those disabilities. The behavioral approach does not support the idea that disability arises because an individual lacks the motivation to overcome their impairments and limitations. Rather, the behavioral model emphasizes that every person is influenced by biological, personal, social, and environmental factors, and those influences are unique to each individual. Indeed, using behavioral models to conceptualize the personal factors component of the ICF supports the aim of the WHO to account for activity and activity limitations in the same terms for all individuals. Within this integrative framework, it is only the relative importance of each factor that differs between people, not the nature of the factors per se. For example, compared to the significant role of impairment, the role of motivational factors is likely to be a much weaker determinant of whether or not a person who has just had a stroke leaves their home to walk into town to visit the cinema. However, over the course of their recovery, the role of impairment factors might reduce and the role of motivational factors might increase, so that 6 months after their stroke, the individual might not walk into town to visit the cinema simply because there are no movies they want (are motivated) to see.

Measuring Disability

Clinical practice and research requires methods of measurement of disability so that the severity of a health condition can be assessed and the effectiveness of interventions evaluated. The ICF provides detailed descriptions of the body structures and functions and activities that should be assessed for any given health condition. However, the ICF does not indicate how those structures, functions, or activities should be assessed. In general, disability is measured by assessing the ability of an individual to perform particular activities relevant to their health conditions. For example, a person who has experienced a stroke might be assessed for their ability to perform activities of daily living, such as the ability to dress, to use the stairs, and to transfer from bed to chair, whereas a person with a diagnosis of dementia might be asked to complete measures of cognitive function.

In general, two methods of measurement are available: self-report and observation. Self-report requires the individual to describe the limitations and difficulties they experience. Self-report measures typically use standard questionnaires, for example, activities of daily living can be measured by a wide variety of instruments, including the Barthel Index, the Sickness Impact Profile (and its UK equivalent the Functional Limitations Profile), and the Katz ADL scale. Self-report measures have the advantage of being suitable for use in a variety of settings, including the person's own home, they are inexpensive, and can assess a wide range of activities over a long time course. In addition, proxy reports are sometimes used; proxy reporters are usually the primary caregiver. However, both self- and proxy reports have the disadvantage of being open to reporting errors.

Observational measures require a trained observer to record whether an individual is able (or not) to successfully perform relevant and defined activities. Observational measures are regarded as being more accurate than self-report measures but have several disadvantages. They are restrictive, in that they typically assess only those activities performed in the limited setting of the hospital or in the limited period available for a home visit, and as such, they too might under or over estimate disability.

Self-report and observational measures can be supplemented by objective electronic measures, for example, pedometers provide step counts, and accelerometers measure activity in general. However, such devices might have restrictive utility for particular groups, for example, elderly people

might walk with a gait that fails to register accurately on pedometers. In addition, with the exception of a step count, these devices do not discriminate between particular behaviors, for example, they are not able to distinguish between the wide variety of activities of daily living measured by self-report instruments, and at best they can discriminate between walking, standing, sitting, and lying.

Information about the WHO-ICF can be found at: http://www.who.int/classifications/icf/en/ this site provides a detailed description of the ICF and contains a great beginner's guide to the ICF http://www.who.int/classifications/icf/training/icfbeginnersguide.pdf

The importance of regarding behavior as a primary health outcome is made very effectively by Professor Robert Kaplan (Kaplan 1990).

Disability-Adjusted Life Years (DALYs)

Marijke De Couck

Definition

The disability-adjusted life year (DALY) has emerged in the international health policy lexicon as a measure of overall "disease burden." It is an expansion on a previous measure, namely, years of life lost (YLL), which did not take into account the impact of disability. DALYs for a disease or health condition are calculated as the sum of the years of life lost (YLL) due to premature mortality in the population and the years lost due to disability (YLD) for incident cases of the health condition: DALY = YLL + YLD (World Health Organization [WHO], 2010). The YLL correspond to the number of deaths multiplied by the standard life expectancy at the age at which death occurs. The basic formula for YLL is the following for a given cause, age, and sex:

$$YLL = N \times L$$

where:

- N = number of deaths
- L = standard life expectancy at age of death in years

L reflects the difference between the standard life expectancy at that age and age of death. Because YLL measure the incident stream of "lost years of life" due to deaths, an incidence perspective is also taken for the calculation of YLD. To estimate YLD for a particular cause in a particular time period, the number of incident cases in that period is multiplied by the average duration of the disease and a weight factor that reflects the severity of the disease on a scale from 0 (perfect health) to 1 (dead). The basic formula for YLD is the following:

$$YLD = I \times DW \times L$$

where:

- I = number of incident cases
- DW = disability weight
- L = average duration of the disease until remission or death (years)

One DALY can be thought of as one lost year of "healthy" life. The sum of these DALYs across the population, or the burden of disease, can be thought of as a measurement of the gap between current health status and an ideal health situation where the entire population lives to an advanced age, free of disease and disability (WHO, 2010).

Several countries and organizations are using DALYs to identify health priorities and cost-effective interventions and to allocate resources for health (The World Bank, 1993). Several treatments or medications can be compared by this measure, which has been done in a few studies (Renaud, Basenya, de Borman, Greindl, & Meyer-Rath, 2009). DALY also measures psychological factors (e.g., emotional, behavioral, cognitive, and social functions), which are considered in the weighted disability. DALY can be used to compare several kinds of interventions, like psychological versus pharmacological, as has been done by several studies (Heuzenroeder et al., 2004).

However, there are a few disadvantages of the DALY. It is a metric which is used to provide a single number to capture all of the health costs caused by a disease. One DALY could represent 1 year of life lost (due to early death), 1.67 years spent with blindness, 5.24 years with significant malaria episodes, 41.67 years spent with intestinal obstruction due to ascariasis (a parasite), or many possible combinations of these and other symptoms (Lopez, Mathers, Ezzati, Jamison, & Murray, 2006). Thus, the same amount of DALYs, though numerically identical, could represent very different disabilities over time, which may not be comparable.

Disclosure

Emotional disclosure

Definition

Disclosure has been defined as sharing of personal information with others through verbal communication or written expression of what individuals verbally reveal about themselves to others (including thoughts, feelings, and experiences).

Description

Disclosure can be a complex process. It is often difficult to know what, how much, when, and to whom to disclose. Many factors influence the decision to disclose information, including personality traits such as anxiety, impulsivity, and extraversion (see Costa & McCrae, 1992), as well as social norms, one's affect, goals, and previous experiences with disclosure, the behavior of the confidant, and one's relationship with the confidant. People often choose not to disclose for fear of negative consequences (e.g., embarrassing or hurting one's confidant, punishment, reduction in autonomy, rejection, harassment, discrimination). Although disclosure can result in negative outcomes, research suggests that disclosure can be beneficial in a variety of ways. Disclosure provides people with an opportunity to express their thoughts and feelings, to elicit social support, gain new coping strategies, and build intimacy in their personal relationships. Disclosure may also allow people to find meaning in traumatic experiences, and may promote personal growth and self-acceptance.

Disclosure has been investigated in a variety of contexts. Researchers have investigated disclosure of a "concealable stigmatized identity," such as mental illness, experiences of abuse or assault, epilepsy, or an HIV-positive diagnosis. In each of these cases, people have personal information that is socially devalued but is not apparent to others. Disclosure has been examined among people who have a chronic illness that is not readily apparent, such as cancer or diabetes. Researchers have also studied disclosure of health information to family, friends, and health care providers (e.g., parents disclosing HIV status to children, adolescents sharing diabetes management information with parents). Research within each of these domains has examined how people make decisions to disclose, how confidants react to disclosure, and how people are affected by their disclosure decisions.

Much of the disclosure literature has focused on the effects of written disclosure on health outcomes. These studies use a laboratory writing technique which typically involves random assignment to one of two (or more) groups: an experimental group that discloses emotional material, and a control group that does not. Both groups are asked to write about assignments for 3–5 days, for 15–30 min each day. Those assigned to the control conditions are asked to write about superficial topics. Those in the experimental group are asked to write about their thoughts and feelings about an important emotional issue that has affected them and their life. Writing for both groups is usually done in the laboratory, with no feedback given. This body of research suggests that disclosure of emotional events can have immediate effects on skin conductance, heart rate, and blood pressure. In addition, written disclosure about emotional issues can have long-term effects on both immune functioning and health outcomes. Disclosure may influence health in several ways. First, research suggests that nondisclosure is a form of inhibition that requires physiological work, reflected in autonomic and central nervous system arousal. Disclosing may reduce inhibition, thus reducing

autonomic and central nervous system arousal and facilitating better health outcomes. Disclosure may also lead to changes in cognitive processes, such as decreases in rumination or increases in mastery, self-acceptance, and self-concept, which in turn have benefits for health. Finally, disclosure may lead to better health by increasing social support. When individuals disclose, they may gain information from others about effective coping strategies or they may obtain emotional support, both of which could contribute to better health outcomes.

Recent research has examined a different form of disclosure – the link between adolescent disclosure to parents and adolescent health outcomes. Prior research identified parental monitoring as an important predictor of a variety of adolescent behaviors including risky sexual behavior, substance abuse, and poor adherence. Additional investigation, however, revealed that measures of parental monitoring were assessing how much knowledge parents had, rather than the way in which they obtained that knowledge. Adolescent disclosure may be the primary source of parents' knowledge about adolescents' activities. Research indicates that among adolescent disclosure, parent solicitation, and parent behavioral control, disclosure is the best predictor of delinquent behavior. Research is now exploring the role that adolescent disclosure to parents plays in explaining adolescent health outcomes, such as adherence to the type 1 diabetes regimen.

Discrimination

Discrimination and Health

Yori Gidron

Definition

This term refers to deliberate inequalities in access to and in care for health conditions or to the unequal exposure to health risks as a function of people's ethnic or demographic background (age, gender, beliefs, skin color, etc.). This problem exists in both developed and developing countries. Furthermore, discrimination and health can even be seen on a more global level – the inequality in health care between rich and poor countries and the consequent disease burden carried by poor countries, where global economic and political forces sustain this. Numerous studies show differences between low and high socioeconomic status (SES) groups on health

conditions, and there is accumulating evidence linking actual and perceived discrimination with poor health conditions (Ahmed, Mohammed, & Williams, 2007; Williams & Mohammed, 2009). Importantly, physicians may even provide less medical advice to people who are less similar to them, i.e., of lower SES (Tschann, Adamson, Coates, & Gullion, 1988). This is doubly harmful since low SES people already have poorer health risks, and receiving less medical advice may add to their health risks. Both biological and psychosocial pathways may link discrimination to poor health (Ahmed et al., 2007). Biologically, low SES people may be exposed to poorer environments (poor sanitation, pollution), whose adverse health effects are clear – infectious diseases, pulmonary problems, and possibly cancers.

However, the mere exposure to environmental stressors (e.g., crowding, social violence) may add onto these biological agents, in contributing to either unhealthy behaviors (e.g., heavy alcohol consumption), or to psychophysiological processes such as stress-induced inflammation (Maes et al., 1998) or stress-induced DNA damage (Gidron, Russ, Tissarchondou, & Warner, 2006), eventually resulting in poorer health. Clear discrimination leading to health problems could be seen when urban or even country institutions marginalize certain parts of society (based on ethnicity or SES) by pressing them to reside in poorer and more health-risky areas of cities (Ahmed et al., 2007). One major challenge to research and of course to curb this severe problem is the assessment of discrimination. Its assessment can be done by analysis of legislative records (institutional discrimination), employment uptake as a function of ethnicity (controlling for education), and at an individual level. The latter includes various scales such as the perceived discrimination scale (Williams, Yu, Jackson, & Anderson, 1997), which assesses 10 daily aspects of discrimination (e.g., being treated as less intelligent or in a less courteous manner than others). This domain is a very important example where behavioral and social sciences interact with biomedical sciences for understanding and beginning to ameliorate such severe health problems at a macro level.

Disease Burden

Jette, Belgium

Definition

The term “disease burden” is a term of major importance in medicine and behavioral medicine.

It refers to the intensity or severity of a disease and to its possible impact on daily life. Thus, it could be at times referring to both illness severity and impact, resulting in confusion between concepts. Concerning disease severity, this reflects the amount of pathology in a given illness. For example, disease burden in cancer may be indexed by level of a tumor marker – e.g., CA125 in ovarian cancer, or CEA in colon cancer. Additionally, tumor stage could reflect disease burden as well. In coronary artery disease (CAD), this can be indexed by the number of arteries occluded over 50%, or the percentage of occlusion in a given artery (e.g., 40%, 99%). In infectious diseases, disease burden could reflect the amount of viral load in HIV patients. Concerning a disease's impact, disease burden can be measured by its effects on longevity or on quality of life (QOL). An illness with a high disease burden would thus impair one's psychological, physical, or social functioning aspects of QOL. For example, a patient with severe CAD could have debilitating chest pain which reduces his or her mobility, thus impairs work, elicits anxiety and depressive reactions, and reduces his or her social contacts with friends, family, and work colleagues.

In behavior medicine, researchers often take into account disease burden as a covariate, when testing the relation between a psychological factor and recovery or prognosis, independent of disease burden. For example, Denollet et al. (1996) showed that the Type-D personality (high distress and social inhibition) predicted mortality in coronary heart disease, independent of disease burden indexed by number of diseased vessels and left ventricular functioning. In a study on patients' recovery from coronary bypass surgery, Scheier et al. (1989) found that patients' trait optimism predicted recovery, independent of disease burden indexed by extent of surgery and number of occluded vessels. Hundreds of studies examine disease burden by assessing its impact on QOL and general well-being. A few standardized disease burden indices exist including the Charlson Index and the index of coexistent disease (Greenfield, Aronow, Elashoff, & Watanabe, 1988). The former only considers the number and severity of comorbid diseases, while the latter additionally considers patients' functional status in 12 categories (e.g., feeding, mental status, vision, respiration). Another unique disease burden index is the Smith index, which considers in a formula with weights a patient's emergency room visits during 6 months, blood urea nitrogen value, arterial pO_2, total white blood cell count, and presence of anemia. These indices can enable researchers in behavior medicine to assess disease burden in a standardized manner across patient conditions, and then examine the role of psychosocial factors in prognosis, independent of disease burden estimates. Finally, one may also estimate the impact of such disease burden indices on psychological functioning.

Definition

Disease management is a patient centered, integrative health care intervention approach for managing the signs and symptoms of chronic diseases in defined populations of individuals. The main aims of disease management interventions are to optimize care, improve quality of life, and reduce costs associated with treating chronic conditions by coordinating patient care using a multidisciplinary approach.

Description

Disease management came about as a response to a changing health landscape wherein the prevalence and complexity of chronic conditions is on the rise requiring treatment regimens to adjust. With traditional approaches, patient information is spread across practitioners and specialists who are responsible for disparate aspects of patient care and respond in reactive ways to acute conditions. In contrast, disease management approaches plan for the long-term management of chronic conditions by reducing fragmentation and improving the continuity and coordination of the patient care process. This strategy is predicated on the understanding that improvements in medical therapy and self management can reduce the signs and symptoms of disease and improve treatment outcomes.

Disease management interventions are based in both primary care and private sector operations. While each of these shares the common goal of improving the health of the patient (e.g., increase functional ability, improve health status, reduce hospitalization time, and increase care compliance with treatment plans) and decreasing associated costs, different approaches are taken. Primary care interventions are integrated into the health care delivery system and focus mainly on communication with patients and between professionals (e.g., physicians, pharmacists, nurses, nurse practitioners, physical therapists). Private sector interventions are adjunct to the health care system (e.g., employers and insurers) and mainly focus on cost containment.

Three common key agents of change emerge in disease management literature: the patient, the health care team, and the environment. The patient is viewed as an active agent in his or her own care. It is up to the individual to seek information and be motivated to carry out the treatment plan. As such, self-management (► Self-management) interventions are hypothesized to affect outcomes (e.g., health status and health care use) by producing behavior change. There are many modifiable lifestyle factors that can be adopted by the patient to prevent or minimize the effects of disease (e.g., adherence to treatment regimens, physical activity, proper nutrition, medical screening, limited sun exposure, and substance avoidance). For example, epidemiological studies reveal that people who are more physically active have a lower risk of certain cancers than those who are sedentary. Evidence of self management interventions consistently demonstrates self-efficacy, and knowledge and skills are important mediators to target behavior change interventions.

The role of the health care team in disease management is to monitor conditions and to create a treatment plan, either alone or with the patient and health care team. A key challenge for the health care professional is to keep abreast of advancing knowledge and expertise necessary to care for patients. Education, decision-making support, time, and resources are targets for disease management intervention that should result in changed attitudes or behavioral intention, which is hypothesized to lead to professional behavior change. Ultimately, professionals who have increased expertise, knowledge, and support should provide higher quality treatment thus improving health outcomes.

Interventions that target the health care environment often focus on organizational design and relational coordination. Effective relational coordination interventions often involve the assembly of a coordinated (coordination within, across, and between care teams and community resources) multidisciplinary patient care team. Effective organizational design interventions often address task allocation, information transfer, appointment scheduling, and case management. These strategies are based on the belief that seamless care delivery (e.g., structural, financial, and

functional) and collaboration among diverse care providers (e.g., nurses, nurse practitioners, dieticians, social workers, physicians, physician assistants, and public health workers) will improve health and fiscal outcomes.

Although there is some evidence to support various disease management strategies, definitive conclusions about the overall effectiveness on patient outcomes and cost reduction cannot yet be made and will require further exploration.

Definition

A disease is a medical condition that is considered to be abnormal, impairs bodily functions, and is associated with specific signs and symptoms. The disease onset is the first time that there has been noted to be a "change" in one's usual health status with the identified signs and/or symptoms being able to be directly attributable to a specific disease process.

Description

Diseases may be identified as having an acute, subacute, or chronic onset with symptoms developing over a wide variety of time from minutes to months. Certain diseases will be easier to identify as to their exact time of origin, or disease onset. An example would be the onset of nausea and vomiting from a food-borne toxin that has been ingested. Other diseases are much harder to characterize as to their onset. Alzheimer's disease, for example, is rarely identified until it has reached clinical significance at which time most individuals and their close contacts on more careful analysis can identify early warning signs that appeared years earlier and likely marked the onset of the disease. While symptoms may present in a classic manner, such as chest pain accompanying the onset of a myocardial infarction, at times, the presentation is atypical/nonspecific, making the diagnosis as to disease onset challenging. In the elderly, for example, it is not uncommon for a myocardial infarction to present with no chest pain but rather shortness of breath being the initial symptom at disease onset.

There are many examples of diseases that have variable disease onset. One such example is coronary artery disease. Individuals who present with coronary artery disease prior to age 50 are more likely to have a genetic predisposition; individuals affected later in life may have additional risk factors including dietary influences and coexisting diseases such as hypertension. Another example of a disease with a variable disease onset is Alzheimer's disease. Individuals affected prior to age 65 are

said to have a presenile dementia of the Alzheimer's type and are more likely to have a genetic predisposition for this earlier onset. Individuals affected after age 65 are said to have senile dementia of the Alzheimer's type (SDAT) (Bertram & Tanzi, 2008).

Disease severity is a term used to characterize the impact that a disease process has on the utilization of resources, comorbidities, and mortality. It is often used by funding agencies to determine what is an appropriate payment for hospitalization or nursing home payments based on Diagnosis-Related Groups or RUGS (Resource Utilization Groups). There are several "severity indexes" that may be used to quantify the severity of illness such as the Glascow Coma Scale for assessing the severity of cognitive dysfunction or the Mini-Mental Examination that quantifies the degree of dementia.

Dispersion

Cardiovascular Safety, Quintiles, Durham, NC, USA

Synonyms

Scatter; Variability

Definition

The spread, or dispersion, of a group of numbers around a central value is an important characteristic of a data set. It can be calculated in various ways. The range, the simplest measure of dispersion, is the arithmetic difference between the largest (maximum) value and the smallest (minimum) value. However, while it can be useful in initial "visual inspections" of a data set, this measure of dispersion is only a rough guide to the amount of variation present. Because it only takes into account two values from a data set, it utilizes a (potentially very) small part of the information available.

Imagine a data set containing 100 numbers. When calculating the range, only two of these numbers would be used. In other words, 98% of the available information would not be used in deriving this measure of dispersion. Consider a hypothetical data set of 100 numbers where the minimum value is 20, the maximum value is 80, and all of the 98 other numbers lie between 55 and 75. Now consider a second hypothetical data set of 100 numbers where the minimum value is again 20, the maximum value is again 80, but the other 98 numbers are spread out between 25 and 55. While the range would be identical in both cases (i.e., 60), it is intuitive that the overall natures of the two sets of numbers are quite different.

Two more sophisticated measures of dispersion for a data set are its variance and its standard deviation. These measures are intimately related to each other and take account of all values in the data set.

Synonyms

Optimism

Definition

Dispositional optimism is a stable personality trait characterized by general positive expectations that influence motivated action. When confronted with obstacles in achieving a desired future state, those who are optimistic anticipate positive outcomes from their actions. According to this self-regulatory model, optimism plays a role in negative feedback loops that guide goal-directed behavior. Consequently, optimistic individuals display a cross-situational tendency to enhance efforts toward their goals instead of disengaging and withdrawing efforts. It is also theorized that optimism is implicated in the propensity to attribute the cause of negative events as external and unstable. This explanatory style then influences future expectancies and behavior.

Various investigations of dispositional optimism have revealed a positive relationship with problem-focused and engagement coping strategies. This is the proposed pathway for optimism's potential benefits for well-being and adjustment to stressors. Dispositional optimism has been linked to positive psychological and physical outcomes among patients with chronic illnesses including cardiovascular disease, AIDS, and cancer.

Dissemination

Department of Health Behavior, School of Public Health, University of Alabama at Birmingham, Birmingham, AL, USA

Synonyms

Diffusion; Implementation

Definition

Dissemination refers to "the targeted distribution of information and intervention materials to a specific public health or clinical practice audience," whereas *implementation* refers to "the use of strategies to adopt and integrate evidence-based health interventions and change practice patterns within specific settings" (National Institutes of Health [NIH], 2010).

Broadly speaking, dissemination and implementation science (D&I) is focused on bridging the research-to-practice gap in health care and public health. The overall objectives of D&I research are to understand barriers toward the effective use of evidence-based health interventions, programs, practices, and treatments in health care and public health and, importantly, to create and test strategies to move such health innovations into everyday settings more quickly, effectively, and broadly.

D&I science is highly interdisciplinary, drawing on expertise from systems science, psychology, sociology, health services research, organizational behavior, and clinical research, among other fields. The field has witnessed considerable growth, expansion, and interest among researchers, policymakers, and practitioners in the United States and international settings in the past decade. This has included the emergence of speciality journals (e.g., Implementation Science), conferences (e.g., National Institutes of Health Conference on the Science of Dissemination and Implementation), review panels, funding announcements, and training programs (e.g., Implementation Research Institute).

Distant Intercessory Prayer

Kevin S. Masters
Department of Psychology, University of Colorado, Denver, CO, USA

Definition

Distant intercessory prayer is simply defined as prayer said on behalf of someone else when that person is not present. This is different from intercessory prayer in which prayer is also said on behalf of someone else but the person being prayed for is present during the prayer.

Description

Intercessory prayer is the age-old practice of praying for someone else. The first empirical study on this topic was conducted by Sir Francis Galton and published in 1872. Galton demonstrated that individuals who were often prayed for, in this case, members of the royal family, did not live longer than others. In the context of modern behavioral medicine, intercessory prayer still usually consists of prayer for improvement in health status or healing. One could serve as one's own intercessor (as when praying for oneself) or could be the recipient of prayers from others, i.e., intercessors. Prayers said by oneself or by others in the presence of the recipient of the prayer could theoretically be effective in improving health through a number of mechanisms including not only the actual prayer itself (i.e., divine intervention or some type of beneficial energy) but also via social support or other naturalistic psychological mechanisms. Distant intercessory prayer, however, occurs when the intercessor is not physically present with the recipient of the prayer. In this way, a more stringent test of the effects of prayer per se can be tested. Further, some studies in this area used blinding strategies wherein patients did not know whether they were in the prayer or no-prayer group, and other studies went even further and included patients who did not even know they were included in a prayer research project.

Empirical research on the effects of distant intercessory prayer has been carried out with patients experiencing many different disorders including various forms of cardiac disease, leukemia, mental health problems, renal failure, rheumatoid arthritis, infertility, sepsis, and alcohol abuse. Reviews and meta-analyses were conducted by Masters and colleagues (Masters & Spielmans, 2007; Masters, Spielmans, & Goodson, 2006) and the more recently published Cochrane Collaboration Review (Roberts, Ahmed, Hall, & Davison, 2011). Each of these analyses found no credible evidence that distant intercessory prayer was associated with a beneficial overall effect. The authors of the Cochrane report carefully pointed out that their review of the empirical data in no way addresses metaphysical questions regarding the existence of God or any deity. Similarly, Masters (2005) argued that distant intercessory prayer studies lack a strong theological basis and also produce noninterpretable findings because, critically, they are not able to control the amount of prayer delivered to or for the no-prayer control group. That is, when a group of researchers assigns individuals to a no-prayer control group, it only means that the researchers or their chosen intercessors will not pray for those individuals. This, however, does nothing to stop family, close friends, health-care professionals, or others from praying for them. There has never been a reason postulated that suggests the prayers of intercessors in a prayer study would be more effective than those of others in the patients' experiential world. Many other questions remain unaddressed in these studies including qualifications of intercessors, theoretical understanding of both significant and nonsignificant findings, within group variations in outcomes, and any firm theory or even coherent hypothesis to offer an explanation for the expected effects. One study (Benson et al., 2006) even suggested that individuals undergoing coronary artery bypass grafting who knew they were receiving intercessory prayer had a higher incidence of complications.

Finally, in some studies, when significant findings were found, they (a) were not on the variables that were the object of prayer and (b) occurred in the absence of controls for multiple comparisons.

It bears repeating, however, that the argument here is not against the conduct of intercessory prayer, distant or present, by those who believe in such practices. Rather, it is an argument that empirical studies have not demonstrated an overall superiority for groups in prayed for versus not prayed for groups and that, because of the inherent methodological limitations of such research, these studies are actually unable to test their central idea/hypothesis and thus will never render a definitive database upon which to ascertain the health effects of intercessory prayer.

Definition

Distraction refers to a classification of coping strategies that are employed to divert attention away from a stressor and toward other thoughts or behaviors that are unrelated to the stressor. In both adult and pediatric populations, distraction (for example, focusing on an external object or imagining a peaceful place) may be used to deal with pain and discomfort during medical procedures. Other examples of distraction include daydreaming or engaging in substitute activities to keep one's mind from ongoing stressors related to a chronic illness. There are many ways to group coping strategies together. For instance, distraction has been considered a type of emotion-focused coping (Lazarus and Folkman, 1984), which involves minimizing the emotional distress related to a stressor. Distraction has also been categorized as passive coping, a type of coping that has been associated with helplessness, avoidance, and poorer psychological outcomes in the long term. Examples of distraction that reflect a sense of helplessness or avoidance are statements such as "I try to think about anything else but my illness because I've quit trying to deal with it" and "I can't think about my illness so I've been watching television or movies to escape."

Diuretic

Definition

A diuretic is a drug that increases the rate of urine flow. As a drug class, the major aim of diuretics is to decrease extracellular fluid volume, and their major site of action is the kidneys. Secondarily, diuretics increase extracellular sodium excretion. Different classes of diuretics work by different mechanisms in the kidneys, and they alter cation and anion levels in the body as well as renal hemodynamics.

The main classes of diuretics include carbonic anhydrase inhibitors, loop diuretics, thiazide diuretics, potassium-sparing diuretics, and osmotic diuretics. Carbonic anhydrase inhibitors (e.g., acetazolamide, dichlorphenamide, and methazolamide) work at the proximal convoluted tubule of the nephron, where carbonic anhydrase plays a role in sodium bicarbonate reabsorption. By inhibiting sodium bicarbonate reabsorption, these drugs cause sodium bicarbonate and water excretion. Carbonic anhydrase inhibitors are used clinically to treat severe acute glaucoma because their effect of decreasing bicarbonate reabsorption leads to decreased bicarbonate secretion in the eye and lowers intraocular pressure.

Loop diuretics (e.g., furosemide, bumetanide, ethacrynic acid, and torsemide) work at the thick ascending loop of henle and inhibit the sodium-potassium-chloride symport, thereby increasing excretion of ions and water. Clinically they are used to quickly get rid of edema in heart failure, ascites, and pulmonary edema.

Thiazides (e.g., hydrochlorothiazide, thiazide, chlorthalidone, indapamide, and metolazone) work at the distal convoluted tubule and inhibit the sodium-chloride symport. They are used mainly in hypertension because they lower blood pressure and to a lesser extent to reduce edema.

Potassium-sparing diuretics act by two different mechanisms. Spironolactone and eplerenone antagonize aldosterone in the collecting tubules while amiloride and triamterene block the epithelial sodium channels in the collecting tubules.

They all increase sodium excretion and decrease potassium and hydrogen excretion. These drugs may be used in combination with loop or thiazide diuretics to counterbalance the potassium wasting of those drug classes. The ones that affect aldosterone are also used in heart failure.

Osmotic diuretics (glycerine, isosorbide, mannitol, and urea) cause excess water excretion from intracellular compartments thereby increasing urine volume and renal blood flow. They are used to maintain high urine flow in certain clinical situations (e.g., severe hemolysis or rhabdomyolysis) and can be used to reduce intraocular or intracranial pressure.

There are multiple types of diuretics whose clinical indications can vary depending on the patient's comorbidities. It is imperative with this class of medications to weigh the impact not just on efficacy but also how these medications can impact their quality of life due to issues with urinary frequency and possibly incontinence.

Diurnal Mood Variation

Brant P. Hasler

Synonyms

Daily mood variation; Diurnal rhythms in mood; Mood variability

Definition

The term *diurnal mood variation* is most commonly used in the context of the symptomatology of mood disorders, referring to noticeable diurnal (daily) changes in overall mood state experienced by some individuals suffering from depression. Historically, the specific patterns of these diurnal mood changes were thought to characterize various subtypes of depression, although empirical evidence for this has been mixed. Diurnal mood variation has been most closely linked to melancholic depression (also known as endogenous or somatic depression), which was thought to be characterized by a pattern of feeling worst (most depressed) upon awakening in the morning, than feeling progressively better as the day continues into the afternoon and evening. The opposite (atypical) pattern – feeling best in the morning, then worsening over the course of the day – was considered to be less common, and thought to characterize atypical (or nonendogenous) depression. Diurnal patterns in mood have also been noted in healthy individuals, and a circadian rhythm component to mood is now well established, although the specific term "diurnal mood variation" is less commonly used in this context.

Description

In the context of depression, diurnal mood variation is typically assessed by asking the patient to retrospectively describe the pattern, either during the course of a clinical interview or as an item on a questionnaire (e.g., Hamilton Rating Scale for Depression). Efforts to assess diurnal mood variation prospectively, both within and across days, suggest that the presence and direction (morning worse vs. evening worse) of diurnal mood variation are highly unstable over time, and vary independently of overall depressive symptoms (Gordijn, Beersma, Bouhus, Reinink, & Van den Hoofdakker, 1994). The instability of diurnal mood variation, as well as poor agreement between assessment approaches, suggests that caution is warranted when interpreting

diurnal mood variation as an indicator of depression subtype (e.g., melancholic vs. atypical). This caution was underscored by a study of 37 patients with major depression that found no relationship between pattern of diurnal mood variation and either typical (i.e., weight loss and insomnia) or atypical (i.e., weight gain and hypersomnia) depressive symptoms (Leibenluft, Noonan, & Wehr, 1992). Likewise, a much larger dataset of 3,744 outpatients with major depression from the STAR*D study also suggested a need to revise the conventional wisdom regarding links between specific patterns of diurnal mood variation and depression subtypes (Morris et al., 2007). Specifically, nearly a quarter of patients reported diurnal mood variation, but the majority of these patients (48.6%) reported evening worsening in mood, with only 31.9% or 19.5% reporting morning or afternoon worsening in mood, respectively. Morris and colleagues also reported that any diurnal mood variation, rather than morning worsening, per se, increased the likelihood of having melancholic symptoms of depression.

Diurnal mood variation is thought to have clinical relevance as a predictor of treatment response, although the empirical evidence for this is mixed. Early studies have suggested that morning worse morning mood predicted favorable treatment responses to total sleep deprivation and tricyclic antidepressants. In contrast, more recent studies indicated that greater mood variability, rather than any specific pattern of diurnal mood variation, is associated with improved response to total sleep deprivation treatment (Gordijn et al., 1994), and that diurnal mood variation does not predict treatment response to selective serotonin reuptake inhibitors (SSRIs) (Morris et al., 2007).

Although the classic conception of diurnal mood variation has thus far proven to have arguable utility, more sophisticated investigations of diurnal patterns in mood may still provide important insights into the pathophysiology of depression. These studies are distinguished from past research by using prospective designs along with more frequent within-day assessments to provide greater temporal resolution of mood variability. A number of studies have been influenced by advances in affective science, and thus used separate scales to assess positive and negative affect rather than using a unidimensional mood measure (Watson, 2000). These studies have generally reported that positive affect shows a 24-h rhythmic pattern, while negative affect lacks systematic daily variation. Positive affect is lowest in the early morning hours, rises throughout the day, to peak in the late afternoon and early evening, and declines during the night. Accumulating evidence indicates that the 24-h patterns in positive affect are due in part to endogenous circadian rhythms and not simply a reflection of affective responses to sociocultural rhythms in the environment (Boivin et al., 1997; Murray, Allen, & Trinder, 2002).

Diurnal rhythms in mood may be altered in depression, most commonly manifesting as a blunted peak in positive affect. In a study by Peeters, Berkhof, Delespaul, Routtenberg, and Nicolson (2006) depressed individuals reported lower peaks of positive affect, and these peaks occured later in the day, compared to healthy non-depressed individuals. The depressed group also reported decreased negative affect throughout the day, with greater moment-to-moment variability. (Negative affect in the healthy group did not follow a systematic pattern, consistent with previous reports.) In interpreting these results, the authors hearkened back to the classic definition of diurnal mood variation, noting that retrospective mood evaluation, via a unidimensional mood construct, likely hinged on an internal calculus of the varying combinations of positive and negative affect occurring throughout the day. A more recent study by Murray and colleagues (Murray, 2007) suggested that changes in the diurnal rhythms of positive affect are not only apparent in categorical comparisons of depressed and healthy individuals, but can also serve to characterize the severity of depression. Compared to a group with mild depression, the group with more severe depression had a less discernable rhythm in positive affect with a notably blunted peak, along greater overall negative affect throughout the day. Cumulative evidence indicates that altered circadian function may be present in depression.

Diversity

Synonyms

Cultural competence; Heterogeneity; Multiculturalism

Definition

Diversity involves a difference between an individual or group in comparison to an established "norm" (Kato & Mann, 1996). This may be influenced by context and based on a number of factors including, but not limited to, ethnicity, race, culture, gender, age, sexual orientation, religion/spirituality, health status, disability, veteran status, or socioeconomic status (Jackson, 2006). Such factors are not mutually exclusive and may occur in any myriad of combinations.

Description

The field of behavioral medicine has made significant advances over the past three decades, providing a strong body of interdisciplinary evidence and theory to support the efficacy of applying research and practice for the promotion of health and prevention of illness (Belar & Deardorff, 2009; Smith & Suls, 2004). Similar to the medical field as a whole, however, these advances have historically focused on the experience of middle-class Euro-American white males and been based on a traditional Western

view of health (Kazarian & Evans, 2001; Smith, Kendall & Keefe, 2002).

Yet demographic diversity within the United States continues to increase in a number of areas (Jackson, 2006). For example, the Census Bureau noted that in 2008, ethnic and racial minorities consisted of approximately one-third of the population. Census projections indicate that by mid-century, these minority groups will continue to increase in number and represent slightly more than a majority of the population as a whole. Latinos, in particular, are projected to account for one in three of all Americans. Over this period, the average age is also expected to increase, resulting in a greater proportion of Americans who are older. Similarly, other diverse groups are projected to continue to grow, including the number of people who identify as members of sexual minority groups.

Diversity is a salient issue as it has a number of implications regarding the prevalence of illness and health-related disparities (Agency for Healthcare Research and Quality, 2009; Smith & Shuls, 2004). For example, compared to whites, African Americans experience significant health disparities in areas such as number of new cases of AIDS, diabetes-related lower extremity amputations, and lack of prenatal care within the first trimester of pregnancy. African Americans, Asian Americans, and Hispanics over the age 50 are significantly less likely to receive preventative screenings such as a colonoscopy or proctoscopy. Similarly, Hispanic and African Americans with depression are less likely than whites to receive mental health care.

An increasingly diverse demographic landscape will require that behavioral medicine adapt in order to appropriately address the needs of diverse groups (Belar & Deardorff, 2009). Through development of cultural competence skills, the field can better understand patients' sociocultural contexts, as well as recognize and appropriately respond to key cultural features. To this end, cultural competence involves development within three domains: self-awareness of one's own attitudes and beliefs; knowledge of the population of interest; and tools that can be applied with diverse groups (Jackson, 2006).

Similarly, cultural competence can be extended to involve a context competence (Smith & Suls, 2004). From this point of view, diversity must be addressed within all aspects of behavioral medicine – clinical practice, research, education, and policy.

This provides the opportunity to explore the ways that sociodemographic characteristics are linked to health, illness, and related behaviors (Smith, Kendall & Keefe, 2002). The call to address diversity within behavioral medicine provides the opportunity to establish generalization of prior findings, as well as explore within-group differences that are related to health-related behavior and health outcomes. Such competence will require added interdisciplinary collaboration, for example, with multicultural psychology, and involve other levels of systems such as members of a community or organization.

Divorce and Health

Marital dissolution; Separation

Definition

Divorce is the legal dissolution of a marriage. It is simultaneously a legal and psychological process (Margulies & Luchow, 1992). Not all people are equally distressed by divorce, and a variety factors contribute to level of distress endured. The degree of distress that stems from the divorce process and from divorced marital status predicts mental and physical health in both the short and long term. Remarriage can reduce the health risks of divorce. Possible mechanisms underlying the relationship between divorce and health (e.g., psychophysiological mechanisms, immune functioning) have been explored.

Description

It has long been understood that marriage, or a stable, long-term intimate relationship, increases life expectancy, decreases morbidity, and enhances quality of life (Burman & Margolin, 1992). In fact, it has been noted that the evidence linking social relationships to health and mortality is as strong as that linking cigarette smoking, blood pressure, and obesity to health (Umberson, Williams, Powers, Liu, & Needham, 2006). However, it is also understood that not all marriages protect equally, and a poor relationship may be more health damaging than no relationship at all.

A number of studies have also found that being divorced is more health-damaging than being married (e.g. Hughes & Waite, 2009; Kiecolt-Glaser, Kennedy, Malkoff, & Fisher, 1988). In an early study on the effects of marriage versus divorce on immunity status among a sample of 32 married versus 32 divorced men, it was found that separated/divorced men were more distressed and lonelier and reported significantly more recent illness than did married men; the former also had significantly poorer values on two functional indices of immunity (antibody titers to two herpes viruses) while not differing significantly on quantitative indices (percentages of helper and suppressor cells and their ratio).

In understanding the complexity of the marital status/marital quality and health relationship, it is important to understand the differences between those who are divorced, those who remain married and those who remarry in terms of morbidity and mortality. In the same study of immunological functioning, it was found that among married men, poorer marital quality was associated with greater distress and poorer immunological functioning. Among separated/divorced subjects, those who had separated within the past year and who had initiated the separation were less distressed, reported better health, and had better immunological functioning than did noninitiators (Kiecolt-Glaser et al., 1988). Taken together, the results suggest that while being married can be advantageous in staying healthy (having

increased immunity against disease), the effects of marriage on health depend on the quality of that marriage. And, given a poor marriage, it is better to be the one initiating divorce than the one who is not the initiator when it comes to immune functioning. Other researchers have attempted clarify the psychophysiological mechanisms underlying the relationship between divorce and health. One study looked at divorce-related psychological adjustment and blood pressure in a sample of recently separated or divorced adults ($n = 70$). Individuals who reported higher degrees of divorce-related emotional distress demonstrated elevated resting blood pressure at study entry. The same study found that men who reported greater emotional difficulty associated with the divorce experience showed greater cardiovascular reactivity when thinking about the divorce (Sbarra et al. 2009).

A lot of the early research on health and marriage compared those who were married with those who were unmarried on health outcomes. Fewer studies have examined the effect of *changes* in marital status on either emotional or physical well-being. Two large sample studies, one of 8,809 people in the United States (Hughes & Waite, 2009) and one of over 5,000 people in Great Britain (Bennett, 2006), looked at transitions into and out of marriage. Results from both studies found a clear positive effect of marriage. It was also found that a change in marital status predicted health worsening (Bennett, 2006; Hughes & Waite, 2009) with a difference between those who were divorced and those who were widowed. Interestingly, for the newly divorced, health problems increased at the point of the divorce, while for the newly widowed, problems increased later in time, perhaps because of a cumulative stress effect (Bennett, 2006). Finally, results revealed strong and consistent effects of marriage on later health in that among those who have ever been divorced or widowed, the remarried generally show better health than those who have not remarried (Hughes & Waite, 2009).

Others have assessed whether findings that divorce is deleterious to health would hold-up to longer-term analyses. In a study focused on the immediate and the more long-term (10 years later) effects of divorce on women's health ($n = 244$), it was found that in the years immediately following their divorce, women reported significantly higher levels of psychological distress than married women; no differences in physical illness were found between groups (Lorenz, Wickrama, Conger, & Elder, 2006). A decade later, the divorced women reported significantly higher levels of illness, even after controlling for age, remarriage, education, income, and prior health. The authors concluded that as a stressor, divorce has a more acute effect on psychological health, while physical illness risk accumulates incrementally in response to the relatively stable dimensions of chronic stress over time. That is, the divorce *process* has more of an acute effect on the psychological health of women while *being divorced* is a chronic stressor, and illness can be understood as a cumulative response to the concomitant chronically stressful conditions (e.g., financial hardship, lack of social support).

In looking at the effects of marriage, marriage transition, and divorce, there are a number of confounding issues including gender effects, age effects, and time married effects that are beyond the scope of this entry. It is clear that divorce affects men and women differently and the young versus the old differently. However, the issue of the relative impact of marriage, divorce, and marriage transitions on the health of men versus women is not a clear one. While some studies have found differences between men and women (e.g., Dupre & Meadows, 2007), others have found no such differences (e.g., Williams, 2003) in health impact. In trying to reconcile these discrepant findings, some have looked at the possibility of different mechanisms underlying the effects for men versus women. A number of studies have associated the mortality disadvantage of divorce on women to the financial losses resulting from divorce, as opposed to the divorce itself (Lillard & Waite, 1995; Prigerson, Maciejewski, & Rosenheck, 1999; Wickrama, Conger, & Lorenz, 1995). In contrast, men seem to benefit from the sense of a "settled life" that marriage provides; they are less likely to engage

in risky health behaviors and experience gain from the household tasks taken over by women in marriage (Lillard & Waite, 1995).

In further trying to elucidate the underlying mechanisms in the relationship between divorce and health, some researchers have looked at divorce and illness prevention behaviors. However, rather than finding that it is a lack of illness prevention among the unmarried that leads to worse health outcomes, the opposite appears to be the case. A number of studies have in fact found that marriage *decreases* healthy behaviors such as weight control (Lee et al., 2005) and fitness levels (Ortega et al., 2011). These findings are consistent among the married versus the nonmarried and across the divorced versus remarried, with remarriage showing the same negative health trends as the continuously married men and women.

Thus, it remains to be determined why marriage is protective and divorce is harmful in terms of health outcomes overall. Other than general health effects, a number of studies have investigated more discrete health outcomes that result from marriage, divorce, and transitions. For example, there have been consistent findings that distressed marriages lead to more specific poor health outcomes such as coronary disease (Eaker, Sullivan, Kelly-Hayes, D'Agostino, & Benjamin, 2007; Zhang & Hayward, 2006), slow wound healing (Kiecolt-Glaser et al., 2005), and cardiac events (Orth-Gomer et al., 2000) compared to happier marriages. It has also been found that marital status determines specific health outcomes. For example, remarriage after divorce significantly reduces risk of COPD incidence, even after adjusting for smoking habit (Noda et al., 2009), and coronary heart disease mortality among divorced, widowed, and never married men and women is greater than among the married (Lindgarde, Furu, & Ljung, 1987; Weiss, 1973; Zhang & Hayward, 2006).

It remains a truism that being married or in another long-term intimate relationship is better for one's health than being single, widowed, or divorced for both general health and a number of specific health conditions. However, the reasons for these findings are not well understood. It is clearly not that married people take better care of themselves physically; in fact, the opposite seems to be the case. It is possible that the stress of divorce accounts for these differences but then again so does the stress of remaining in an unhappy relationship. For women, this stress seems to be primarily financial, while for men, this stress appears more task-oriented. It is also better to be remarried than to remain divorced or widowed, although the transitions into and out of marriage themselves seem to be harmful. Clearly, more information is needed to understand the complicated relationships between marital status and health, marital history and health, and marital quality and health.

Dizygotic Twins

Fraternal twins; Nonidentical twins

Definition

Dizygotic (DZ) twins are pairs of siblings resulting from the same pregnancy. They develop from two separate eggs that have each been fertilized by a different sperm. These siblings share, on average, 50% of their genes, as do ordinary full siblings. In contrast to monozygotic (MZ) twins, who are always same-sex pairs, DZ twins can be same-sex pairs or opposite-sex pairs.

The employment of opposite-sex pairs in twin studies allows assessments of whether genetic and shared environmental familial influences on behavior are different for males and females. If there are sex differences, the correlation for opposite-sex pairs will typically be lower than that for same-sex pairs.

The acronym DNA is now so well known in popular as well as scientific literature that it often appears with no accompanying definition: The words deoxyribonucleic acid are rarely heard, but they are what the acronym represents. DNA is a very large molecule or macromolecule, with each word of its full name being descriptive of its nature. Ribose is one form of sugar (along with glucose, fructose, sucrose, and others). The prefix "deoxy-" specifies a ribose that has lost one of its oxygen atoms at a specific site in the molecule. Nucleic acids are a group of complex compounds derived from carbohydrates, purines and pyrimidines, and phosphoric acid.

Nucleic acids are found in all living cells, and also in viruses, which themselves are not actually "alive" until they hijack another cell's genetic material and make it work to their advantage. Nobel Laureate Sir Peter Medawar has captured this occurrence very well by calling a virus "a piece of nucleic acid surrounded by bad news" (cited by Bryson, 2004).

DNA molecules contain many copies of four bases: adenine (A), guanine (G), thymine (T), and cytosine (C). Each of these bases can be regarded as a molecule in its own right, being comprised of carbon, hydrogen, oxygen, and nitrogen atoms. Adenine and guanine are purines, chemical structures composed of two carbon rings, and thymine and cytosine are pyrimidines, which are composed of one ring of carbon atoms.

Purines and pyrimidines join together (or bond) with a deoxyribose molecule that also contains a phosphate group. The combination of A, G, T, and C with a deoxyribose molecule leads to the formation of four different nucleotides, two purine nucleotides (A and G) and two pyrimidine nucleotides (T and C). Hundreds of thousands of individual nucleotides can link together to form a polynucleotide strand. Each DNA molecule is comprised of two strands of nucleotides that are attached together. This molecular structure and the ensuing three-dimensional molecular geometry of DNA lead to its characteristic double helix nature. Once formed, single strands of DNA are matched with and then attached to another strand in a nonrandom manner governed by these rules: An adenine base can only be matched with and attached to a thymine base, and a guanine base can only be matched with and attached to a cytosine base, leading to A-T and G-C pairings. The term "complementary bases" reflects that each of the four nucleotide bases has a complementary base to which it becomes attached. A critical consequence of this arrangement is that once the sequence of nucleotides in one strand is known, the sequence of nucleotides in the other strand is known.

Replication, the process by which DNA produces an exact copy of itself, is facilitated by this phenomenon. The two polynucleotide chains that comprise a DNA molecule split apart from each other, and each then becomes attached to a newly formed chain, that is, an exact replicate of its original partner. This creates two identical DNA molecules, which can then continue to create replicates in an exponential manner.

The Relevance of Genetics for Behavioral Medicine

While this encyclopedia is not focused on molecular genetics, genetic inheritance is of considerable importance in behavioral medicine, and therefore the information conveyed by this entry and other related genetic entries is deserving of inclusion. In some cases, inheriting certain alleles can be the sole and readily identifiable cause of a disease. A case in point is phenylketonuria (PKU), which is inherited in an autosomal recessive manner. Those who inherit the disease do not have the ability to create an enzyme called phenylalanine hydroxylase, which metabolizes the amino acid phenylalanine, a component of many foods. Accumulating levels of phenylalanine are harmful to the central nervous system. Fortunately, a very strict diet low in phenylalanine provides successful treatment.

In contrast, for complex diseases of interest in behavioral medicine, a multi-gene etiology is typical, and it has proved very difficult to isolate and identify individual genes/alleles that are responsible for sizeable amounts of variation in the dispersion of a disease. What has become apparent, however, is that environmental (behavioral) influences are of great importance in many such complex disorders. Consider the case of alcoholism, since it well exemplifies the interesting phenomenon of disposition rather than predetermination. Clinical data suggest that, when inherited, the genes that underlie alcoholism liability confer a vulnerability to alcoholism expression rather than the certainty of it. Genetic inheritance of alcoholism liability can thus be highly sensitive to environmental modulation (McGue, 2005).

The role of behavioral influences is important both in disease etiology and disease treatment. Given a certain genetic inheritance, some environments can tend to increase the likelihood of a disease's expression, while others tend to decrease it. This also means that behavioral interventions can be very successful at preventing or ameliorating behaviorally influenced conditions of clinical concern. Thus, behavioral medicine is concerned with both genetic predisposition to complex disease states and environmental influences that interact with them.

Do Not Resuscitate Order: DNR

Description

Do Not Resuscitate Order: DNR

A do not resuscitate (DNR) order is a directive that cardiopulmonary resuscitation (CPR) should not be initiated if an individual's heart stops or if the individual stops breathing. State law determines who may issue a DNR order such as whether a health-care practitioner other than a physician is authorized to do so. Health-care facilities will have established protocols for resuscitating patients when there is no DNR order, in accordance with state law. Competent patients or their authorized decision maker or proxy should be consulted about any proposed DNR order. The authority of a decision maker or proxy to consent to a DNR order can be affected depending on (a) whether that person is an agent under an advance directive, representative under a durable health care power of attorney, surrogate under state law, or guardian appointed by a court and (b) the scope of any such authorizing document. State law also determines if or how a physician may or may not have the authority to enter a DNR order without a direction by a competent patient or authorized decision maker or proxy, based on a determination that CPR would be medically futile in a particular case. Hospitals may have special procedures, consistent with established policy and state law, on the circumstances under which a DNR order may be suspended during surgery.

Doctor-Patient Communication: Why and How Communication Contributes to the Quality of Medical Care

Description

The patient–physician relationship and its expression through the medical dialogue have been described or alluded to in the history of medicine since the time of the Greeks. Nevertheless, historians of modern medicine have tracked an undeniable decline in the centrality of communication to the care process. In his study of the history of doctors and patients, Shorter (1985) attributes the denigration of communication through the twentieth century to the ascendancy of the molecular and chemistry-oriented sciences as the predominant medical paradigm. This change was fundamental in directing medical inquiry away from the person of the patient to the biochemical makeup and pathophysiology of the patient. It was not coincidental that it was during this period of scientific advance that the practice of interviewing patients from a written outline designed around a series of yes–no hypothesis-testing questions largely replaced unstructured medical histories. Conversation was largely curtailed by these changes; patients were restricted to answering the questions asked and the medical dialogue was recast as a medical interview with the exchange directed by the scientist-physician.

Professional dominance of physicians over patients, and scientific objectivity over the patient

perspective, was noted (and lamented) by influential authors in the medical and social sciences (Freidson, 1970; Szasz & Hollender, 1956), but the issue did not attract the attention of medical educators and policymakers until communication was convincingly linked to patient outcomes. It is in this light that the critical role of technical advances in the 1960s that made audio recording of the medical visit logistically possible may be seen and that the methods that allowed investigation of the relationships between the medical dialogue and outcomes may be appreciated.

The objectives of this essay are threefold: (1) to present evidence establishing the importance of medical visit communication to a variety of valued outcomes, (2) to provide insight into how medical communication is assessed by using a popular coding method, and (3) to briefly consider future directions for improving medical communication in light of current national initiatives in health-care policy and reform.

Why Medical Communication Is Important

Within 20 years of the groundbreaking study by Barbara Korsch and colleagues (1968) documenting pediatric visit communication was described and related to patient satisfaction and adherence with medical recommendations, a convincing body of literature had emerged linking medical communication to patient outcomes. As reflected in a meta-analysis of medical communication and its correlates, covering the period from 1964 to 1988, relationships between specific elements of medical visit communication and patient outcomes were apparent in regard to patient recall of medical information, patient satisfaction, adherence, and patient assessment of technical care quality (Hall, Roter, & Katz, 1988). These relationships, however, varied depending on which aspect of communication was measured. For instance, when the doctor offered more information, asked fewer questions overall, but more questions about compliance in particular, and was more positive and less negative (both verbally and nonverbally), the patient was significantly more adherent. Satisfaction was also found to be higher when the doctor offered more information, actively enlisted patient involvement in care, was more positive (verbally and nonverbally), engaged in more social conversation, and when there was more visit talk overall. Communication predictors of patient recall of information included more information, positive talk and partnership building, but less question asking. Thus, some elements of physician communication like information giving and positive talk were significantly correlated with all outcomes, while elements such as question asking, partnership building, and overall talk were only related to particular outcomes.

Although not as commonly studied as satisfaction and adherence, there is a small but extremely important body of work that has linked doctor-patient communication to other measures of outcome, including indicators of patient health status. Included among these measures are physiologic indicators such as levels of glycosylated hemoglobin (HbA1c) in the blood of diabetic patients and blood pressure in hypertensive patients. In addition, such measures as functional status (the patient's sense of his or her ability to perform usual daily routines) and a patient's overall sense of well-being and emotional coping have been linked to elements of the medical dialogue (Griffin et al., 2004).

Finally, there are a few studies that have explored how physicians are affected by factors associated with the way in which they relate to patients and perform their work. Among these outcomes are physician satisfaction and the likelihood of becoming involved in medical malpractice litigation. An appreciation for these outcomes is underscored by the relatively high levels of physician stress and burnout, particularly in specialties associated with rising malpractice rates, and the medical workforce shortages made worse by increasing numbers of physicians taking early retirement. It should not come as a surprise that many of the predictors of patient satisfaction also affect physician satisfaction as the communication of emotion is highly reciprocal. The positive regard associated with patient satisfaction with care and judgments of good performance, interpersonal rapport, and personal warmth and affection are all likely to inspire physician satisfaction and similar feelings

of liking. The opposite is true as well; critical judgments and perceptions of rejection or disregard also inspire similarly negative emotions. Not only are patient and physician satisfaction and liking related to one another, but when these measures of a positive interpersonal and professional relationship are absent, patient compliance is lowered, therapeutic effect is diminished, and physician risk for malpractice litigation is heightened (see Roter & Hall, 2006 for a review of this literature).

How Communication Is Assessed

A review of the methods used to analyze the medical communication in the 61 studies included in the meta-analysis described earlier found that 28 different coding systems were used (Roter, Hall, & Katz, 1988). Only three systems, Bales' Interaction Process Analysis, the Verbal Response Mode (VRM), and the Roter Interaction Analysis System (RIAS), were used in multiple studies, and these were applied in only a handful of studies (ranging from five to seven studies each). The Bales' system and the VRM taxonomy were originally devised as a general-purpose system for coding speech acts but applied within the medical context, while the RIAS was developed specifically to reflect communication dynamics of the medical dialogue. Many of the systems coded information exchange in some form, while others focused on particular kinds of expression like empathy or concern. A subsequent review of communication assessment instruments, covering the period 1986–1996, identified 44 unique instruments, but only four of these were used in multiple studies (Boon & Stewart, 1998).

While investigators continue to develop and apply new coding approaches, the RIAS has clearly gained prominence in the research literature with more than 250 published studies using the system as of 2011. Studies have been conducted in 23 countries in a variety of medical care contexts and provider types and specialties with translations to Spanish, French, German, Italian, Swedish, Norwegian, Danish, Dutch, Swiss-German, Portuguese, Japanese, Korean, Chinese, Arabic, Hebrew, and Swahili. (See https://riasworks.com for a bibliography of RIAS studies.) Because of its widespread use, a brief description of the RIAS and examples of coding categories will be presented.

Derived loosely from social exchange theories related to interpersonal influence and problem solving, the system takes a perspective of the medical encounter as a "meeting between experts," grounded in an egalitarian model of patient-provider partnership that accounts for the contributions of each speaker (Roter & Hall, 2006). The basic system is comprised of 40 mutually exclusive and exhaustive codes applied to all dialogue statements expressed by each speaker in the encounter. This is usually the patient and physician, but may also include one or more family members or friends accompanying the patient to the visit or multiple providers including consultant or attending physicians, nurses, or technicians. The codes are applied to the smallest unit of expression to which a meaningful code can be assigned, generally a complete thought, simple sentence, phrase, or clause in a compound statement but sometimes a single word. In addition to verbal exchange, RIAS coders globally assess the emotional tone of the visit at the close of a session for each speaker in terms of overall levels of irritation, anxiety, dominance, interest, and friendliness. The global ratings have been found to capture vocal qualities independent of literal verbal content and can thereby be considered as an indicator of nonverbal communication (Hall, Roter, & Rand, 1981).

A useful framework for organizing and grounding RIAS-coded communication in the clinical encounter is the four-function model of medical interviewing that includes data gathering, patient education and counseling, responding to emotions, and partnership and activation. Specific codes and dialogue examples in each of these areas are presented in Table 1.

Future Directions for Improving Medical Communication

The appearance of patient-centered medical care on the national health-care agenda reflects a sea change in the value attributed to communication by policymakers, medical educators, and the

public. The influential Institute of Medicine report on Health Care Quality identified patient-centered care as key to any significant future improvements in health-care quality, alongside core medical care quality requisites of safety, timeliness, effectiveness, efficiency, and equity (Institute of Medicine [IOM], 2001). In a similar vein, patient-centered communication was recognized as a significant vehicle for the prevention of medical errors and malpractice litigation (Kohn, Corrigan & Donaldson, 1999). The scientific evidence reflected in these important reports not only has implication for the routine practice of medicine, but it has also influenced national health policy. The Surgeon General has targeted an increase in the proportion of persons who report that their health-care providers have satisfactory communication skills among the key objectives for the nation (Surgeon General Report, Healthy People 2010, Health Objective 11.6). This goal is integrated into objectives in screening, diagnosis, treatment, prevention, and hospice care applicable to chronic diseases and cancer. Most recently, patient-centered care has been included among the quality benchmarks for Accountable Care Organizations as part of the Patient Protection and Affordable Care Act, Public Law 111–148 (Levinson, Lesser, & Epstein, 2010).

Responding to these same pressures, the American Association of Medical Colleges (AAMC) and the Accreditation Council for Graduate Medical Education (ACGME) have required documentation of communication skills training as part of the accreditation criteria for undergraduate and graduate level medical training programs. Consequently, virtually all US medical schools now require that some portion of their curriculum be dedicated to this area. Despite this progress, medical education challenges remain as the intensity and format vary widely and training is often concentrated in the first 2 years of training before medical students begin to see patients (Levinson et al., 2010). Requirements for medical certification have also been expanded to include demonstration of proficiency in communication skills as part of the United States Medical Licensing Exam (USMLE). The clinical skills portion of the exam assesses candidates' performance using standardized patients (actors trained to portray patients) presenting cases that a physician is likely to encounter in clinics, doctors' offices, emergency departments, and hospital settings (http://www.usmle.org/index.html). Furthermore, recent changes by the American Board of Medical Specialties (ABMS) now require communication skills for recertification every 5 years (Levinson et al.).

This essay began by suggesting that medicine had lost its focus on the person of the patient in embracing the scientific advances of the twentieth century, but there is reason for optimism in anticipating that the scientific, educational, and policy advances of the twenty-first century will return the patient to the center of care. Recognition of communication's centrality to the heart and art of medicine as well as its science is well

reflected in the words of an early advocate of biopsychosocial medicine, George Engel, "It is not just that science is a human activity, it is also that the interpersonal engagement required in the clinical realm rests on complementary and basic human needs, especially the need to know and understand and the need to feel known and understood" (Engel, 1988, p. 136).

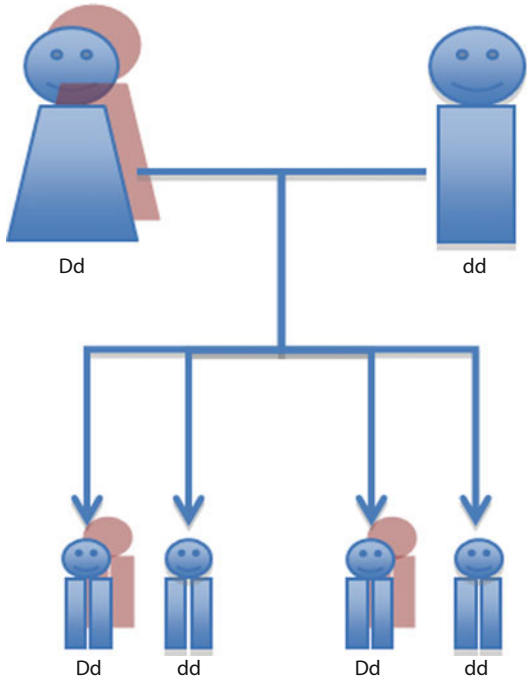
Definition

A trait with dominant inheritance is expressed in the presence of the dominant allele, both in individuals who are homozygous for the locus of interest (DD, the same alleles) and in those who are heterozygous (Dd, differing alleles).

Humans have two versions of all autosomal genes, called alleles, one from each parent.



Dominant Inheritance, Fig. 1 Dominant inheritance diagram. Highlighted individuals are affected by the disease given by the dominant D allele

Dominant inheritance refers to the situation when an allele of a gene is expressed (dominant allele) over the alternate gene allele, which is masked (recessive allele). An example of a disease with dominant inheritance is Huntington's disease, where affected individuals carry at least one defective allele, leading to production of the defective protein and resulting in disease (Walker, 2007). To illustrate, the children of an affected heterozygous parent have a 50% chance of inheriting the disease allele and of being affected (see pedigree, Fig. 1). Children of a homozygous affected parent have a 100% chance of inheriting the allele and developing disease.

Dopamine

Michela (Micky) Marinelli
Department of Cellular and Molecular Pharmacology, Rosalind Franklin University of Medicine and Science, North Chicago, IL, USA

Definition

Dopamine is a catecholamine neurotransmitter produced in dopamine neurons of the brain.

Description

Dopamine is a catecholamine produced in dopamine neurons of the brain.

Anatomy

Approximately, 75% of all of the dopamine cells of the brain originate in the midbrain. From the midbrain, three main pathways project to mesocorticolimbic structures, where dopamine acts as a neurotransmitter (for review, see Zahm, 2006).

The mesocorticolimbic or A10 pathway: Dopamine neurons originate from the *ventral tegmental area* and project primarily to the ventral striatum, amygdala, hippocampus, and frontal cortex.

The nigrostriatal, *mesostriatal*, *or A9 pathway*: Dopamine neurons originate from the *substantia nigra pars compacta* and project primarily to the dorsal striatum.

The retrorubral or A8 pathway: Dopamine neurons originate from the *retrorubral field* project primarily to the dorsal and ventral striatum, hippocampus, and parts of the extended amygdala.

Another dopaminergic pathway originates from the *hypothalamus* and projects to the anterior lobe of the pituitary (*tuberoinfundibular pathway or A12 and A14 pathways*), where dopamine acts as a neurohormone.

Transmission

Dopamine is stored in synaptic vesicles and is released upon neuronal depolarization. Once released, it acts on dopamine receptors. Dopamine receptors are metabotropic (G-protein-coupled) receptors. They are divided in two classes: D1-like (D1, D5 receptors) and D2-like (D2, D3, and D4), which respectively stimulate or inhibit adenylyl cyclase and consequent formation of cAMP. Most released dopamine is cleared from the synapse by reuptake into the dopamine neurons, via dopamine transporters.

Function

While dopamine released from the tuberoinfundibular pathway inhibits prolactin release, dopamine released in mesocorticolimbic and motor structures serves to modulate movement, emotions, and reward.

In particular, the mesostriatal pathway is mostly involved in movement control: This is most notable in the neurodegeneration of dopamine neurons of this pathway, which is associated with ▶ Parkinson's disease.

Dopamine from the mesocorticolimbic and mesostriatal pathways plays an important role in reward. In particular, the activity of dopamine cells increases in response to unexpected rewarding events, or the cues that predict them (Schultz, 2002).

Dopamine is also one of the major players mediating the rewarding effects in ▶ drug abuse and drug dependence (Marinelli, Rudick, Hu, & White, 2006; Volkow, Fowler, Wang, & Goldstein, 2002). Addictive drugs have the common action of increasing dopamine levels in the striatal complex (Di Chiara & Imperato, 1988; Imperato et al., 1992). This effect is mediated by different mechanisms, such as blocking the reuptake of dopamine at the level of the dopamine transporter, reversing the transporter from reuptake to release, or increasing the activity of dopamine neurons. In addition, animal studies show that subjects with heightened dopaminergic transmission are more prone to self-administer drugs of abuse compared with subjects expressing reduced dopaminergic transmission. Furthermore, treatments that decrease dopaminergic transmission generally produce a decrease in drug responding and relapse, whereas treatments that increase it have opposite effects (Marinelli et al., 2006). Similarly, human studies show a positive correlation between dopamine levels and behavioral responses to psychostimulant drugs (Leyton et al., 2002; Oswald et al., 2005). While this suggests that *increased* dopaminergic tone is a facilitator of drug abuse, there is also evidence for *decreased* dopaminergic tone to play a role (Melis et al., 2005). Thus, withdrawal from long-term use of addictive drugs can lead to a hypo-dopaminergic state that could promote the search for drug, to counteract the decrease in dopaminergic tone. These views are not incompatible; thus, it has been proposed that drug craving and relapse in the could result from two separate phenomena: "chronic craving," which is an attempt to alleviate a state of hypo-dopaminergia and "instant craving," which is instead caused by a temporary increase in dopaminergic tone that triggers relapse (Childress & O'Brien, 2000; Franken et al., 2005; Pilla et al., 1999).

Antipsychotic drugs that block dopaminergic transmission are effective in treating some aspects of schizophrenia (mostly delusions and hallucinations), suggesting that hyperdopaminergia may underlie these conditions; however, the matter is controversial because it is still unclear if patients with schizophrenia have impaired dopaminergic transmission (Howes & Kapur, 2009; Moncrieff, 2009; van Os & Kapur, 2009).

Dose: Intensity, Response

Nicole Brandt
School of Pharmacy, University of Maryland, Baltimore, MD, USA

Definition

The underlying mechanism of dose intensity and response deals with drug-receptor interactions. Drugs can bind to a receptor and enhance the effect of that receptor (agonist), inhibit the effect of that receptor (antagonist), or enhance the effect of that receptor at less than the maximum response (partial agonist). Clinically, the goal of a drug dose, or dose regimen, is to provide a patient with maximal benefit and minimal

toxicity. To accomplish this, one must know about a drug dose's pharmacological potency and maximal efficacy. Potency is defined as the dose of drug required to produce 50% of the drug's maximal effect. The more potent a drug is, the lower the dose needed to produce a desired clinical response. Drug potency depends on the affinity of receptors to bind the drug and how effectively the drug-receptor interaction leads to a clinical response. Drug potency is the main factor considered when deciding a dose to administer.

A dose's response relates to how effective a drug is at a particular dose in relation to clinical response. How effective a dose is and what type of response it can have in a patient varies based on the route of administration, the absorption, the distribution in the body, and the clearance from the blood or site of action. When deciding on a drug and dose, not only does the dose's efficacy response have to be taken into account, but the dose's toxic response also has to be considered. Each drug has a therapeutic window and the goal is to give a dose of drug that is above the bottom line of that window (clinical efficacy) but not over the top line of that window (clinical toxicity). In short, the overall aim is to give the smallest dose possible that has the greatest efficacy and least toxicity.

In addition to the characteristics of the drug (pharmacokinetics), the intensity and response are also based on the characteristics of the patient. The intensity of effect of a drug dose can be increased or decreased if the patient is hyperreactive or hyporeactive (compared to the majority of patients) to the drug. How reactive a patient is to a drug depends on multiple factors such as genetics, age, gender, body size, comorbidities, and concomitant medications (i.e., drug-drug interactions). There is also the issue of tolerance that may develop with some medication classes (e.g., narcotics). Basically, continued administration leads to decreased dose intensity, and when this happens, the patient is said to have built up a tolerance to the drug at that specific dose. All of these variables need to be taken into consideration when deciding on a drug dosing regimen.

Double-Blind Study

J. Rick Turner
Cardiovascular Safety, Quintiles, Durham, NC, USA

Definition

A double-blind research study is one in which neither the subject nor the researcher knows which treatment a subject is receiving.

Employing the double-blind methodology is a hallmark of pharmaceutical clinical trials. In some trials, an investigational drug is compared with a placebo. Both drug products must therefore look, smell, and taste the same so that subjects cannot deduce from one of these characteristics which treatment they are receiving. These drug products must also be manufactured, and similarly shipped to the sites running the trials, in a manner that does not allow the physician investigators to know which treatment subjects are being administered. The same applies for a trial in which two active drugs are being compared. While the double-blind process takes considerable work, it is certainly possible to implement it successfully.

This methodology can be much more difficult to implement in studies of behavioral medicine interventions.

Drug, Adverse Effects/Complications

Adverse drug events; Adverse drug reactions

Definition

Adverse drug events (ADE) are noxious events that occur during the use of a medication, but there is not always a causal link (ICH, 1994). An ADE can be a direct injury from the medication, like an adverse drug effect such as a fall. It can also be some form of harm due to the way in which the medication is used, such as discontinuing the medication abruptly, causing an adverse drug withdrawal event such as confusion or increased blood pressure (VA, 2006).

Adverse drug reactions (ADR) are "unintended, harmful responses to a usual dose of a medication during normal administration, with a direct causal relationship" (Nebeker, et al., 2004). Adverse effects or reactions differ from side effects in that medication side effects can be beneficial or harmful, while adverse drug effects are always adverse or negative. Allergic reactions are a type of adverse effect that is elicited by the immune system, for example, hives or shortness of breath. It is important to monitor for and document drug adverse effects in order to provide the best possible care and to prevent subsequent harm (VA, 2006).

Biographical Information

Jacqueline Dunbar-Jacob was born in Detroit, Michigan. She received her BSN degree from Florida State University, earned her MS degree in Psychiatric Nursing from University of California, San Francisco, and earned her Ph.D. degree in Counseling Psychology from Stanford University. In 1984, Dunbar-Jacob joined the faculty at the University of Pittsburgh, Pittsburgh, PA, as assistant professor and director of Nursing at Western Psychiatric Institute and Clinic and later rose through the ranks in the School of Nursing to become professor in 1993. She subsequently received secondary appointments as professor of Psychology, Epidemiology, and Occupational Therapy. Since 2001, she has served as the dean at the University of Pittsburgh School of Nursing. She has been internationally recognized for her study of patient adherence to treatments across a variety of patient populations including rheumatologic conditions, cardiovascular disease, and diabetes.

Major Accomplishments

Dunbar-Jacob's research has been supported by the National Science Foundation and several institutes within the National Institutes of Health (NIH) including the National Institute of Nursing Research; National Heart, Lung, and Blood Institute; and National Institute of Diabetes and Digestive and Kidney Diseases.

Dunbar-Jacob is director of a P01 program project grant from the NIH on translating interventions related to patient adherence and quality of life. She has served as the director of the NIH-funded Center for Research in Chronic Disorders at the University of Pittsburgh. She has served on three NIH safety and data monitoring boards, as a behavioral scientist for three NIH-funded multicenter clinical trials, and on 20 NIH working groups addressing research agendas. She served on the NIH Prevention of Alzheimer's Disease Consensus Panel and is currently a member of the technical expert panel for the AHRQ comparative effectiveness project on

adherence interventions. Her work has been recognized with the PA Nightingale Award for research, the Pathfinders Award for research by the Friends of the NINR, and her induction into the Sigma Theta Tau International Inaugural Nurse Researcher Hall of Fame.

Her current leadership roles include president of Friends of the National Institute of Nursing Research, chair of the Advisory Board for the Institute for Health Care Communication, and cochair of the Pennsylvania Center for Health Careers Supply-Demand Committee. Dunbar-Jacob has also served as the chair of the AACN Task Force on the Future of the Research Focused Doctorate and chair of the Scientific Advisory Board for NIH Roadmap Initiatives for the Patient Reported Outcomes Measurement Information System (PROMIS). Recently, she was a fellow in the Robert Woods Johnson Executive Nurse Fellows Program and a member of the National Institute of Nursing Research Advisory Council. She is also past president of the Academy of Behavioral Medicine Research and past president of the Society for Behavioral Medicine.

Dyslipidemia

Ronald Goldberg
Diabetes Research Institute, University of Miami Miller School of Medicine, Miami, FL, USA

Synonyms

High cholesterol; Hypercholesterolemia; Hypertriglyceridemia

Definition

The term dyslipidemia refers to an abnormality of circulating lipoproteins, which are the protein-lipid complexes that transport the major blood lipids, cholesterol, and triglyceride through the circulation. The standard test for circulating lipids and lipoproteins consists of the measurement of the total serum cholesterol, its low-density (LDL-C) and high-density lipoprotein cholesterol (HDL-C) subfractions, and the fasting triglyceride level. Dyslipidemia is then defined as a higher than acceptable total cholesterol, LDL-C or triglyceride level, or a low HDL-C value, or various combinations of these. The clinical importance of these abnormalities relates to the association of elevated cholesterol, LDL-C, and in many instances of hypertriglyceridemia with an increased risk of cardiovascular disease (CVD). Conversely, HDL-C is inversely associated with the risk of CVD. Although not readily measured with standard testing, there are other circulating atherogenic lipoproteins, such as intermediate density lipoprotein and lipoprotein (a), that are believed to increase risk for CVD. Very high triglyceride values (>1,000 mg/dl) are also associated with an increased risk of pancreatitis.

Etiology

The etiology of dyslipidemia is complex. Primary forms of dyslipidemia may be due to monogenic or as yet mostly poorly defined polygenic abnormalities of lipoprotein metabolism. Clinically, these manifest as predominant (and sometimes severe) hypertriglyceridemia, moderate to severe elevations in LDL-C, or combinations of these two abnormalities. Hypertriglyceridemia is commonly associated with low HDL-C levels as well as smaller than normal LDL particles which may have increased atherogenicity. In addition, isolated HDL deficiencies may primarily be due to genetic disturbances of HDL metabolism. More commonly, dyslipidemia is due to effects of secondary factors acting on the particular genetic substrate of the individual to produce a range of lipid abnormalities. Common secondary causes of hypertriglyceridemia, small LDL particles, and low HDL-C include abdominal obesity, insulin resistance, and type 2 diabetes, while the most common reason for an elevated LDL-C is the high fat diet that is typical of Western societies.

Clinical Evaluation and Intervention

The clinical evaluation of dyslipidemia has been guided by the recommendations of the National Cholesterol Education Program (NCEP) which published its initial Adult Treatment Panel (ATP I) recommendations in 1987 for diagnosis and treatment of lipid disorders, and these were revised in 1994 (ATP II) and 2001 (ATP III) with an update in 2004. ATP IV will be published in due course. The current guidelines recommend that attention to LDL-C should be the first

priority because of its close association with CVD event rates, except in patients with severe hypertriglyceridemia (>500 mg/dl), where urgent triglyceride lowering to prevent pancreatitis should be the initial treatment.

The question of what constitutes an LDL-C level requiring treatment has undergone considerable evolution as clinical trial data showing benefit from statin drugs in different population subgroups have been reported. In essence, the population is divided into low-risk, moderate-risk, and high-risk subgroups. Cut points for dietary intervention or pharmacologic intervention have been defined for each group according to severity of CVD risk and in 30 mg/dl increments of LDL-C; however, because these cut points and the targets of treatment are somewhat arbitrarily defined and are also a subject of debate, these values are given as a range. Thus, for low-risk subjects (with no more than one major CVD risk factor), the cut point for therapeutic lifestyle changes, focusing largely on lowering cholesterol, and saturated fat intake is recommended at 130–160 mg/dl, while drug therapy is recommended at 160–190 mg/dl, aiming for an LDL-C of 130–160 mg/dl – the average for the general population.

For those with at least two major risk factors, but without diabetes or evident CVD, the cut points for pharmacologic and lifestyle change are 130–160 and 100–130 mg/dl respectively, and the goal is <100–130 mg/dl (an LDL-C of ≤100 mg/dl is considered optimal for the general population). For highest-risk subjects, a single cut point for combined lifestyle and drug therapy is set at 70–100 mg/dl, with a target of ≤70 mg/dl. Statin drugs are the first choice, with add-on agents such as ezetimibe and bile sequestrants available in the event that statin therapy is inadequate or not tolerable. Because LDL-C reflects only the cholesterol content of LDL and may not adequately reflect the full range and impact of atherogenic lipoproteins before and on treatment, the use of alternative or secondary measures such as non-HDL-C (calculated by total cholesterol minus HDL-C) or apolipoprotein B (the protein component of all atherogenic lipoproteins) has been proposed.

Elevation in triglyceride levels is less directly related to CVD risk, and it is likely that there is considerable heterogeneity in this relationship across the population. Subjects with triglyceride values >150 mg/dl are said to have borderline hypertriglyceridemia, and those with values >200 mg/dl have hypertriglyceridemia which should be considered for treatment. In this population, non-HDL-C or apolipoprotein B measurements may have special advantages because hypertriglyceridemia alters the LDL-C value. The initial approach is therapeutic lifestyle change in which overweight is an important target. Medications such as fibrate drugs, high doses of omega 3 fatty acids, or niacin may be added if lifestyle therapy is considered inadequate, although evidence for CVD benefit with these medications is weaker than that for statin drugs.

Lastly, low HDL-C, defined as <40 mg/dl in men and <50 mg/dl in women, is considered to be an independent CVD risk factor. Weight reduction and increased physical activity may modestly raise HDL-C and are prudent approaches to management of low HDL-C. However, drug therapy with HDL-raising drugs such as fibrates or niacin remains a challenge because of the lack of a full understanding of the relationship between HDL and CVD, side effects of medications, and the paucity of data that this approach clearly adds to the benefit of statin therapy. Considerable efforts are being made to improve our understanding and the management of dyslipidemia.

Dyspnea

Valerie Sabol
School of Nursing, Duke University, Durham, NC, USA

Definition

Dyspnea, or shortness of breath, is a frequently reported symptom of unpleasant and/or uncomfortable respiratory sensations with many potential underlying etiologies (e.g., pulmonary disease, primary manifestation of cardiac disease, neuromuscular disease, obesity, anxiety). The American Thoracic Society (1999) defines dyspnea as a "subjective experience of breathing discomfort that is comprised of qualitatively distinct sensations that vary in intensity; the experience derives from interactions among multiple physiological, psychological, social, and environmental factors, and may induce secondary physiological and behavioral responses." Although older adults with chronic pulmonary and/or cardiac disease may have a blunted response to dyspnea, perhaps as a result of adaptation over time, it is still an important clinical history finding (e.g., acute exacerbation of a chronic disease process).

There are variations in the clinical reporting of dyspnea; words used by individuals to describe their breathing discomfort may provide insight into the underlying pathophysiology of their disease. For example, words used to describe difficulty inspiring is associated with upper airway obstruction (e.g., aspiration), and words used to describe difficulty with expiratory flow is associated with obstruction of the smaller bronchioles (e.g., asthma). The inability to breathe while in a recombinant position is known as orthopnea, and complaints of sudden onset of coughing or difficult breathing after sleeping in a recombinant position (typically after 1–2 h) is known as paroxysmal nocturnal dyspnea (PND), and is typically associated with heart failure. Dyspnea on exertion (DOE) is common in obstructive and restrictive pulmonary diseases. Dyspnea that is described as painful may have an underlying inflammatory or trauma-related etiology. Signs of air hunger include mouth breathing, use of accessory muscles, and/or inability to finish a sentence without pausing to breathe. Some individuals, however, are able to adjust their physical activities to limit or prevent dyspnea and more objective testing may be warranted.

Depending on the most likely underlying etiology, there are several diagnostic studies that could be used to evaluate dyspnea. For example, exercise testing (e.g., 6-min walk test), spirometry, and other pulmonary function tests (PFTs), pulse oximetry, arterial blood gas sampling, blood chemistries (e.g., b-type natriuretic peptide, anemia, renal function), and chest radiography may provide information to aid in a differential diagnosis and help target treatment strategies. Treatment strategies include self-help strategies (e.g., accurate self-assessment and regulation of breathing), smoking cessation, avoidance of infection, and environmental stressors (e.g., weather extremes, poor air quality, pollutants), pulmonary rehabilitation, and chronic disease management.

Chronic depression; Chronic depressive disorder; Dysthymic disorder

Definition

Dysthymia is a form of chronic depression, characterized by persistent ("most of the days, for more days than not") depressed mood lasting for at least 2 years. It is a diagnostic category within the mood disorders in the current versions of the Diagnostic and Statistical Manual of Mental Disorders (DSM-IV) and the International Classification of Diseases (ICD-10). In addition to a depressed mood, two or more of the following symptoms must have been present most of the time (i.e., the person must not have been symptom-free for more than 2 months at a time):

1. Poor appetite or overeating
2. Insomnia or hypersomnia
3. Low energy or fatigue
4. Low self-esteem
5. Poor concentration or difficulty making decisions
6. Feelings of hopelessness

In children and adolescents, a dysthymia diagnosis requires at least 1 year of depressed or irritable mood, and two of the above symptoms. Exclusion criteria are manic, hypomanic or mixed episodes, presence of a major depressive episode during the first 2 years, and psychosis.

Description

Dysthymia is a mood disorder of low symptom intensity. Nevertheless, it is associated with markedly decreased quality of life, and functional impairments are significant. While generally able to cope with everyday life, affected persons struggle with workplace or school demands, social and intimate relationships. Lack of energy, feelings of worthlessness, general negativity and pessimism are common and foster the stigma of "character weakness" and interfere with help-seeking.

The comorbidity with other mental as well as physical disorders is high. Because of under-recognition and under-treatment, persons with dysthymia are high-users of the health-care system, which results in substantial direct (health-care consumption) and indirect (absenteeism, loss of productivity) costs.

Persons with dysthymia have an increased lifetime risk of developing a major depressive episode. When dysthymia worsens into a major depressive episode, this is termed "double depression." Clinically, this form of depression is distinct from others as it is marked by extreme hopelessness and a poor prognosis.

Epidemiology and Risk Factors

Reports of the lifetime prevalence of dysthymia range from 0.1% to 6%, with higher rates in higher income countries and among females.

Persons with comorbid chronic medical disorders, anxiety disorders, a history of substance abuse, and personality disorders are at increased risk for dysthymia and other forms of chronic depression. A special risk group comprises persons who experience depressive symptoms early in life (before the age of 21).

Treatment

The most effective treatment for dysthymia consists of a combination of antidepressant medication and psychotherapy. Randomized controlled trials have shown that both the treatment duration and the intensity need to be higher for dysthymia than for major depressive episodes in order to achieve similar response rates. This is possibly due to the high rates of comorbidities as well as the chronic nature of dysthymia, which often results in yearlong struggles with everyday social and occupational life, which are not easily overturned (Dunner, 2001). Many factors influence the choice of treatment: comorbid illnesses, previous experience with similar medication or psychotherapies, interactions with other medications, side-effect profile, short- and long-term effects, and, most importantly, patient tolerability and individual preferences for type of treatment. Several guidelines and treatment algorithms are available to guide the initial treatment choices as well as the dosage augmentation or switches in therapy when symptom improvement is insufficient.

Since residual or subthreshold depressive symptoms carry a strong risk of depressive symptom relapse, the treatment goal is complete remission from all symptoms.

Importantly, any treatment should be followed by a maintenance phase, which can last as long as a patient's lifetime, in order to prevent the recurrence of depressive symptoms. Maintenance therapy can involve the long-term treatment with efficacious antidepressant medication, regular professional depression symptom monitoring, and patient education about medication side effects, the importance of medication adherence, and the connection between psychosocial stressors and symptom recurrence.

Eating Behavior

Definition

Eating behavior is a broad term that encompasses food choice and motives, feeding practices, dieting, and eating-related problems such as obesity, eating disorders, and feeding disorders. Within the context of behavioral medicine, eating behavior research focuses on the etiology, prevention, and treatment of obesity and eating disorders, as well as the promotion of healthy eating patterns that help manage and prevent medical conditions such as diabetes, hypertension, and certain cancers.

Description

Eating behavior is complex; humans make hundreds of food decisions each day that are influenced by a variety of personal, social, cultural, environmental, and economic factors. What people eat and how much they eat has a considerable influence on their health. An ecological model that considers the impact of individual factors, social environments, physical environments, and macro-level environments on food choices is useful in understanding the multitude of determinants of eating behavior. Intraindividual factors influencing eating behavior and food choice include physiological processes (e.g., hunger, satiety, innate preference for sweet foods, brain mechanisms) and psychological processes (e.g., learned food preferences, knowledge, motivations, attitudes, values, personality traits, cognitive processes, self-regulation). The social environment has also been shown to have a substantial effect on eating behavior. Eating behavior is shaped indirectly through observing others and internalization of food rules, as well as directly (i.e., one eats more in the presence of others than when alone). The physical environment, including availability of foods, the context in which foods are provided, and the external cues, such as proximity to food, salience of food, packaging, plate/serving size, and variety of food assortments, have all been shown to affect the type and amount of food eaten. Finally, macro-level environments, including economic systems, food and agricultural policies, food production and distribution, food marketing, and cultural norms and values, may have a more indirect yet powerful impact on food choices and eating behavior. The research on determinants of eating behavior has largely emphasized intraindividual variables, whereas there is considerably less known about the environmental influences and the interaction

between these. In particular, there is a need to conduct multilevel research, among diverse subgroups, using better measures, in order to better understand the mechanisms involved in eating behavior (Larson & Story, 2009).

Eating Disorders: Anorexia and Bulimia Nervosa

Anna Maria Patino-Fernandez
Department of Pediatrics, University of Miami, Miami, FL, USA

Definition

Prevalence

Anorexia nervosa afflicts an estimated 0.9% of females, with 0.5% of men reporting having anorexia at some time in their lives (Hudson, Hiripi, Pope, & Kessler, 2007). Bulimia nervosa is estimated to occur in 1.5% of females and in 0.5% of men (Hudson et al., 2007). Approximately 3.5% of women and 2% of men reported having binge-eating disorder (BED) at some point in their lives (Hudson et al., 2007). BED affects about 8% of people who are obese. Eating disorders typically (86%) are reported by the age of 20, with the majority of those affected (43%) with anorexia reporting onset between the ages of 16 and 20. Thirty percent of those afflicted report duration from 1 to 5 years, and 31% report duration from 6 to 10 years. The full recovery rate of women with bulimia has been reported to be significantly higher than that of women with anorexia, with 74% of those with bulimia achieving full recovery, whereas only 33% of those with anorexia achieved full recovery (Herzog et al., 2009). Approximately one third of both women with anorexia and with bulimia relapse after full recovery (Herzog et al., 2009).

Adolescent and young women account for 90% of cases (women between the ages of 12 and 25) of eating disorders (American Psychiatric Association [APA], 2000). In anorexia, there is a female to male ratio of about 11 to 1. Bulimia has a female to male ratio of about 30 to 1. Anorexia nervosa may arise in children as young as 8 years of age, whereas bulimia rarely appears before the age of 12. Increasing numbers of older women and men have these disorders with up to 5–10% of all cases of eating disorders occurring in males (Academy of Pediatrics Committee on Adolescence [AAP], 2003). Teen boys have shown an increasing trend in dieting, use of diet products, and their use of exercise for weight control, with Hispanic boys being the most likely to practice weight control, followed by black and then white boys. Binge-eating disorder is more prevalent than both anorexia nervosa and bulimia nervosa, but the treatment outcome for individuals with BED is also more favorable (Fairburn, Cooper, Doll, Norman, & O'Connor, 2000).

There is relatively little data on the role of ethnicity or racial background in eating disorders. Some data show that ethnic minority women who

seek treatment for anorexia have lower admission weights than white women, suggesting that anorexia may go undetected or untreated longer in minority women. Typically a disorder of white affluent women, disordered eating appears to be increasing among nonwhite groups, including Hispanics and American Indians (Croll, Neumark-Sztainer, Story, & Ireland, 2002).

Etiology

There is no one single cause but rather a complex interaction between biological issues, such as genetics and metabolism; psychological issues, such as control; coping skills; personality factors; family issues; and social issues, such as a culture that promotes thinness and media that transmits this message.

Comorbidities

People with eating disorders suffer higher rates of other mental disorders including depression, anxiety, obsessive-compulsive disorder, and substance abuse (Hudson et al., 2007). There is an increased frequency of mood disorders in individuals with anorexia and bulimia nervosa, which may develop at the same time, or the mood disorder may precede the eating disorder (APA, 2000). Obsessive-compulsive features are prominent in individuals with anorexia nervosa, whereas increased frequency of more general anxiety symptoms is more common in those with bulimia (APA, 2000).

Ecological Fallacy

Jane Monaco
Department of Biostatistics, The University of North Carolina at Chapel Hill, Chapel Hill, NC, USA

Synonyms

Ecologic bias

Definition

Ecological fallacy is improperly inferring an association (or lack of association) at an individual-level based on a group-level relationship.

Ecologic studies use measures taken at the level of a group (such as a country, school, or hospital) rather than at the individual (such as patient) level. Ecologic studies are widespread in behavioral medicine literature due their low cost and convenience since ecologic data can often be obtained through census records or existing surveys and records. Two typical behavioral medicine ecologic examples are a study investigating the association between alcohol availability and violence (Gorman, Zhu, & Horel, 2005) in which data were collected at the census tract level and a study investigating the association between needle exchange programs and HIV seroprevalence among injecting drug users (Hurley, Jolley, Kaldor, 1997) in which data were collected at the city level.

When risk factors and outcomes are measured at an aggregate level, the relationship between the group-level variables may be different than the relationship between variables measured at the individual level. An often-cited example used to illustrate the issue involved a nineteenth century study which found higher suicide rates within Prussian provinces that had higher proportions of Protestant residents (Durkheim, 1951). The conclusion that Protestant individuals (rather than Catholic individuals) were more likely to commit suicide cannot be inferred based on the observed association among the provinces (Morgenstern, 1982; Robinson, 2009). One possible scenario is that Catholic residents within the largely Protestant provinces had the high suicide rates, resulting in a positive association between percent Protestant and suicide rate. Extrapolation of aggregate results to individuals is a mistake in logic which can lead to a potentially misleading conclusion.

Because of the many limitations of ecologic studies, including ecological fallacy, they are often used as exploratory or hypothesis-generating studies rather than as confirmatory.

Definition

Ecological models are a series of models/frameworks that emphasize multiple levels of influences on behaviors. These influences usually include intrapersonal, interpersonal, organizational, community, physical environment, and policy (Sallis, Owen, & Fisher, 2008). Numerous ecological models have been created to explain specific behavior or to guide behavioral interventions. Although different ecological models may involve different terminology, they share two basic principles: (1) multiple levels of influence on behaviors and (2) interactions across levels of influence. In the context of behavioral change interventions, two additional principles apply as follows: (1) effectiveness of multilevel interventions and (2) emphasis on behavior-specific ecological model (Sallis et al., 2008).

Description

History of Ecological Models

The evolution of ecological models highlights a process of proliferation, diversification, and specification. At the early stage, the conceptual basis of ecological models was the general idea that the environment influenced behaviors. Skinner conceptualized most behaviors as a product of interactions between individuals and the environment (i.e., "operant behaviors") (Skinner, 1953). Barker was a founder of environmental psychology (a.k.a. "ecological psychology") and emphasized "behavior settings," where behaviors take place (Barker, 1968). Later on, Bronfenbrenner developed Ecological Systems Theory and defined the "microsystem," "mesosystem," and "macrosystem" as different levels of environmental influences (Bronfenbrenner, 1979). The more recent models were created specifically for health behaviors. McLeroy at al.'s Ecological Model of Health Behavior emphasized five sources of influences on health behaviors, including intrapersonal, interpersonal, institutional, community, and policy factors (McLeroy, Bibeau, Steckler, & Glanz, 1988). Stokols' Social Ecological Model for Health Promotion offered theoretical guidance for behavioral interventions (Stokols, Allen, & Bellingham, 1996; Stokols, Grzywacz, McMahan, & Phillips, 2003). Hovell et al.'s Behavioral Ecological Model (Hovell, Wahlgren, & Adams, 2009; Hovell, Wahlgren, & Gehrman, 2002) incorporated Skinner's Operant Learning Theory (Skinner, 1969) and emphasized multiple contingencies of reinforcement for behavior. Some models were created for a specific health behavior, such as Glanz and colleagues' Model of Community Food Environments (Glanz, Sallis, Saelens, & Frank, 2005), Sallis and colleagues' Ecological Model of Four Domains of Active Living (Sallis et al., 2006), and Fisher and colleagues' Resources and Skills for Self-Management Model (Fisher et al., 2005).

Ecological Models and Physical Activity

The development of ecological models parallels the conceptual evolution of the field of physical activity. Decades ago, "exercise" (i.e., planned physical activity for fitness purpose) was the main focus of physical activity research and most behavioral interventions applied cognition-based theories and targeted individual-level correlates (Sallis et al., 2006). The limitations of these interventions included small number of target individuals who benefited from interventions, small-to-moderate effect sizes

(Dishman & Buckworth, 1996; Dishman, Oldenburg, O'Neal, & Shephard, 1998), and lack of maintenance of behavioral change (Marcus et al., 2000).

More recently, the concept of "active living" emerged to expand previous understanding of physical activity by emphasizing different domains of physical activity, including occupational, leisure-time, household activities, and active transportation (Pratt, Macera, Sallis, O'Donnell, & Frank, 2004). Disciplines outside public health, such as urban planning, transportation, and leisure science, became involved in physical activity research because the multiple levels of influence and domains of activity highlighted needs for expanded expertise. As a result of multidisciplinary collaboration, ecological models have been widely accepted and applied in the field of physical activity.

Sallis et al. (2006) summarized empirical findings and conceptual associations from multidisciplinary research and developed Ecological Model of Four Domains of Active Living (Sallis et al.). In this model, factors influencing physical activity are multilevel and domain specific (Sallis, Adams, & Ding, 2011). Based on the model, physical activity is influenced by intrapersonal factors (e.g., demographic and psychosocial variables), interpersonal factors (e.g., social support and social modeling), perceived environment (e.g., safety, convenience, aesthetics), behavioral settings (e.g., home equipment, walking and biking facilities, parks), and policy environment that directly influences the built environment (e.g., zoning codes, park policies, transportation policies) (Sallis et al., 2006). Most environmental influence is domain specific, for example, bike lanes provide settings for bicycling (especially for transportation purpose), while parks provide settings for leisure-time physical activity. Similarly, transportation policies and parking regulations are more likely to influence transportation physical activity, while policies regarding parks and recreation facilities are more likely to influence leisure-time physical activity (Sallis & Glanz, 2009; Sallis et al., 2011).

Strengths and Limitations of Ecological Models in Physical Activity Research

A major strength of ecological models is the comprehensiveness. Unlike most cognition-based models that include mostly psychosocial variables, ecological models place an individual's behavior in a larger context and take into account multiple levels of influence external and internal to the individual. This approach offers a wide range of opportunities for interventions. Furthermore, ecological models emphasize the effects of the built environment and policies on physical activity and prioritize environment and policy changes to promote active life-styles. Once these changes have been implemented, they are likely to affect a large population and promote sustainable behavioral change.

Current ecological models have weaknesses. First, most models lack specificity and do not include behavior-specific or setting-specific factors; therefore, they cannot provide clear research hypotheses or intervention strategies (Sallis et al., 2008). Second, ecological models do not provide information about mechanisms of how specific factors affect behaviors and how different influences interact across levels. Third, although multilevel interventions have been recommended as an effective approach for producing behavioral change, such interventions are extremely difficult to implement and evaluate. Because it is not feasible to randomly assign individuals to neighborhoods, randomized controlled trials cannot normally be conducted to determine the effectiveness of a specific environment or policy intervention (Sallis & Glanz, 2009).

Ecological Momentary Assessment

C. Renn Upchurch Sweeney
VA Salt Lake City Healthcare System,
Salt Lake City, UT, USA

Definition

Ecological momentary assessment (EMA) refers to a collection of methods often used in behavioral medicine research by which a research participant repeatedly reports on symptoms, affect, behavior, and cognitions close in time to experience and in the participants' natural environment (Stone Shiffman, 1994). Technologies such as written diaries, electronic diaries, telephones, and physiological sensors are often utilized in EMA studies. EMA studies can be utilized to study a variety of topics such as depression, social support, relationships, diet, work activity and satisfaction, psychotherapy, drug use, allergies, psychological stress, medications, self-esteem, and asthma.

Description

EMA is not a single research method. Instead it encompasses a range of methods that differ in their particular design, assessment schedule, content, and technology. However, all EMA studies have four aspects in common. They all assess research subjects in their natural environments,

in their current or recent states, at selected times, and repeatedly over time (Shiffman, Stone, Hufford, 2008). First, in all EMA approaches, data are collected in real-world environments as subjects go about their normal lives. EMA recognizes that many behaviors and experiences are affected by the context in which they are studied. For an assessed experience or behavior to be representative, it has to be sampled in the context in which it naturally occurs. Therefore, with EMA, psychological processes are not studied in a laboratory environment, but in the natural setting of the subject. EMA allows for improved ecological validity (generalization to the subjects' real lives and real-world experience) because data are collected in the subject's natural setting.

Second, all EMA assessments focus on a subject's current state. For example, EMA self-report items ask about current feelings (or very recent ones), rather than asking for recall or summary over long periods. This aims to reduce biases associated with retrospection. That is, errors or inaccuracies in recalling information are not just random, but are often systematically biased and can change the data in systematic ways. For example, people are more likely to retrieve positively charged information when they are in a good mood, thus introducing biased reporting. Because EMA assesses behaviors, attitudes, emotions, and other characteristics at the moment they occur, it reduces cognitive biases that are often a part of retrospective recall reports.

Third, the moments that are assessed with EMA are strategically selected for assessment. This avoids pitfalls associated with allowing participants to choose when they will provide data. Strategic selection of assessment points can be based on particular features of interest (i.e., occasions when subjects smoked), by random sampling, or by other sampling schemes.

Finally, subjects complete multiple assessments over time. These multiple assessments provide the researcher with a rich picture of how subjects' experiences and behaviors vary over time and across various situational contexts in the participants' normal environment. EMA studies range in the frequency of assessments. Some studies may implement a very frequent schedule of assessment (i.e., assessing subjects every 30 min over a period of days). In other studies, subjects are assessed less frequently (e.g., daily) over periods as long as a year.

Although there are many advantages of EMA such as increasing ecological validity, avoiding retrospective recall, avoiding global summarizations, and being able to study dynamic processes that unfold over time, there are also drawbacks to EMA studies. For example, EMA methods are onerous for participants and require a tremendous level of compliance (Shiffman Stone, 1998). Depending on the design of the study, subjects can be required to stop what they are doing and complete an assessment multiple times a day. EMA studies also place demands on the investigator (Shiffman & Stone). For example, automated methods for prompting or data capture can be expensive. Additionally, the volume of data collected can make data management challenging.

Definition

Ecosystems: Basic units of nature within which living organisms continually interact with non-life forms, whose boundaries are arbitrary, and which exist in "dynamic equilibrium."

Ecosystem services: A way of thinking about the benefits provided to humans and other species by nature; examples range from obvious (oxygen, food, water) to subtle (regulation of the carbon cycle) and psychological (aesthetic beauty). Sometimes called "nature's services."

Biodiversity: Abundance of biological variety.

EcoHealth: A term that indicates linkages between human and ecological well-being.

Sustainability: A debate exists concerning the definition of "sustainability" (or its earlier formulation "permanence"). One pole is anthropocentric (humans first), the other is biocentric (life in its basic form first). A formulation that many would consider anthropocentric is: "capacity to meet long-term human needs enduring over many generations." In this definition, human coexistence with a sufficient quantity and quality of nature is only implicit. The definition risks interpretation as meaning that nature can be replaced with human-made substitutes. A biocentric definition is: "a process of living within the limits of available physical, natural, and social resources in ways that allow the living systems in which humans are embedded to thrive in perpetuity." This is explicit about the need for ecosystems to thrive but is vulnerable to the criticism that human well-being may be exchanged in order to preserve nature, whether for itself or for the benefit of future generations.

Description

The original definition of an "ecosystem" dates only to 1935 (Tansley, 1935). It linked nature with physics, describing "basic units of nature" within which living organisms continually interact with non-life (the abiotic), including the climate system. The "system" part of the term is linked with ideas of holism, synthesis, emergence, self-organization, cybernetics (from the Greek for steersman, or governor), and, more recently, complexity theory (Fauth, 1997). More recently, Lovelock has extended the ideas of Tansley and Vernadsky by conceptualizing the Earth system as a self-regulating organism floating in space. This insight recognizes that a continual interaction between life and non-life maintains planetary balance (homeostasis).

Tansley coined the term "ecosystem" to contrast alternatives such as "complex organism" and "biotic community." He suggested that ecosystems belong to a category of physical systems in a catalogue from "the universe to an atom." He recognized that the boundaries between these components, including differently configured ecosystems, are arbitrary but argued that such reductionism (i.e., thinking non-systemically) was essential for their analysis. Tansley also

recognized that ecosystems are in "dynamic equilibrium," an idea he traced to the Scottish philosopher Hume and the Roman philosopher Lucretius. Implicitly, this recognizes that ecosystems are never stable but are constantly evolving and changing, including sometimes between alternative new states. A related concept is biodiversity, a contraction of "biological diversity," a term now about 30 years old.

Ecosystem Services and Human Well-Being

Ecosystems are of more than philosophical and scientific interest. Ecosystems and their services have probably been recognized as essential (though not necessarily conceptualized in these terms) by indigenous populations since the time that concepts of any kind evolved (Berkes, Kislalioglu, Folke, & Gadgil, 1998). However, as humans became more urbanized and reliant on technology, the complete dependence of humans on nature's services has become more disguised and less direct. Indeed, since the industrial revolution some 175 years ago, civilization's selected path has led to whole cultures becoming disconnected from the ecosystems that fundamentally sustain them, leaning increasingly on technology as a substitute for the services formerly derived from nature.

A widely used classification of ecosystem services was developed in the 2001–2005 Millennium Ecosystem Assessment, which conceptualized four forms of ecosystem goods and services: provisioning, regulating, culturally enriching, and supporting (see Table 1) (Millennium Ecosystem Assessment, 2003). Some ecologists have criticized the idea of "services" as excessively anthropocentric. From an extreme biocentric (deep ecology) position, the intrinsic value of an algal bloom, jellyfish swarm, or school of cod may be considered proportional to its biomass; however, such arguments seem like sophistry to those concerned with sustainable human well-being. The framers of the Millennium Ecosystem Assessment classification argued that an anthropocentric perspective was a necessary strategy with which to better engage policy makers, most of whom were thought to prioritize monetary over other kinds of value.

Ecosystems influence the entire human enterprise and incorporate, for example, wilderness, cornfields, oceans, and palm oil plantations. The vast human population (now over seven billion) could not be fed solely by hunting and gathering of wild species. For at least ten millennia, it has been increasingly dependent on domesticated plants and animals, grown ever more intensively through agriculture. Even ecosystems that appear wild, with no apparent significant human modification, such as remote mountains, deserts, rainforests, and tundra, have been altered through invasive species, the environmental atmospheric transportation of pollutants (e.g., organochlorines), and via anthropogenic climate change. Indeed, humans have been called the single greatest patch disturbers of all species on the planet (Soskolne et al., 2008).

Extensively transformed ecosystems, such as farms, are today essential for human well-being in order to provide goods in huge quantities, including food, fiber, biofuel, timber, and medicinal agents. But wild and minimally transformed ecosystems are also vital. While both categories of ecosystems provide all four categories of ecosystem service (see Table 2), it would be hubristic if humanity were to imagine that it could successfully transform the whole planet into a farm or garden. Wild places have intrinsic ("existence") value, but perhaps of even more importance, they provide enormous ecosystem regulating services which benefit humanity on a scale that modified ecosystems cannot approach. They also hold a vast reservoir of poorly catalogued species, some of which will be discovered to hold important pharmaceutical and other uses (Chivian & Bernstein, 2008). In general, wild ecosystems are shrinking, with their cultural and regulating services being exchanged for greater provisioning services.

Current economic models ignore (externalize) the costs of harming or maintaining ecosystem services. This practice intensifies several forms of inequity, including polarization between rich and poor and between current and future generations. Those who purchase goods and services tend to underpay, while others, especially the poor, bear the burden of risk and remediation,

Ecosystems, Stable and Sustainable, Table 1 The Millennium Ecosystem Assessment classified ecosystem "services" into four kinds. The selected examples represent only a tiny fragment of a very rich and complex set. Many ecosystems provide multiple ecosystem services; for example, a forest may provide food, fiber, water regulation, water purification, and cultural services. Most employment is provided by provisioning services, including through the transformation of wilderness to farms and plantations

Ecosystem service	Examples of benefit	Ecosystem examples
Provisioning	Food (calories, nutrients), fresh water, fiber, medicinals	Rice fields, aquaculture ponds, bamboo groves, cattle feedlots, wild plants, and wild animals
Regulating	Soil erosion reduction, coastal storm protection, atmospheric carbon stabilization, some cases of infectious disease limitation (e.g., malaria, Lyme disease)	Forests (including on slopes), coastal wetlands, mangroves, extinction of the passenger pigeon contributed to a cascade of ecological changes that enhanced habitat for ticks that transmit Lyme disease
Culturally enriching	Inspiration, aesthetic beauty, spiritual refreshment, religious observation, ancestral links, ceremonial materials, tourism income	Sacred groves, charismatic landscapes and species e.g. coral reefs, tiger reserves, old growth forests, bird of paradise feathers
Supporting	Soil fertility, nutrient cycling, pollination, insect control; many indirect benefits for other services	Many species enhance soil fertility, pollinate, and disperse seeds; bats and birds help control insects; bacteria and fungi recycle nutrients

Ecosystems, Stable and Sustainable, Table 2 Ecosystems can be grouped between two extremes, minimally and extensively transformed; no ecosystem is entirely "natural." Both kinds perform valuable ecosystem services. In general, wild ecosystems are shrinking, with their cultural and regulating services being exchanged for greater provisioning services. To flourish, humanity requires all four kinds of service in abundance

Ecosystem service	Extensively transformed ecosystem	Wild or minimally transformed ecosystem
Provisioning	Farms, plantations, greenhouse vegetables, farmed fish	Game, bushmeat, ocean fish, timber, a reservoir of species with potential human benefit
Regulating	Trees planted to reduce soil erosion, carbon sink from a long lived tree plantation, artificial wetlands	As opposite, but benefits vastly larger in scale; e.g., carbon sink of Amazon forest, scavenging services by wild birds and mammals
Culturally enriching	Bonsai tree, flower garden, zoological garden, artificial wetland; some people find cultivated areas very attractive	Knowledge of the existence of wild areas and species, wilderness hiking, contact with wild birds and mammals adapted to urban ecosystems
Supporting	Earthworms in a garden, planted legumes that fix nitrogen, complementary plantings that reduce pesticide use	Species that pollinate and disseminate seeds, animals that improve soil water absorption, algal varieties that enhance water purification

such as hazardous exposures and waste disposal costs. Indeed, accumulating impacts increasingly approach thresholds which threaten the collapse of crucial ecosystems, harming both present and future generations. Internalization of such costs would motivate consumer behavior more conducive to sustainability (Daly, 1996). A powerful reason for the transformation of wild ecosystems to one which provides intense provisioning services is that greater monetary profits can be made and that more people can be employed. But this transformation is always at a cost: not only to the species which are altered or lost but also, in many cases, to indigenous populations who lack sufficient political and economic power to resist.

Human Health

All ecosystem services are essential, directly or indirectly, for health, a concept captured by the term "ecohealth" (Wilcox, Aguirre, & Horwitz, 2011). Some ecosystem properties, including biodiversity, influence the distribution of important human infectious diseases, including malaria, onchocerciasis, Lyme disease, Chagas disease, and sleeping sickness (Keesing et al., 2010).

Although there are claims that ecosystems that are less transformed by human action provide an infectious disease-regulating "service," such that intact ecosystems lower infectious diseases, the picture is more complex (Butler, 2008). For example, there are many cases in which ecosystem transformation has improved health, such as the clearing of swamps, which reduces mosquito habitat and may thus lower malaria transmission. Somewhat relatedly, "paddies paradox" describes how health can improve even where increased irrigation leads to more potential mosquito habitat in malarial areas. Increased malaria is not inevitable; for example, some of the increased wealth generated by irrigated agriculture can be used to promote technologies and behaviors which are health protective, such as treated bed nets, insecticides, and health services. Areas of high biodiversity may also harbor infectious agents, such as Ebola and HIV, in reservoir species including bats and some nonhuman primates.

Disease introduction can have profound effects on ecosystems, and indirect human health effects. In the late nineteenth century, the epizoonosis (a disease that infects only nonhuman animals) rinderpest entered eastern Africa via imported cattle, causing catastrophic harm to the ecology and human well-being. Immunologically naive oxen (domesticated and wild) died in huge numbers. The loss of oxen reduced plowing and thus agricultural productivity. Infection in wild animal species also reduced meat available for hunting. Exacerbated by periodic droughts, as many as one third of the Ethiopian population and two thirds of the Maasai people of East Africa died in this period, a time known to the Maasai as the *Emutai* ("to wipe out") (Gillson, 2006).

Psychological Health and Ecosystem Cultural Services

Ecosystems are also an important source of "cultural services," essential for good psychological health and thus for individual and community well-being. Ecosystems that help provide this vary from sacred groves (Ramakrishnan, Saxena, & Chandrashekara, 1998) that maintain species with spiritual or symbolic value to viable populations of charismatic species within national parks and tracts of roadless wilderness. Many cultural symbols, decorations, and ceremonies rely on materials from nature, including sacred plants, fungi, and animals or seasonal displays, such as animal migration.

There is increasing evidence that exposure to gardens and wild areas is beneficial for behavior and good mental health (Louv, 2008). This effect may be particularly strong among those with high biophilia (sensitivity to nature) (Wilson, 1984).

Supporting Ecosystem Services

The fourth category of service described by the Millennium Ecosystem Assessment is "supporting" ecosystem services. This category may be the least obvious, but brief reflection shows that they are fundamental because they underpin all the other forms of ecosystem services. Examples include pollination, seed dispersal, and the recycling of nutrients and the formation and aeration of soil by earthworms, ants, and termites. In Western Australia, the brush-tailed bettong *Betolgia pwicillata* (an endangered species) has been shown to improve the absorptive capacity of moisture in soil through its habit of digging for fungi. Many birds, bats, and other mammals assist in seed dispersal, forest maintenance, and insect control. White nose syndrome, a devastating fungal disease affecting several bat species in the USA will lead to increased insect populations, forcing increased reliance on pesticides and fossil fuels to maintain agricultural productivity. This illustrates the interdependency of life, including of our own species.

Prospects

Globally, the progression toward an increase in ecosystems which provide provisioning ecosystem services, such as the exchange of biodiverse forest ecosystems for monocultural plantations that provide food or biofuels, seems unstoppable (Danielsen et al., 2008). Fundamentally, this transformation has been driven by the enormous expansion of human populations since the industrial revolution supported by fossil fuels and agriculture. But there are now numerous warnings

that these processes are unsustainable and that this path places not only health and well-being, but civilization itself at increasing risk of grave harm (Soskolne et al., 2008). This risk occurs through multiple pathways, particularly the accumulation of greenhouse gases which worsen climate impacts and which threaten diverse and adverse feedbacks that could lead to the crossing of system thresholds with extreme danger (Lovelock, 2009).

Solutions

There is widespread denial about the extent, trend, and consequences of the relentless transformation of ecosystems. Many highly transformed ecosystems also risk degradation due to overuse, overgrazing, and contamination by chemicals, invasive species, and even landmines. Human well-being will inexorably decline if these trends are permitted to continue. Indeed, in some countries, constitutional law is changing in ways that will provide better ecosystem protection (Soskolne et al., 2008).

The tragedy of the commons can be overcome (Buck, 1985). But this will not happen without a vast amount of effort, exceeding that of the Space Race or even World War II. As Aldo Leopold wrote (using land as a synonym for ecosystems):

> We abuse land because we regard it as a commodity belonging to us. When we see land as a community to which we belong, we may begin to use it with love and respect. There is no other way for land to survive the impact of mechanized man, nor for us to reap from it the aesthetic harvest it is capable, under science, of contributing to culture (Leopold, 1949).

The question of why, collectively, humanity seems incapable of changing its economic and consumer models to ones that are more sustainable is beyond the scope of this entry. Suffice it to say that denial is made possible because humans are remarkably adaptive; many seem to live in hope of a technological solution to the crises that await under current trends. Ultimately, consciousness of humanity's inseparable dependence on nature's services is required if a functioning civilization is to be maintained.

Education, Lack Of: As a Risk Factor

Socioeconomic status (SES)

Definition

Lack of education as a risk factor of health conditions is part of the category of factors termed socioeconomic status (SES). Level of education can be measured in several manners including years of education (e.g., 5, 10, 18 years), stage of education (e.g., primary school, secondary school, professional vocation, academic degree, graduate studies), as well as types of education (e.g., vocational, humanities, engineering, biomedical, social sciences). Low education has been shown to be a risk factor of multiple disease outcomes and can be construed as a source of health inequalities. For example, (Clegg et al. 2009) found that level of education below high-school education was a risk factor of cancer in men and women. In a Scottish study, lower education was associated with shorter height, high blood pressure, smoking, poorer lung functioning, and higher risk of death (Davey Smith et al., 1998). In the same study, occupational status however emerged as a more important risk factor than education. Nevertheless, these studies show that lack of education can be a risk factor of known disease risk factors (e.g., smoking, high blood pressure) and of actual illnesses (e.g., cancer).

Among the mechanisms suggested to link low education with poor health outcomes are poor health behaviors (e.g., smoking, poor diet), stress, and physiological factors (e.g., inflammation, cardiovascular reactivity, oxidative stress). For example, Finkelstein, Kubzansky, Capitman, and Goodman (2007) found an inverse correlation between levels of education (below 12 years, 12–15 years, college, professional) and stress levels. Janicki-Deverts, Cohen, Matthews, Gross, and Jacobs (2009) found that initially high education levels predicted lower levels of oxidative stress and higher levels of antioxidants. Oxidative stress is a major etiological factor of multiple chronic diseases including cancer, heart disease, and dementia. Taken together, low education level is a risk factor of poor health, possibly via various psychophysiological pathways, access to material and health resources, and inadequate health behaviors.

Health education

Definition

Patient education is a basic step in medical care, reflecting empowering patients with knowledge on the risk of or nature of an illness, how to prevent it, how to perform self-care, and when to seek help. Patient education can be provided by physicians, nurses, physiotherapists, health psychologists, etc. and is a basic part of adequate clinician-patient communication. This can be seen as part of health education, where people learn to prevent, identify the signs, seek treatment for an illness, and perform self-care behaviors. This reflects the move in medicine from a hierarchical doctor-patient style toward a more self-managed and active patient role. Patient education can include, for example, information on the consequences of smoking and excessive alcohol consumption, use of condoms and the consequences of not using condoms, how to perform self-monitoring and management of insulin levels in diabetic patients, and adherence to medical treatment in cardiac patients after surgery. Lagger, Pataky, & Golay (2010) reviewed 35 meta-analyses of 598 studies on therapeutic patient education in asthma, cancer, and diabetes, among various chronic diseases. They found that in 64% of studies, improvements were found. However, unlike "therapeutic education," patient education alone relies mainly on increasing knowledge, but rarely addresses patients' psychological factors that impede healthy behaviors such as barriers and social pressures against adopting healthy behaviors. Studies have found multiple barriers in relation to healthy eating, physical activity, and in cardiac patients' medical adherence (e.g., Zunft et al., 1999). Furthermore, in the context of condom use, for example, studies have shown that education led to little or no increases in condom use (Gallant & Maticka-Tyndale, 2004). In contrast, use of the "psychological inoculation" method, which precisely trains people to break their own barriers, may have better effects than health education alone (Duryea, Ransom, & English, 1990). Thus, while patient education is an essential element of prevention and treatment, its effectiveness can be increased when accompanied by cognitive-behavior skills for reducing patient barriers and increasing self-efficacy, or by including simple behavioral tips for moving patients along different stages of behavior change.

Effect Modification

J. Rick Turner
Cardiovascular Safety, Quintiles, Durham, NC, USA

Definition

Effect modification occurs when an effect modifier is associated with both an apparent case and an apparent effect and modifies the association of interest (Katz, 2001).

Consider the example of the association between vigorous exercise and risk for heart disease. This association is real, but its direction varies with level of fitness. An individual who is essentially fit will in all likelihood reduce his or her risk of heart disease by exercising vigorously. However, an individual who is unfit may acutely increase his or her risk by participating in such exercise, or by engaging in other vigorous physical activity. An unfortunately too frequent example of this occurs when unfit individuals attempt to shovel heavy snow, a very physically demanding task, and suffer a myocardial infarction. The association between vigorous exercise and heart disease, therefore, while real, is not unidirectional, but is modified by an individual's level of physical fitness.

Efficacy

J. Rick Turner
Cardiovascular Safety, Quintiles, Durham, NC, USA

Definition

The efficacy of a treatment is a measure of its influence on a clinical characteristic or outcome of interest when administered in tightly controlled, near-ideal circumstances. It is a measure of benefit.

The term "efficacy" can be meaningfully differentiated from the related term, "effectiveness." Effectiveness, which is of greater clinical interest, is a measure of the treatment's influence under real-world conditions (Katz, 2001).

Efficacy is typically assessed wherever possible in a randomized controlled clinical trial, since this provides the best approximation to "near-ideal circumstances." A paradox of such assessment, however, is that the deliberate (and, at this point in time, desirable) nature of the tightly controlled environment in which the treatment is assessed limits the generalizability of the therapeutic results obtained to interventional therapy administered outside that setting. There are many reasons for this, including the relatively homogenous nature of the subjects participating in the trial: Strict inclusion and exclusion criteria are typically employed. From a statistical perspective, this tightly controlled subject population is beneficial in that it reduces extraneous variation that may lead to a genuine treatment effect being difficult to detect. However, a clinically important effect seen in a well-controlled trial may not be reflected when the treatment is applied to a heterogeneous population in circumstances of real-world clinical practice.

This is why effectiveness assessments are so important. Various approaches can be employed. One is to conduct large-scale trials (sometimes called mega-trials or large simple trials) which employ much more simple measurement schedules that focus on the one aspect of interest and that are conducted in conditions much more akin to clinical practice.

Efficacy Cognitions

Jorie Butler
Department of Psychology, University of Utah, Salt Lake City, UT, USA

Definition

Efficacy cognitions: Efficacy cognitions are thoughts that develop from self-efficacy. Self-efficacy is the belief in personal ability to successfully perform challenging life tasks (Bandura, 1977a). Self-efficacy develops from mastery experiences, modeling, social persuasion, and physiology (Bandura, 1977b).

Description

Efficacy cognitions include thoughts about performance that are optimistic, pessimistic, productive, or self-debilitating. Efficacy cognitions are influenced by mastery experiences which promote cognitive expectations. Efficacy cognitions can be modeled similar to self-efficacy. Social persuasion, in the form of encouragement from others to achieve, or stated positive expectations, promotes positive efficacy cognitions. Negative persuasion in the form of discouragement or deflating comments promotes negative efficacy cognitions. Negative interpretations of physiological responses such as strong emotions (e.g., anxiety) and the physiological accompaniments (fast heart rate) influence efficacy cognitions as negative, "I'll never be able to do this, I'm terrified" or positive, "I've got this in the bag, I'll just enjoy it!" Efficacy cognitions spring from interpretations and can contribute to habitual interpretations.

Efficacy cognitions are not perfectly aligned with reality – hence the concert pianist overcome with doubts about their potential to produce beautiful music and the exuberant child overestimating the pleasantness in tone of their singing voice. Efficacy cognitions contribute to motivation to perform an activity, personal well-being, positive health behavior, and future achievement. Negative efficacy cognitions result in avoidance of the activity, whereas confident efficacy cognitions promote engagement in the task. Emotions related to activity performance will ally with the tone of the efficacy cognitions – stress and anxiety for tasks about which efficacy cognitions are negative, joyful immersion for activities about which efficacy cognitions are positive.

Productive efficacy cognitions contribute to a view that difficult tasks are challenges to be mastered. Armed with such thoughts, people are more likely to approach the difficult task at hand with zestful effort. Self-debilitating efficacy cognitions are centered on tasks as insurmountable or fearsome result in activities that are dropped after minimal obstacles intervene. Optimistic efficacy cognitions promote task enjoyment whereas pessimistic thoughts promote task-associated distress and early failure. Efficacy cognitions influence action planning for future goals. Individuals planning to implement a health behavior change – such as smoking cessation, eating a healthier diet, exercising, or adhering to recommendations for managing a chronic illness – are more likely to be successful at

implementation when efficacy cognitions are positive. In the health behavior change model, individuals progress through stages of change that culminate in maintaining lasting change (Prochaska & Vellicer, 1997). Early in the process, during the contemplation stage, efficacy cognitions are particularly important. Individuals who doubt they can make a successful health change during the contemplation may not reach the preparation stage – in which planning for change will occur – or the action stage when substantive changes are made.

The expectancies in efficacy cognitions may influence future performance more than objective measures such as past performance (Schunk & Pajares, 2005). Efficacy cognitions have wide-ranging implications as the perception that one can accomplish something can be as motivating as having accomplished the task in the past. Thus, positive efficacy cognitions can have a tremendous effect on personal motivation and willingness to experience activities. Conversely, negative efficacy cognitions – even in the face of contradictory objective evidence – can stymie efforts to engage in challenging tasks. Individuals expecting poor outcomes, "I'll never be able to quit smoking, I've tried and failed a dozen times" may indeed be more likely to experience poorer outcomes. In contrast, individuals facing health behavior change with positive expectations may be able to incorporate adaptive strategies for success into their planning more effectively (Gollwitzer, 1999; Schwarzer, 1992).

Efficacy cognitions do not develop in complete independence from objective evidence of past performance and therefore often are realistically correlated with outcomes. Multiple factors influence the development of efficacy cognitions in addition to experiences – such as environmental factors or propensity for anxiety. Individuals who might be expected to feel competent based on other predictors may not if efficacy cognitions have developed in the face of physiological state challenges (anxiety, stress, fear), negative expectations from the social environment (such as stated gendered expectations for performance in athletics or mathematics), or faulty interpretations of past experience (not recognizing a strong or poor performance) (Schunk & Pajares, 2005). Positive efficacy cognitions are strongly associated with performance because such cognitions promote action and use of skills. Negative efficacy cognitions hold individuals back from achieving all they might in their lives and for their health.

Definition

eHealth is a broad term that refers to the use of information and communications media to facilitate access to health-related information and to support or deliver healthcare. eHealth can include health informatics, health knowledge management, and health data management. Telemedicine and telehealth are subsets of eHealth. Telemedicine refers to the provision of clinical services via telecommunications technologies (e.g., phone, instant messaging), while telehealth is a more general term (Jordan-Marsh, 2011) that refers to the broader use of telecommunications in healthcare and health promotion (e.g., electronic access to personal health records, websites allowing patients to schedule appointments).

Although healthcare providers and administrators are also targets of eHealth, we will restrict this review to the use of communication technologies aimed at changing patients' behaviors, cognitions, and emotions in the service of better health outcomes. We refer to these interventions as Behavioral Intervention Technologies (BITs). BITs promote behavior change through electronic provision of didactic material, skill-building tasks, feedback, decision-making aids, risk self-assessments, or patient self-management tools.

Description

Remote Provision of Clinical Services. The use of videoconferencing, telephone, and instant messaging harnesses communications technologies to extend care geographically while preserving the traditional structure of behavioral treatments. Videoconferencing has been shown to be an effective treatment delivery medium for a variety of mental health problems, as well as teaching self-management strategies for chronic conditions and providing support to caregivers of older adults. Older studies used videoconferencing to extend care to remote clinics where there was an absence of specialized care, but newer studies are harnessing the capacity to videoconference directly into patients' homes.

Many trials have examined the telephone-based delivery of behavioral interventions to address a wide range of targets including preventive health behaviors such as weight loss and smoking cessation, self-management interventions for chronic illnesses, and mental health. Telephone treatments have generally been shown to be effective, and there is evidence that the use of the telephone may improve access and reduce attrition. A few studies have also indicated that the use of instant messaging to deliver

standard psychological interventions can be effective.

While extending care, each of these delivery modalities progressively decreases the "bandwidth" for social cues (e.g., nonverbal behavior; Mohr, Cuijpers, & Lehman, 2011), which has raised concerns that the reduction in cue bandwidth may reduce efficacy. There is no evidence to date that videoconferencing or telephone delivery reduces efficacy, although this has not been rigorously tested. The evidence for instant messaging is too preliminary to begin to speculate on its comparative efficacy.

Web-Based BITs. Web-based BITs have been evaluated for a growing number of health behavior and mental health problems, including weight loss, physical activity, insomnia, adjustment to illness, depression, and anxiety. While most, but not all, trials find evidence supporting the efficacy of web-based BITs, the effect sizes vary considerably and range from negligible to effects on par with traditional face-to-face care. This variability is likely due to a variety of factors, including website design, implementation, and support features.

The structure of web-based BITs can vary on a wide variety of dimensions, including the degree to which they present static information versus interactive features, the degree of personalization, the use of multimedia, the manner in which patients progress through the intervention (e.g., all material being completely available from the beginning, versus some or all material being presented according to criteria such as time or task completion), the expected length of engagement with the intervention, whether the website is freely available to the general public versus contingent on patient characteristics or healthcare system, and the degree of human support. Improvement in health behaviors is maximized by the incorporation of features such as automated text messages and email, personalized feedback, human support via email or telephone, use of multiple behavior change strategies, and a theoretically informed choice of participants and intervention content (Webb, Joseph, Yardley, & Michie, 2010).

Lower efficacy is often associated with poor patient adherence (e.g., few logins to the site) or treatment dropout (ranging from extremely high, >95% for free-standing depression websites with no human support, to minimal). Website usage may be increased by ensuring that the site is easily usable and navigable, provides tools and information that help the user to achieve his/her goals, is attractive, and conveys credibility (Fogg, 2003). Periodic updates to the website content are likely to draw users back to the site (Brouwer et al., 2011). In addition to website design, a fairly consistent body of literature has shown that the adherence and efficacy of web-based BITs are enhanced when the website is supported by human interaction (Andersson & Cuijpers, 2009; Brouwer et al., 2011). One theoretical model to explain the benefits of human support, called supportive accountability, posits that adherence is enhanced by accountability to a supportive coach or provider. Mutually-agreed-upon process goals (e.g., logging into the website or using website tools) are monitored by a supportive coach, and the user is expected to account for use or nonuse at pre-specified times through personal contact via brief telephone calls, email, or messaging (Mohr et al., 2011).

Variability in adherence may also be associated with the selection of research participants. Trials that have extensive screening processes likely select for patients who are more motivated and more likely to adhere. When screening involves contact with an evaluator, adherence may be even higher. Websites that are accessible to the general population with little or no entry processes can produce high rates of initial access, with few participants returning to the website after one or two visits. It is not yet clear the degree to which these low return rates are due to large numbers of potential users, for whom the website is not appropriate, being able to easily find and investigate the site, versus design and implementation flaws, or users finding the information or help they desired more quickly than expected.

Internet Support Groups. Internet support groups have proliferated, often with the aim of fostering empowerment and sense of community, decreasing illness-related stigma, promoting the sharing of information, and increasing social

support. There is some evidence that therapist-moderated internet support groups can reduce distress. However, findings regarding the efficacy of un-moderated internet support groups are mixed. Some trials demonstrate modest improvement, but many trials find no significant effect or even increased distress for some users. This suggests that assumptions as to why and how these groups might be helpful may be erroneous. Thus, while the appeal of social media is considerable, little is currently known about how to effectively harness online social networks to improve health outcomes.

Emerging BITs. Web-deployed virtual worlds offer a diverse range of health intervention and educational experiences. For example, Second Life is being used to provide health-related information, meetings, support groups, simulations of medical procedures or symptoms, discussion groups, appointments with human healthcare providers, movies, and opportunities to practice new skills (e.g., role plays; Beard, Wilson, Morra, & Keelan, 2009). Serious gaming is a field in which the entertainment value of games is harnessed for a purpose, such as improving health (Zyda, 2005). Serious health-related games have been developed, in particular to increase physical activity and improve diet in children. Although outcomes have been promising, more research is needed to demonstrate clinical efficacy.

Mobile BITs. Mobile electronic devices (e.g., handheld computers, mobile phones) and wireless technology can be used to establish a continuous connection with patients as they conduct their daily lives. This subset of eHealth is often referred to as mHealth. Real-time delivery of intervention (e.g., encouragement, information, therapeutic tools) can be provided to the patient in their own environment. mHealth BITs can also collect information about the patient's current state and provide tailored intervention based on that state. Finally, as Smartphones can access the web, web-based and mobile components can be integrated into the same intervention.

A growing number of studies have examined mobile phone BITs that target preventive health behaviors (smoking cessation, weight loss, and physical activity), self-management of chronic illnesses (e.g., diabetes, asthma), mood and anxiety disorders, schizophrenia, and medication adherence. Trials have found positive short-term benefits. However, literature on the effects of mHealth is still limited in many clinical areas, and not enough high-quality studies have been conducted to enable a reliable quantitative meta-analysis (Heron & Smyth, 2010).

Most mHealth BITs include SMS messages, which vary on a number of dimensions. Some studies send informational messages or reminders, while other interventions employ SMS dialogues which are commonly automated and lead to the provision of tailored information. SMS dialogues are often initiated by the intervention, but some focus on or allow patient-initiated SMS dialogues. For example, many of the disease self-management interventions require the patient to provide information (e.g., blood pressure for hypertension interventions), which then results in tailored SMS feedback. The frequency of the SMS messages can vary from 5+ per day to a little as once weekly, and is usually tied to the expected frequency of the targeted behavior. Degree of tailoring and personalization also varies, with some mHealth BITs providing highly tailored messages, while others provide more generic messages or tips. Finally, mHealth BITs vary to the degree to which they rely solely on the mobile intervention or are supplemented by other intervention strategies such as interactive websites or consultations with healthcare providers.

An emerging area in mHealth is the development of passive data collection methods that avoid problems related to patient's reluctance to log information. In this way, mHealth BITs can detect when intervention is needed, without requiring the patient to self-report their current state. Passive data collection uses sensors to automatically collect data that can help to infer patient states. Such sensors can be located within the mobile device itself (e.g., GPS, accelerometer), or through wirelessly connected external devices (e.g., heart rate or glucose monitors). There are two ways in which intervention delivery can be informed by sensor data. First, algorithms can be developed based on existing scientific knowledge (i.e., expert systems).

The algorithms are then applied to make inferences regarding the patient's state, and consequently their need for intervention, from the sensor data. As mobile devices can also allow patients to self-report their current states, the second approach is to use machine learning techniques (Witten & Eibe, 2005) to model the relationship between sensor data and patient states. These models are then used to predict patient's states solely from new sensor data, with the advantage being that the models were automatically generated and personalized. Use of machine learning in this way is a new and complex approach that has been applied to detect physical activities, mood, and social context with varying levels of accuracy (e.g., Burns et al., 2011).

Potential Benefits of BITs. The primary anticipated benefit of BITs is increased access to behavioral healthcare services. Telehealth can be used to assess and provide services to patients living in rural areas, those with medical conditions that affect mobility, or patients for whom travel to service providers is too time consuming given their employment, caregiving, or other responsibilities. Web-based and mHealth BITs are expected to deliver care at substantially reduced costs, and there are some preliminary studies suggesting that web-based BITs can be very cost effective. For example, BITs are usually designed to require less time burden on clinicians, and since BITs can be delivered remotely, they might also reduce the patient's transportation costs and lost work productivity due to time spent in transit. However, there is still a paucity of cost-effectiveness studies examining eHealth compared to usual care, and results may vary based on whether costs and benefits are calculated in terms of the individual patient, the healthcare system, or society as a whole.

Given the prevalence of obesity, smoking, chronic illness, and mental illness, there will never be enough behavioral health specialists to meet population needs for behavioral care. BITs offer the possibility of bridging the gap between behavioral health interventions, which have traditionally been delivered on an individual or small group basis, and population-level public health intervention. Access to the web is growing rapidly. Mobile phones have reduced the Digital Divide between racial/ethnic minority and majority groups in the United States, with African American and English-speaking Hispanic adults using mobile devices to access the web at greater rates than White, non-Hispanic adults (Smith, 2011). Thus, mobile BITs might be used to more equitably distribute healthcare services. Should BITs fulfill expectations to increase access to care in underserved populations, this may also facilitate a transition away from acute, crisis-based care toward preventive care.

eHealth interventions, particularly those involving remote patient monitoring or real-time outreach, may increase detection of emergency situations. Often, web-based and mobile BITs also allow patients a 24-h capability to send messages to providers. This convenience may encourage patients to report their difficulties in real time rather than at their next scheduled appointment, by which time the problem may have worsened or the patient may have forgotten important information. Many studies have demonstrated safe implementation of BITs in specific clinical areas.

Potential Risks of BITs. The Digital Divide refers to continuing disparities in internet access and familiarity based on age, race/ethnicity, and socioeconomic status. These disparities may be reduced by sensitivity to differences in the way technology is used between different populations. For example, only 2% of mobile phone owners 65+ years of age access social networking sites using their mobile phone, while 24% use text messaging (Smith, 2011). Trends suggest that text messaging will be used by increasing numbers of the elderly; thus, if peer support is involved in a BIT for older adults, the forum for peer communication at this time should likely be text messaging rather than a website. Community-based participatory research and careful usability testing of BITs should also be conducted with underserved populations to address issues of access, level of familiarity with the technology, and concordance with the ways in which the population already uses and perceives the technology.

Privacy and security are hotly debated issues in BITs research. Privacy refers to the prevention of

improper disclosure of personal information, while security refers to the technical and procedural mechanisms used to protect privacy. Security protocols are a necessary part of any BIT, and they require ongoing consultations with an IT expert who will remain current on security vulnerabilities in supporting components (e.g., the operating system and servers; Bennett, Bennett, & Griffiths, 2010). Encrypted data transmission and restricted access to research data should be standard protocols. Increasingly, however, the efficiency of BITs is being maximized by conducting much of the computing on the user's device. This introduces privacy risks when the patient uses devices that are shared or monitored by others, such as public or work computers. Protocols for wiping data on these remote devices should thus be in place.

Assuming adequate technical security measures, privacy is more likely to be compromised by procedures associated with the interventions, and by the users themselves not taking advantage of security measures such as passcodes. Research staff require ongoing training to avoid procedural errors (Bennett et al., 2010) and effectively teach patients to do the same. Another challenge is conveying to patients how their health information will be handled in terms that are clearly understood. This is an ethical responsibility, and may also help to gain the trust of individuals whose privacy concerns or unanswered questions may prevent them from accessing or fully utilizing potentially beneficial BITs.

Future Directions. BITs research integrates and absorbs methodology from many disciplines, including behavioral science, medicine, computer science, engineering, human computer interaction, computer-mediated communication, visual design, education, and public health. There is a need for individual researchers with expertise across a number of these areas, as well as multidisciplinary team science. New, integrated theoretical frameworks are also needed to describe interactions between use of technology and behavioral change processes. For example, given the virtually ubiquitous presence of information and communication technologies and their resulting ability to engage with individuals as they interact with multiple spheres of their daily lives (e.g., intrapersonal, interpersonal, institutional, the natural environment, and macro-social factors such as public policy and economic realities), an ecological intervention model has been created that would encompass expertise in each of these domains (Patrick, Intille, & Zabinski, 2005).

Due to the rapid development of new technological capabilities, new methods are evolving to evaluate the efficacy of BITs. The randomized controlled trials traditionally used to demonstrate efficacy are time intensive, and by the time such trials are concluded, the technology being evaluated is likely to be outdated. Disciplines outside of clinical science, in which the rapidity of technological advances has long been a common concern, may be well suited to help behavioral researchers address this challenge. Methodologies that borrow from engineering, such as Multiphase Optimization Strategies (Collins, Murphy, & Strecher, 2007), may be more appropriate in optimizing and evaluating new BITs.

Dissemination. Strategies to disseminate and integrate BITs into healthcare are largely unexplored. BITs can be deployed independent of healthcare delivery systems; this is evidenced by the growing number and use of websites aimed at supporting diet, weight loss, and health lifestyle, as well as the proliferation of mHealth Smartphone applications. There is little efficacy data for many of these BITs, or information on how their use impacts health, healthcare utilization, or healthcare cost. There is also considerable interest in integrating BITs into existing healthcare delivery systems. This integration will require research on at least four levels: (1) Research should determine how BITs will fit in with existing treatment options. For example, stepped care models may first provide the patient with a BIT, and reserve more clinician-intensive treatments for patients who fail to respond. (2) BITs can be integrated into electronic medical records and patient management systems to facilitate referrals, treatment monitoring, follow-up care, and integration of the

BIT into the patient's overall treatment plan. (3) Demonstrated cost-effectiveness of BITs relative to existing treatments will be required for adoption by healthcare systems. (4) Implementation research will be required to identify implementation barriers and opportunities, as well as develop implementation models that can optimize the uptake and use of efficacious BITs by both patients and healthcare providers.

Elderly

Ivan Molton
Department of Rehabilitation Medicine, University of Washington, Seattle, WA, USA

Synonyms

Aged; Older adult; Senior

Definition

The term "elderly" is derived from the Middle English word *eald* (meaning old) and generally refers to an individual who is near or surpassing

the average life expectancy for his or her community, culture, and historical period. The term differs from clinical or medical language used to describe older adults (e.g., senescent or geriatric) in that it does not describe biological aspects of aging. Rather, "elderly" is used more broadly in the context of social gerontology, and carries the connotation of having achieved a certain degree of respect, status, expertise, or wisdom with advanced age (i.e., as an *elder*). For the purposes of research and policy efforts, the age cut off for "elderly" is often set in western countries at 65 or 70, based on the age at which individuals have historically been able to receive government retirement benefits. However, the term is descriptive rather than scientific, and does not typically denote a particular age band within older adulthood.

Electrocardiogram (EKG)

Douglas Carroll
School of Sport and Exercise Sciences, University of Birmingham, Edgbaston, Birmingham, UK

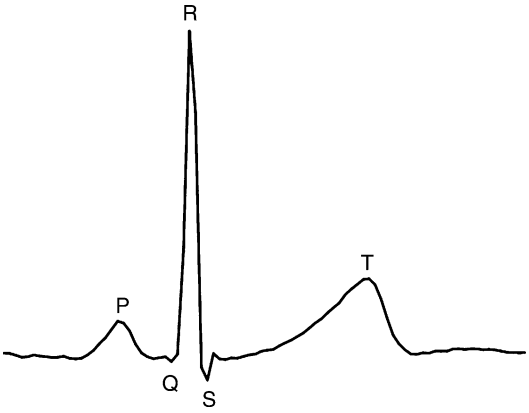
ECG

Definition

The electrocardiogram (EKG) is the noninvasive record of the electrical activity of the heart muscle, as reflected in tiny electrical changes on the skin, during the heart's active (systole) and passive (diastole) phases (Hampton, 2008). The EKG can be recorded easily from two electrodes placed on either side of the heart, for example, on the chest or on the left and right arms. For clinical and diagnostic purposes, however, it is usual to attach an array of 12 electrodes at various bodily sites so that the EKG can be recorded from different orientations. The characteristic wave form (see Fig. 1) that identifies the heart's active phase, i.e., when it beats and pumps blood into the systemic circulation, was first described in 1903 by Willem Einthoven, in Leiden in the Netherlands, although electrical records of heart beats had been made as early as 1872. In 1924, Einthoven was awarded the Nobel Prize for Medicine for his research in EKG. The first wave in the three-wave systolic portion of the EKG record is the P-wave, and it represents the depolarization, i.e., the contraction, of the atrial chamber of the heart. Next, the R-wave, usually considered at the whole QRS complex, reflects the depolarization of the ventricles. Finally, the T-wave represents the repolarization, i.e., recovery, of the ventricles. In behavioral medicine, interest in the EKG is usually confined to the derivation of heart rate, the number of systoles in a given minute, or to its reciprocal, heart period, the time between successive R-waves. The former indicates the speed at which the heart is beating under specified circumstances, such as during relaxed rest or psychological stress exposure. Unfortunately, this tells us nothing about volume of blood being pumped by the heart into the circulation: for that, we need



Electrocardiogram (EKG), Fig. 1 EKG waveform

other techniques, such as impedance cardiography and, more recently, Doppler echocardiography. The latter, heart period and its variability, can, particularly when subject to spectral analysis of frequency, tell us about the extent of activation of the heart by the main parasympathetic nerve, the vagus, and about the balance between parasympathetic and sympathetic neural activation of the heart. Finally, the precise configuration of the EKG can tell us other useful things, particularly in clinical settings. For example, a blunted or inverted T-wave is a reasonable indicator of cardiac ischemia, where the heart muscle is suffering from impaired blood flow and hence a restricted oxygen supply.

Electrodermal Activity (EDA)

Hugo Critchley and Yoko Nagai
Brighton and Sussex Medical School, University of Sussex, Brighton, East Sussex, UK

Definition

Electrodermal activity (EDA) reflects the output of integrated attentional and affective and motivational processes within the central nervous system acting on the body. EDA is a valuable tool in behavioral medicine as a biomarker of individual (state and trait) characteristics of emotional responsiveness, as an index for direct examination of axis of stress-related effects on bodily function, and as a potential avenue of treatment of psychosomatic conditions through biofeedback training. Below is an overview of EDA with examples of its application to behavioral medicine.

Description

What Is Electrodermal Activity?

Electrodermal activity (EDA) is a measure of neurally mediated effects on sweat gland permeability, observed as changes in the resistance of the skin to a small electrical current, or as differences in the electrical potential between different parts of the skin. The EDA signal reflects the action of sympathetic nerve traffic on eccrine sweat glands. There are two salient features of this sympathetic innervation that enhance the usefulness of EDA in psychophysiology and behavioral medicine. First, there is no antagonistic parasympathetic innervation of sweat glands (i.e., EDA reflects only sympathetic activity not sympathovagal balance), and second neurotransmission at the effector synapse is (almost completely in adults) cholinergic, i.e., mediated by acetylcholine release. This differs from the noradrenergic neurotransmission typical of other sympathetic effector synapses and further makes the EDA signal independent of circulating adrenaline and noradrenaline levels.

Sympathetic neural activity in skin is closely coupled to changes in mental state: In the laboratory setting, at rest and constant temperature, EDA indexes change in attention and cognitive and emotional states of arousal, expressed both as sustained shifts in tonic level (skin resistance level, SRL, or skin conductance level, SCL; see below) and transient responses evolving over the course of a few seconds (galvanic skin response, GSR, sympathetic skin response, SSR, skin resistance response, SRR, or skin conductance response, SCR) (Venables & Christie, 1973). Tonic and phasic aspects of EDA interrelate, yet are dissociable.

Within the brain, psychological influences on EDA are thought to emerge from activity within reticular formation centers within the brainstem and thalamus, in turn influenced by cortical mechanisms controlling orientation to salient

information (Luria & Homskaya, 1970). Frontal lobe regions strongly influence the orienting electrodermal reflex (Venables & Christie, 1973). Correspondingly, the magnitude of EDA responses in humans is reduced following discrete lesions to the prefrontal cortex and also related "attentional centers" within the anterior cingulate and right parietal lobe (Zahn, Grafman, & Tranel, 1999). Moreover, individual differences in the frequency of discrete EDA responses correlate with the size of prefrontal lobe regions (Raine, Lencz, Bihrle, LaCasse, & Colletti, 2000). Functional imaging studies implicate ventromedial prefrontal cortex (Critchley, Elliot, Mathias, & Dolan, 2000) and anterior cingulate and amygdala (Williams et al., 2000) in phasic EDA responses to motivationally important stimuli. Nagai, Critchley, Featherstone, Trimble, and Dolan (2004a), using EDA biofeedback during functional neuroimaging, showed differential coupling of brain regions to phasic EDA responses (widespread enhancement within the anterior cingulate/dorsolateral prefrontal cortices and subcortical thalamic and brainstem centers) when compared to the tonic EDA level (which was inversely correlated with activity in ventromedial prefrontal cortex and subgenual cingulate). This latter observation links the EDA level to processes ascribed to the "default mode network" of brain function (Raichle et al., 2001).

Applications of Electrodermal Activity

Among the autonomic nervous system responses, EDA is a particularly useful parameter because EDA responses are easy to measure and to elicit reliably (much more difficult to suppress). However, EDA is sensitive to a wide variety of stimuli, hence careful interpretation is required. Changes in EDA also typically occur as part of a complex, patterned autonomic reaction wherein EDA may serve as a circumstantial marker of an accompanying physiological response. As noted, a number of functional variables can be derived from recorded EDA. The basal (tonic) level of electrodermal arousal reflected in SRL/SCL can be used to track individual differences in the general level of arousal and the integrity of diurnal rhythms: The skin resistance level rises during sleep and drops sharply in the morning on awakening, returning to approximately the same level of presleep resistance by the evening. Phasic electrodermal responses such as SRR and SCR are easily elicited by emotional stimulation or a change in attention and interact with the tonic basal level of electrodermal arousal. Thus EDA in a combined form has been widely applied as an index of physiological and emotional arousal in studies of stress responsivity, including challenges with pain shock, emotional films, and mental and physical effort (e.g., Folkins, 1970).

Psychological and Psychosomatic Illness

This relevance of such studies to understanding the psychological and physical manifestations of chronic stress is based on the notion that individuals with increased physiological (EDA) reactivity to stressors are most at risk of long-term detrimental health consequences. In clinical populations, higher skin conductance level and increased phasic responsivity are reported in anxiety patients (Raskin, 1975). In this context, EDA may be a more specific biomarker; patients with panic disorder and agraphobia showed delayed habituation and greater nonspecific phasic fluctuation compared with other anxiety patients (Birket-Smith, Hasle, & Jensen, 1993); patients with posttraumatic stress disorder (PTSD) also show slower habituation even in response to neutral stimulation (this has been suggested as a trait marker for PTSD susceptibility; Rothbaum et al., 2001).

In contrast, EDA hypo-responsivity and hyporeactivity are reported with patients with depression (Williams, Iacono, & Remick, 1985) and related to higher occurrence of suicidal attempts (Thorell, 1987). Faster EDA habituation is reported in patients with a history of suicidal attempt compared to those with non-suicidal attempts (Jandl, Steyer, & Kaschkaet, 2010). Hyporesponsivity and risk is also a feature of psychopathy (Hare, 1978). While in some countries EDA is incorporated in polygraphy used in criminal justice proceedings and forensic evaluations, it is worth noting that hyporesponsivity may be present across constitutional, or developmentally acquired, disorders of empathy.

Personality factors are commonly linked to differences in vulnerability to stress-related disease, the concept of Type A personality being particularly studied. Type A behavior is characterized by excessive competitiveness, aggressiveness, impatience, chronic haste, and striving for achievement. People with characteristics of Type A behavior are reportedly more prone to coronary heart disease (CHD) related to psychological (emotional) stress and its impact is mediated by brain-triggered autonomic nervous reactions as well as neuroendocrine responses. It is hypothesized that Type A individuals are physiologically hyperresponsive to stress stimuli, evoking greater sympathetic activity (accompanied by shifts in sympathovagal cardiac responses and enhancement within both adrenomedullary and hypothalamic-pituitary-adrenocortical systems). Type A behaviors such as impatience and hostility have been proposed to reflect underlying sympathetic reactivity. However, while EDA shows some promise as a functional biomarker for cardiac vulnerability and Type A personality, findings are inconclusive (Steptoe & Ross, 1981). Thus in psychosomatic medicine, EDA can be used to quantify individual differences in autonomic reactivity to salient challenges, where enhanced reactivity in one sympathetic axis (EDA) may signal risks (e.g., of hypertension or arrhythmia) mediated through related autonomic pathways.

Therapeutic Applications of Electrodermal Activity

EDA biofeedback has been studied as a treatment tool for anxiety states and stress-sensitive physical disorders. Biofeedback is a biobehavioral treatment approach where an individual/patient learns to gain volitional control over an involuntary bodily process, e.g., the "emotional arousal" associated with sympathetic innervation of the skin. In contrast to other biofeedback approaches including neurofeedback with electroencephalography, EDA biofeedback is easy to implement. Typically EDA biofeedback has been used to train people to reduce their sympathetic arousal with the aim to induce psychological as well as physiological relaxation states that alleviate stress-related tension. One of the earliest applications was for the treatment of tension headaches, where a significant reduction in frequency and intensity of patients' headaches was attained. EDA biofeedback relaxation therapy has been shown to be successful in treating the irritable bowel syndrome (IBS) (Leahy, Clayman, Mason, Lloyd, & Epstein, 1998), where 4 weeks of biofeedback relaxation training improved scores across a range of IBS symptoms (Leahy et al.). EDA biofeedback relaxation training has been tried for other specific psychological (anxiety disorders, hyperkinesis) and physical (hyperhidrosis, bruxism, weight control, migraine, tics, tremor) conditions. However, the research evidence base is limited and inferences regarding the effectiveness of these approaches are constrained by variation in treatment delivery. In recent years, it has become clear that EDA biofeedback arousal, i.e., training to increase sympathetic arousal in the skin, has therapeutic value. In neurological patients with drug-resistant epilepsy, electrodermal biofeedback was applied to reduce seizure frequency (Nagai, Goldstein, Fenwick, & Trimble, 2004b). Electrodermal biofeedback to increase the sympathetic arousal level was neuroscientifically motivated from the observation of an inverse relationship between the EDA level and the central cortical arousability quantified using electroencephalography. In a small randomized controlled trial, 1 month of electrodermal biofeedback training was associated with a significant decrease in seizure frequency, with 6 of 10 actively treated patients exhibiting more than a 50% seizure reduction at 3 months (and a subset reporting sustained effects at follow up over 3 years).

Conclusion

Electrodermal activity provides an accessible index of the brain's neural influence on the bodily organs, and hence a measure of the emotional capacities and psychophysiological vulnerabilities of individuals. As a route for biobehavioral intervention EDA shows promise, with potential advantages of low cost and implementability.

Electronic Health Record

Definition

The electronic health record (EHR) is a computer-based record of patient health information. It is generated by one or more encounters in any healthcare delivery setting. The EHR includes information on patient demographics, progress notes, medications, vital signs, clinical history, immunizations, laboratory results, and reports of diagnostic procedures. The EHR documents evidenced-based decision-making, quality management, and patient outcomes.

Although the term EHR is used interchangeably with the electronic medical record (EMR), there are differences. The EMR most often refers to a single healthcare event whereas the EHR includes the entire patient record of healthcare encounters.

Description

Computer-based health records have been shown to be far superior to paper records not only because they decrease error due to handwriting and documentation issues, but also allow for the portability of and timely access to data. Other benefits include the aggregation and privatization of health data to facilitate research and promote the further education and knowledge base of clinicians.

In addition to safe, efficient, and high quality care, patients expect privacy, rights to access, and the opportunity to give consent for research uses of their health information. An EHR system must satisfy its users regarding privacy, confidentiality, and security. In the United States, the Health Insurance Portability and Accountability Act (HIPAA) ensures that these goals are met (http://www.hhs.gov/ocr/hipaa/).

There are other practical, economic, political, and professional concerns that arise regarding the implementation of computerized documentation. Individual physicians and practice groups have concerns related to cost, time to implementation, and learning curves associated with the EHR. There are also questions about whether to convert current records retrospectively or prospectively.

Research has shown that the healthcare industry will save approximately 80$ billion dollars annually by adopting electronic documentation. National mandates dictate that by 2014 all health documentation be in a computerized form. The EHR has the potential to improve patient outcomes, improve coordinated care (optimally worldwide), automate adverse event and medical error disclosure, as well as to allow for more efficient diagnosis and treatment.

Definition

Emotional control can be thought of as a facet of emotion regulation, but refers primarily to attempts by an individual to manage the generation, experience, or expression of emotion, and/or one's emotional responses (Gross, 1999). Emotional control, like emotional expression, is tied the broader context of emotion regulation. Emotional control can occur as part of antecedent-focused regulation prior to generation of emotion or through response-focused regulation after an emotion has been generated (Gross, 1998a). Emotional control can refer to the ability to exercise influence over emotion, and modulate emotion through the use of cognitive or behavioral strategies (Gross, 1998b; Lazarus & Folkman, 1984). The ways in which individuals are able to achieve emotional control have implications for health and well-being (Beck, 1995; Berg, Skinner, & Ko, 2009).

Description

Emotional control has varied definitions in literature on stress and coping and emotion regulation. Emotional control includes efforts by the individual to alter the generation of emotion, emotional experience, and emotional expression. Strategies aimed at emotional control can impact health in both positive and negative ways and are contextually dependent on situation, individual differences in personality and social context, and well as demographic factors such as ethnicity, culture, gender, and age (Berg, Skinner, & Ko, 2009).

Emotional control is an important facet of emotion regulation and can be facilitated by types of emotion regulation. Antecedent-focused regulation can have an influence on emotional control (Gross, 1999). Antecedent-focused regulation refers to altering and regulating aspects of a situation and emotional experience prior to generation of emotion (Gross, 1998a). There are several ways that an individual may use antecedent-focused regulation for emotional control. Essential parts of antecedent-focused regulation are situation selection, selective attention, and cognitive appraisal. Situation selection is defined as deciding where to go, what to be exposed to, or who to be exposed to as a means of controlling emotion (Gross, 1998a). Selective attention is defined as choosing aspects of a situation to minimize emotional impact such as distraction or attending to less emotionally salient features of the situation (Gross, 1998a; Strecher & Rosenstock, 1997). Cognitive appraisal is defined as changing the meaning of situations so as to mitigate emotional impact such as looking at positive aspects or minimizing importance (Gross, 1999, 2007; Strecher & Rosenstock, 1997).

Use of antecedent-focused regulation strategies as a means of emotional control can lead to health outcomes, both positive and negative. For example, situation selection can reduce the likelihood that someone might encounter negative emotional experiences. However, selecting to avoid activities can potentially lead to decline in physical, emotional, and social functioning that may be associated with morbidity and mortality (Gross, 2007). Shifting attention, such as use of distraction, may be adaptive in the short-term (e.g., pain management) (Berg et al., 2009; Gross, 1998a). Prolonged use of distraction may not allow individuals to address aspects of problems that they can control or may prevent

accurate detection of symptoms (Gross, 1998a, 2007). Cognitive appraisal can prevent misinterpretations of situations known to impact emotional and physical health such as catastrophizing, emotional reasoning, or black and white thinking (Beck, 1995). However, if one appraises problems as nonthreatening then appraisals may not translate to appropriate emotional reaction or "over control" when it may be appropriate to react leading to worse outcomes (Lazarus & Folkman, 1984; Strecher & Rosenstock, 1997).

In contrast to antecedent-focused regulation, response-focused regulation occurs after emotion has been generated and includes direct attempts to alter experiential, physiological, and behavioral responses to the experience of emotion after the emotion has occurred (Gross, 1998a, 1999, 2002). Response-focused regulation is also a means of emotional control. Emotion can be controlled by situation modification. Situation modification is defined as changing aspects of a situation to reduce emotional impact. Situation modification relies on coping strategies such as generation of multiple solutions and problem solving (Gross, 1998a). Once an emotion has been generated, individuals may choose to actively solve the problem which can allow for emotional arousal to subside. Use of problem-solving skills may provide health benefit when problems are well-defined and controllable (Berg et al., 2009). However, when problems are ill-defined, ambiguous, and perceived as uncontrollable, use of problem solving may prolong stress, reactivity, and negative emotion. Thus, the way an individual chooses to control emotions can depend on the context of the problem.

Emotional control is an important facet of emotion regulation and can occur through efforts to minimize negative emotional experience prior to emotion generation (e.g., antecedent-focused regulation) or following an event through the use of coping strategies (e.g., response-focused regulation). Such skills are taught to individuals engaging in cognitive behavioral therapy for management of illness, psychopathology, and everyday problems (Beck, 1995). Cognitive and behavioral strategies can help individuals have greater control over emotional arousal that produces ill health effects (Gross, 1999). Emotional control can be achieved through provision of skills related to problem solving (Gross, 1998a, 1999). These include behavioral skills to facilitate emotional control such as stress management skills (e.g., deep breathing, progressive muscle relaxation), exercise, and/or, engaging in regular healthy behaviors such as sleep hygiene and diet. Similarly, using cognitive appraisal skills to alter ongoing emotional experience may be helpful. Use of antecedent- and response-focused regulation for emotional control can help downregulate negative emotion and reduce physiological reactivity which may confer health benefits (Gross, 1999, 2002). Inability to effectively control emotion can have detrimental effects on health and well-being. Difficulty in controlling emotional reactions has been linked to psychopathology such as personality disorders, anxiety disorders, as well as risky behavior all of which have adverse association with health (e.g., poor social support, prolonged interpersonal stress, substance abuse, risk-taking behaviors) and may have a neural basis (Gross, 2007; Strecher & Rosenstock, 1997).

Emotional Expression

Definition

Emotional expression refers to how one conveys emotional experience through both verbal and nonverbal behavior (Gross, 1998b, 1999). Emotional expression should be distinguished from emotional experience in that it is possible to experience emotions without expressing them. Emotional expression is an important part of emotion regulation and can affect health outcomes. Emotional expression is embedded in the broader domain of emotion regulation, which is defined as how individuals, either consciously or unconsciously, influence, experience, and express emotions (Gross, 1999). Emotion regulation unfolds over time in a given situation either before emotional experience, during emotional experience, or in response to emotional experience (Gross, 1998a). Emotion regulation involves coordination of several systems including how one thinks about emotion, physiological reactivity elicited by emotion, and behavioral responses such as emotional expression and utilizing coping strategies that either promote health or contribute to poorer health. Emotional expression can be adaptive or maladaptive and may be dependent on context (Gross, 1998a, 2002).

Description

Emotional expression is part of the emotion regulation process and functions as a way to communicate internal states to others. Emotional expression can include behavioral, nonverbal, and/or verbal expressions (Gross, 1998a). Emotional expression can be beneficial when adaptive and fit to a given situation. For example, suppression of emotion may be inappropriate in some instances such as displays of anger or sadness while at work. However, prolonged suppression of emotion can result in poorer health. Links between maladaptive emotional expression and prolonged suppression have been made to cardiovascular disease. Similarly, "venting" negative emotion may perpetuate negative emotion via physiological and social responses to venting. Thus, the popular idea that "letting it out" may be beneficial for well-being or health may be inaccurate (Gottman, 2000; Gross, 2002; Hatfield, Cacioppo, & Rapson, 1994). Expression of positive emotions may also help to in buffering

negative emotional experience and has been shown to impact the affiliative quality of marital relationships (Gottman, 2000). It is important to acknowledge that emotional expression involves many components of the emotion regulation process and that health effects can be dependent on contextual factors of the situation and individual difference characteristics such as age, ethnicity, and gender (Gross, 1999).

Emotional expression as a means of emotion regulation has its roots in the stress and coping paradigm originally put forth by Lazarus and Folkman (Gross, 1999; Lazarus, 1991). The stress and coping paradigm asserts that emotional expression can act as a coping strategy and thus may impact health and well-being. Lazarus and Folkman made a distinction between emotion-focused coping, defined as changing the internal state to meet the demands of the stressor (e.g., altering emotions associated with stressor, reappraisals of stressor) and problem-focused coping, defined as changing the environment to meet the demands of the stressor such as finding a problem solution (Lazarus). Emotion-focused strategies (e.g., controlling emotional expression, changing the way one thinks about a stressor, acceptance) were thought to be associated with poorer health outcomes (Lazarus). However, recent models of emotion regulation have recognized nuances of regulatory process as emotion regulation unfolds at points over time in a given situation.

Points of regulation specifically linked to emotional expression are defined as antecedent-focused regulation or as response-focused regulation (Gross, 1998a). Antecedent-focused regulation refers to altering and regulating aspects of a situation and emotional experience prior to generation of emotion (Gross, 1998a). In contrast, response-focused regulation occurs after emotion has been generated and includes direct attempts to alter experiential, physiological, and behavioral responses to the experience of emotion after the emotion has occurred (Gross, 1998a, 1999, 2002). Emotional expression can be altered through both antecedent-focused coping and response-focused coping.

The clearest link between emotional expression and health outcomes occur as a function of response-focused coping and how one chooses to express emotion after an emotion has been generated. Individuals may choose to express emotions in a productive way (conveying how they feel or felt through communication with others, journaling), in an aggressive manner (punching, kicking, self-mutilation), or suppress emotions all together (Gross, 2002; Kennedy-Moore & Watson, 1999). Emotional expression can include behavioral expressions of emotion such as engaging in risky health behaviors (e.g., substance use, overeating). Risky health behaviors may be useful for altering emotion and physiological reactivity in the short term but can damage health over time. The ability to use adaptive coping strategies can attenuate physiological reactivity (Gross, 1998b, 1999, 2007) and can confer health benefits. For example, adaptive coping mechanisms might reduce cardiovascular risk, promote feelings of control, and self-efficacy which are important in choosing positive health behaviors. Adaptive coping responses can protect against prolonged negative mood states associated with metabolic dysregulation, poor immune response, inflammatory processes, and insomnia (Gross, 2007). Conversely, maladaptive coping strategies such as substance abuse and risky behaviors can be associated with physical injury, poorer health status, morbidity, and mortality (Gross, 2007; Kennedy-Moore & Watson, 1999).

The effect of emotional expression on health may be contextually bound. Emotional suppression can decrease emotionally expressive behavior but simultaneously may not impact physiological responding. In certain instances, suppression of emotion may be effective as a coping mechanism but long-term suppression can negatively impact life satisfaction and depression. Emotional suppression can dampen emotional expression in the context of social interactions resulting in less positive social support which may lead to poorer health. Expression of emotion may also convey health benefits. For example, expression of emotion through writing

has been associated with better adjustment in cancer patients, especially in patients that may prefer to avoid or deny managing cancer-related problems. Emotional expression in the context of support groups for health problems may help patients to tolerate and find benefit through others' emotional expression as they react to an illness (Kennedy-Moore & Watson, 1999). In close relationships, being able to express emotions in a less negative way may reduce the negative emotional arousal that can affect members of a couple (Gottman, 2000; Hatfield, Cacioppo, & Rapson, 1994). It should also be noted that the expression of positive emotion can also contribute greater satisfaction in relationships and can be associated with more affiliation and less hostility as couples interact (Gottman, 2000).

Definition

Emotions are defined as multicomponent response tendencies that unfold over a relatively short span of time. Emotions occur in response to a stimulus or event. The emotional response consists of an appraisal process, during which individuals determine the personal significance of the stimulus or event (e.g., is it harmful or beneficial, does it affect personal goals). The emotional response also includes the subjective experience of emotion, cognitive processing, and physiological changes (e.g., activation of the amygdala and hypothalamus, and subsequent release of

epinephrine, norepinephrine, dopamine, and cortisol). Emotions are believed to have evolved to promote behaviors necessary to survive and thrive. Researchers often conceptualize emotions as varying along two dimensions: (1) valence (i.e., negative to positive); and (2) activation (aroused to unaroused). Discrete emotion theorists, in contrast, consider each emotion as a distinct entity. Researchers who examine emotional responses to a stimulus or event (e.g., emotional responses to stress) commonly measure multiple aspects of the multicomponent response. For example, when examining emotional responses to a laboratory stressor, researchers may measure cognitive appraisal components (appraisals of threat or harm), affective components (e.g., reports of anxiety and fear), and physiological components (e.g., rising cortisol levels).

Sometimes, the terms emotion, affect, and mood are used interchangeably. Many researchers, however, make distinctions among these terms. Whereas emotions are short-lived responses to stimuli, moods are relatively long-lasting emotional states, and are not always linked to a stimulus or event. Affect is a term used to describe the conscious, subjective aspect of an emotion, separable from any physiological response.

Emotions are defined as multicomponent response tendencies that unfold over a short span of time, and include cognitive processing, physiological responses, and the subjective experience of emotion (i.e., affect). Emotions are often conceptualized as varying in valence, from positive (e.g., happiness, excitement, contentment, curiosity) to negative (e.g., sadness, anger, anxiety, disgust). Subjectively, people experience positive emotions as feelings that reflect a level of pleasurable engagement with the environment. Negative emotions, in contrast, reflect a general feeling of distress. Emotions are thought to have evolved to promote the behaviors necessary to survive and thrive. Positive emotions facilitate approach behavior or continued action; experiences of positive affect prompt people to engage with their environments and partake in activities which are adaptive. Negative emotions, on the other hand, prompt withdrawal behavior and signal when a particular behavior or course of action may not be adaptive.

Description

There is some debate in the emotion literature about whether positive emotions and negative emotions are bipolar extremes of the same factor, or whether they are orthogonal or independent factors. Evidence suggests that positive and negative emotions may be managed by different structures in the nervous system (i.e., positive emotion activation in left frontal cortex; negative emotion activation in right frontal cortex), and that neurotransmitters may respond differently to negative versus positive emotions, which supports the notion that negative and positive emotions are orthogonal factors. In addition, in many studies, researchers have noted the unique contribution of negative and positive emotions (i.e., each contributed to outcomes after controlling for the other), and the low correlation between negative and positive emotion. Some studies, however, have observed moderate to strong (negative) correlations between positive and negative emotion (particularly when "state" vs. "trait" emotions are measured), and many studies do not find unique effects of negative and positive emotion. Research on the distinction between negative and positive emotions is ongoing; thus, while most consider positive and negative emotions to be orthogonal factors, some researchers consider positive and negative emotions to be opposite ends of the same scale.

There are several measures currently used to assess positive and negative emotions. Among them are two commonly used self-report measures that ask people to rate their experience of positive and negative emotions. Because these measures are assessing the subjective experience of emotion, they are more appropriately labeled measures of affect. The PANAS (Positive and Negative Affect Schedule) includes a 10-item Positive Affect (PA) scale and a 10-item Negative Affect (NA) scale. High scores on the PA scale reflect high energy and concentration (e.g., attentive, interested, alert), whereas high NA reflects a state of general distress (e.g., guilty, hostile, irritable). The POMS (Profile of Mood States) is another measure commonly used to assess positive and negative affect. The POMS has one PA scale reflecting "vigor" (e.g., alert, energetic, cheerful, active, lively), and four NA subscales measuring depression, anger, fatigue, and tension-confusion. For both the PANAS and the POMS, instructions can be modified to ask for current state (which is most likely to reflect "emotion"), as well as mood in the last day, general mood, or mood over the last few weeks or longer (note that mood is longer lasting compared to emotions, which are short-lived). Researchers often distinguish "state" PA and NA (current emotion, or mood in the last day) from "trait" PA (general mood or mood over the last few weeks or months). In addition to measuring the subjective experience of emotion, researchers have also used mood induction procedures to generate positive and negative emotions in the laboratory and observe their effects on outcomes. In general, research (largely correlational) suggests that positive emotions are beneficial for health, and that negative emotions are detrimental for health. Researchers urge caution in interpreting these findings, however, as most studies linking negative emotion and health do not control for the effect of positive emotions, and most studies linking positive emotion and health do not control for the effect of negative emotion.

There is some debate in the literature about the value of distinguishing individual positive and negative emotions (e.g., happiness, excitement, sadness, anger) versus aggregating positive emotions and aggregating negative emotions. Some research suggests that people are not sensitive to individual emotions and experience similar responses across emotions within a valence (i.e., positive or negative). However, there is also research to suggest that different emotions within a valence have different associations with outcomes (e.g., distinct positive and negative emotions are associated with distinct immune responses). Most researchers currently examine aggregated emotions, distinguishing only positive from negative, but increasingly research suggests that there may be value in distinguishing among emotions within a valence.

Empathy

Linda C. Baumann and Alyssa Karel

Definition

Empathy is the ability of a person to perceive, understand, and accept the experiences of another. It is having the capacity to identify with another's feelings without actually experiencing the situation. In a healthcare setting it is often therapeutic for clients going through difficult situations to have healthcare professionals that can be empathetic to their situations.

Empathy is different than sympathy, which is concern or pity for another person generated by a subjective perspective. Oftentimes this subjective perspective is a barrier to problem solving. The most therapeutic approach to clinical situations is often an objective empathetic approach.

Emphysema

Chronic bronchitis; Chronic obstructive pulmonary disease

Definition

Emphysema is defined as the pathological enlargement and destruction of lung alveoli. Along with chronic bronchitis, which describes the clinical manifestation of chronic cough with

sputum production, these two terms have traditionally been used to refer to the two phenotypes of chronic obstructive pulmonary disease (COPD). Recently, however, the Global Initiative for Chronic Obstructive Lung Disease (GOLD) has advocated defining COPD based on airflow limitation that is not fully reversible, is progressive, and is associated with an abnormal inflammatory response of the lung to noxious particles or gases. As patients with COPD usually have overlapping features of both emphysema and chronic bronchitis, the distinction is rarely of clinical significance.

Description

COPD remains one of the most common causes of morbidity and mortality globally. In the United States in 2000, it accounted for eight million outpatient visits, 1.5 million emergency room visit, and 673,000 hospitalizations. COPD is currently the fourth leading cause of death in the USA and is projected to become the third most common cause of death worldwide in 2020 (Global Initiative for Chronic Obstructive Lung Disease, 2008). One reason for this rise is the strong, dose-dependent relationship between cigarette smoking/exposure and the prevalence of COPD, although other genetic and environmental factors also play important roles, since many smokers never develop clinically significant disease. It has been known, for instance, that genetic defects causing severe deficiency of the protease inhibitor α1-antitrypsin lead to a form of early-onset COPD, especially in those who are also smokers. Other known risk factors include exposure to occupational dust and chemicals, indoor and outdoor air particle pollutants, as well as low birth weight. On a cellular level, it has been demonstrated that inhaled cigarette smoke and other noxious particles promote inflammation through the recruitment of neutrophils, macrophages, lymphocytes, and eosinophils. This in turn activates proteinases that degrade lung parenchyma and cause mucus hypersecretion, leading to impaired gas exchange, fibrosis of small airways, expiratory flow obstruction, and hyperinflation (Barnes, Shapiro, & Pauwels, 2003; Eisner et al., 2010).

Patients with COPD typically present with cough, sputum production, and exertional dyspnea. The hallmark of the disease, expiratory airflow obstruction, may be present for years before medical attention is sought (Hogg, 2004). While early on the physical examination may be normal, most patients will demonstrate diminished air movement with a prolonged expiratory phase and wheeze on exam. Pulmonary function testing with spirometry is used to characterize the degree of airflow obstruction and provide prognostic information. When airflow obstruction becomes severe, cyanosis may develop as a manifestation of hypoxemia, and the patient may adopt pursed-lip breathing and the classic "tripod" position to recruit accessory muscles and improve expiratory flow. Another marker of poor prognosis is the development of pulmonary hypertension from chronic hypoxemia, which can result in right heart failure or cor pulmonale. Death from respiratory failure is unfortunately a common outcome for patients with end-stage COPD (Reilly, Silverman, & Shapiro, 2006).

Many patients with COPD will also experience episodic exacerbations, characterized by increased shortness of breath and changes in pattern and quantity of sputum. These are often triggered by viral or bacterial infections and, depending on severity, may require hospitalization for treatment. For exacerbations, inhaled β-agonists and anticholinergic agents, antibiotics, glucocorticoids, and supplement oxygen for hypoxemia are the mainstay of pharmacological therapy. Noninvasive positive pressure ventilation and conventional mechanical ventilation can be used to stabilize patients in severe respiratory distress. For treatment of stable COPD, only smoking cessation and oxygen therapy in those with chronic hypoxemia have been shown to improve survival. Inhaled β-agonists and anticholinergic agents can provide symptomatic benefit, while inhaled glucocorticoids can be used to reduce exacerbations. Pulmonary rehabilitation has also been shown to improve quality of life and exercise capacity as well as reduce

hospitalizations. Finally, in select patients with severe COPD but limited comorbidities, lung transplantation can be pursued and provides significant symptomatic and survival benefit (American Thoracic Society, 2004).

Employer-sponsored assistance programs

Definition

Employee Assistance Programs (EAPs) are programs offered to employees; they include policies and procedures for identifying or responding to employee difficulties that may or may not interfere with job performance (Walsh, 1982). These programs often provide counseling or treatment to those who require these services, and can also be provided to the employee's family members. EAPs are aimed to be preventative services, and these services can address psychological issues, alcohol, and drug abuse (Muto, Fujimori, & Suzuki, 2004). Other areas include, but are not limited to, health, marital, family, financial, legal, or stress issues that may influence job performance (EAPA, 2010). EAPs are beneficial in helping employees balance demands while meeting employer's goals of workplace productivity (Jacobson, 2010).

Description

Employee benefit assistance programs typically include programs that address a variety of personal and workplace issues that impact job performance such as stress management, weight reduction, workplace violence, and financial management.

EAPs were modeled after Alcoholics Anonymous (AA) programs, and both AA and EAPs understand the importance of acknowledging the problem as the initial step of treatment (Walsh, 1982). Since alcoholism has negative impacts on job performance, alcoholism was the first problem addressed by EAPs, followed by substance abuse. It was later recognized that many substance abuse problems have roots in psychosocial problems, which further expanded the outreach of EAPs. EAPs use the importance of retaining the job as a motivating factor to have employees seek help. That is, the services can help fix a problem or difficulty that could threaten employment.

The services offered by EAPs have many positive impacts on the employees receiving them, as well as the organization providing them. Reported benefits include a reduction in expenses associated with medical claims, accident benefits, mental health care costs, absenteeism, lost wages, medical costs, and employee turnover (Hargrave, Hiatt, Alexander, & Shaffer, 2008).

EAPs have a variety of components, including written policies and procedures, labor and management cooperation in program development, referral systems, program information conveyed to the work force, health insurance covering the treatment, and total confidentiality (Walsh, 1982). These factors are integral in the success of the EAP (Richard, Emener, & Hutchison, 2009). The policy statement, a statement in which the institution states what the philosophy and the intent of the program is, keeps the EAP on target of the goals. This statement should make it clear that human problems can interfere with work performance, but are inevitable; assistance is available to aid these problems, and the employee will not be terminated on the basis of that problem. The services should be administered through the EAP confidentially and professionally, which helps the employees feel secure in their recovery. The EAPs should be accessible, and employees should be able to receive the services in a timely and efficient manner (Richard et al., 2009).

There are various methods of delivery of services depending on the corporation and EAP model. In "internal" EAPs, the professionals delivering the services are employed with the company offering the EAP, whereas "external" EAPs hire service professionals who are outside contractors from the company. "External" methods are most commonly found. However, a third method, "combination" or "hybrid" EAP, is a delivery system in which the professionals began as internal employees, and then expand services to other workplaces. The "hybrid" EAP is a way in which smaller companies can share the cost of an EAP. Additionally, services can be accessed in a variety of ways, including in-person, via phone, or via the Internet (Jacobson, 2010).

EAPs have become popular within businesses. Within USA state and local government in 2008, more than 75% of employees have access to EAPs. About 39% of employees working within the public sector, part-time, had access to EAPs, and 54% of full-time workers in the public sector had access. Of those working in the private sector, 15% of part-time workers and 28% of full-time workers had access to EAPs (U.S. Department of Labor, Bureau of Labor Statistics, 2008).

Empowerment

Mann Hyung Hur
Public Administration, Chung-Ang University, Seoul, Korea

Definition

The origin of empowerment as a form of theory is traced back to the Brazilian educator Freire (1971), when he suggested a plan for liberating the oppressed people through education. Empowerment is a form of power that helps people gain control over their own lives. It is described as a social process that fosters power in people, their communities, and in their society (Page & Czuba, 1999).

The process of empowerment can be synthesized into five progressive stages: an existing social disturbance, conscientizing, mobilizing, maximizing, and creating a new order, as seen in Fig. 1. Empowerment has two interrelated forms such as individual empowerment and collective empowerment. Each form has its own components. A set of four components, including meaning, competence, self-determination, and impact, are found in individual empowerment. A set of four components, including collective belonging, involvement in the community, control over organization in the community, and community building, are explored in collective empowerment. The goal of individual empowerment is to achieve a state of liberation strong enough to impact one's power in life, community, and society. The goal of collective empowerment is to establish community building so that members of a given community can feel a sense of freedom, belonging, and power that can lead to constructive social change (Hur, 2006).

The term, empowerment, has become a widely used word in the social sciences in the last decade across a broad variety of disciplines, such as community psychology, political theory, social work, education, women studies, and sociology. Community psychology is one of the disciplines in which the word *empowerment* is most frequently used. The typological approach to the study of empowerment is useful for field workers, social workers, community psychologists, and educators who help the disadvantaged (Hur, 2006). These people, including the disadvantaged, the aged, and the young, can actualize the latent powers that an individual or group possesses, or enable them and use their capacities and power more effectively (Weil & Kruzich, 1990). The process and components can be guidelines for practitioners who hope to develop the latent power of the "have-nots," actualize

their upward mobility, and finally establish a value of justice in a given society.

Definition

Endocrinology is the study of the endocrine system and its diseases. The endocrine system includes hormones (chemical mediators) and the organs/cells which secrete them. Endocrinology includes the study of the biosynthesis, storage, chemistry, and physiological function of hormones and the tissues that secrete them. The endocrine system consists of different parts of the body that secrete hormones directly into the blood rather than into a duct system. Hormones have many different functions and modes of action. They may act locally or away from their site of origin. They often interact with other biological systems.

End-of-Life Care

Andrea Croom
Department of Psychology, University of Texas Southwestern Medical Center, Dallas, TX, USA

End-of-life issues; Terminal care

Definition

End-of-life care is a general term used to describe all aspects of care received by patients with a terminal illness or terminal condition that has become advanced, progressive, and/or incurable. End-of-life care has become increasingly important in the past century as life expectancies have increased and causes of death have predominantly moved from acute illnesses (e.g., infections) to chronic and terminal illnesses (e.g., cancer and heart disease). The general goal of end-of-life care is to help patients achieve a "good death" as they define it. End-of-life care is provided through palliative care and hospice services and frequently incorporates complementary and alternative medicines (e.g., massage therapy, pet therapy, music therapy, aromatherapy, acupuncture, etc.). These services aim to improve patient *quality of life* through reducing pain and managing symptoms, addressing spiritual and emotional needs, and providing family/caregiver support.

Description

Issues for Patients (Advance Care Planning)

End-of-life care emphasizes the importance of patient autonomy through advance care planning, which is the process of patients, healthcare professionals, and caregivers discussing and formally documenting the patients' preferences for healthcare treatment as death approaches. The Patient Self Determination Act (PSDA) passed by the United States Congress in 1990 requires healthcare facilities that receive federal funding to educate patients and the community about advance directives. Advance directives are oral and written instructions about the patients' goals and wishes concerning future medical care that becomes effective only when a person cannot speak for him or herself. Decisions are commonly made about desires for mechanical ventilation (e.g., respirator), nutrition, and hydration (e.g., feeding tubes), kidney dialysis, and antibiotic treatments. Advance care planning also involves making decisions about receiving cardiopulmonary resuscitation (CPR) when vital functions cease. Patients who do not wish to receive CPR can complete a Do Not Resuscitate (DNR) order, which is kept as part of their medical file. Finally, patients are able to appoint a durable medical power of attorney (sometimes referred to as a healthcare proxy). This is the person who will be responsible for making decisions for the patient about healthcare treatment after the patient lacks the capacity to do so for him or herself. Advance care planning should be formally documented as well as verbally communicated between patients, caregivers, and healthcare professionals to ensure that the patients' wishes are known and understood. All states legally recognize some form of advance directives.

Issues for Healthcare Professionals

Healthcare professionals are responsible for many important aspects of end-of-life care. Healthcare professionals must formulate and communicate information to patients about their prognosis (i.e., how long the patient is expected to live). Developing an accurate prognosis is difficult to do considering the unpredictability of disease, the large number of life-extending technologies available, and the great number of unknown and unmeasureable variables that influence how and when a person will die. Communicating this information to

patients is equally difficult due to concerns about over- or under-estimating life expectancy, instilling or destroying hope, and cultural differences about discussing death. Healthcare professionals are also responsible for helping patients to engage in advance care planning and determining when specific treatments are not likely to benefit the patient (i.e., medically futile treatments). Healthcare professionals' major responsibility is to identify and manage symptoms, which typically become more severe as the illness or condition progresses. These symptoms commonly include: (1) pain, (2) increased sleep, drowsiness, or unresponsiveness, (3) decreased needs for food and fluids, loss of appetite, nausea or vomiting, (4) decreased socialization and increased withdrawal, (5) depression, (6) confusion about time, place, or identity (i.e., delirium), (7) changes in bladder or bowel control, (8) changes in temperature regulation (e.g., skin feels cool), and (9) respiratory changes (e.g., irregular and shallow breaths). Finally, healthcare professionals aid in assessing the patients' capacity to make healthcare decisions (i.e., capacity assessment).

Issues for Caregivers

Caregivers play an important role in end-of-life care as family members and friends are often responsible for most of the day-to-day care of patients during the end of life. The risk for caregiver stress is high as caregivers have to balance their normal daily activities, additional care giving responsibilities, efforts to help the patient adjust to the illness, and their personal emotional reactions to and fears about the illness. Even though family members report high levels of satisfaction with the care-giving experience, they also report more depressive symptoms and psychosocial stress than the general public. As the illness progresses, there are additional caregiving needs and the psychosocial distress of caregivers becomes more prevalent. Untreated psychosocial distress in caregivers is associated with poorer patient care, increased health problems for caregivers, and more severe grief reactions after patient death. Caregivers must learn how to care for the patient while continuing to practice good self-care. Caregivers also have the additional stress of surrogate decision making when the patients lacks the capacity to make their own healthcare decisions.

Ethical Issues

End-of-life care is an area of medicine that frequently involves ethical dilemmas. The majority of laws related to end-of-life care are governed by individual states and there is wide variation in how the states approach these issues.

Early debates focused on determining when a patient is legally dead. Death was traditionally considered the point at which a patient's vital physical functions cease; however, advances in life support technology have made it more difficult to determine when someone's body is no longer functioning. The Uniform Determination of Death Act (UDDA), written by the President's Commission on Bioethics in 1981, confronts the complexities concerning the declaration of death. The UDDA states that a person can be declared dead when *either* the heart and lungs *or* the brain and brain stem stop functioning permanently, but specific guidelines are determined by individual states. Declaring the point at which a patient has died can be an important issue in organ donation.

One of the most prominent debates related to end-of-life care has been the issue of euthanasia (also referred to as "hastened death"). Euthanasia is an act where a third party, usually implied to be a physician, terminates the life of a person either passively or actively. Physician-assisted suicide is a specific form of euthanasia where a doctor provides a patient with a prescription for drugs that the patient can choose to voluntarily use to end his or her life. The main distinction between physician-assisted suicide and active euthanasia is that the physician is not the person physically administering the drugs. The Oregon Death with Dignity Act (1997) and the Washington Death with Dignity Act (2008) made it legal in these two states for patients to hasten their own death with a prescribed lethal dose of medication from a physician.

There are several unique patient populations which carry their own ethical concerns. First, until recently children with terminal conditions have been granted limited autonomy in making decisions about their end-of-life care. As recently as the 1960s, the consensus was that children should not be informed of a terminal diagnosis because they would not be able to understand and would find the news too upsetting. Parents have legal rights to make decisions for their children, but many healthcare professionals now feel that it is beneficial for children to be included in healthcare discussions and to be permitted to make their wishes known. Ethical dilemmas arise when parents and children disagree about healthcare decisions, when two parents with equal custodial rights disagree about healthcare decisions, or when parents refuse physician treatment or do not appear to be acting in the "best interest" of their child. Second, culturally diverse populations have been found to favor different treatment preferences (e.g., African Americans and Hispanics are more likely than European Americans to express a preference for life-sustaining treatment), to engage less frequently in advance care planning, to use services such as hospice less frequently, and to report higher levels of insufficient pain management. Many cultures do not prioritize patient autonomy and prefer to pass decision-making responsibilities to others in the family. Healthcare professionals must balance respecting cultural differences while still sufficiently providing end-of-life care and informing patients of their options.

Definition

Endogenous opioids are neuropeptides with morphine-like activity that are naturally synthesized within the body. These neuropeptides have widespread distribution throughout the central and peripheral nervous systems, and various endocrine and other tissues. Opioids function as neurotransmitters and hormones, with a wide variety of biobehavioral effects in health and disease. Their effects on physiological and psychological responses to intense aversive and appetitive stimuli suggest potentially important roles in the etiology and treatment of self-regulatory disorders of appetite, affect, and adaptation to stress.

Description

Classification of Opioid Peptides and Receptors

Endogenous opioids systems include several different neuroactive peptides that are linked, in turn, to a matrix of distinctive receptor systems. The opioid peptides are divided into basic subgroups, e.g., endorphins, enkephalins, and dynorphins, based on their biosynthetic parent molecules. A separate group of endomorphins has been identified, but these peptides are not yet well characterized. Opioid receptors are part of the family of G-protein-coupled receptors and are classified into multiple receptor types and subtypes based on relative affinity for selective agonists and antagonists. For example, μ (mu) receptors demonstrate high affinity for morphine and endomorphins, while δ (delta) receptors are highly selective for enkephalins, and κ (kappa) receptors show high affinity and activity for dynorphins. Another putative receptor type, the ε (epsilon) receptor, has been postulated to explain beta-endorphin activity not mediated via the other receptor types.

Distribution of Opioid Peptides and Receptors

Endogenous opioids and receptors are localized in the central and peripheral nervous systems, including neuroendocrine stress pathways, and in brain areas mediating reward and reinforcement. For example, opioid peptides and/or receptors are found in afferent and integrative pain nuclei, as well as in the two major stress effector pathways, the hypothalamic-pituitary-adrenocortical (HPA) axis and the hypothalamic-sympatho-adrenomedullary (SAM) axis. Enkephalins have an abundant distribution throughout the limbic and sympathetic systems, while endorphin-containing cells are prominent in the hypothalamus and in the anterior pituitary. Dynorphins are widely distributed throughout both central and peripheral nervous systems. Opioid systems are intimately incorporated into peripheral organs including the heart and the gastrointestinal system. The diversity of opioidergic molecular representation yields, in turn, a diversity of functions, with important behavioral and physiological effects.

Role of Opioids in Stress, Neuroendocrine Reactivity, and Homeostasis

Endogenous opioids are important regulators of both the anterior and the posterior pituitary. Endogenous opioid mechanisms inhibit both the SAM and the HPA axes, suggesting opioidergic input to corticotropin-releasing factor neurons in the paraventricular hypothalamus. Opioids influence stress-induced pituitary release of adrenocorticotropic hormone (ACTH) and prolactin, as well as release of growth hormone and luteinizing

hormone. In the posterior pituitary, endogenous opioids inhibit release of both vasopressin and oxytocin. Therefore, regulation of the HPA axis and other important neuroendocrine pathways is mediated, in part, via endogenous opioids.

Peripheral opioid peptides and receptors are especially prominent in pituitary systems intimately involved in maintenance of homeostasis during stress. For example, beta-endorphin is localized in anterior and intermediate pituitary and is co-stored and co-released with ACTH. Therefore, activation of the HPA cascade is associated with pituitary release of beta-endorphin into the systemic circulation, where it has critical roles in the integrated response to psychological stressors.

The SAM axis, including the peripheral sympathetic nervous system and the adrenal medullae, is subject to central opioidergic control in the hypothalamus and elsewhere (McCubbin, 1993). CNS opioids are capable of both excitatory and inhibitory functions, and these effects are especially pertinent to biobehavioral function and dysfunction. Opioids have been shown to inhibit sympathetic and adrenomedullary responses at multiple levels of the SAM axis. For example, peripheral enkephalins are found in autonomic ganglia and in the spinal sympathetic cell columns. Enkephalins have been shown to inhibit release of catecholamines from peripheral sympathetic nerve endings as well as from the adrenal medullae.

Opioids in Health and Disease

Endogenous opioids play important roles in motivational integration of appetitive and aversive behavior and are critical in the maintenance of visceral homeostasis. The importance of these basic mechanisms of adaptation suggests that opioid dysfunction could underlie a variety of disorders involving dysregulation of appetite, affect, and neuroendocrine reactivity.

Appetitive Mechanisms Maintaining Chemical and Behavioral Dependencies

Opioid input to mesolimbic dopaminergic and other CNS systems suggests a potentially important role in appetitive reward and reinforcement mechanisms that maintain behavioral and chemical dependencies (Koob & Le Moal, 1997). Moreover, the important role of endogenous opioids in mediation of CNS reward systems may point to better treatment strategies in substance abuse and other disorders of appetite regulation (Reece, 2011). One overarching theory is that if opioids mediate the CNS reward mechanisms in dependency, then pharmacological opioid blockade may disengage brain mechanisms that reinforce and maintain a variety of different chemical and behavioral dependencies. For example, clinical trials are currently underway to examine the potential therapeutic effects of opioid antagonists, either alone or in combination with other drugs, in several appetitive disorders, including nicotine and alcohol dependence, and obesity. (Note: The efficacy of opioid antagonists in treatment of heroin/morphine dependencies operates via multiple complex mechanisms.) Therefore, opioid brain mechanisms may point to novel strategies for development of new behavioral and pharmacological treatments for dependencies and other diseases of appetite regulation.

Acute and Chronic Pain

Opioid systems contribute to important endogenous analgesic mechanisms, such as stress-induced analgesia and the hypoalgesia accompanying elevated blood pressure. These effects on pain sensitivity may be intimately associated with higher CNS integration of pain perception. For example, endogenous opioids do much more than simply inhibit pain perception; they may also have significant effects on regulation of affective responses to both painful and nonpainful aversive stressors. This observation reinforces the notion that endogenous opioid systems play an important role in the higher-level integration of affect in the appraisal of emotionally meaningful stimuli.

Endogenous opioidergic analgesia appears to be important for coping with both acute and chronic pain. Evidence suggests that chronic pain patients have reduced opioid levels in

plasma and cerebrospinal fluid. This is consistent with the opioid depletion hypothesis, which proposes that chronic pain is associated with progressive depletion of endogenous opioid analgesic neurochemicals and/or downregulation of opioid receptors (Bruehl, McCubbin, & Harden, 1999). This depletion of analgesic opioids results in dysfunction of an important endogenous mechanism for coping with chronic pain. Opioids may also have a role in the expression or maintenance of self-injurious behavior.

Depression and Posttraumatic Stress Disorder (PTSD)

Endogenous opioids play an important role as physiological mechanisms for coping with psychological stress, and these systems have been implicated in stress-related disorders, including depression and PTSD (Merenlender-Wagner, Dikshtein, & Yadid, 2009). Opioid blockers can reverse stress analgesia and performance deficits in learned helplessness, and can worsen symptoms of PTSD. Persons exposed to traumatic stress may utilize their endogenous opioid analgesic and/or affect regulatory mechanisms to cope. Thus, the role of opioids in HPA axis regulation, endogenous analgesia, and multiple CNS pathways provide a neurobiological rationale for role of opioids in regulation of affect and coping with traumatic stress.

Cardiovascular Disease

A biobehavioral link between opioids and risk for cardiovascular disease is found in work with the opioid antagonists, naloxone and naltrexone. These studies suggest that opioids can inhibit sympatho-adrenomedullary and blood pressure responses to psychological stress in young persons with normal circulatory risk profiles. However, young persons at increased risk for hypertension show reduced opioid inhibition of sympathetic, HPA, and circulatory responses to stress (McCubbin, 1993). This apparent dysfunction of inhibitory opioids may underlie exaggerated blood pressure reactivity to stress and its attendant cardiovascular health consequences. Moreover, there is some evidence to suggest that opioid hypoalgesia is associated, at least in part, with blood pressure elevations and increased risk for hypertension development. Recent evidence points to gender differences in opioid effects on blood pressure control that are dependent, in part, on estrogen. The relationship between reduced opioid inhibition of the HPA and SAM axes, blood pressure dysregulation, and hypoalgesia requires additional work to better characterize these complex interactions.

Opioids and Behavioral Therapies

Behavioral control of endogenous opioid tone may become an important strategy in prevention and treatment of self-regulatory disorders of appetite and adaptation to stress. Interestingly, studies of aerobic fitness, relaxation, and systematic desensitization suggest that these forms of stress management operate, at least in part, via activation of endogenous opioid mechanisms (McCubbin et al., 1996). For example, opioid blockade with naltrexone can reverse the reductions in cardiovascular stress reactivity associated with aerobic fitness and progressive relaxation training. Thus, in persons at risk for hypertension who lack robust opioidergic inhibition of the SAM axis, some behavioral stress-management interventions can restore normal opioid inhibitory function. Behavioral prevention and treatment strategies that target normalization of endogenous opioid tone may become more common as sophistication of these peptide systems grows.

Summary

The endogenous opioid neuropeptides and receptors form a diverse set of basic neuroendocrine systems that modulate behavioral and physiological reactions to aversive and appetitive stimuli. These systems have become critical for understanding integrated responses to psychological stress in health and disease. Better understanding of these neuropeptide systems will provide insight into the developmental etiology and new

treatment strategies for self-regulatory disorders of appetite, affect, and adaptation to stress.

Definition

Endometriosis (EM) is a common, benign disorder defined by the presence of endometrial tissue outside of the uterus (Giudice, 2010). EM can be asymptomatic, but it may be associated with severe dysmenorrhea (painful menstruation or "cramps"), pelvic pain (intermittent non-menstrual or continuous pain in the pelvic area), dyspareunia (pain during sexual intercourse), and infertility in affected women. The prevalence of pelvic EM is 6–10% in the general population whereas it approaches 35–50% in women with pain, infertility, or both (Houston, 1984; Sensky & Liu, 1980). The etiology of the disease appears to involve a complex interplay of multiple genetic, environmental, immunologic, and potential psychological factors (Guo, 2009); however, the ultimate pathogenesis of EM is unknown to date. Surgical assessment, by laparoscopy or laparotomy, remains the diagnostic gold standard in order to diagnose EM. The extent of the disease is classified by the American Society for Reproductive Medicine (ASRM) revised classification system for EM (rAFS score, American Society for Reproductive Medicine [ASRM], 1997). The rAFS scoring system categorizes EM into four stages (I through IV), with the higher stages representing more extensive disease. While rAFS staging tends to correlate with infertility, the severity of EM does not show consistent

associations with pain ratings, suggesting that further mechanisms mediate pain perception in women with EM (Asante & Taylor, 2011).

The successful treatment of EM-associated symptoms typically requires medical as well surgical interventions: Medical therapies include agents that suppress ovarian function and limit the growth of endometriosis, such as androgens, progestagens, GnRH agonists, and contraceptive steroids. The treatment of EM-associated pain has been well studied and most major medical therapies appear to be superior to placebo. EM-associated infertility, however, does not respond to medical therapies alone. Surgical treatment (via laparotomy or laparoscopy) as well as assisted reproduction techniques were found to be beneficial in restoring fertility in EM (Giudice & Kao, 2004; Practice Committee of the American Society for Reproductive Medicine, 2004). Surgery commonly provides temporary pain relief, but symptoms recur in 50% of the women within 2 years. Because of the associated pain and due to the fact that so far there is no cure for EM, affected women often report higher levels of distress than healthy controls (cf., Kaatz, Solari-Twadell, Cameron, & Schultz, 2010). In line with this, increased rates of anxiety and depressive symptoms as well as impaired overall quality of life were found in EM. Also, women suffering from EM have an increased risk of several medical conditions, including hypothyroidism, fibromyalgia and chronic fatigue syndrome, autoimmune inflammatory diseases, allergies, and asthma (Sinaii, Cleary, Ballweg, Nieman, & Stratton, 2002). These data suggest a common immunological and endocrinological aspect to EM and these conditions, which in turn might further increase disease burden. As a consequence, a multilevel approach to EM should include an evaluation of psychological distress, and in some women psychological interventions can be helpful in order to reduce impairment.

Definition

Blood vessels consist of three layers. The inner layer is the intima, which is made up from endothelial cells. The middle layer, the tunica media, consists of mainly smooth muscle cells, which are important for the maintenance of the vessel diameter. Finally, the outer layer, the tunica externa, consists of connective tissue. The endothelium is a dynamic organ with several functions, such as regulation of the vascular tone, platelet aggregation, thrombosis, and adhesion of leucocytes, which are vasoprotective.

Description

The peripheral vascular system consists of arteries, capillaries, and the veins. The arteries supply the organs with blood, the capillaries allow for the exchange of metabolites between the blood and the organs, and the veins facilitate the return of the blood to the heart. Blood vessels consist of three layers. The inner layer is the intima, which is made up from endothelial cells. The middle layer, the tunica media, consists of mainly smooth muscle cells, which are important for the maintenance of the vessel diameter. Finally, the outer layer, the tunica externa, consists of connective tissue. The relative thickness of these individual layers is dependent on the position of the vascular tree of the vessel wall. For example, in capillaries, the vessel wall mainly consists of endothelial cells to optimize metabolite exchange (Vander, Sherman, & Luciano, 2006).

The endothelium is a dynamic organ with several functions, such as regulation of the vascular tone, platelet aggregation, thrombosis, and adhesion of leucocytes, which are vasoprotective. However, when damage to the endothelial cells occurs, this can result in endothelial dysfunction, which is a precursor of atherosclerosis (Lerman & Zeiher, 2005). The activity of the endothelial cells can be influenced by sympathetic nerve activity, hormones, and inflammatory molecules among other factors (Levick, 2003). From a behavioral medicine perspective, endothelial function has been associated with health behaviors such as physical activity (Green et al., 2003) and smoking (Toda & Toda, 2010). In addition, sympathetic activation through acute exercise or mental stress can influence vascular function (Joyner & Halliwill, 2000).

Assessing Endothelial Function

An important function of endothelial cells is the maintenance of vascular tone, which is emphasized by the release of several vasoactive substances by the endothelial cells. Therefore, it is not surprising that most in vivo endothelial function assessments are concerned with the capacity of the endothelium to vasodilate. A principal vasodilator released by the endothelial cells is nitric oxide (NO). Following the conversion from L-arginine under the influence of nitric oxide synthase, NO starts a cascade of conversions which leads to smooth muscle cell relaxation, i.e., vasodilation (Sandoo, Veldhuijzen van Zanten, Metsios, Carroll, & Kitas, 2010). It is outside the scope of this section to describe the mechanisms of NO and other vasoactive substances in detail.

Various methods are available for the assessment of endothelial function in the peripheral circulation. Most functional assessments examine vasodilation in response to a standardized stimulus, with an attenuated vasodilatory response indicative of endothelial dysfunction. As described above, a major contributor to vasodilation bioavailability of NO starts a cascade of events, which results in the relaxation of the vascular smooth muscle cells. Therefore, impaired vasodilation can be due to both reduced NO bioavailability in the endothelium or impaired capacity of the vascular smooth muscle to dilate. Consequently, most endothelial function assessments involve both measures of endothelial-dependent vasodilation (related to NO bioavailability) and endothelial-independent vasodilation (related to vascular smooth muscle function) (Sandoo et al., 2010). Given the difference in anatomy and function of arteries, the functional assessments vary depending on their position in the arterial tree. The microvasculature involves conduit arteries, such as the brachial and femoral artery, whereas microvasculature entails arterioles or resistance vessels. In addition to the functional assessment described below, the structure of the

vessel walls can be examined with intima medial thickness (for conducting artery, such as carotid) and nailfold capillaroscopy (for capillaries) (Sandoo et al., 2010).

Microvascular function can be assessed using iontophoresis or forearm blood flow. Iontophoresis assessment involves the administration of vasoactive substances through the skin by applying a small electrical current. The most commonly used substances are acetylcholine (ACh) for the assessment of endothelium-dependent vasodilation and sodium nitroprusside (SNP) for endothelium-independent vasodilation. Perfusion of the vessels in the skin is assessed using either laser Doppler flowmetry, when examining a single point, or laser Doppler imaging, when the area of interest is a larger area of skin (Turner, Belch, & Khan, 2008).

Forearm blood flow is most commonly used together with venous occlusion strain gauge plethysmography. For this assessment, venous outflow of the vessels is occluded, while allowing arterial inflow (Joyner, Dietz, & Shepherd, 2001). Changes in arm circumference are assessed using strain gauge plethysmography, with the slope of the increase in arm circumference reflecting of blood flow. The advantage of this assessment is that it can be carried out at several time points throughout a testing session, so immediate changes of blood flow in response to mental stress or exercise can be investigated using this method. Strain gauge forearm blood flow assessments are also carried out in response to intravenous infusion of vasoactive substances, such as ACh and bradykinin.

Macrovascular function can be assessed using flow-mediated dilation. Blood flow to the arm will be occluded for a period of 5 min by inflating a brachial cuff placed around the arm to at least 50 mmHg above systolic blood pressure. Release of the cuff will result in a sudden inflow of blood into the arm. The increase in shear stress as a result of the surge of blood (reactive hyperemia) will induce vasodilation in healthy arteries, which is dependent on NO production of the endothelium. Endothelial-independent vasodilation is assessed by investigating the vasodilation in response to the administration of glyceryl trinitrate (GTN). Macrovascular dilation is most commonly quantified by recording the vessel diameter using high-resolution ultrasound (Corretti et al., 2002).

Finally, arterial stiffness is related to the compliance of the vessel wall and can be classified as both a structural as well as a functional measure of endothelial function. This assessment explores the capacity of the vasculature to accommodate pressure pulsations. Reduced elasticity will increase the afterload on the heart, which means that the strain on the heart is increased. Applanation tonometry is used to record the arterial pressure waveforms. For pulse-wave analyses, the waveforms of one artery are explored and this results into the calculation of the augmentation index, which is derived from the first and second systolic peak in pressure. For pulse-wave velocity, waveforms are recorded on two sites on the arterial tree and the combination of the transit time between the waveforms and the distance between assessment points will be used to calculate pulse-wave velocity. An increase in augmentation index and an increase in pulse-wave velocity are indicative of arterial stiffness (Sandoo et al., 2010).

It is worth noting that substantial training is necessary in order to carry out these vascular assessments to a sufficient standard. In addition, all these assessments are influenced by several factors such as timing of assessment, fasting, caffeine consumption, and smoking. Therefore, it is important that all assessments are carried out following published guidelines (Corretti et al., 2002; Turner et al., 2008).

Chronic kidney disease (CKD)

Definition

The kidneys serve four primary functions: (1) to clean the blood of toxins, (2) to remove excess fluid and waste, (3) to balance chemicals (i.e., sodium, potassium, phosphorus), (4) and to release hormones that control blood pressure, the production of red blood cells, and contribute to bone strength. End-stage renal disease (ESRD) is reached when the capacity of the kidneys declines such that they are no longer able to adequately perform these functions, ultimately requiring the affected individual to initiate treatment in the form of renal replacement therapy to sustain life.

Description

Cause, Symptoms, and Diagnosis of ESRD

ESRD most commonly manifests as a secondary condition resulting from poorly managed diabetes or hypertension. Chronic elevations in blood glucose and blood pressure cause damage to the small blood vessels in the kidneys, which over time can progress to ESRD. Other causes of ESRD include autoimmune diseases such as lupus, complications of infection such as glomerulonephritis, and genetic abnormalities such as polycystic kidney disease.

Many symptoms are associated with the progression of kidney disease to ESRD, including weakness, fatigue, lack of energy, appetite and weight loss, nausea and vomiting, metallic taste in the mouth, breath smelling like ammonia, changes in skin color, rash or itching, cognitive impairment, changes in urination, swelling, shortness of breath, feeling cold, and leg or flank pain.

According to the National Kidney Foundation's Kidney Disease Outcomes Quality Initiative (KDOQI), chronic kidney disease (CKD) can

Note: Some of the data reported here have been supplied by the United States Renal Data System (USRDS). The interpretation and reporting of these data are the responsibility of the author(s) and in no way should be seen as an official policy or interpretation of the U.S. government.

progress through stages of severity, with stage 5 typically denoting a diagnosis of ESRD and a need for treatment initiation. The stages of disease are determined by the level of kidney damage (i.e., pathologic abnormalities) and/or the degree of deficiency in the individual's estimated glomerular filtration rate (eGFR), a commonly used biomarker to diagnose ESRD. The eGFR is calculated based on serum creatinine, age, race, and gender; values less than 15 mL/min/1.73 m^2 are suggestive of stage 5 kidney disease, or ESRD. These values indicate that the kidneys are performing at less than 15% of normal functioning. In addition, increases in blood urea nitrogen (BUN) and protein in the urine (proteinuria) are markers of ESRD.

Prevalence of ESRD in the US Population

The Annual Data Report from the United States Renal Data System suggests that the number of individuals affected by ESRD increases annually, with a record high of 571, 414 patients receiving treatment in 2009. There exist significant racial and ethnic disparities in ESRD, with African Americans nearly four times more likely to develop ESRD than Whites. Native Americans and Asians are at least twice as likely to be diagnosed with ESRD compared to Whites, and the rate of ESRD in the Hispanic population is 1.5 greater than that of non-Hispanics. With regard to age and gender, the ESRD rates are higher among older adults and males. Recent reports suggest that the growing number of new ESRD patients has been driven by a linear increase in diagnoses among individuals aged 45–64; in contrast, there has been minimal change in the incidence rates of patients age 65 and older over the last several years.

Treatments for ESRD

Hemodialysis is the most common type of treatment for ESRD, with 65% of the affected population (approximately 372,000 patients) utilizing this treatment modality. Individuals who participate in hemodialysis typically come to a hospital or clinic 3 days per week for 3–5 h treatments. During this time, they are connected to a machine via an insertion site such as arteriovenous fistula or graft surgically configured in the forearm or a port catheter in the chest. The hemodialysis machine removes blood from the body, filtering accumulated toxins and removing excess fluids, and then returns the cleaned blood. This process is primarily directed by a nurse or dialysis technician, leaving the patient a relatively passive recipient of treatment. Hemodialysis can also be conducted in the home environment, though this is less commonly implemented due to expense and caregiver burden.

Peritoneal dialysis is an intervention for ESRD that requires the patient to be a more active participant in the treatment process. There are two forms of this treatment: continuous ambulatory peritoneal dialysis (CAPD) and continuous cycler-assisted peritoneal dialysis (CCPD). In CAPD, a permanent catheter is inserted into the patient's abdomen, which allows for a bag of sterile dialysis solution called dialysate to be connected to the body. The patient is responsible for performing "exchanges" which involve draining the dialysate into the peritoneal cavity via a sterile tube, allowing for the blood to filter through the peritoneal membrane leaving the excess fluid and toxins behind in the dialysate, and then discarding the used solution before reinitiating the procedure. Patients usually perform 3–4 exchanges throughout the course of the day while ambulatory and one longer overnight exchange while they are sleeping. In contrast, CCPD utilizes an automated cycler to perform the exchanges, with 3–5 cycles overnight while the patient sleeps and one long exchange during the day being the typical prescription. Recent reports indicate that approximately 6–7% of the ESRD population utilizes peritoneal dialysis as their treatment, which is a notable decrease from the 12–18% prevalence in the 1980s and 1990s. However, there is some evidence to suggest that the number of peritoneal dialysis users will increase in upcoming years.

Transplantation is often considered the preferred option for treatment of ESRD as it offers advantages including increased survival time and improvements in quality of life. Due to the continued shortage of donor organs,

contraindications to surgery in some patients, and concerns about rejection, however, this treatment is less commonly prescribed for ESRD compared to dialysis. Approximately 30% of the ESRD population undergoes renal transplantation with organs from either a deceased or living donor. According to the Organ Procurement and Transplantation Network (OPTN), an average of 17,000 renal transplants have been performed annually over the last 5 years, with approximately 65% from deceased donors and 35% from living donors. Survival of the renal graft across donor type is relatively high for renal transplant recipients (i.e., 1-year = 92%, 3-year = 82%, and 5-year = 71%), and living donor grafts tend to fare better than deceased donor grafts.

Adherence to ESRD Treatments

All patients undergoing treatment for ESRD are required to follow a lifelong regimen that necessitates ongoing behavioral involvement to ensure that the medical intervention remains safe and effective. For patients whose ESRD is treated with renal transplantation, adherence to an immunosuppressant medication regimen for the remainder of life is required to prevent the body from rejecting the transplanted organ. Individuals receiving hemodialysis as their method of ESRD treatment have an arguably more complex behavioral regimen to follow. Although patients undergo lengthy treatments several days per week, this does not fully compensate for normative kidney function; specifically, excess fluid and toxins build up and remain in the body between hemodialysis sessions. Fluid overload can lead to deleterious consequences, including congestive heart failure, pulmonary edema, cramping on dialysis, hypertension, fatigue, and decreased life expectancy. Similarly, buildup of chemicals that are dysregulated in ESRD can lead to complications such as myocardial infarction, stroke, heart arrhythmias, increased mortality, and bone demineralization. Thus, it is necessary for patients to restrict the amount of fluid ingested, and also their sodium, phosphorus, and potassium intake while their ESRD is being treated with hemodialysis.

Given the multifaceted and complex nature of the ESRD treatment regimen, the majority of patients have difficulty adhering to these recommendations. Research indicates that approximately 40–60% of ESRD patients do not adhere to one or more central aspects of the medical regimen. Adherence to fluid intake restrictions is most commonly measured by documented interdialytic weight gains (IWG). Individuals with ESRD are weighed before and after their hemodialysis treatments. The amount of weight gained *between* treatment sessions, calculated, for example, by subtracting the post-dialysis weight on a Monday from the pre-dialysis weight on a Wednesday, is considered a proxy for the amount of fluid the individual ingested during that time. One kilogram (kg) of weight is equivalent to 1 L of fluid; the recommended limitation is 1 L of fluid per day (including fluid in solid foods), which would equate to 2–3 kg of weight gained between sessions. Though patients tend to have the most difficulty with fluid restrictions, dietary adherence is also problematic. Sodium, potassium, and phosphorus intake is typically measured by serum levels drawn each month. There is modest evidence to suggest that in nearly half of cardiac-related ESRD patient deaths, nonadherence to dietary restrictions is the most significant contributor to mortality.

Researchers have also documented that patients experience the extreme restrictions on fluid intake as the most stressful and behaviorally challenging aspect of the ESRD hemodialysis regimen. There are a number of factors that likely contribute to this experience. First, individuals with ESRD tend to have increased thirst at baseline, often related to high blood glucose levels in those with diabetes and/or medication side effects. Second, the hemodialysis process itself, which rapidly removes excess fluid and toxins, leads to an electrolyte imbalance, increasing sodium appetite and thirst. Finally, contextual and behavioral factors impact patients' ability to follow fluid recommendations. For example, restricting fluid intake contradicts social norms about the health benefits of consuming large amounts of water, drinking has become habitual

for many individuals and habits are difficult to break, and there exist substantial environmental cues and social pressures to consume fluid in many different contexts. The fluid intake adherence problem often becomes cyclical in nature: increased thirst leads to greater fluid consumption, which leads to larger interdialytic weight gains and longer dialysis sessions, which further increases electrolyte imbalance and thirst, maintaining and increasing the severity of nonadherence.

Determinants and Interventions Related to ESRD Adherence

As might be expected based on reviews of the general adherence literature, a comprehensive understanding of the factors that contribute to nonadherence among ESRD patients has proven difficult to attain. Researchers have studied several factors thought to influence adherence in this population, and the results have been mixed. For example, some findings indicated that family support and marital adjustment were predictors of improved fluid intake adherence, while other studies found no evidence of an association between social support and fluid or dietary adherence among dialysis patients. The impact of cognitive and personality factors on adherence in ESRD has also been examined, including self-efficacy, health locus of control, perceived barriers, conscientiousness, and hostility. Higher self-efficacy expectations have been associated with improved fluid adherence in dialysis and better medication adherence in both dialysis and transplantation, whereas greater perceived barriers were related to poorer medication adherence. The findings relating health locus of control and adherence have been inconsistent. Personality characteristics such as conscientiousness and hostility have been significantly associated with adherence in ESRD patients in some work.

Some researchers have posited that the examining the interaction between patient characteristics or preferred style of coping with stress and the contextual features of the treatment regimen might help us to better understand adherence in this population. For example, individuals who endorse avoidant coping styles or prefer to have less control/involvement in their treatment have been found to display better adherence to hemodialysis performed in a center or hospital where the contextual demands (i.e., staff-directed, passive patient role) match the individual's preferences.

Some researchers have theorized that difficulties with adherence are related to deficits in self-regulation skills, suggesting that building these skills through interventions focused on self-monitoring, goal-setting, self-reinforcement, and increasing individuals' ability to delay gratification may be an effective strategy. Educational, cognitive, and cognitive behavioral interventions have been cited most frequently in the literature, though the results have been mixed. A recent review of randomized controlled trials designed to improve adherence in hemodialysis patients found that interventions utilizing cognitive or cognitive behavioral techniques showed the largest effects and warrant future research.

Depression and ESRD

Mood disorders have been documented as one of the most common psychiatric diagnoses in patients with ESRD. The prevalence of depression varies based on the type of assessment used; approximately 20–45% of patients endorse symptoms of depression on self-report instruments, and 15–20% may be diagnosed with a depressive disorder following a clinical interview. While depression is recognized in a large number of individuals with ESRD, underdiagnosis and lack of adequate psychological treatment remain significant problems in this population. One of the difficulties in diagnosing depression in ESRD relates to the overlap in somatic depression symptoms with the uremic symptoms of kidney disease. Fatigue, loss of interest in sex, difficulty sleeping, loss of appetite, and problems with concentration and attention could be attributed to both depression and ESRD; thus, the etiology of these symptoms is often unclear. As a result, it has been suggested that assessing the cognitive or nonsomatic symptoms may enable

researchers and clinicians to more accurately identify depression in patients with ESRD.

Several factors have been studied in order to better understand contributors to depression in individuals with kidney disease. The research suggests that perceptions of control and of how intrusive the illness is in disrupting important life domains are related to depression in this population. More specifically, incongruence between beliefs about control or illness intrusiveness and the relevant contextual or situational factors are predictors of depression in ESRD. The effects of social support on moderating depression symptoms have also been examined, and the results have been inconsistent.

Depression has been found to have deleterious consequences for patients with ESRD and earlier stages of CKD, including increased nonadherence to treatment recommendations, morbidity, and mortality. Some research has also suggested that depression is associated with decisions to prematurely terminate dialysis treatment. Thus, adequate treatment of depression in ESRD is essential. A review of the literature suggests that pharmacologic treatment with certain serotonin-selective reuptake inhibitors may be safe and effective for patients with later stage CKD and ESRD. Cognitive behavioral therapy was also found to be one of the most promising interventions for depression in this population. Future behavioral medicine research is necessary to expand our understanding of ESRD, particularly as the prevalence of this chronic illness is projected to increase over time.

Definition

Energy expenditure refers to the amount of energy an individual uses to maintain essential body functions (respiration, circulation, digestion) and as a result of physical activity. Total daily energy expenditure is determined by resting or basal metabolic rate (BMR), food-induced thermogenesis, and energy expended as a result of physical activity.

BMR is the minimum amount of energy that the body requires for essential organ and cellular function when lying in a state of physiological and mental rest. BMR accounts for typically 65–75% of total energy expenditure. Differences in BMR exist between genders and across ages. Females tend to have a lower BMR than males, and BMR decreases with age. These differences can largely be accounted for by differences in fat-free mass, which is proportional to BMR.

Food-induced thermogenesis refers to the increase in energy expenditure following the ingestion of food. This increase in energy expenditure is a result of digestion, absorption, and transportation of nutrients and accounts for approximately 10% of total energy expenditure.

Physical activity refers to energy expended when carrying out everyday tasks and exercise. It typically accounts for 15–30% of energy expenditure, but can vary greatly between individuals. For example, energy expenditure expended through physical activity would be greater in an individual who exercises regularly or is an athlete, compared to someone who is sedentary.

Energy intake is the amount of energy produced by an individual taken in from food consumption; this is typically measured in calories (kcal). Energy intake must be matched with energy expenditure to ensure *energy balance*. If food intake exceeds energy expenditure, through overeating or sedentary behavior, then energy storage occurs resulting in weight gain. This potentially can lead to an individual becoming overweight and at risk of obesity. Alternatively, a negative imbalance can occur where energy expenditure exceeds energy intake. This can occur as a result of undereating, possibly as a result of an eating disorder, or when an individual is involved in a high level of physical activity but failing to match this expenditure with food intake. A negative energy balance subsequently results in weight loss. Although a state of negative energy balance is desirable for overweight individuals in order to lose weight, in the long term if energy intake does not match energy expenditure, this may cause an individual to

Engel, George

Marc D. Gellman
Behavioral Medicine Research Center, Department of Psychology, University of Miami, Miami, FL, USA

Biographical Information

George Libman Engel was born in New York City in 1913. He completed his undergraduate studies in chemistry at Dartmouth College, graduating in 1934. He then studied medicine at the Johns Hopkins University School of medicine, graduating in 1938. He was an intern at Mount Sinai Hospital (New York City), a research fellow at Harvard Medical School, and a graduate assistant in medicine at the Peter Bent Brigham Hospital (now Brigham and Women's Hospital).

In 1942, Engel moved to Cincinnati at the invitation of John Romano, who left Harvard to become the chair of the department of psychiatry at the University of Cincinnati. Both Engel and Romano then moved to the University of Rochester Medical School in 1946.

When commencing his medical career, Engel believed strongly in physical explanations of disease processes, even though some colleagues were incorporating psychosomatics into clinical practice. However, during his time at the University of Cincinnati, he slowly but surely became "converted" to the psychosomatic school. During his career, he became a prominent member of the American Psychosomatic Society, being elected as president and also serving as the editor of its journal, *Psychosomatic Medicine*.

Major Accomplishments

Engel published numerous books and articles on the relation of emotion and disease and on the incorporation of these ideas into medical training and clinical practice. Under his direction, the program at the University of Rochester became a leading center in the development of psychosomatic theory and training. Over time, he developed the "biopsychosocial model," which posits that health and illness are consequences of the interaction of biological, psychological, and social factors. This model was described in his 1977 paper entitled "The need for a new medical model: a challenge for biomedicine," published in the journal *Science*. The abstract of this paper reads as follows:

The dominant model of disease today is biomedical, and it leaves little room within its framework for the social, psychological, and behavioral dimensions of illness. A biopsychosocial model provides a blueprint for research, a framework for teaching, and a design for action in the real world of health care.

The literature is now replete with work addressing the biopsychosocial model, both as a theoretical framework and an approach to clinical practice. As Borrell-Carrio, Suchman, and Epstein (2004) observed, "The biopsychosocial

model is both a philosophy of clinical care and a practical clinical guide. Philosophically, it is a way of understanding how suffering, disease, and illness are affected by multiple levels of organization, from the societal to the molecular. At the practical level, it is a way of understanding the patient's subjective experience as an essential contributor to accurate diagnosis, health outcomes, and humane care."

During the 1980s and 1990s, the biopsychosocial model and biopsychosocial medicine "became the watchword of progressive unification of the medical and behavioral sciences, including psychiatry, in a search for etiological and preventive factors in human health and disease" (Dowling, 2005). Perhaps not surprisingly, given its eminence, various authors since then have suggested modifications and emphasized the importance, too, of other approaches. For example, Kontos (2011) commented that recognizing that medicine is made up of heterogeneous tasks, "no one model, including the biopsychosocial model, tends to all of them." Nonetheless, a quote from Dowling (2005) reviewing Engel's life is an appropriate way to conclude this entry: "He would appreciate the fact that some of us have taken on a bit of his flintiness, attempt his wry humor, and retain his determination to see our patients as 'united, biopsychosocial persons' rather than as 'biomedical persons' divorced from their psychological and social dimensions."

Editors' Note: Dr. Engel passed away in 1999.

Epidemiology

G. David Batty
Department of Epidemiology and Public Health, University College London, London, UK

Definition

Derived from the term epidemic, epidemiology is the study of the distribution and determinants of health-related states or events, particularly disease (communicable or noncommunicable). The discipline of epidemiology is eclectic, comprising facets of sociology, statistics, medicine, and demography. Although its development may be traced back to the scientific revolution of the 1600s, it was not until the nineteenth century that it was recognized as a subject area in its own right.

The goal of the discipline of epidemiology is disease control and prevention. As such, various methods can be used to carry out epidemiological investigations: descriptive studies (usually based on a cross-sectional design) can be used to investigate distribution of disease; analytical studies (e.g., case control, cohort, randomized controlled trial) can be used to examine determinants of disease.

Knowledge of the occurrence, etiology, and subsequent control of communicable diseases such as typhoid fever, smallpox, and cholera stemmed from early epidemiological studies, such as John Snow's investigation of the infamous 1854 cholera epidemic in London. The emergence of noncommunicable diseases such as coronary heart disease earlier last century led to epidemiology occupying a wider remit. Modifiable determinants of the growing epidemic of coronary heart disease were identified from large-scale epidemiological investigations beginning with the Framingham, the Seven Countries and Whitehall cohort studies.

Today, a growing body of professionals from health education, environmental and occupational health, and health service administration, in addition to medical science students, are required to have some knowledge of the foundations of epidemiology. Further details can be found in Hennekens and Buring (1987) and Rothman (2002).

Epigenetics

Alicia K. Smith[1] and James W. Schroeder[2]

Definition

Epigenetics is the study of changes in gene expression that cannot be attributed to variation in DNA sequence. The etymology of this term comes from the Greek "epi-," meaning "above" genetics and refers to covalent modifications

of the DNA, its associated proteins, or mRNA transcripts.

Description

All somatic cells within an organism contain the same DNA sequence, but epigenetic patterns regulate the timing and magnitude of gene expression by restricting the areas of the genome available for transcription and translation. This allows cells with the same genome to differentiate into specialized cells that perform a variety of functions (Jaenisch & Bird, 2003).

Epigenetic regulation participates in vital developmental processes. For example, one of the two X chromosomes in each cell of a female is permanently silenced through a series of epigenetic changes in a process called X-chromosome inactivation (Jaenisch & Bird, 2003). Epigenetic mechanisms also regulate genomic imprinting, a process in which an organism's parents contribute distinct epigenetic patterns that result in expression of only the maternally or paternally derived alleles in their offspring. Failure of these regulatory mechanisms can lead to developmental disorders such as Prader-Willi Syndrome or Angelman Syndrome (Feinberg, 2007).

Previously established epigenetic patterns responsible for cellular differentiation, X-chromosome inactivation, and imprinting are generally maintained through mitosis. However, some aspects of the epigenome are labile such that they may respond to environmental conditions and change over the course of an organism's lifespan (Feinberg, 2007).

DNA interacts with packaging proteins known as histones, which can be posttranslationally modified and facilitate dynamic gene regulation. Both the core (H2A, H2B, H3, and H4) and linker (H1 and H5) histones can be modified through methylation, acetylation, phosphorylation, ubiquitination, sumoylation, or citrullination. Each element of this histone code has a specific function. For example, histone acetylation typically promotes gene transcription while histone methylation can promote or repress transcription based on the where it occurs (Bannister & Kouzarides, 2011).

Histone modifications often correspond to changes in methylation of DNA at the 5′ position of the pyrimidine ring of cytosines within CpG dinucleotides (also called CpG sites). DNA methylation is the most widely studied epigenetic modification. It is concentrated in repetitive elements of the genome such as Alu sequences to repress transcription of latent retroviral elements. CpG sites are overrepresented in the promoter region of many genes, and when they cluster in sufficient density, the region is called a CpG island. Methylation of cytosines regulates gene expression by influencing the recruitment and binding of regulatory proteins to DNA. Specifically, gene expression typically increases when CpG methylation of that gene decreases and vice versa (Jaenisch & Bird, 2003).

Epigenetic regulation of gene expression can also be accomplished by a variety of non-protein coding RNA molecules (ncRNAs), which are continuously being discovered and characterized. RNA interference (RNAi) is a process by which ncRNA molecules bind to messenger RNA (mRNA) to regulate its translation into protein. As part of this process, small microRNA (miRNA) can bind a complementary strand of mRNA and repress its expression by targeting it for degradation or by directly preventing its translation. Similarly, small interfering RNA (siRNA) promotes mRNA cleavage and posttranscriptional silencing of a gene through induction of the RNA-induced silencing complex known as RISC (Taft, Pang, Mercer, Dinger, & Mattick, 2010).

Many epigenetic changes can occur over the course of an organism's lifetime as part of normal development, randomly as the organism ages or in response to environmental insults. However, if epigenetic changes occur in germ cells that participate in fertilization, epigenetic changes can be inherited from one generation to the next and may persist through multiple generations. With these and other recent discoveries, the role of epigenetic mechanisms in health and disease is being illustrated (Richards, 2006).

Epinephrine

Adrenaline

Definition

Epinephrine is a major neurotransmitter of the sympathetic nervous system. Epinephrine partially mediates the body's reaction to stress by elevating heart rate, blood vessel tone, sweating, tremor, and blood pressure. Epinephrine is released primarily from the central region (medulla) of the adrenal gland in response to stressful situations. An alternate name for epinephrine is adrenaline.

Epinephrine interacts with at least five major protein receptors to produce a plethora of biological responses, typically characterized by an elevation of blood pressure and mobilization of energy stores. The major receptor interactions are with the following: α1 to both constrict blood vessels, resulting in increased vascular resistance, and an elevation of blood pressure and activate sweat glands to promote nervous sweating; α2 receptors to reduce the release of other catecholamines, such as norepinephrine, but also to constrict blood vessels; ß1 receptors to elevate heart rate and renin secretion, both resulting in elevated blood pressure; ß2 receptors on smooth muscle, particularly in bronchioles to ease breathing, and on skeletal muscle to sensitize the muscle to other stimuli resulting in tremor; and ß3 receptors on adipose tissue to stimulate the breakdown of fat stores. The stimulation of both α1 and ß2 receptors also mobilizes energy stores by activating glycogenolysis.

The physiological actions of epinephrine primarily involve augmentation of the sympathetic nervous system to promote rapid heart rate, arterial constriction, higher blood pressure, mobilization of fuel stores, sweating, and dilation of bronchioles and pupils of the lung and eye, respectively.

Epinephrine is a catecholamine synthesized from norepinephrine primarily in the central portion (medulla) of the adrenal gland. The entire synthetic pathway involves conversion of an amino acid, tyrosine, to dihydroxyphenylalanine (DOPA), followed by conversion of DOPA to dopamine, and dopamine to norepinephrine and the final step is the conversion of norepinephrine to epinephrine. The enzymes involved in the pathway are the following: tyrosine hydroxylase, DOPA decarboxylase, dopamine ß hydroxylase, and phenylethanolamine *N*-methyl transferase. The latter strictly controls the synthesis of epinephrine and is most abundant in the adrenal medulla.

In addition to the adrenal medulla, other tissues capable of synthesizing epinephrine are the following: brain stem, retina, and left atrium of the heart. The distinguishing feature of the tissues

synthesizing epinephrine is the presence of phenylethanolamine *N*-methyl transferase. The gene controlling synthesis of this enzyme is located on chromosome 17 in humans. The enzyme consists of 282 amino acids and has a molecular mass of 30,835 g.

The primary behavioral role for epinephrine involves mediation of stress responses such as tachycardia, vasoconstriction, hypertension, sweating, shaking, piloerection, and liberation of energy stores such as glucose and fatty acids. Epinephrine levels in the brain are depleted in Alzheimer's disease brains. Epinephrine has been shown to increase memory in humans but the effect is mimicked by exogenous epinephrine infusions which cannot penetrate the brain; therefore, the effect must be caused by peripheral actions of epinephrine and not central brain effects. Intracerebral epinephrine infusions in animals also can produce excitation or depression.

Definition

EBV was formally identified by M.A. Epstein and Y.M. Barr in 1964 while examining tissue from a Burkitt's lymphoma patient. EBV is a very common type of herpesvirus found in humans. About 95% of Americans will have contracted the virus by the age of 40. The virus is highly contagious and is difficult, if not impossible, to prevent. It is often called the "kissing disease" due to its ease of transmission between individuals through saliva. Children often acquire EBV through close contact with family members and the people around them who are likely to have the virus. In adolescents and young adults, EBV leads to infectious mononucleosis 30–50% of the time. Symptoms of active EBV, or infectious mononucleosis, commonly include swollen lymph nodes, swollen throat, and fever. Treatment is limited and focuses on minimizing symptoms of the infection. The incubation period from contraction to presentation of symptoms can range from 4 to 6 weeks. Symptoms of infectious mononucleosis can last up to 1–2 months, but EBV remains dormant in the body for the rest of a person's life. EBV is present in the saliva and blood of infected persons and remains in some bodily cells after contraction. Since it functions as a virus, the body will develop antibodies to help fight off the virus. A "mono spot" test, which looks for these antibodies, is often administered for a formal diagnosis. Additionally, an elevated white blood cell count is indicative of active infection in the body. At times of immunosuppression, such as during cancer treatment, patients may experience reactivation of the virus, with or without associated symptoms. In some people, EBV may play a role in the development of Burkitt's lymphoma and nasopharyngeal carcinoma. Other people may live with the latent form of EBV for a number of years without reactivation.

Erectile Dysfunction

Definition

Erectile dysfunction is a sexual dysfunction characterized by the consistent inability to develop or maintain an erection of the penis firm enough for satisfactory sexual performance. Symptoms of erectile dysfunction include trouble getting an erection, trouble keeping an erection, and/or reduced sexual desire.

Description

In the United States, it is estimated that erectile dysfunction affects 20–30 million men. The prevalence of erectile dysfunction of any degree is estimated to be approximately 39% in men 40 years old and up to 78% in men 75 years and older. Comorbid medical conditions such as obesity, diabetes, heart disease, or hypertension may increase the risk of developing erectile dysfunction. In men older than 50 years, approximately 40% of erectile dysfunction is due to atherosclerotic complications. The most common conditions associated with the development of erectile dysfunction include cigarette smoking, high blood pressure, lipid problems (cholesterol, triglycerides), and diabetes. Among diabetes patients, the prevalence of erectile dysfunction is approximately 50%, depending on age, duration, and severity of the diabetes. A high prevalence of erectile dysfunction is also observed with chronic renal failure, hepatic failure, sleep apnea, chronic obstructive pulmonary disease, multiple sclerosis, Alzheimer's disease, and endocrine disorders such as low testosterone and thyroid problems. Pelvic or perineal trauma such as pelvic surgery (major prostate, bladder, and bowel operations) and pelvic radiation therapy are associated with erectile dysfunction, as is direct trauma to the perineum, which can lead to vascular problems.

Pathophysiology

Erectile dysfunction can be classified as psychogenic, organic, or mixed psychogenic and organic. That is, psychologic, neurologic, hormonal, arterial, or cavernosal impairment factors alone or in combination may cause erectile dysfunction. The mixed psychogenic and organic form of erectile dysfunction is the most common. Common psychological factors include performance anxiety and personal and/or relationship distress, which often result in lack of sexual arousal, overinhibition, and decreased libido. Erectile dysfunction may occur despite experiencing sexual desire and maintaining the ability to have an orgasm and ejaculate. Psychiatric disorders such as depression and schizophrenia have been related to increased risk of erectile dysfunction. Neurogenic causes of erectile dysfunction include the presence of disorders such as Parkinson's disease, Alzheimer's disease,

stroke, and cerebral trauma, which often lead to decreased libido or failure to initiate nerve impulses or interrupted neural transmission that lead to an inability to develop an erection. Hormonal factors associated with erectile dysfunction include hypogonadism and hyperprolactinemia. Androgen deficiency may also result in loss of libido and decreased nocturnal erections. Vasculogenic factors include generalized penile arterial insufficiency and veno-occlusive dysfunction. Inadequate arterial flow may be the result of hypertension, hyperlipidemia, cigarette smoking, diabetes, and pelvic or perineal trauma. Impaired veno-occlusion is associated with old age, Peyronie's disease, structural damage to the cavernous muscle and endothelium, and poor relaxation of the trabecular muscle, as well as diabetes and pelvic or perineal trauma. Drug-induced erectile dysfunction may result from a number of antipsychotic, antidepressant, and antihypertensive drugs that affect central neurotransmitter pathways involving serotonin, androgen, and dopamine. Additionally, cigarette smoking is associated with vasoconstriction and penile venous leakage and chronic alcohol abuse is associated with hypogonadism and polyneuropathy. Finally, old age is associated with a progressive decline in overall sexual function such that older men report decreased penile sensitivity, decreased testosterone levels, less turgid erections, less forceful erections, decreased ejaculation volume, and lengthened refractory period between erections. Age-related declines may be exacerbated with comorbid medical conditions such as diabetes, coronary heart disease, and chronic renal failure that lead to neural and/or vascular dysfunction.

Diagnosis

Initial evaluation of a man presenting with erectile difficulties includes a thorough examination of medical, sexual, and psychosocial histories, physical examination, and appropriate laboratory tests. Psychosexual factors to consider include alterations of sexual desire, ejaculation, and orgasm, presence of genital pain, and lifestyle factors, such as sexual orientation, presence of spouse or partner, and quality of the relationship with the partner. Risk factors including smoking, trauma, or surgery to the pelvic, perineal, or penile areas, and prescription or recreational drug use should be considered. A detailed medical history should be taken and evaluation may also include laboratory tests to detect and rule out medical conditions that may be the cause of or comorbid with erectile difficulties and that may contraindicate certain therapies. Testing of testosterone levels, vascular and/or neurologic functioning, and monitoring of nocturnal erections may also be indicated in some patients. A physical examination should be conducted of the abdomen, penis, testicles, secondary sexual characteristics, and lower extremity pulses. The purpose of the initial evaluation is to identify psychosocial dysfunctions and organic comorbidities that contribute to erectile dysfunction. Assessment of patient's (and partner's) goals of treatment and preferences should also be conducted.

Treatment

Treatment of erectile dysfunction should address all the contributing factors associated with erectile difficulties. Appropriate treatment options should be utilized in a stepwise fashion according to medical expertise and patient preference. Healthcare professionals should carefully assess patients' (and their partners') goals for treatment; patients should be made aware of the risk involved with increasingly invasive treatments so that well-informed decisions are made with regard to the likelihood of treatment efficacy.

Escape-Avoidance Coping

Urs M. Nater
Department of Psychology, University of Marburg, Marburg, Germany

Definition

Coping is a cognitive-behavioral process that takes place in the context of a situation or condition perceived as personally relevant, challenging, or that exceeds an individual's resources to adequately deal with a problem. Coping styles may be dysfunctional or maladaptive in various contexts. Particularly in various patient groups, it has been shown that patients tend to use significantly more maladaptive strategies than healthy controls. Maladaptive coping styles have been shown to be associated with clinical features (e.g., fatigue, impairment, illness burden, psychosocial problems, or psychiatric comorbidity).

One of the best examined maladaptive coping styles is escape-avoidance coping. Escape-avoidance coping involves disengaging or staying away from a stressful situation and its behavioral and cognitive/emotional consequences. Typical strategies in response to a stressful situation might encompass cognitive avoidance ("Refused to believe that it had happened"), avoidant actions ("Slept more than usual"), denial ("Refused to believe that it had happened"), or wishful thinking ("Wished that the situation would go away or somehow be over with it") (examples are items of the Ways of Coping Checklist which is the most widely used instrument for assessment of coping styles).

It should be noted that, according to Lazarus, coping strategies are not inherently adaptive or maladaptive, but their effectiveness depends on individuals' personal circumstances, goals, and expectations. Coping styles should be considered in the context of stress-related cognitions and their consequences in everyday life. Escape-avoidant coping in a stress context may result in an inadequate regulatory adaptation to stress

as well as in exaggerated or prolonged stress responses that may in turn be associated with increased neuroendocrine, autonomic and immune activation. Escape-avoidant coping (and other coping styles) must be considered in studies of risk factors, clinical course, pathophysiology, and therapy of illnesses relevant in behavioral medicine.

Essential Fatty Acids

Definition

Essential fatty acids (EFA) are fats that cannot be synthesized by the body and must be obtained through diet. The two types are omega-3 fatty acids from alpha linolenic acid and omega-6 fatty acid from linoleic acid. Omega-9 fatty acid is necessary yet "nonessential" because the body can manufacture a small amount on its own, provided essential EFAs are present. EFAs are used to support the cardiovascular, reproductive, immune, and nervous systems.

The body has a very limited capacity for making the omega-3 fatty acids eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) from linolenic acid, so these are often classified with essential fatty acids. EPA is believed to play a role in the prevention of cardiovascular disease, while DHA is necessary for proper brain and nerve development.

The richest sources of omega-6 fatty acids are safflower, sunflower, corn, and sesame oil. The richest sources of omega-3 fatty acids are flaxseed, sardines, salmon, cooked soybeans, and halibut.

The current ratio of omega-6 to omega-3 fatty acids in the typical American diet is approximately 11:1. However, the recommended ratio is 4:1. High doses of supplemental EPA/DHA have been shown to lower triglycerides in patients with elevated triglycerides. The American Heart Association recommends two servings of fatty fish a week to increase intake of EPA and DHA.

Definition

Estrogens represent a group of steroid hormones that primarily influence the female reproductive tract in its development, maturation, and function. There are three major hormones – estradiol, estrone, and estriol – and estradiol is the predominant one (Blair, 2010).

The major sources of estrogens are the ovaries and the placenta (the temporary organ that serves to nourish the fetus and remove its wastes); additional small amounts are secreted by the adrenal glands, by the male testes, and by intracrine synthesis in several peripheral cells/tissues (i.e., adipose tissue, which is also an important source of estrogen in postmenopausal women; macrophages in inflamed tissues) (Cutolo et al., 2004; Simpson, 2003).

Cholesterol is the parent molecule from which all ovarian steroid hormones are formed. Cholesterol is converted to pregnenolone, and pregnenolone is converted to progesterone. The steps in the conversion of progesterone to the main estrogens – estradiol and estrone – include the intermediate formation of several androgens (male sex hormones): dehydroepiandrosterone, androstenedione, and testosterone (Blair, 2010).

Practically, androgens are precursors of estrogens: they are converted to estrogens through the action of an enzyme known as aromatase (Chumsri, Howes, Bao, Sabnis, & Brodie, 2011). The ovaries are the richest source of aromatase. Estradiol, the most potent estrogen, is synthesized from testosterone. Estrone can be formed from estradiol, but its major precursor is androstenedione. Estriol, the weakest of the estrogens, is formed from both estrone and estradiol.

At its target tissues, the free hormone penetrates the cell surface and then binds to a protein known as an estrogen receptor in the cytoplasm of the cells (Gibson & Saunders, 2012). The estrogen-receptor complexes enter the cell nucleus, where they influence the rate at which particular genes are transcribed.

Recently, chemicals like xenoestrogens, which can mimic endogenous hormones or interfere with endocrine processes, may affect normal estrogen signaling (Singleton & Khan, 2003).

Bone metabolic actions of estrogens are related to bone development and bone maintenance including the stimulation of bone formation and the closure of bone epiphyses, which causes linear growth to cease at the end of puberty, and the maintenance of bone throughout the reproductive years, which limits bone resorption and preserves bone strength (Callewaert, Sinnesael, Gielen, Boonen, & Vanderschueren, 2010).

However, estrogen replacement therapy to treat menopause is not recommended, since The National Cancer Institute found in 2003 a very significant drop in the rate of hormone-dependent breast cancers among women, related to the fact that millions of women stopped taking

hormone therapy in 2002 after the results of a major government study found the treatment slightly increased a woman's risk for breast cancer, heart disease, and stroke (Rossouw et al., 2002).

Estrogens exert enhancing activities on the immune humoral response (B-cell activities) and are considered among risk factors involved in the higher frequency of autoimmune diseases in females (Schmidt et al., 2009). Estrogen administration is contraindicated in patients with active autoimmune diseases (i.e., systemic lupus erythematosus); therefore, progestogen-only pills offer a convenient and readily reversible method of contraception that is suitable for women with contraindications for estrogens (Ahrendt, Adolf, & Buhling, 2010).

Increased intracrine synthesis (action of local aromatases) and levels of peripheral estrogen metabolites (i.e., alpha-hydroxylated) are observed in fluids of patients affected by autoimmune diseases (i.e., synovial fluid of rheumatoid arthritis patients of both sexes) and in tissues affected by cancer (i.e., both breast and prostate cancer) (Cutolo, Sulli, & Straub, 2011; Cutolo, Straub, & Bijlsma, 2007; Nelles, Hu, & Prins, 2011).

Definition

Ethical issues arise in the situation where values conflict. There are several ethical issues in the area of behavioral medicine. One of typical ethical issues is the problem of informed consent in the clinical settings and the research involving human subjects.

Ethics of behavioral therapy is a topic of ethical issues in behavioral medicine to be proposed. Ethics has been a priority among behavior therapists. If the application of a technique can inflict pain or clients are relatively powerless or are involuntarily the subjects of treatment, ethical concerns arise. The aversion technique is one of major techniques causing behavioral modification. However, using an aversion procedure becomes one focus of ethical criticism in behavioral therapy. In the case that clients cannot offer informed consent due to lack their competency, desirability of treatment outcome goals has to be weighed against the rights of the client, because using an aversion technique opposes nonmalficience which is major principle of biomedical ethics. Behavior therapists ethically ought to give positive consideration to reduce the target behavior through nonaversive means before applying an aversion procedure. Only when the target behavior has been conclusively shown to be impervious to other means, aversion therapy should be used.

Definition

Ethics is the study or examination of morality and moral life. The concepts of ethics fall into two main categories. The first category comprises notions having to do with morality, virtue, rationality, and other ideals or standards of conduct and motivation; second, notions pertaining to human good or well-being and the "good life" generally. Several major approaches to the study of morality are encompassed under the broad term "ethics." Perhaps, the best-known approach is normative ethics, which attempts to identify those moral norms, values, or traits that should be accepted as standards or guides for moral behavior and moral judgment. Famous ethical theories of normative ethics are deontology, consequentialism, or virtue ethics. Deontology treats moral obligations as requirements that bind us to act, in large measure, independent of the effects our actions may have on our own good or well-being and, to a substantial extent, even independent of the effects of our actions on the well-being of others. Consequentialism contrasts with deontology. In consequentialism, all moral obligation and virtue are to be understood in terms of good or desirable consequences. Virtue ethics is conceiving what is admirable about individuals in terms of traits of character, rather than in terms of individual obedience to set of moral or ethical rules or requirement.

Definition

An ethics committee is a committee dedicated to the rights and well-being of research subjects and makes decisions regarding whether or not proposed research studies are ethical to permit to go ahead.

The emphasis on ethical research arose out of concern regarding unethical experiments on humans that occurred during the Second World War. This led to the "Nuremberg Code," which continues to inform current day ethics statements. This includes the ten basic principles that must be observed when performing medical experiments in order to satisfy moral, ethical, and legal concepts (BMJa, 1996). The Nuremberg Code was informed the Declaration of Helsinki, which was devised in 1964 in order to meet the needs of the biomedical community (BMJb, 1996). This has been revised six times; the most recent version was written in 2008. The Declaration of Helsinki stipulates that research protocols should be reviewed by specially appointed committee independent of the investigator and the sponsor. It also stipulates that research that does not directly benefit the patient is restricted to healthy volunteers or for individuals where the experimental design is not related to their illness. Importantly, it also states that any research that does not have ethical approval should not be accepted for publication. Researchers are now increasingly assessed for Good Clinical Practice as developed by the International Conference on Harmonization (http://www.ich.org/home.html), which developed from the Declaration of Helsinki.

In the UK, most research concerning human subjects is required to be approved by ethics committees prior to being conducted. This is overseen by the National Research Ethics Service (http://www.nres.npsa.nhs.uk/), which has the following dual mission:

- To protect the rights, safety, dignity, and well-being of research participants
- To facilitate and promote ethical research that is of potential benefit to participants, science, and society

Definition

Although there is no standardized definition for ethnicity, it has generally been agreed upon that ethnicity encompasses, but is not limited to, elements such as shared cultural background, customs and practices, values and norms, and common language or religious traditions that are usually maintained across generations and tied to a collective sense of identity (Dein, 2006; Lee, 2009). Moreover, ethnicity is a complex and dynamic concept that is dependent on both context and time (Boykin & Williams, 2010; Dein, 2006; Lee, 2009).

Description

The concept of ethnicity is commonly used interchangeably with the term "race" within the health literature, although both concepts are different from one another. A clear distinction between the two terms is that race is a scientifically unfounded taxonomy that categorizes individuals based on phenotypical characteristics (e.g., skin color, facial features) and geographic origin; it is a socially and ideologically constructed category (Sheldon & Parker, 1992; Williams, Lavizzo-Mourey, & Warren, 1994). Moreover, race has poor predictive validity for biological differences, and the amount of genetic variation that exists for any one particular ethnic group is larger than that found between "racial" groups (Sheldon & Parker, 1992), providing evidence for the lack of biologic or genetic basis for racial categorizations (Lin & Kelsey, 2000). On the other hand, despite that ethnicity is sometimes used in research as a fixed term, a distinguishable feature of it from that of race is that ethnicity is a much broader concept that also captures notions of self- and group identity (Sheldon & Parker, 1992). Although the fluidity of boundary demarcations as it relates to ethnicity (as can be noted, for example, throughout the different U.S. Decennial Census forms) is a limitation of the concept, many social scientists advocate for the use of "ethnicity" over "race" in order to avoid biological reductionism. Indeed, many researchers argue that ethnicity as a concept can better capture the environmental, cultural, behavioral, and sociopolitical experiences that affect health and illness (Dein, 2006). The term "ethnicity" is more commonly used in other countries (e.g., the UK and Canada) compared to the United States (Boykin & Williams, 2010). Significantly, despite that both majority and minority social groups have an ethnicity, the term "ethnicity"

has mostly been used (erroneously) to refer to ethnic minorities (Sheldon & Parker, 1992).

Ethnic and racial health disparities have been widely documented. However, the focus on ethnicity (and race) as fixed demographic categories and etiological factors has limited researchers' ability to adequately identify and delineate underlying mechanisms of these disparities (Sheldon & Parker, 1992). For example, despite that scientists are increasingly using ethnicity (and race) in biomedical and genetics research, when ethnic (or racial) differences are found, researchers typically fail to define the mechanisms through which these social categories operate in their statistical models or in actual life (Dein, 2006; Williams et al., 1994). Such a practice runs the risk of erroneously attributing noted differences in health status to ethnic minorities themselves, which may further contribute to pathologizing already socially marginalized groups (Sheldon & Parker, 1992; Williams et al., 1994). Similarly, ethnic differences in disease processes and/or health outcomes are usually attributed to culture, particularly to aspects of diet, lifestyle, and behavioral practices (Sheldon & Parker, 1992). However, researchers have noted that ethnic differences in health are not only due to behavioral and cultural factors but also due to larger social processes and structures, including historical, political, socioeconomic, environmental, and contextual factors, as well as discrimination and racism (Boykin & Williams, 2010; Pierce, Foliaki, Sporle, & Cunningham, 2004; Sheldon & Parker, 1992).

Methodological assessments of ethnicity in health research have some limitations. For example, a common methodological approach is that ethnic groups are usually grouped together to represent an ethnicity based on their national origin. However, ethnic differences may exist within national origin groups based on a number of factors, including cultural and linguistic ones. For example, whereas Mexican persons might be grouped together, differences exist in ethnic groups in Mexico (e.g., indigenous persons who might also speak a different language). This may apply to many other national origin groups that are typically collapsed into one ethnic category. Likewise, although there are certainly some advantages to grouping all Latino or Asian subgroups into one ethnic category, for example, this practice can simultaneously obscure the heterogeneity that exists among subgroups across social, contextual, political, and historical contexts, which in turn may come to differentially affect the health of such groups.

Given the diverging definitions, classifications, and use of ethnicity across geographic contexts and time, understanding disease processes and outcomes as well as health/health service disparities will require further and more explicit clarification and assessment of ethnicity (and race), as well as of mechanisms through which both ethnicity and race may come to affect health (e.g., discrimination, social class, access to care) (Boykin & Williams, 2010; Lin & Kelsey, 2000).

Definition

The terms "etiology" and "pathogenesis" are closely related to the questions of *why* and *how* a certain disease or disorder develops. Models of *etiology* and pathogenesis therefore try to account for the processes that initiate (*etiology*) and maintain (*pathogenesis*) a certain disorder or disease.

Etiology

Etiology (consisting of two Greek terms for "origin" and "study of") refers to the study of the causes of a mental or physical disease. As parts of the *etiology* of a respective disease, only causes that directly initiate the disease process (and therefore necessarily temporarily have to precede the onset of the disease) are considered as *etiological* factors. *Etiological* factors can thus be considered as *necessary conditions* for the development of a disease. The *etiology* of a certain condition is mostly defined not only by one but rather by the interplay of many different conditions (biological, environmental, etc.). As an example, the *etiology* of the common cold is based on an infection by Rhinoviruses causing a viral upper respiratory infection (e.g., Eccles & Weber, 2009). Additionally, multiple environmental and immunological factors modulate the infectious *etiology* of the common cold (Eccles & Weber, 2009). In the realm of mental disorders, dysregulations of the endocrinological stress system, especially the hypothalamic-pituitary-adrenal axis (e.g., caused by early traumatic experiences and early life stress), are considered as *etiological* factors relevant for the development of certain disorders (e.g., depression, posttraumatic stress disorder, somatoform disorders) (Ehlert, Gaab, & Heinrichs, 2001). However, in many complex mental and physical disorders, the exact *etiology* is still either entirely or partly unknown (e.g., depression, obesity). Especially regarding mental disorders, the causes of certain symptoms and syndromes remain vague and speculative. An exception is the diagnosis of a posttraumatic stress disorder, in which case the *etiology* is unambiguously defined by the occurrence of a traumatic event.

Pathogenesis

Pathogenesis, in turn, refers to the process and factors associated with the perpetuation and maintenance of a respective mental or physical disorder. Factors associated with the *pathogenesis* also comprise behavioral changes (e.g., avoidance of normal physical activities in chronic pain conditions) that may maintain and even worsen a specific condition (e.g., physical inactivity often aggravates chronic pain conditions). Accordingly, *pathogenetic* factors, as opposed to *etiological* factors, do not necessarily have to precede the onset of a certain mental or physical disorder. As an example, a depressive disorder might initially develop as the result of early dysregulation in the stress system paired with acute adverse or stressful life events, but might be maintained and even exacerbated due to cognitive and behavioral *pathogenetic* factors (e.g., social isolation, lack of physical activity, and ongoing self-blame).

Definition

Euthanasia is broadly defined as the practice of ending a life as a means of relieving pain and suffering. Assisted suicide refers to actions by which an individual helps another person voluntarily bring about his or her own death. Despite the fact that physician assisted suicide (PAS) is illegal in most of the states in the USA, medical practitioners often receive requests from patients and their families to perform euthanasia, and many clinicians honor these requests. The reasons for these requests have not been well studied, but it appears that it involves a complex combination of physical and psychosocial symptoms and concerns. Euthanasia is currently legal in a small number of US states (Montana, Oregon, and Washington) and a limited number of European countries. The American College of Medical Quality (2001) has published guidelines for physicians confronted with a patient's request for physician-assisted suicide.

Euthanasia and PAS remain extremely controversial due to the moral, ethical, and religious issues that surround them. There are strong arguments for and against the legalization of PAS and euthanasia in the USA. One concern regarding the practice of euthanasia and PAS is the established association between depression and requests for euthanasia. Research suggests that euthanasia requests from depressed patients are often transitory, while in nondepressed, severely ill patients, the desire to hasten death tends to be enduring.

Definition

Evidence-based behavioral medicine (EBBM) is that branch of the evidence-based practice (EBP) movement that addresses behavioral interventions to promote health and mitigate the impact of illness. Evidence is comprised of research findings derived from the systematic collection of data through observation and experiment and the formulation of questions and testing of hypotheses. Evidence-based practice is an approach that aims to improve the process through which high quality scientific research evidence can be obtained and translated into best practical decisions to improve health. The evidence-based practice movement establishes consensus on the standards used to conduct, report, evaluate, and disseminate research results so as to increase their uptake and impact on practice and policy. Best available research is defined as best in quality, according to consensually accepted scientific standards for different kinds of questions, and most contextually relevant. Evidence-based practice entails the use of conscientious, explicit decision making that integrates consideration of best available research evidence, client characteristics, and resources. Many practical decisions relevant to evidence-based practice concern the selection of

an assessment or intervention. Whereas the treatments evaluated in evidence-based medicine usually involve drugs or devices, those appraised in evidence-based behavioral medicine more often comprise non-drug, non-device, behavioral or psychosocial interventions.

Description

History of Evidence-Based Practice

The evidence-based practice movement began as an effort to distinguish valid health practices from illegitimate ones. By now, all major health professions endorse evidence-based practice, and the Institute of Medicine identifies EBP as a core competence for all twenty-first-century health professionals (Greiner & Knebel, 2003). The EBP movement emerged from evidence-based medicine (EBM) and can be traced to three influences on the history of medicine in the twentieth century: the Flexner Report, the Cochrane Collaboration, and the clinical epidemiology group at McMaster University.

First, the Flexner Report, commissioned by the American Medical Association and the Carnegie Foundation and published in 1910, represented a major effort to reform medical education by placing it on a scientific foundation. To prepare the Report, Abraham Flexner, a research scholar at the Carnegie Foundation for the Advancement of Teaching, surveyed 155 medical schools that were in operation in the United States and Canada. Flexner severely criticized the training offered by many medical schools. He described a curriculum that was not based on science, lax clinical training, and a predominant profit rather than public service motivation for many schools' existence (Flexner, 1910). The Flexner Report established an educational quality standard that many existing medical schools could not meet. In consequence, by 1935, more than half of all medical schools had been closed (Beck, 2004).

A second main catalyst for the EBM movement arose from British epidemiologist, Archibald Cochrane's efforts to establish a rational, systematic basis for determining health care coverage (Cochrane, 1972). Cochrane argued that because resources for health care are inevitably limited, it is essential that scarce dollars only be allocated for procedures of demonstrable worth. His conclusion that Randomized Controlled Trials (RCTs) offer the most reliable, unbiased method to evaluate the effectiveness of treatments led others to formulate a hierarchy of evidence. According to this evidence hierarchy, findings from high quality RCTs are given greater credence than those from observational studies, case studies, and expert opinion when making determinations about whether a treatment works. To aggregate and disseminate findings from RCTs, Cochrane's followers established the worldwide network known as the Cochrane Collaboration (www.cochrane.org), whose contributors track, critically appraise, synthesize, and disseminate RCT findings via the internet.

A third engine that drove EBM forward was the group of clinical epidemiologists working at Canada's McMaster University in the 1990s under the leadership of David Sackett and Gordon Guyatt. This group's ambitious agenda was to close the research-to-practice gap by socializing physicians to engage in lifelong learning about new research findings (Sackett & Rosenberg, 1995a, 1995b). The McMaster team was motivated by evidence that clinicians primarily implement practices learned during training but neglect alternative, new, and often more efficacious treatments (Isaacs & Fitzgerald, 1999). In order to encourage physicians to routinely ask questions and consult research, the group developed methods that allowed practitioners to find, appraise, and apply research results during the actual clinical encounter. They encountered resistance from clinicians who felt that an exclusive emphasis on research devalued the importance of clinical expertise to quality care provision (Haynes et al., 1996). To overcome that barrier and encourage clinical implementation, Gordon Guyatt renamed the approach "evidence-based medicine," in place of the earlier phrase "scientific medicine" (Guyatt et al., 1992). Instead of a single circle (research), subsequent models of evidence-based medicine have used a "three circles" or "three legged stool" model of EBM.

That is to say, they depict evidence-based practice as tying together research, patient characteristics, and expertise (Haynes et al., 1996; Sackett, Rosenberg, Gray, Haynes, & Richardson, 1996).

From EBM to EBBM

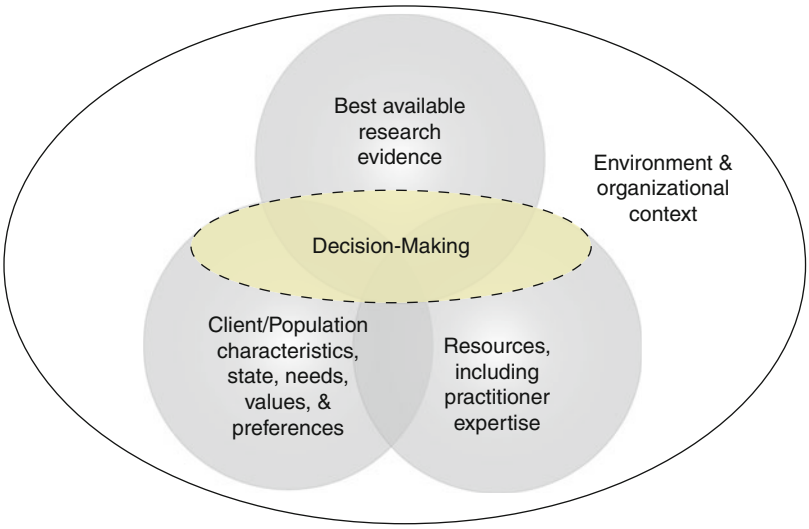
A necessary precondition for EBBM was to consider carefully how well the core principles of evidence-based medicine apply to research on behavioral (non-drug, non-device) interventions. That evaluation was undertaken initially by the Society of Behavioral Medicine's EBBM Committee, established in 2000 with support from the National Institutes of Health (NIH) Office of Behavioral and Social Science Research (OBSSR) under Acting Director, Peter Kaufmann. The EBBM Committee, first chaired by Karina Davidson, defined its scope to include behavioral interventions that prevent disease, promote health and adherence to treatment, or change biological determinants of behavioral conditions (Davidson et al., 2003). Initial efforts were dedicated to familiarizing behavioral medicine researchers with the CONSORT guidelines that support comprehensive, transparent reporting of RCTs in medical journals (Schulz et al., 2010a). Partly as a result of the Committee's efforts, the CONSORT guidelines were adopted by journals that publish behavioral medicine RCTs, including the *Annals of Behavioral Medicine, Health Psychology*, *International Journal of Behavioral Medicine*, and *Journal of Consulting and Clinical Psychology*. Additional efforts to improve the quality of behavioral medicine clinical trials addressed a frequent weakness in their analytic approach, i.e., failure to use the intent to treat principle whereby all randomized participants are included in study analyses according to the condition to which they were assigned (Pagoto et al., 2009; Spring, Pagoto, Knatterud, Kozak, & Hedeker, 2007).

Still other efforts of the EBBM Committee addressed common fears and misperceptions about what evidence-based practice entails (Spring et al., 2005). One frequent misunderstanding is that the approach neglects all but RCT evidence. Actually, the principle is that the optimal research design depends upon the question being asked. For example, a prognostic question about the likely course of a patient's condition is answered more effectively by an observational cohort study than by an RCT. Also addressed was the misperception that evidence-based practice equates to cookbook treatment and the false belief that RCTs inevitably exclude complex patients in real world settings.

From EBBM to EBBP to, Simply, EBP: The Conceptual Model

By 2006, the U.S. health care crisis had arrived. With it came the need for and promise of a better integrated system of care that addresses mental as well as physical health and prevention as well as care of the sick, and that accomplishes all this by the coordinated efforts of an interprofessional team. A horizon scan made apparent the need to upgrade and harmonize the approach to evidence-based behavioral practice across the health professions that offer behavioral interventions. Accordingly, OBSSR sponsored the Council on Evidence-Based Behavioral Practice (EBBP), chaired by Bonnie Spring, and its scientific and practitioner advisory boards. Composition of these groups was determinedly interprofessional, combining representatives from medicine, nursing, psychology, social work, public health, and information sciences (www.ebbp.org). The Council's first task was to formulate a conceptual model that could accommodate the diverse historic traditions as well as the individual and population level behavioral interventions that different health professions implement.

Medicine's initial conceptual model of evidence-based practice had emphasized a single parameter: research. EBM was defined simply as "the conscientious and judicious use of current best evidence in making decisions about the care of individual patients" (Sackett et al., 1996). Subsequent EBM definitions emphasized the need to balance considerations in addition to research: For example, "Evidence-based medicine requires the integration of the best research evidence with clinical expertise and the patient's unique values and circumstances" (Strauss, Richardson, Glasziou, & Haynes, 2005).



Evidence-Based Behavioral Medicine (EBBM), Fig. 1 The three circles of interprofessional evidence-based practice (Source: Spring & Hitchcock, 2009)

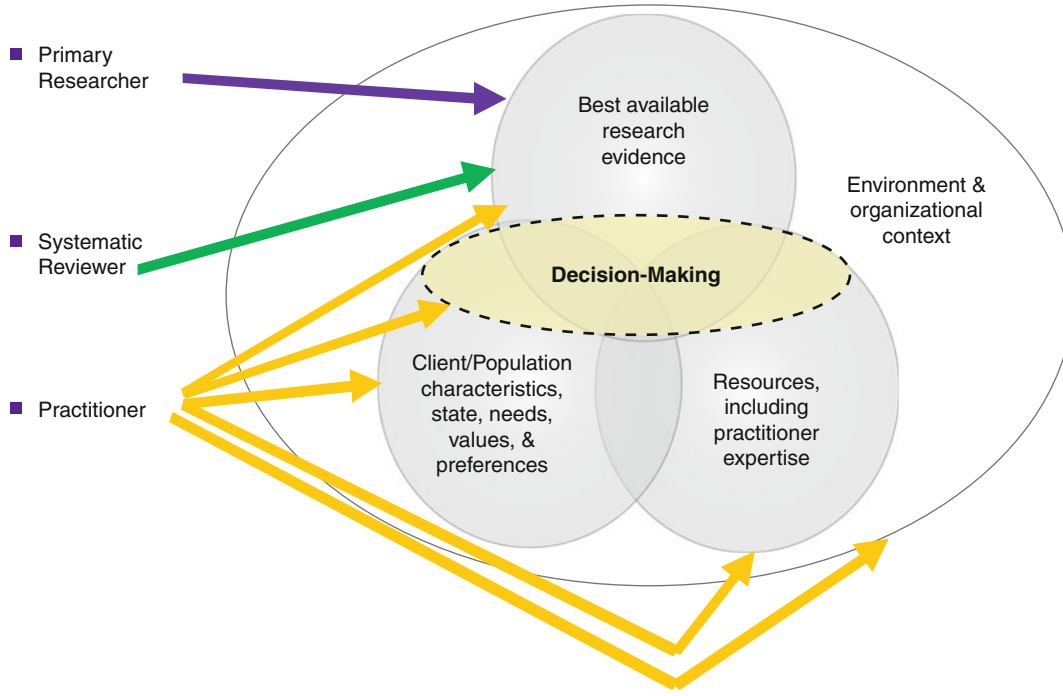
The EBBP Council worked to integrate the historic conceptualizations of evidence-based practice developed in medicine, nursing, psychology, public health, and social work (Satterfield et al., 2009). The aim was to develop a new, harmonized conceptual model suitable to be shared by the more diverse interprofessional health care teams of the future, whose members all require core competency in EBP (Greiner & Knebel, 2003). Because the shared conceptual model supports jointly held vocabulary, foundational assumptions, and practice principles that unite the team, a unified model of evidence-based practice supplants the need to have separate models for different disciplines or for behavioral versus medical interventions (Satterfield et al., 2009; Spring & Hitchcock, 2009).

The interprofessional model of evidence-based practice appears in Fig. 1.

Note that the model depicts three circles (data strands) that need to be integrated in EBP and that evidence-based decision making is shown as the skill that knits these strands together. As in all prior EBP models, best available research evidence remains a circle, occupying the top position because it reflects the cumulative, unbiased body of knowledge about what is effective for the health issue. The client's characteristics, including current state, prior history, values, and preferences, are a second key data strand that needs to be integrated by engaging the client in shared decision making. The third data strand involves resources because these can constrain the available treatment options. Resources include influences such as insurance coverage, other financial resources, available trained interventionists, community facilities, and time or capability to access treatment. The surrounding, outer circle acknowledges that, inevitably, EBP occurs in a particular organizational and environmental context that will influence what interventions are endorsed and how readily they can be implemented.

Health Professionals' Roles in EBP

It is no understatement to say that "it takes a village" to sustain the infrastructure of evidence-based practice. As shown in Fig. 2, health professionals can play three different and essential roles in relation to EBP. First, as primary researchers, they directly contribute to creating the evidence base. They develop new interventions, and they design, conduct, analyze, and report research that evaluates the efficacy and effectiveness of treatments. If random assignment to treatments is feasible, they will usually conduct RCTs. If it is not, as is often the case for policy interventions, they may use alternative designs, such as intermittent time series to evaluate whether a treatment works.



Evidence-Based Behavioral Medicine (EBBM), Fig. 2 Health professionals' roles in EBP

In the second role, as systematic reviewers, health professionals are evidence synthesizers. They aggregate primary research that was conducted by others to create and disseminate research syntheses that can be accessed efficiently and used by practitioners. The research synthesizer role is a critical underpinning in the infrastructure of EBP. Because of the rapid pace at which the scientific literature proliferates, few full-time practitioners can stay comprehensively abreast of new research, while also managing their patient care responsibilities. Systematic reviewers play a critically important role in EBP. By culling and analyzing the full body of new and old studies that address clinically important questions and disseminating their findings to clinicians in the form of pithy summaries, they make the EBP enterprise feasible for practitioners. To accomplish this, systematic reviewers first develop a comprehensive and unbiased protocol to locate the primary research that addresses a practical question. Having acquired the relevant studies, they critically appraise, extract, and synthesize the data to provide an answer. Depending upon the heterogeneity of the interventions and study designs included in the review, they may synthesize and report the findings solely qualitatively or also quantitatively, using meta-analysis. Systematic reviewing is itself a sophisticated and evolving form of research methodology that is increasingly used as the basis for health policies, including practice guidelines.

Finally, in the third role as practitioners, health professionals play the most complex and challenging role in EBP. The clinician extracts and uses data from each of the three EBP circles. Clinicians are research consumers: They access research evidence and appraise its quality and relevance for their context. For efficiency in a busy practice context, clinicians are advised to turn first to the secondary, synthesized, critically pre-appraised sources of evidence such as systematic reviews or the evidence-based practice guidelines to be found on www.guidelines.gov. However, in some instances, there may be no applicable treatment guidelines or systematic review, requiring the clinician to search the primary literature to locate relevant original

research. Moreover, the health professional adopting the practitioner role interacts more directly than either primary researchers or evidence synthesizers with the remaining two circles of the EBP model: client characteristics and resources. To simplify the practitioner's complex job, the 5-step evidence-based practice process, shown in Fig. 3, maps out a recommended series of steps that practitioners can follow in order to address each of the three circles.

The Five Steps of Evidence-Based Practice

Evidence-based practice entails both a conceptual model (shown in Fig. 1) and the 5-step process shown in Fig. 3. Each step represents an integral part of the EBP process and a competency to be mastered by the clinician. Note that assessment is assumed to precede the onset of the EBP process and to recur throughout it, rather than being considered a formal step. Step 1 is to ask questions that are formulated and structured in a manner that facilitates finding the relevant research. Step 2 is to acquire the best available evidence regarding the question. Step 3 is to critically appraise the evidence on two parameters: its validity and its applicability to the problem at hand. Step 4, Apply, is the most complex phase in the EBP process and the step that links most directly to the conceptual model depicted in Fig. 1. Apply is the step during which the practitioner engages in evidence-based decision making that balances and integrates best available research evidence, client characteristics, and resources to determine a treatment approach. Moreover, to increase the likelihood of treatment uptake and adherence, it is important for the decision-making process to be shared with the affected individual(s) and/or group(s). Choosing and collaboratively applying the best research-supported intervention represents a beginning rather than an end to the EBP process. The treatment supported by best available evidence will be the one that has proved cumulatively most effective for the average patient in an average environment. But what matters most for the evidence-based practice process is the single (N = 1) patient under the clinician's care. Step 5, the final step in the EBP process is to assess that client's response to the intervention, analyze progress, and, if warranted, adjust the course of treatment.

Educational Resources

The www.ebbp.org website created by the NIH-sponsored EBBP project offers access to information, tools, and training modules that facilitate research-to-practice translation for behavioral medicine. Nine online modules are available free of charge, covering a mixture of content relevant to learning objectives in research or practice. Free registration in the online portal conveys access to pre- and post-tests for each module and enables learners to stop and save their progress on a partially completed module. Of particular relevance to primary researchers are the learning modules about Randomized Controlled Trials, as well as the module on Critical Appraisal. The Critical Appraisal module offers an overview of the strengths and weaknesses of alternative research designs for evaluating whether a treatment works. A module on Systematic Evidence Reviews provides an introduction to research synthesis for learners interested in exploring that activity. The module on Searching for Evidence offers useful tips about search strategies for practitioners as well as primary researchers. Its overview of the many available online research databases is of particular relevance for systematic reviewers.

The remaining modules are geared particularly toward those trying to conduct research to

practice translation in behavioral medicine. Of these, three are oriented toward clinicians who work with individuals or practitioners who work with communities or populations. The EBBP Process module provides an overview of how to perform the 5-step evidence-based practice process. The learner is given a choice about whether to work with either an individual or a community. Two separate modules on Shared or Collaborative Decision Making illustrate how to engage individuals or communities, respectively, in the Apply step of the evidence-based practice process. These Process and Shared Decision-Making modules are highly interactive and experiential, giving learners an opportunity to experiment, make mistakes, and ask experts while practicing new learning in a safe environment. Finally, the Stakeholder and Implementation Modules are intended to be used by both researchers and practitioners wishing to engage in collaborative translational research about evidence-based practice. Featuring a series of interview clips with academic researchers, clinicians, and community advocates, the Stakeholder module presents a glimpse of widely varying worldviews about research. The final Implementation module presents a conceptual model of implementation science and offers two different case studies of successful implementation of evidence-based behavioral programs: one involving in-person training and the other involving internet-delivered training.

The resources at www.ebbp.org are meant to be used by either individual learners or by instructors as part of a course on research methods, interventions, or evidence-based practice. In addition to tools provided by the EBBP project, other online tutorials about evidence-based practice are made available by both University of North Carolina and Vanderbilt University.

Definition

Executive function (EF) is an emergent quality of cognitive function that arises from the operation of several brain structures situated at least partly

in the prefrontal cortex of the human frontal lobes. These cognitive operations are minimally reducible to the ability to inhibit prepotent responses, hold items in working memory, and direct attention. These core abilities in turn potentiate a variety of behavioral tendencies that include the capacity to avoid impulsive responding, the ability to remain mindful of and effectively pursue goals, the ability to avoid distraction, and the capacity to delay gratification.

Description

Interest in EFs emerged predominantly from the study of "frontal lobe" patients, or individuals who have sustained damage to the frontal lobes of the brain. Such individuals were initially observed to demonstrate intact general cognitive abilities, but evidenced specific impairments in several areas of function that were thought to be central to notions of personality and everyday social functioning. Early clinical descriptions of these patients in the neurological literature led to more specific formulations of the operations of the frontal lobes (see Stuss & Knight, 2002) and to vigorous inquiry regarding the nature of the concept of executive function itself in cognitive psychology.

EFs are thought to be a set of related cognitive operations that are housed within the frontal lobe of the brain, and they are specifically associated with the operation of the prefrontal cortex. As a group of related cognitive processes, EFs exhibit both unitary and diversity of function and so can be understood in relation to both their general level of operation, or the operation of the specific subfacets (Miyake et al., 2000). Some of the subfacets of general EF include behavioral inhibition, working memory, and task switching abilities. However, there are several conceptualizations of the structure of the executive system, which give prominence to one or more of these components (see Shallice, 1988).

Executive functions are frequently measured using a variety of neuropsychological tests. These include, but are not limited to, the following: the Stroop test, the go-no go test, trails B, digit symbol (subtest of the Wechsler Adult Intelligence Scales), Tower of London/Hanoi, Iowa gambling task, stop signal, and the flanker task. Many of these have been used for decades and represent a class of tasks with similar characteristics, rather than single tasks with exactly specified parameters. For example, the Stroop task involves viewing a series of color names (i.e., the word "red") displayed one at a time. The respondent is required to name the color of font – ignoring the word itself – as quickly and accurately as possible. On some trials, the font color matches the word (i.e., the word "red" is presented in red font; "concordant trials"), and on other trials, the font color is inconsistent with the word itself (i.e., the word "red" is presented in blue font; "discordant trials"). The dependent measure may be any number of parameters including the reaction time on correct trials, error rate, or ratio of reaction times on discordant versus concordant trials. The actual modality of presentation of the stimuli and responses varies depending on the specific requirements of the researcher, as do the number of trials. The Stroop test is thought to measure predominantly the inhibition facet of EF, though strong performance would naturally also correlate with working memory and attention as well.

In addition to such "behavioral" measures of EF, there is considerable interest in measurement of the activation of the underlying brain structures that give rise to EFs. Such approaches to imaging EF engagement include functional magnetic resonance imaging (fMRI), electroencephalogram (EEG), positron emission tomography (PET), and functional near-infrared spectroscopy (fNIRS).

Individual differences in EF are subject to both strong dispositional influences and potential for state-like fluctuation. For instance, EFs are among the most sensitive cognitive functions to the adverse effects of chronic health conditions, as well as the effect of both natural and pathological aging processes (e.g., Alzheimer's disease and other dementias). Nonetheless, in the absence of disease-related cognitive decline, individual differences in EF among cognitively intact individuals are subject to substantial genetic loading (the latter including both genetic and gene x environment interactions).

Interest in EFs in the field of behavioral medicine has increased partly as a function of the significance of EFs for self-regulatory processes in health behavior performance, emotional regulation, and mortality (Hall & Fong, 2007).

Leisure physical activity; Physical activity

Definition

Any bodily movement produced by skeletal muscles that results in an expenditure of energy (Caspersen, Powell, & Christenson, 1985).

Description

The term exercise is often used interchangeably with the term physical activity but is more appropriately used to refer to leisure physical activity performed for fitness or pleasure.

Domains of Physical Activity

The way people spend their time can be categorized into five domains: sleep, leisure, occupational, transportation, and household (SLOTH; Pratt, Macera, Sallis, O'Donnell, & Frank, 2004). Physical activity can occur in each domain but is not likely to occur during sleep. Most efforts to promote physical activity have focused on leisure physical activity, which is activity engaged in during free time, often for fitness or pleasure. This includes working out, playing sports, and recreational walking. Occupational physical activity is any movement resulting in energy expenditure that occurs while working. A person working in manual labor likely engages in more occupational physical activity than someone working a desk job. Transportation physical activity is activity engaged in for the purpose of getting from one place to another, such as walking or bicycling to a destination (e.g., grocery store). Transportation walking declined drastically during the twentieth century and is viewed as a promising domain for physical activity promotion (Handy, Boarnet, Ewing, & Killingsworth, 2002). Household physical activity includes household chores, such as washing dishes, and is not typically a focus of physical activity promotion.

Types of Physical Activity

There are four primary types of physical activity (Sallis & Owen, 1998). Aerobic activity (also called cardiovascular exercise) involves large muscle movement for a sustained period of time. Examples include walking, running, bicycling, and swimming. Aerobic activity is often the focus of physical activity promotion efforts. Anaerobic activity involves muscles working against an applied force, such as resistance training and weightlifting. Bone-strengthening activity involves weight-bearing

exercises that strengthen the body's bones, such as squats and body extensions. Flexibility exercises, such as stretching, are those that increase the range of movements of joints and muscles.

Physical Activity Intensity levels

Movement is commonly classified into four intensity levels based on the amount of energy used by the body per minute of activity. Sedentary activity refers to no or little body movement and often involves sitting (for more information, see "► Sedentary Behaviors"). Light-intensity physical activity refers to slight body movements that lead to energy expenditure but are not strong enough to be considered moderate or vigorous. Moderate-intensity physical activity is the primary intensity level promoted in behavioral medicine. Moderate-intensity physical activity is often defined as activity during which a person's heart rate is 50–70% of his or her maximum heart rate (obtained by subtracting the person's age from 220). This generally includes brisk walking, dancing, gardening, and bicycling. Vigorous-intensity physical activity occurs when a person's heart rate is 70–85% of his or her maximum heart rate. Examples of vigorous-intensity activities include race walking, jogging, running, and hiking (Centers for Disease Control and Prevention (CDC), 2010).

Benefits of Physical Activity

Considerable evidence suggests that regular physical activity reduces the risk of many adverse health outcomes, such as cardiovascular disease, type 2 diabetes, some cancers, and mortality (Blair et al., 1996; Haskell, Blair, & Hill, 2009). Physical activity is also beneficial for mental health and quality of life and has been successfully used as a treatment for mental health disorders such as depression (Dunn, Trivedi, & O'Neal, 2001). Most health benefits occur with at least 150 min a week of moderate-intensity physical activity; additional benefits occur with more physical activity, and some physical activity is better than none (U.S. Department of Health and Human Services, 2008). For more information on health-related benefits of physical activity, see "► Physical Activity and Health, ► Physical Activity."

Physical Activity Recommendations

The US Department of Health and Human Services produced physical activity guidelines for children/adolescents, adults, and older adults (U.S. Department of Health and Human Services, 2008). The recommendations are as follows:

- Children and adolescents should engage in at least 60 min of physical activity daily, including vigorous-intensity physical activity at least three days a week. As part of their 60 min or more of daily physical activity, children and adolescents should include muscle-strengthening physical activity on at least three days of the week and bone-strengthening physical activity on at least three days of the week.
- Adults should engage in at least 150 min of moderate intensity, or at least 75 min of vigorous-intensity physical activity per week. Aerobic activity should be performed in episodes of at least 10 min. Adults should also do muscle-strengthening activities that are moderate or high intensity and involve all major muscle groups on two or more days a week.
- Older adults ($\geq$ age 65) have the same guidelines as other adults, except when older adults cannot do 150 min of moderate-intensity aerobic activity a week because of chronic conditions, they should be as physically active as their abilities and conditions allow.

Prevalence of Physical Activity in the United States

Nationally representative data showed that in 2007, 64.5% of US adults met the US Department of Health and Human Services physical activity guidelines. Women, older adults, people of racial/ethnic minority, less educated people, and those who were obese reported lower amounts of physical activity (Carlson et al., 2008). This data is based on how much physical activity people report they are doing. Objective physical activity rates were measured in 2004 using physical activity monitoring devices. Results were that fewer than 42% of children, 8% of adolescents, and 4% of adults met physical activity guidelines (Troiano et al., 2008). Although physical activity prevalence rates vary drastically when measured

with self-report versus physical activity monitors, prevalence rates found using each method point to a need for increasing physical activity.

Exercise Testing

Physical fitness testing; Stress testing

Definition

Exercise testing is a method used to evaluate a number of physiological parameters and conditions, such as heart and lung capacities and pathologies, as well as physical ability. Clinical exercise tests, which evaluate vital organ functioning, are typically designed to incorporate large muscle groups, and these tests use modalities such as treadmills or cycle ergometers. Maximal exercise testing protocols are structured to be progressive to the point of exhaustion, whereas submaximal exercise tests are conducted at a lower exercise intensity in a single-stage or multistage protocol and are terminated at a predetermined point.

An individual performs an exercise test, and data is collected by the test administrator. The collected data/information can then be analyzed to assess the nature of the physiological measure or disease/condition that the test was specifically designed to evaluate. Exercise tests can not only be used as diagnostic tests, such as in the case

of evaluating heart conditions, but are also an important part of designing safe exercise programs for patients with a chronic disorder. In addition, exercise tests can also be used to monitor the improvements or detriments resulting from the individual's treatments or physical training: an exercise test is conducted before the treatment to establish a baseline and then conducted again after the treatment; the effects of the treatment can then be evaluated.

It is also important to note that, in the case of exercise testing batteries, where more than one exercise test will be administered at a given time, the order of the tests may alter the results. For example, nonfatiguing exercise tests and exercise tests requiring muscular coordination should be conducted before fatiguing tests so as to not tire out the individual prematurely. By carefully selecting the order of the tests in the exercise testing battery, one can ensure more accurate results.

ESM; Experience sampling method

Definition

The experience sampling method (ESM) is an attempt to provide a valid instrument to describe variations in self-reports of mental processes. It can be used to obtain empirical data on the following types of variables: (a) frequency and patterning of daily activity, social interaction, and changes in location; (b) frequency, intensity, and patterning of psychological states, i.e., emotional, cognitive, and conative dimensions of experience; (c) frequency and patterning of thoughts, including quality and intensity of thought disturbance (Csikszentmihalyi & Larson, 1987).

ESM represents a valuable way of assessing clinical phenomena in real-world settings and across time. It can be used in various settings. In ESM studies, participants are required to fill in questions about their current thoughts, feelings, and experiences when prompted by an electronic device (e.g., a wristwatch, PDA). Entries are typically made at fixed or random intervals over a period of days (a week is a typical period). Briefing, debriefing, which sampling procedure to use, adherence, data management, and analytical issues must be considered carefully in the study design phase to ensure optimum data collection and hence optimum results from the study.

A growing body of research suggests that momentary assessment technologies that sample experiences in the context of daily life represent a useful and productive approach in the study of behavioral phenotypes, and a powerful addition to mainstream cross-sectional research paradigms (Myin-Germeys et al., 2009). These authors described momentary assessment strategies for psychopathology and presented a comprehensive review of research findings illustrating the added value of daily life research for the study of (1) phenomenology, (2) etiology, (3) psychological models, (4) biological mechanisms, (5) treatment, and (6) gene-environment interactions in psychopathology. They concluded that variability over time and dynamic patterns of reactivity to the environment are essential features of psychopathological experiences that need to be captured for a better understanding of their phenomenology and underlying mechanisms (Myin-Germeys et al.).

The last decade has seen an increase in the number of studies employing the ESM in clinical research (see Trull & Ebner-Priemer, 2009). Further research is needed to examine the optimal equipment and procedure for different clinical groups. Consider for example psychiatric studies. Despite its theoretical advantages, using this methodology in psychiatric populations is challenging (Palmier-Claus et al., 2011).

Experimental Designs

J. Rick Turner
Cardiovascular Safety, Quintiles, Durham, NC, USA

Definition

There are two fundamental types of study design: experimental and nonexperimental (Piantadosi, 2005). Piantadosi defined an experiment (an experimental design) as a series of observations made under conditions in which the influences of interest are controlled by the research scientist. In contrast, in nonexperimental studies, the research scientist collects observations but does not exert control over the influences of interest.

The classic example of an experimental design is the randomized clinical trial, in which the subjects (participants) are randomized to one of two or more experimental groups, thus receiving the intervention given to all members of each group. The simplest form of this design contains an experimental group receiving the intervention of interest (e.g., a behavioral intervention to lower blood pressure) while a second group receives a control intervention. The results obtained for each group are then compared to examine any statistically significant and clinically significant differences between the groups.

Two commonly used designs are the crossover design and the parallel groups design. In the first, each subject will receive each intervention, while in the second different groups of subjects receive just one of the interventions. When possible, the crossover design is preferable since each subject acts as his or her control subject.

Experimental Group

J. Rick Turner
Cardiovascular Safety, Quintiles, Durham, NC, USA

Definition

As noted in the ▶ Experimental Designs entry, experimental designs are those in which the influence(s) of interest are controlled by the research scientist. An experimental group is a group of subjects who receive a particular treatment or intervention. Experimental subjects are randomly assigned to one of the treatment groups so that many potential influences that cannot be controlled for (e.g., sex, height, and weight) are likely to be as frequent in one experimental group as they are in the other.

It should be noted that the term "treatment group" is related to the term "experimental group," but they are not synonymous. Experimental groups can be thought of as a subset of treatment groups, i.e., groups formed by research scientists before administering the treatment or intervention of interest. Treatment groups can be formed retrospectively. For example, a research scientist may wish to collect follow-up data for patients who received two kinds of intervention for the same illness or condition. A simple example might be to determine the percentages of patients still alive 10 years following the

cessation of Treatment A and Treatment B, two treatments given for the same serious condition. Such individuals could be classified as Treatment Group A and Treatment Group B. A meaningful comparison in this case would require the identification of groups of patients who were as similar as possible in every other regard except which treatment they received, a challenge common to many retrospective research strategies.

Explanatory Models of Illness

Yori Gidron
Faculty of Medicine and Pharmacy, Free University of Brussels (VUB), Jette, Belgium

Definition

This term refers to the manner in which patients explain their health conditions and consequences. Much theoretical work has been done in health psychology/behavior medicine on this topic, and it has been applied to prediction of patient coping and adherence with treatments and to prediction of disease outcomes. An important part of appraising an illness is making sense of it, and patients often search for causes to which they attribute the onset of an illness. As such, these "explanations" reflect patients' explanatory models of illness, in contrast with scientifically based models of illness. One may contrast explanatory models that attribute diseases to physical causes with those that attribute disease to psychosocial causes. They first may include one's genetic profile, an underlying pathophysiological process (e.g., inflammation), injury, or infectious agents, to mention but a few examples. The second include "stress," often a generic term referring to a life event or events, one's mental state (e.g., depression, anxiety, anger) or psychosocial context such as exposure to violence, poverty, or solitude, to mention but a few examples. Murdock (1980) found that among 139 societies worldwide, the prevailing causal attribution of illnesses was psychosocial.

One of the most scientifically tested explanatory models of illness is the Common Sense Model of Leventhal, Diefenbach, and Leventhal (1992). This model is a self-regulation model – people react to and regulate their behavior in light of an illness. The model's core is a patient's illness representation – a set of cognitions which guide patients in coping with, making sense of, and adapting to an illness. These cognitions include illness identity (label of a condition and its symptoms), cause (perceived or attributed cause, not necessarily biomedically-based), timeline (expected duration of an illness), consequences (physical and social consequences), and curability/controllability (extent of doctor and patient control over the illness). Illness representations, the core of patients' explanatory model, are dynamic and change over the course of one's experience with an illness. This model has been tested in relation to coping and outcomes of arthritic patients, psoriasis, multiple sclerosis, cardiac surgery, to name but a few examples (e.g., Hale, Treharne, & Kitas, 2007). Other investigators have proposed that explanatory models of illness are part of a cultural context of making sense of illness, deriving from one's personal and social experiences. Yet, these models can often exacerbate rather than ameliorate, especially medically unexplained somatic symptoms (Kirmayer & Sartorius, 2007). Thus, while explanatory models of illness are pivotal to

understanding how people understand and cope with their illnesses, these can have important implications for their well-being. Hence, explanatory models of illness can also be targets of therapeutic interventions.

Explanatory Style

Yori Gidron
Faculty of Medicine and Pharmacy, Free University of Brussels (VUB), Jette, Belgium

Definition

This term refers to the manner in which people explain events in their lives and is considered a trait characteristic. Stemming from the pioneering work on learned helplessness by Overmier and Seligman (1967), this phenomenon became important for its relevance to learning and to the understanding of the etiology of depression. Animals initially exposed to uncontrollable stress generalized their lack of control to a controllable stressful situation, manifesting what was termed "learned helplessness." Such animals even continued to receive adversities (e.g., small shocks) with little attempt to control them, though they were in a novel but controllable situation. However, when extrapolating similar studies to humans (mostly using uncontrollable noise stress), it was found that not all people developed learned helplessness. In an attempt to explain this outcome, Abramson, Seligman, and Teasdale (1978) found that people exposed to uncontrollable stress, and who attribute this stress to internal and stable causes which have global effects on their lives, develop learned helplessness and later depression. This pattern of cognitions including internal, stable, and global attributions for negative events was termed "explanatory style." This theoretical change reflected the consideration of a situation × personality interaction in relation to outcomes.

In 1986, Sweeney, Anderson, and Bailey (1986) reviewed over 100 studies with various methodologies on explanatory style and depression. They found that following a negative uncontrollable stressor, people attributing its cause to an internal (rather than external cause), a stable (rather than unstable) cause, of global implications (rather than specific implications), had greater risk of depression. Conversely, people attributing a positive event to external and unstable causes of specific implications are also at risk for depression. The construct can be assessed in several manners, namely, by the Attribution Style Questionnaire (Peterson et al., 1982) or by using the Content Analysis for Verbatim Explanations (CAVE, Schulman et al., 1989) to analyze written texts.

The concept of explanatory style has received important predictive validity, some of crucial relevance to behavior medicine. For example, a study by Peterson, Seligman, and Vaillant (1988) found that a negative explanatory style predicted risk of physical illnesses, over a 35-year follow-up period. In that study, explanatory style was based on open-ended questions, completed by Harvard University students when they were at age 25. Pessimistic explanatory style predicted more risk of poor physical health at the ages of 45–60, after controlling statistically for baseline physical and mental health.

Another study found that a negative explanatory style predicted higher risk of nonfatal and fatal myocardial infarction (MI) in the Normative Aging Study (Kubzansky, Sparrow, Vokonas, & Kawachi, 2001). In contrast, Tomakowsky, Lumley, Markowitz, and Frank (2001) found that a negative explanatory style predicted a smaller decline in CD4 counts but more subjective symptoms in HIV patients. Thus, more evidence supports the notion that a negative explanatory style predicts poor health; though in some samples, this is not the case. A negative explanatory style can also serve as a framework for cognitive interventions in treating depressive people, given the relative consistent role of explanatory style in depression and given its clear structure and functions.

Definition

Expressive writing is a form of therapy in which individuals write about their thoughts and feelings related to a personally stressful or traumatic life experience. Expressive writing is sometimes referred to as written disclosure, because writers are instructed to disclose personal information, thoughts, and feelings. Unlike communicative forms of writing, expressive writing is personal, free flowing, and informal, often without concern for style, spelling, punctuation, or grammar.

Description

Origins

Expressive writing resembles journaling, which had its heyday the 1970s following the publication

of Ira Progoff's book, *At a Journal Workshop*. In the late 1980s, researchers James Pennebaker and Sandra Klihr Beall conducted one of the earliest controlled scientific investigations into the therapeutic effects of expressive writing. In that study, college students in an expressive writing intervention condition wrote for 15 min on 4 consecutive days about the "most traumatic or upsetting experiences" of their lives, while their counterparts in a control group wrote about superficial topics. Students who wrote about the facts and their associated feelings surrounding a life trauma evidenced short-term increases in arousal and negative mood, but also evidenced fewer health center visits months after the writing intervention relative to controls. Subsequently, dozens of studies have investigated the potential power of writing to bring about benefits in behavioral, psychological, and physical health outcomes. In the 1990s and early 2000s, investigators began to focus more on understanding how expressive writing influenced such a broad array of outcomes ranging from preventing depressive symptoms and health center visits for illness to altering immune functioning and working memory. Work on identifying theoretical mechanisms continues to this day, but mostly current research focuses on testing the efficacy of expressive writing for mitigating problems in an ever widening range of populations, including children and various high-risk or clinical populations (Lepore & Smyth, 2002).

Expressive Writing Interventions and Variations

Expressive writing interventions are usually quite brief, consisting of several 15- to 20-min writing sessions spread over multiple days. Benefits have been observed in interventions using just a single writing session or as many as 8 weekly sessions, but there is some evidence that effects are most powerful when the writing sessions last at least 15 min and are repeated at least three times. Typically, investigators instruct participants to write about nonspecific traumas of their choosing, but a growing number of studies have focused on evaluating the potential benefits of writing about specific traumas and stressful life events (see Box 1 for sample instructions). Whereas writing about major upheavals can be broadly beneficial, focused writing about a specific topic also appears to confer benefits. For example, writing about an upcoming graduate school examination has been shown to reduce depressive symptoms, and writing about breast cancer resulted in greater declines in physical symptoms when compared with control writing.

Whereas the core instructions of writing about one's deepest thoughts and feelings surrounding a traumatic or stressful life event are apparent in most expressive writing studies, investigators have experimented with the procedure in an effort to isolate mechanisms of action or to improve upon the intervention. For example, the writing might be private or shared with an investigator, conducted in a single writing session or multiple sessions, possibly include booster sessions, focus on past or ongoing events, consider either positive or negative aspects of life stressors. In addition, there have been variations in location of writing (e.g., home versus laboratory), as well as mode of writing (e.g., longhand versus typing). It appears that the beneficial effects of expressive writing are robust, resulting in benefits despite variations in instructions, settings, and procedures. The effects of expressive writing are somewhat stronger when people write at home or in a private setting, the outcomes are measured within a month after writing rather than later in time, the writing focuses on recent or previously undisclosed stressors, and the instructions provide directed questions, information on switching topics, and specific examples of what to disclose in writing. Some variations in the writing instructions have little or no effect on the benefits of writing, including the spacing between the writing, the positive or negative valence of the writing, whether the writer or the experimenter selects the topic of writing, or the mode of writing.

Effects of Expressive Writing

As shown in Box 2, the effects of expressive writing interventions are quite broad. Scholars have examined the impact of expressive writing on physiological functioning, self-reported health

Box 1. Sample Expressive Writing Instructions

A. Writing About Self-identified Stressors

For this writing exercise, please write for 15 min about your very deepest thoughts and feelings about the most traumatic experience of your life or an extremely important emotional issue that has affected you and your life. In your writing, really let go and explore your deepest thoughts and feelings. You might tie your topic to your relationships with others, including parents, lovers, friends or relatives; to your past, your present or your future; or to who you have been, who you would like to be, or who you are now. You may write about the same or different issues, experiences and topics each day. All of your writings will be confidential. Don't worry about spelling, grammar or sentence structure. The only rule is that once you begin writing, you continue until the time is up.

B. Writing About Specific Stressors

For this writing exercise, please write for 15 min about your deepest thoughts and feelings concerning your cancer. For example, you might write about the various ways the cancer has changed your life, what your life was like before the diagnosis, after diagnosis, during treatment and now. For some people, dealing with a cancer diagnosis is just one of many stressors in their life. You do not have to limit your writing to how cancer has affected your life. You may focus on other highly upsetting experiences in your life. The most important thing is that you should explore your very deepest emotions and thoughts. All of your writings will be confidential. Don't worry about spelling, grammar or sentence structure. The only rule is that once you begin writing, you continue until the time is up.

and health behaviors, psychological well-being, attitudes, and general life functioning. Meta-analytic reviews have revealed modest but significant effects of expressive writing across diverse outcomes and populations (Frattaroli, 2006; Frisina, Borod, & Lepore, 2004). Recent work has extended earlier investigations by studying the effects of expressive writing on outcomes as varied as emotional intelligence, workplace incivility, homesickness, caregiving stress, and gay-related stress.

Both objective and subjective indicators of physical health have been examined in response to expressive writing. Some of the most striking effects of expressive writing interventions are on physiological outcomes, including immune parameters (e.g., IL-8, CD8, T-helper lymphocytes, T-cytotoxic lymphocytes, Epstein-Barr antibodies), HIV viral load, and liver functioning. What is not yet clear is whether the changes in the immune parameters and other biomarkers are clinically meaningful. The evidence linking expressive writing to other theoretically plausible and objective biological outcomes has not always been positive, with some studies failing to find significant effects on outcomes such as blood lipids, blood pressure, lung capacity, heart rate, strength, joint condition, and body composition. Effects on self-reported physical health are fairly robust. Expressive writing reduces health-care utilization, pain, somatic illness symptoms (e.g., upper respiratory illness symptoms), disease severity ratings, and illness behaviors. However, with the exception of some studies that have found effects of writing on a healthy diet, most analyses have failed to show effects on health behaviors, including physical activity, substance use, sleep, and adherence to medical treatment. Thus, health behaviors are not likely mediators of the health benefits of expressive writing interventions.

In general, the effects of expressive writing on psychological health and well-being are weaker

than for physical health. Studies of psychological well-being have included assessments of depression, positive and negative mood, anger, aggression, grief, distress, anxiety, post-traumatic stress and growth, dissociation, adjustment to school, coping, cognitive schemas, and emotion regulation. Consistently strong effects have been observed for depression and positive attitudes and mood; effects are equivocal for post-traumatic growth and for anxiety, with some studies showing heightened anxiety in response to writing and others showing reductions in anxiety. There is no evidence that expressive writing has reliable effects on coping, cognitive schemas, or self-regulation.

As research on expressive writing has blossomed, scholars have extended outcomes beyond physical and psychological well-being to include broader indicators of functioning. There is strong evidence that expressive writing interventions affect work-related behaviors such as reemployment, absenteeism, and incivility in the workplace; the quality of social relationships, including forgiveness; cognitive functioning such as working memory and reaction time; and school outcomes, such as grade point averages and adjustment to college life.

Who Benefits from Expressive Writing?

One way to understand who benefits from expressive writing is to examine the kinds of populations that respond favorably to the intervention. Many of the early studies on expressive writing focused on nonclinical populations. Indeed, healthy college students have been the subjects in numerous expressive writing studies. In the past 15 years, though, an impressive number of clinical trials have been conducted involving high-risk and clinical populations, and even youth. Another way to understand who benefits from expressive writing is to look for subgroups of writers in intervention studies who benefit relatively more or less than other writers in the intervention.

Expressive writing interventions have been applied to populations confronting a wide range of clinical health problems, including cancer, arthritis, asthma, post-traumatic stress disorder, HIV infection, cystic fibrosis, chronic pain, and sleep disorders. There is evidence of benefits of writing in clinical populations, but it is mixed. For example, one expressive writing intervention study showed improvements in lung function and physician-rated disease severity, respectively, in participant with asthma or rheumatoid arthritis. However, these findings have not been replicated in follow-up studies. Perhaps the most frequent clinical population targeted for expressive writing interventions has been cancer survivors. The results have been mixed. Some studies have reported select benefits in cancer populations, such as reduced postoperative medical illness visits in good prognosis breast cancer survivors,

better sleep quality among renal cancer patients, and reduced pain perception among prostate cancer survivors; yet just as many studies have reported absolutely no significant benefits of expressive writing. In only a few trials with clinical populations, specifically participants with post-traumatic stress disorder, have possibly serious adverse effects been identified. It is possible that for psychiatric populations writing should be guided by a therapist and used only as an adjuvant to more traditional therapies. The vast majority of studies with clinical populations suggest that it is a safe intervention, if not particularly powerful and reliable. The quality of the interventions, writing instructions, measured outcomes, settings, and time to follow-up vary tremendously from one clinical trial to the next, so the evidence of the efficacy of this intervention with clinical populations is still inconclusive.

Although most expressive writing interventions are conducted with adults, there are a growing number of randomized clinical trials that have been conducted with children and adolescents. Approximately half of these trials have been conducted with clinical populations outside of the school context; the remaining trials have been conducted in a school context with general populations of youth. The findings with youth have not been as promising as findings with adults. Across studies, effects of writing on internalizing symptoms have been equivocal, with fewer than half of the trials reporting improvements on measures of psychological well-being. With respect to indicators of physical health, no study has reported improvements in somatic complaints due to writing, but several studies with small samples have reported improvements in functional ability and declines in medical and emergency room visits. Some of the equivocal findings with youth may be due to use of writing with youth who do not have the cognitive capacity to process their stressful experiences. Additionally, youth who are not dealing with significant stressors may see their anxiety increase in response to writing interventions. Because writing uses few resources and fits into normal school activities, there is a potential for writing interventions to have a large impact on school populations provided that it is used with youth who have experienced significant stress and have the cognitive capacity to process their stressful experiences.

Individual studies and meta-analytic reviews have investigated whether specific subgroups of writers benefit more or less from the intervention, or whether identifiable factors alter or moderate the effects of expressive writing on outcomes. One problem with such analyses is that they cannot establish cause-effect relationships because other unmeasured variables might explain any observed differences between subgroups. Nonetheless, as evidence on subgroup differences and moderators accumulates, it might suggest feasible targets for intervention and methods for improving upon the intervention. Analyses in this vein have shown that a number of factors do not appear to alter the effects of expressive writing, including participant age, ethnicity, education level, severity of stressor or trauma, baseline psychological health levels, negative affectivity, and level of inhibition or prior disclosure status. One caveat, however, is that not all studies that have examined individual moderators have had adequate representation within all the levels of the subgroups, so it is possible that future research will derive different conclusions. Other factors do appear to make a difference, but the evidence is mixed, since effects fail to replicate or have not yet been investigated in multiple studies. There is some evidence that the individuals who benefit the most are male, have higher stress or physical health problems prior to writing, have lower optimism, perceive that they are socially constrained in talking about their stress, have no difficulty in identifying and labeling emotions, and do not habitually repress negative emotions.

How Does Expressive Writing Work?

There are two dominant theoretical models to explain the array of beneficial effects of expressive writing, the disinhibition model and the self-regulation model. Relatively few studies have directly tested the theoretical mechanisms explaining the benefits of expressive writing, and evidence on the validity of all of the

mechanisms is mixed (Lepore & Smyth, 2002; Sloan & Marx, 2004).

The disinhibition model is based on the notion that individuals inhibit or avoid thoughts, reminders, and feelings of traumatic life events because they are distressing and can evoke negative social responses. Inhibition potentially influences health via the chronic physiological strain and arousal caused by the work of inhibition. Expressive writing theoretically counteracts the adverse effects of inhibition by encouraging individuals to disinhibit themselves by disclosing their deepest trauma-related experiences and associated thoughts and feelings. Numerous writing studies have challenged this model. For example, individuals writing about non-inhibited future events, such as an upcoming graduate school entrance examination, reported significantly lower depressive symptoms than controls. In addition, the benefits of expressive writing appear to be equivalent whether individuals write about previously disclosed or non-disclosed traumas, or write about positive or negative aspects of past traumas.

The self-regulation model is based on the notion that individuals who have excessively high or low levels of control over their emotions have an elevated risk for health problems due to the pathophysiological effects of emotion dysregulation. Research supports the notion that emotion regulation relates to health outcomes. For example, there is evidence that the inhibition, or non-expression, of anger is associated with heightened physiological arousal, which appears relevant to cardiovascular health. However, there is also evidence that individuals with little control over their expression of anger have heightened levels of physiological arousal and risk for cardiovascular disease. Individuals who are optimally regulated in their expression of anger may be at the lowest risk for health problems. According to the self-regulation model, individuals experiencing stressful life events need to strike a balance between emotionally overreacting and underreacting. Expressive writing is thought to facilitate emotion regulation processes by directing attention, facilitating habituation, and aiding in cognitive restructuring. Briefly, by directing attention to different aspects of a stressful experience and one's emotional response and thoughts, expressive writing increases habituation (desensitization) to the negative thoughts and feelings associated with the stressor and potentially allows for the creation of new and less-threatening appraisals and feelings to be attached to the memories of the stressor. Consistent with this theory, there is evidence that expressive writing desensitizes individuals to stress-related thoughts. In addition, there is evidence that expressive writing can reduce stress-related intrusive thoughts, which may be symptomatic of incomplete cognitive processing of stressors. This evidence, however, is not consistent across studies.

Additional research is needed to better understand how expressive writing results in positive social, behavioral, and health outcomes. Although scholars have posited a variety of plausible social, psychological, and biological mechanisms, empirical evidence does not strongly support or rule out any particular explanation. All of the identified mechanisms may be sufficient to influence the outcomes linked to expressive writing, either directly or indirectly. It is likely that there is no single mechanism of action given the diversity of outcomes studied and the mixed evidence on each mechanism.

Ex-Smokers

Definition

The term ex-smoker refers to an individual who has given up (i.e., quit) cigarette and/or tobacco smoking. Ex-smokers were previous current smokers, but are no longer smoking.

Tobacco smoking is defined as the practice of burning and inhaling tobacco, and cigarette smoking is the most common form of tobacco smoking. National surveys define a current smoker as an individual who has smoked at least 100 cigarettes in their lifetime and currently smokes on at least some days.

Description

Cigarette smoking is the most important modifiable risk factor for chronic disease; yet, there is not a consensus in the way smoking status is classified. The harmful effects of cigarette smoking on various health outcomes have been determined by comparing individuals who are (1) current smokers, (2) ex-smokers, and/or (3) never smokers. Therefore, the definition of an ex-smoker is important for making cross-study comparisons regarding the health consequences of smoking and cessation. Most national surveys ask whether a person has a history of smoking 100 lifetime cigarettes *and* whether they currently smoke on some days. Respondents who indicate "yes" to the first question and "no" to the second are categorized as ex-smokers. Other research specifies a time period of smoking cessation needed for ex-smoker classification; however, that time (e.g., 1 day, 1 week, 3 months, 5 years, etc.) varies across studies. Nonetheless, results of studies comparing current smokers with ex-smokers have shown unequivocally that quitting smoking, for even a relatively short time period, decreases the risk of chronic disease.

Because there is unquestionable evidence that cigarette smoking is the leading preventable cause of multiple cancers (e.g., lung and esophageal), heart disease, and stroke, attention has focused on the specific effect quitting smoking has on health. The evidence shows that quitting, even after an extended period of smoking, decreases the risk of associated illnesses. Moreover, the disease risk decreases as the number of years since quitting increases. The 1989 US Surgeon General's report indicated that after 10 years of smoking cessation, the risk of lung cancer is decreased by almost 50% (Centers for Disease Control and Prevention, 1989). Still, ex-smokers continue to have an increased risk of developing a chronic disease compared to never smokers. In comparing the three groups on chronic disease risk (i.e., current smokers, ex-smokers, and never smokers), ex-smokers have a reduced risk compared to current smokers, but they have approximately twice the risk compared to never smokers (Ebbert et al., 2003). The absolute risk of lung cancer remains higher among ex-smokers than never smokers even after smoking cessation (Halpern, Gillespie, & Warner, 1993). However, the excess chronic disease risk for an ex-smoker is reduced to that of a never smoker after 15 years of abstinence. Additionally, Thornton, Lee, and Fry (1994) found that recent ex-smokers were similar to current smokers in the prevalence of chronic

disease risk factors (e.g., low vegetable consumption); and ex-smokers who were smoke-free for 20+ years (i.e., long-term ex-smokers) were similar to never smokers. Compared to current smokers, ex-smokers are more likely to engage in healthy lifestyle behaviors (e.g., attempting to lose weight, cutting down on fatty foods, and increasing vegetable consumption; Thornton et al., 1994), which may further reduce chronic disease risk.

Relapse prevention is important for ex-smokers, considering that approximately 90% of people who quit return to smoking within one year (Brandon, Tiffany, Obremski, & Baker, 1990; Garvey, Bliss, Hitchcock, Heinold, & Rosner, 1992). Although the risk of relapse after a long period of time (i.e., 6–12 months) is relatively low, smoking even one cigarette after quitting is likely to lead to a full relapse. Even with the vacillating status of many ex-smokers, approximately 10% of those who relapse are able to quit again permanently in the future (Wetter et al., 2004). Therefore, interventions for relapse prevention among ex-smokers have been designed and evaluated. A systematic review by Agboola, McNeill, Coleman, and Bee (2010) found that bupropion and nicotine replacement therapy (e.g., the nicotine patch, nicotine gum, and nicotine lozenge) are efficacious in preventing relapse among ex-smokers who quit smoking using such aids. Self-help materials may also be useful in preventing relapse among ex-smokers who quit smoking on their own (Brandon et al., 2004).

In summary, ex-smokers reduce their risk of chronic disease the longer they abstain from smoking. Because exposure to smoke causes significant harm to the body, ex-smokers still have an increased risk of several diseases compared to those who have never smoked. Over time, however, successful ex-smokers are comparable to never smokers on several risk factors for chronic disease.

External Locus of Control

Gary Davis
Medical School Duluth, University of Minnesota, Duluth, MN, USA

Synonyms

Helplessness; Low self-efficacy

Definition

External locus of control is the belief that one's behavior will not lead to valued reinforcement that is available in the environment and therefore not under one's control. The occurrence of reinforcement is believed to be a function of factors out of one's control such as luck, chance, or randomness.

Description

External Locus of Control

External locus of control anchors one end of a continuum of the locus of control construct with the other end anchored by internal locus of control. The construct developed out of work by E. Jerry Phares and Julian Rotter in the 1950s at Ohio State University and was influenced strongly by Alfred Adler's earlier work on striving for superiority. Feelings of inferiority were thought to be associated with externality. Rotter published his initial paper containing the external locus of control construct in 1966 that included the now famous Internal-External Locus of Control Scale (I-E) to measure the locus of control construct. It has subsequently become one of the most frequently cited papers ever published in psychology. The construct was embedded in Rotter's social learning theory and reflects his strong belief in the importance of theoretical frameworks. Some research over the years has been criticized because of the tendency to use the scale and the construct in a manner disconnected from their theoretical home.

External locus of control is defined as the belief or expectation that one's behavior will not lead to valued reinforcement that is available in one's environment; rather, the occurrence of reinforcement is a function of factors out of one's control such as luck, chance, or randomness. In Rotter's terms, external locus of control is a generalized expectancy, meaning that across a range of situations, people who are externally oriented, would have the expectation that control over reinforcements lies outside of their control. In its simplest form, the potential for any behavior to occur is a function of the expectation for reinforcement and the value of that reinforcement. Early in his work, Rotter represented that by the equation BP (behavior potential) $= f$ (E (expectation) $\times$ RV (reinforcement value)).

External locus of control is commonly measured or assessed by the Internal-External Locus of Control Scale. The original scale has 29 items, including 6 filler items, in a forced choice format that requires subjects to agree or disagree with statements. High scores are in the direction of externality. Two examples of "external items" are: *I have often found that what is going to happen will happen* and *Getting a good job depends mainly on being in the right place at the right time*.

Not surprisingly, since creating new tests seems to be one of the things that psychologists do best, many scales have been spawned to measure the construct of locus of control since Rotter's original scale was published. Some of these have been developed as a result of dissatisfaction with the forced choice format and other methodological issues. Others have been developed for use with specific populations or environments such as with children, medical patients, and organizational settings.

Many dissertations and published research papers have included the external locus of control construct. This widespread interest probably reflects our almost natural inclination to be interested in our fate and factors that influence it. Examples of some of the research results on externality are that external locus of control has

been related to low self-efficacy, low self-esteem, helplessness, depression, low achievement motivation, low risk-taking, less independent thinking and greater conformity, and less creativity.

Of particular interest to researchers has been the question of the role that external locus of control plays in the maintenance of health and the adjustment to illness. For the past 30 years, numerous patient populations, both acutely and chronically ill, have been studied to learn about the impact of externality on their illness experiences. The findings generally lend support to the notion that externality influences illness experiences, but the results have not been consistent across patient groups. For example, externals have been found to ask fewer questions of health-care staff and have less information about their illnesses. But other research has found that at least with certain chronic illnesses, such as, diabetes, externals are about as informed as internals. An interesting line of research pursued the idea of matching treatment approaches in a congruent manner with locus of control orientation. For example, it has been found that there is little difference in cardiac rehabilitation outcomes when externals who are in a highly structured and regimented program are compared to internals who are involved in a more self-directed program. However, the inconsistency in research outcomes and very modest association of locus of control to health and illness behaviors clearly suggests that many factors, including the nature of the illness itself, interact with locus of control and influence health behaviors. This conclusion, that many variables interact with locus of control, also holds for health maintenance behaviors for which it may be intuitive to think that externals would be less likely to engage in preventive measures.

A notable contribution to this literature, and the subject itself of considerable investigation, is the Multidimensional Health Locus of Control Scales by Wallston. The MHLC is a group of three scales intended to assess beliefs about health status control and beliefs about control over illness and disease. Numerous other disease-specific scales (e.g., cancer, diabetes, pain) to measure external locus of control have been developed in recent years.

Extrinsic Religiousness (Religiosity)

Kevin S. Masters
Department of Psychology, University of Colorado, Denver, CO, USA

Definition

Extrinsic religiousness (initially and still sometimes referred to as extrinsic religiosity) is characterized as religion that primarily serves other more ultimate ends rather than central religious beliefs per se. Thus, individuals described by extrinsic religiousness use their religion to fulfill more basic needs such as social relations or personal comfort, but "the embraced creed is lightly held or else selectively shaped to fit more primary needs" (Allport & Ross, 1967, p. 434).

Description

Extrinsic religiousness was first described by Gordon Allport and colleagues in the 1960s (see Allport & Ross, 1967) when investigating the possible reasons for discrepant findings in the area of religiousness and prejudice. At that time,

some studies demonstrated that religiousness was positively associated with prejudice, whereas other studies found the opposite. Allport hypothesized that one's religious orientation, or sentiment, may provide guidance in sorting out these findings. The construct of religious orientation was later clarified by Gorsuch (1994) to be a motivational variable.

Extrinsic religiousness has often been measured by the Religious Orientation Scale (Allport & Ross, 1967). More recently, Gorsuch and McPherson (1989) developed the I/E-Revised scale as a more psychometrically sound instrument. Based on previous work (Kirkpatrick, 1989), Gorsuch and McPherson anticipated, and subsequently verified, two subscales on the extrinsic scale, extrinsic-personal (Ep) and extrinsic-social (Es). A prototypic Ep item is "What religion offers me most is comfort in times of trouble and sorrow" and for Es "I go to church mainly because I enjoy seeing people I know there." Scholars in the psychology of religion have debated the relative strengths and weaknesses of the religious orientation construct (e.g., Kirkpatrick & Hood 1990; Masters, 1991), but it remains the most empirically investigated and heuristic construct in this area of work. Investigators attempting to determine the relations between religion and health have also turned to religious orientation. Smith, McCullough, and Poll (2003) in a meta-analytic study found that extrinsic religiousness was associated with higher levels of depressive symptoms. Similarly, Masters and Bergin (1992) provided a narrative review of the literature and found extrinsic religiousness to be related positively with depression, anxiety, and obsessive-compulsive symptoms, whereas McCullough and Willoughby (2009) reported that extrinsic religiousness may be negatively related to self-control. Recent investigations found extrinsic religiousness related to greater laboratory-induced cardiovascular reactivity in older adults (Masters, Hill, Kircher, Lensegrav Benson, & Fallon, 2004), and Masters and Knestel (2011) found that among a random sample of community dwelling adults, those characterized by extrinsic religiousness were more likely to be divorced, reported overall worse health, higher body mass index, greater cigarette use, and a higher number of daily drinks of alcohol than did those characterized as intrinsically religious. There were no differences in the percentages of individuals who were classified as extrinsically religious based on religious denomination. Nevertheless, it is not entirely clear how extrinsic religiousness may interact with religious denomination, and some have suggested that the construct, as currently conceptualized and measured, is more congruent with Protestant notions of religiosity and perhaps most appropriately applied to this religious group (Cohen, Pierce Jr., Chambers, Meade, Gorvine, & Koenig, 2005).

Definition

An eye tracker is a computerized system used to record the activity of eye movements and visual overt attention, hence making it possible to study human behavior. Data obtained from an eye tracker session is useful for testing everything that could be visually observed.

Description

Eye tracking as a means of measuring and monitoring eye movements is widely used in different fields of human behavior research, for example, cognitive psychology, psycholinguistics and reading research, neurophysiology, ophthalmology, usability and human-computer interaction studies, and market research.

Eye Movement Measurement Methodologies

There are four eye movement measurement techniques (Duchowski, 2003) as follows:

- Electrooculography (EOG) – eye movement recording method commonly used in the 1970s. It is based on measuring potential differences of electrodes placed on the skin close to the eye.
- Sclera Contact Lens/Search Coil Lens – an old and very precise eye movement–measuring method based on a contact lens placed on the eye with a reference object, for example, wire coil, attached to the lens.
- Photo-oculography (POG) or Video-oculography (VOG) – a number of eye movement–recording methods based on measurement of different features of the eyes such as shape of the pupil, position of the limbus, etc. The above mentioned methods mainly measure the position of the eye relative to the head.
- Video-Based Combined Pupil-Corneal Reflection (Remote Eye Tracking) – noninvasive eye tracking methods providing measurement of position of the eye in space (not relative to the head). This technique is widely available and most suitable for eye tracking in real time.

Basic Operating Principles of Remote Eye Trackers

Remote eye trackers, that is, Pupil-Corneal reflection eye trackers, use infrared diodes to generate reflection patterns on the corneas of the studied person's eyes. The system uses image sensors to collect images of the eyes and

Eye Tracking,

the reflection patterns. Sophisticated image processing algorithms identify relevant features, including the eyes and the corneal reflection patterns. Complex mathematics is used to calculate the position of each eyeball and finally the gaze point, in other words, where and on what the person is looking. The development of eye trackers is based on present neuroscience knowledge. Here the brain's physiological and functional processes represented of the Mango- and Parvo-cellular pathways are of great importance (Duchowski, 2003).

The performance of an eye tracker can be described in terms of gaze accuracy and precision, and track robustness. Accuracy describes the angular average distance from the actual gaze point to the one measured by the eye tracker. Gaze precision describes the spatial variation between successive samples collected when the person fixates at a specific point on a stimulus, for example, an image on the screen (Duchowski, 2003). Sampling rate and Latency are also important characteristics: the first one determines how fast the movement of the eye is measured; the second determines how fast the gaze point information from the eye tracker is obtained (important for gaze contingency and interaction).

The most commonly used systems for investigation of eye movements are categorized into eye tracking systems for human-computer interaction and diagnostic use of eye movement analysis. The interactive systems include selective and gaze-contingent systems and the latter are either screen-based or model-based. Examples of eye tracking systems usage are shown in Figs. 1–3.

Applications

Eye tracker systems are used to study human visual behavior by measuring gaze parameters like (a) fixation duration in milliseconds (gaze time and/or gaze fixation time), (b) average number of fixation points lasting between 200 and 300 ms, (c) saccade duration in milliseconds, that is, quick, simultaneous movements of both eyes, (d) proportion of left-to-right saccades, (e) proportion of saccade regressions and proportion of vertical saccades, (f) pupil dilation, (g) number of blinks, (h) smooth pursuit, (i) occurrence of nystagmus, (j) attention, and (k) inattention priority. The recorded data is statistically analyzed and graphically rendered and applied to measure visual search efficiency, priority, navigation usability, and real observing

Eye tracking is used to answer an endless array of *scientific research* questions regarding animal habits, for example, for studying chimpanzees' face scanning patterns (Kano & Tomonaga, 2010) and human visual habits. The human research is performed in the fields of behavioral medicine; linguistics; ophthalmology; cognitive, developmental, and behavioral psychology; and neurophysiology sometimes integrated with electroencephalography (EEG) in real time. For example, eye tracking technology is applied in developmental research, used as a diagnostic tool, for example, to children suffering from dyslexia, attention deficit hyperactivity disorder (ADHD), and autism, for oculomotor differential diagnosis in neurological disorders, discriminating between Parkinson's and Alzheimer's disease, diagnosis and treatment of neurological disorders, for example, mild traumatic brain injury, schizophrenia, and occurrence of macular degeneration, and in linguistics studies. Studies of fatigue and gaze attention are helpful to understand the effectiveness of work performed by

	Linguistic research Brain physiology	Eye behavior investigation of attention	Seven eye movement variables were investigated: (a) fixation duration in milliseconds, (b) average number of fixations lasting between 200 and 300 ms, (c) saccade duration in milliseconds, i.e., 7–9 letter spaces, (d) proportion of left-to-right saccades, (e) proportion of saccade regressions, i.e., occurrences of re-reading, and proportion of vertical saccades, and (f) total time for reading three sets of words and three sentences. The aim was to understand which variable (a–f) would best discriminate between 6 years and 12 years old children with the diagnoses reading disability and attention deficit hyperactivity disorder (ADHD) compared to a control group of "normal" developed children. There were significant differences between the control group and the disability groups, who showed *atypical eye movements* for all variables apart from *saccade duration*. However, the results do not yet support the use of these eye movement variables to distinguish between the groups of participants with reading disorders and ADHD. truck chauffeurs, captains, police officers, and air traffic controllers. Moreover, eye tracking provides unique methods to perform *marketing and media research*, for example, evaluate how users and consumers experience and perceive different media like websites and communication messages or make decisions about attractive products in shops and restaurants. The eye tracking technology is extensively used for *usability* studies, on websites, computer applications, games, and other human-made objects. Individually adapted eye tracker systems are used as assistive devices for people with complex motor and language disabilities, making them able to communicate, receive information, and play games by using eye pointing as demonstrated in video filmed cases (AbiltyNetGate, 2011). The recent technological development in the eye tracking field promises that eye movement will be the future way of controlling computers (Norrby, 2008; Wolverton, 2011) and other apparatus in home and work. Among these endless numbers of possible eye tracking applications some publications, emphasizing the various gaze parameters, are shown in Table 1.

Fall Risk Behavior

Lindy Clemson
Ageing, Work & Health Research Unit, Faculty of Health Sciences, University of Sydney, NSW, Lidcombe, Australia

Definition

Older people tend to define a fall as loss of balance and attribute it to external factors such as an obstacle or the weather, whereas health professionals relate it to intrinsic causes such as medications, medical reasons, or muscle strength. Although older people recognize inattention as important, neither group easily includes behavioral risks in their attribution.

The WHO definition of behavioral fall-risk factors includes those concerning human actions, emotions, beliefs, and daily choices. These are potentially modifiable and include, for example, sedentary behaviors, management of medications, inclusion of appropriate exercise in weekly routines, and better choices in safe shoe selection. Behaviors can be examined from their contribution to causing falls to the crucial part they play in reducing fall risk. For example, an individual's risk of falls is inexplicably related to the interaction between their mobility and balance capacity, their environmental demands and stressors, and their fall-risky lifestyle and behaviors.

Description

Fall-risk behaviors can be conceptualized as sequential events with a number of contributing factors which may be antecedents, present or consequential to the fall event. There has been some limited work in exploring risk behaviors surrounding the fall event, predictors of falls over time, personal characteristics, and socioeconomic and cultural influences. The consequences of falls can relate to the sequelae of injury, fear of falling, or reduced activity. Even for those who

M.D. Gellman & J.R. Turner (eds.), *Encyclopedia of Behavioral Medicine*,
DOI 10.1007/978-1-4419-1005-9,

experience slight injuries such as contusions there are frequently reported short-term physical function decreases and a loss of confidence. The earlier cohort studies on risk factors focused predominantly on intrinsic factors though several did identify reduced activity, leaving home less often, and in one cohort study, more than ten activities per week significantly increased fall risk. Older people who have fallen often attribute actions such as "hurrying," "carelessness," or "inattention" as causal fall behaviors.

A longitudinal study following fallers over an 8-year period has shown that depression and lower levels of morale are associated with increasing fall rates (Anstey et al., 2008). It may be that depression can contribute to motor or cognitive disturbances that can predispose people to falls. One intervention study (Salminen, Vahlberg, Salonoja, Aarnio, & Kivela, 2009) provided psychosocial group support for persons assessed with depression which lessened depression, enhanced involvement in the exercise components of the program, and resulted in a reduction of fall risk.

There are different cognitive profiles for those who have occasional falls, associated with subtle aging changes such as accuracy, planning, or inhibition of a response, compared to those who are having recurrent falls, which may be associated with broader deficits in processing speed, task-switching, and visual attention (Anstey, Wood, Kerr, Caldwell, & Lord, 2009). Few demographic characteristics are linked to falls though living alone is associated with a greater risk of multiple falls. Other profiling that highlights differences in risk behaviours has been identified in certain groups: those that are frailer compared to those who are very active; those in rural compared to city, particularly in terms of the type and extent of indoor/outdoor activities; and, differences in extreme weather conditions. Gendered responses to risk have been shown to vary, with women tending to blame themselves or others and men quicker to accept responsibility, and how family members respond which can vary from overprotective sons for women and younger female relatives who engage in negotiating actions for the men (Horton, 2007).

English-speaking people in Australia and Caucasians in the USA have higher falls injury admission rates than other groups. However, it is less clear whether this is a function of increased falls or is due to better access to health services. In countries where there are numerous immigrant groups with changing aging demographics, there is an increasing need to tailor falls prevention programs to meet particular linguistic and cultural requirements and differences in health-seeking behaviors and attitudes (Bradley & Harrison, 2007).

Fear of falling can be associated with falls but it has become evident that it is an independent phenomenon that can result in activity avoidance leading to social isolation, physical de-conditioning, and reduced quality of life whether or not falls occur. Delbaere, Close, Lord, and co-authors (2010a, b) have led important research defining how perceived risk of falling and "real" risk measured by validated physiological measures interact with psychological states. Four groups were identified: vigorous, anxious, stoic, and aware. The anxious group had a high-perceived fall risk compared to real risk and was related to depressive symptoms, neuroticism, and decreased executive functioning. The stoic group had attributes that protected them from falling, being positive, physically active, and participated in community life. This work suggests that measures of efficacy beliefs (e.g., *Assessment of Fear of Falling in Older Adults: The Falls Efficacy Scale-International* (*FES-I*), by S.A. Greenberg, http://consultgerirn.org/uploads/File/trythis/try_this_29.pdf) or fear of falling need to be considered in terms of other fall-risk factors and that better defining rational or irrational fears would be useful in falls prevention.

Michie et al. (2005) assert that in developing prevention guidelines, there needs to be better specificity in describing and defining the kinds of causal behaviors and to identify construct domains to help explain the underlying behavioral processes and therefore, the kinds of opportunities for change.

Two studies used recall and reenactment to explore themes and patterns associated with falls that occur at home (Connell & Wolf, 1997) and

those that occur in public places (Clemson, Manor, & Fitzgerald, 2003). Themes such as: or beliefs that a change in eyeglass prescription can cause deterioration of eyesight resulting in a reluctance to change; and low mobility self-efficacy affecting how the person safely negotiates the environment. Drawing on this work and conducting a review of studies that reported causes of falls, the *Falls Behavioural* (*FaB*) *Scale for older people* (Clemson, Cumming, & Heard, 2003) was developed to assess the kinds of subtle, day-to-day behaviors, both habitual and intentional, that offer an older person protection from falling during daily activity. Using factor analysis, dimensions within the scale were detected, which provided a profile of the kinds of adaptations people make or, alternatively, do not make, for example, *cognitive adaptations* (behaviors associated with reflection, intention, and planning, e.g., paying enhanced attention to changes in balance, level of alertness, etc., when trying a new medication) and *protective mobility* (protective mobility – negotiating the environment in a supportive or protective way, e.g., using defensive walking strategies such as heel toe walking and scanning ahead while walking). Clemson's and co-workers research has contributed to developing programs that incorporate evaluation of daily routines, the situational factors that shape these routines, and the kinds of adaptations the participants make. Programs need to incorporate techniques that support changing habits and maintaining them.

Habitual behaviors can be either risk taking or protective and are described as situational-guided goal-directed behaviors, and hence, behavioral responses are automatically elicited when a particular situation arises. Situational cues can be a specific place and a specific time, or other specific feature of the environment or pattern of interaction with the environment. There is evidence that habitual behaviors can be broken and new habits instituted in the same context by using planned *implementation intentions* (Holland, Aarts, & Langendam, 2006; Trope & Fishbach, 2004). These refer to a planned commitment to a behavioral response followed up with practiced and repeated actions in the same context. Thus, with conscious planning and repetition the new action is brought into active memory until it replaces the older action and becomes stable and enduring. The LiFE program, embedding balance and strength training in daily life activity, is an example of a program developed using these principles.

Knowing about their perception of falls risk and their fall experiences will assist in facilitating follow through of fall prevention strategies (Clemson, Cusick, & Fozzard, 1999). Older people tend to describe the fall in terms of its consequences and they do not easily make the link to "falls prevention" reporting this notion to be unfamiliar and puzzling. Recommendations center around ensuring that interventions are compatible with a positive identity, that they are tailored to the circumstances and values of the individual, and that validated methods are used to maintain longer-term adherence. If these are not addressed then older people are reluctant to participate (Yardley, 2007). There is also evidence on the importance of prevention strategies to include individual plans, to be contextually relevant and valued by the older person, and to recognize, in working with older people, the importance of self-identity and sense of control. The importance of reflecting on their falls and why they happened are directly related to engagement in adaptive strategies and hence are more likely to experience positive outcomes (Roe et al., 2008).

Two evidence-based programs tested in randomized trials that have been developed based on specific cognitive behavioral models are *Matter of Balance* (MoB) (Tennstedt et al., 1998), which reduced fear of falling and increased activity engagement, and the *Stepping On program* (Clemson et al., 2004), which reduced the rate of falls. The conceptual model of MoB recognizes self-efficacy, outcome expectations, and attributions as important influences on an older adults' sense of control over the course and consequences of aging. The program using cognitive restructuring exercises to address volitional attitudes and beliefs about falls before focusing on behaviors associated with the reduction of modifiable fear of falling risk factors such as activity avoidance. The conceptual model of *Stepping On*

draws on the process of decision-making operationalized into a framework to facilitate the adoption of behaviors to reduce fall risk and uses principles of enhancing self-efficacy, adult education, and story-telling as a technique to encourage reflective thinking, reframing, and problem-solving.

The outcome of a fall experience is complex and intricately related to personal, biological, and environmental factors. There needs to be a greater focus on understanding the behavioral and psychosocial effects of a fall. The aim for the older person is to understand and engage in protective behaviors and lifestyle choices that reduce risk thereby avoiding falls and remaining active and connected with community.

Definition

In the context of medical diagnosis, a false-negative error occurs when an individual with a disease is "identified" by a diagnostic test as not having the disease.

In general science, if something is said to be true when in actuality it is false, the terms "type I error," "alpha error," or "false-positive error" are used. If something is said to be false when in actuality it is true, the terms "type II error," "beta error," or "false-negative error" are used (Jekel, Katz, Elmore, & Wild, 2007).

False-negative errors are meaningfully discussed along with false-positive errors.

If something is said to be false when in actuality it is true, the terms type II error, beta error, or false-negative error are used (Jekel, Katz, Elmore, & Wild, 2007).

When a diagnostic test is administered to a large group of individuals, it is very likely that, in truth, some will have the disease of interest and some will not. In the ideal scenario, all of those who have the disease will be correctly identified as having it, and all of those who do have the disease will be correctly identified as not having it. Unfortunately, such perfection is rare. As just noted, a false-positive error occurs when an individual without a disease is "identified" by a diagnostic test as having the disease. Another error that requires consideration is the false-negative error. In this case, an individual who does have the disease is incorrectly "identified" as not having the disease.

Associated terms are sensitivity and specificity (Katz, 2001). Sensitivity is the proportion of

those with the disease for whom the test result is positive. Specificity is the proportion of those without the disease for whom the test result is negative. Sensitivity and specificity are performance characteristics of every diagnostic test. To interpret the result of a test, and remain vigilant for false-positive and false-negative errors, these characteristics must be known along with the context in which the test is operating.

Family Aggregation

Definition

Family aggregation of health behavior refers to the extent to which family members behave in the same or similar ways in areas that have consequences for health. In the literature, family aggregation often refers to the degree to which children exhibit the same behaviors as their parents. In review studies, significant evidence exists for the family aggregation of many health behaviors, including diet, physical activity, smoking, and alcohol and drug use (see Rossow & Rise, 1994). Despite the evidence of family aggregation, the findings within each health behavior are often inconsistent. Common methodological issues in the family aggregation literature are the inclusion of only one parent in studies and reliance on only one reporter to measure health behavior of both parents and children. Because family aggregation is heavily influenced by parental modeling, including only one parent in the research design does not provide the information necessary to detect the presence of aggregation or the mechanisms by which health behavior is transmitted from parent to child. Studies that rely on children to report on both their own and parent behaviors (and vice versa) tend to have inflated estimates of family aggregation due to mono-method bias. As a result of these methodological issues, family aggregation research has been somewhat inconsistent for certain health behaviors.

The childhood obesity problem in the United States has motivated intense scrutiny into the familial aggregation of obesity-related health behaviors. Research shows that parent/child concordance tends to be high for many diet- and eating-related constructs, including attitudes and perceptions about food, food preference, feeding styles, and eating behaviors (see Patrick & Nicklas, 2005). Parents influence their child's obesity-related health behavior not only through modeling but also through parental manipulation of the social and physical environment. Because parents purchase and provide food for the home, they largely dictate what and how much children are eating. Unlike tobacco, alcohol, or drugs, it is a parents' job to provide food for their children, and parents and children often eat together. As such, it is not surprising that the most consistent findings for parent/child concordance of health behaviors are in the areas of diet and eating. The

research findings for exercise and physical activity have been somewhat less consistent. Although many studies have not found parent/child concordance of physical activity, most of the work in this area has lumped the physical activity of mothers and fathers together (see Ferreira et al., 2006). When studies separate out father's and mother's physical activity, father's levels are highly positively correlated with those of their children while mother's levels are mostly unrelated.

There has been a large body of work devoted to examining the familial aggregation of tobacco use. Typically, familial aggregation of smoking is studied through genetic epidemiological studies (such as adult twin studies which have found genetic factors account for 50% of the variance attributed to regular tobacco use) and social risk factors (e.g., socioeconomic status, age, and gender). Despite the vast quantity of work in this area, there is little evidence that has been gained in support of the familial aggregation of smoking. Limitations in methodologies result in difficulties parceling out social and genetic influences in familial risk of smoking. For example, to date, there are no known family studies that examine the systematic development and maintenance of smoking within families. Nevertheless, in a recent review, Avenevoli and Merikangas (2003) found that in the 87 articles they reviewed, having a sibling who smoked was consistently found to be a predictor of current and lifetime smoking, while the evidence for parents was inconsistent.

Familial aggregation of alcohol use has been well established (McGue & McGue, 1994). Research shows that if child has a parent who drinks, he is three times more likely to drink and two times more likely to do drugs than a child with nondrinking parents. Results from twin and adoption studies suggest a significant genetic component to alcohol dependence. Although more of the research has focused on alcohol, family aggregation of drug use is also well established. Researchers estimate that relatives of individuals with drug disorders are 8 times more likely to use drugs than relatives of controls (Merikangas, 1998). Classic adoption studies also suggest a strong genetic component to substance abuse disorders (e.g., Cadoret, Troughton, O'Gorman, & Heywood, 1986), and twin studies have found the heritability of drug abuse to be even greater than that of alcoholism.

Definition

The Family and Medical Leave Act (FMLA) entitles eligible employees of covered employers to take unpaid leave for family and medical reasons with continuation of health insurance coverage under the same terms and conditions as if the employee had not taken leave.

A covered employer must grant an eligible employee up to a total of 12 workweeks of unpaid leave during any 12-month period for one or more of the following reasons:

- The birth of a child and to care for a newborn child within 1 year of birth
- The placement and care of an adopted or foster care child within 1 year of placement with the employee
- To care for the employee's spouse, child, or parent who has a serious illness
- A serious health condition that renders the employee unable to perform the essential functions of his or her job

A covered employer must also grant an eligible employee who is a spouse, child, parent, or next of kin of a current member of the Armed Forces with a serious injury or illness up to 26 workweeks of unpaid leave during a "single 12-month period" to care for the service member.

Eligibility

To be eligible for FMLA benefits, an employee must:

- Work for a covered employer
- Have worked for the employer for a total of 12 months
- Have worked at least 1,250 hours over the previous 12 months
- Work at a location in the United States or in any territory or possession of the United States where at least 50 employees are employed by the employer within 75 miles

Job Restoration

An employee's use of FMLA leave cannot result in the loss of any employment benefit that the employee earned or was entitled to before using FMLA leave, nor be counted against the employee under a "no fault" attendance policy. An employee must be restored to the employee's original job or to an equivalent job with equivalent pay, benefits, and other terms and conditions of employment upon return from FMLA leave.

Family Assistance

Psychiatry, Children's Medical Center, UT Southwestern Medical Center, Dallas, TX, USA

Synonyms

Family aid; Office of family assistance

Definition

Family assistance refers to the provision of aid to families in need, usually with a focus on economic welfare and self-sufficiency.

The Office of Family Assistance

The Office of Family Assistance under the Administration for Children and Families is part of the United States Department of Health and Human Services. The Office of Family Assistance administers the Temporary Assistance for Needy Families (TANF) and Child Care and Development Fund (CCDF) programs.

Temporary Assistance for Needy Families (TANF)

TANF is designed to help needy families achieve self-sufficiency by providing assistance and work opportunities to needy families through grants of federal funds to states, territories, and tribes to allow for wide flexibility to develop and implement their own welfare programs.

The four major purposes of TANF are:

1. Aiding needy families so that children can be cared for in their own homes
2. Promoting job preparation, work, and marriage by reducing the dependency of needy parents
3. Preventing out-of-wedlock pregnancies
4. Encouraging the formation and maintenance of two-parent families

In February 2006, former President George W. Bush signed the Deficit Reduction Act of 2005 (DRA), which reauthorized the TANF program. The DRA reauthorization also included $150 million for discretionary grants to support programs designed to help couples form and sustain healthy marriages. Up to $50 million of this amount may be used for programs designed to encourage responsible fatherhood.

The Child Care and Development Fund (CCDF) Programs

The CCDF program enables low-income families to access child care, which in turn makes it possible for more parents to achieve economic self-sufficiency. The program also helps children succeed in school and life through affordable, quality early care and afterschool programs.

The Healthy Marriage Initiative is designed to strengthen families, foster safe and healthy relationships between married men and women, and promote the well-being of children.

The Responsible Fatherhood Program is designed to enable fathers to improve their relationships and reconnect with their children.

Other Forms of Economic Family Assistance

Other forms of economic family assistance are provided through Women, Infants, and Children (WIC), Low Income Home Energy Assistance Program (LIHEAP), and other emergency assistance programs available through government and nonprofit agencies.

Women, Infants, and Children (WIC)

WIC is administered by the Food and Nutrition Service as part of the USDA. WIC provides federal grants to States for supplemental foods, health-care referrals, and nutrition education for low-income pregnant, breastfeeding, and non-breastfeeding postpartum women, and to infants and children up to age 5 who are found to be at nutritional risk.

Low Income Home Energy Assistance Program (LIHEAP)

The mission of the Low Income Home Energy Assistance Program (LIHEAP) is to assist low-income households, particularly those with the lowest incomes that pay a high proportion of household income for home energy, primarily in meeting their immediate home energy needs.

Emergency financial assistance is usually temporary in nature.

Noneconomic Forms of Family Assistance

Noneconomic forms of family assistance include family counseling and intervention. Through family therapy, families or individuals within a family learn better ways to interact with each other and resolve conflicts. Family therapy is usually provided by clinical social workers or licensed therapists known as marriage and family therapists.

Definition

Family planning is the practice of regulating the number and spacing of human births through the use of contraception and abortion. It allows couples and individuals to control the timing of their childbearing, and thereby to pursue educational and career goals, as well as to care for existing children and/or other family members, while limiting the possibility of pregnancy.

Description

Introduction

Family planning can be a controversial topic among different religious and cultural groups, and even at times within the medical community. Nonetheless, the World Health Organization, the American Medical Association, the American Congress of Obstetricians and Gynecologists, the American Medical Women's Association, the American Society for Reproductive Medicine, and the Society for Adolescent Medicine promote unbiased access to a wide range of family planning options as a fundamental component of comprehensive health care (Association of Reproductive Health Professionals, 2011).

Such an emphasis is placed on family planning for a variety of reasons. First, adequate

contraception decreases maternal mortality, both from high-risk pregnancies and unsafe abortions (World Health Organization, Department of Reproductive Health and Research, [WHO] 1995). Pregnancy prevention can be especially important in groups at high risk for complications, including very young women, older women, and women with certain coexisting medical conditions such as heart disease, kidney disease, certain cancers, and autoimmune diseases. Moreover, certain forms of contraception decrease the incidence of many sexually transmitted infections (STIs), the development of cancers of the female genital tract, and the prevalence of some common medical conditions. For example, hormonal contraceptives can protect against iron-deficiency anemia from menorrhagia, can prevent the growth and complications of ovarian cysts and uterine fibroids, and can decrease the risk of ovarian and endometrial cancer. In addition, barrier contraceptives decrease the transmission of STIs, including human immunodeficiency virus and human papillomavirus, which, in high-risk strains, can lead to cervical cancer (WHO, 1995). In addition, proper spacing of pregnancies improves infant and child health. An inter-pregnancy interval of less than 18 months has been associated with preterm labor and preterm delivery, as well as small-for-gestational-age infants, all of which increase neonatal morbidity and mortality (WHO). Limiting the overall number of children in a household also enables families to dedicate more resources to each individual child.

Contraception

Options and Use

In the United States, approximately 62% of all women of childbearing age are currently using a form of birth control (Guttmacher 2010a). There are multiple forms of birth control available in the USA, which vary by presence or absence of hormones, required frequency of administration, permanence, route of administration, as well as several other factors. One set of nonhormonal options that rely purely on planned human behavior includes abstinence, menstrual calendar-based method (avoiding intercourse on days 8–19 of the cycle, which are the woman's most fertile days), natural family planning (avoiding intercourse on days when a woman is most likely to have ovulated based on measurements of basal body temperature and cervical mucus), and withdrawal. Other nonhormonal options are barrier contraceptives, which must be used with each sexual encounter, including male and female condoms, diaphragms, sponges, and spermicides. Self-administered hormonal contraceptives include pills, which are taken daily, a transdermal patch, which is changed weekly, and a vaginal ring, which is changed monthly. Depo-Provera is an injectable progesterone which is dosed every 3 months. In addition, long-acting reversible contraceptives include intrauterine devices (or IUDs) and Implanon, a subcutaneous implant. Finally, permanent options for contraception include male and female sterilization (Trussell, 2007).

Among women in the USA, different age, racial, and socioeconomic groups tend to choose different birth control methods. In addition, the choice of a method often changes over the course of a woman's reproductive lifespan. For example, the birth control pill is the predominant method used by women younger than 30 years of age, whereas female sterilization is the predominant method used by women older than 30. Moreover, while white women most often select the pill, black and Hispanic women most often select female sterilization (Guttmacher, 2010a).

Women choose a birth control method based on several factors, both medical and personal. These frequently include risks and side effects of the method, cost, coexisting medical conditions, number of sexual partners, frequency of intercourse, number of desired children, and access to health care. Currently, apart from abstinence, the most efficacious contraceptive method is the Implanon device, with 0.05% of women experiencing an unintended pregnancy within the

first year of use. In comparison, with typical use of condoms, 15% of women per year will experience an unintended pregnancy (Trussell, 2007).

Access to Contraception

According to data from the 2002 National Survey of Family Growth, 49% of all pregnancies in 2001 were unintended. Of these unintended pregnancies, 44% ended in births, 42% ended in abortions, and 14% ended in fetal losses. Unintended pregnancy rates are highest among women aged 20–24, women with low incomes, and women who are unmarried, of a minority (especially black) race and who have not completed high school (Finer and Henshaw, 2006).

In response to the high rate of untended pregnancy, especially among low-income women, public funding has been made available for contraceptive services and supplies. Medicare, state appropriations, and Title X of the Public Health Service Act provide such funding, with Medicare being the largest contributor (approximately 71%). In 2008, 17.4 million women were in need of these services, and 54% of these women received contraceptive care from a publicly funded family planning center. For many women, these centers are also the only source of primary medical care (Guttmacher 2010c).

Abortion

Definition

Abortion is the termination of a pregnancy and can be spontaneous or induced. A "spontaneous abortion," or what is more commonly known as a "miscarriage," is the natural loss of a pregnancy prior to 20 weeks' gestation. An "induced" abortion refers to a medical or surgical intervention performed with the intention to terminate a pregnancy (Kottke and Zieman, 2008).

There are several possible methods available for the termination of a pregnancy. The choice of method is largely based on the gestational age of the pregnancy, patient preference, and provider experience. Suction curettage, or the emptying of uterine contents by suction aspiration, is the most common method used up to 12 weeks' gestation. Medication abortion can also be performed up to 9 weeks' gestation, depending on the medication regimen used. These regimens consist of a combination of antiprogestins and prostaglandin analogues, and/or the use of methotrexate. In comparison, termination of pregnancy in the second trimester can be performed using dilation and evacuation (D&E) – dilation of the cervix with evacuation of uterine contents by suction, with or without extraction, at greater than 13 weeks' gestation – or induction of labor. D&E is performed more frequently than induction as it is a less

expensive and shorter procedure that does not require hospitalization (Kottke and Zieman, 2008, and Paul and Stewart 2007).

Epidemiology

An estimated four out of every ten unplanned pregnancies in the United States end in induced abortion. In 2000, a total of 1.31 million abortions were performed, but in 2005, this number decreased to 1.21 million. Approximately one-third of all American women will have had an abortion by the age of 45 years (Guttmacher 2010b). When asked to describe why they seek pregnancy terminations, women cite a variety of reasons: inability to afford a child (or another child); need to delay childbearing in order to devote time to work, school, or other family members; concerns about their own health or the health of the fetus; lack of access to contraception; relationship problems with the father of the pregnancy; and desire to end a pregnancy that resulted from rape or incest (Guttmacher Institute; Paul and Stewart 2007).

The demographics of women who have abortions are broad and include women of all ages, races, socioeconomic groups, and religions. Roughly half of all abortions are obtained by women aged 20–30, by women who have never been married, and by women who already have at least one child. Thirty-six percent of women seeking pregnancy termination are non-Hispanic white, 30% are non-Hispanic black, 25% are Hispanic, and 9% are of other races (Guttmacher Institude, May 2010). The rate of induced abortion is higher among low-income and black women, which many researchers attribute to lack of access to adequate contraception (Kottke and Zieman, 2008).

Health Impact

As stated by Speroff et al., "the legalization of abortion reduced maternal morbidity and mortality more than any single development since the advent of antibiotics to treat puerperal infections and blood banking to treat hemorrhage" (Speroff, Glass, & Kase, 1999). After abortion was legalized in 1973 through the *Roe v. Wade* Supreme Court case, the abortion-related mortality rate declined by 90%. Currently, the abortion-related mortality rate ranges from 1 in 1,000,000 for procedures performed prior to 8 weeks' gestation, to 8.9 per 100,000 for procedures performed after 21 weeks (Kottke and Zieman, 2008). In comparison, the maternal mortality rate for women who go on to deliver live infants in the United States was 13.3 per 100,000 live births in 2006 (U.S. Department of Health and Human Services, Health Resources and Services Administration, Maternal and Child Health Bureau, 2009). An overwhelming majority (greater than 85%) of all abortions occur within the first trimester of pregnancy (i.e., prior to 14 weeks' gestation). These early terminations pose the lowest health risks, both immediate and long-term, to women (Paul and Stewart 2007).

The long-term physical and mental sequelae of abortion have been studied extensively. These studies indicate that there is no increased risk of miscarriage, ectopic pregnancy, or infertility associated with first-trimester abortions. The outcomes of second-trimester procedures are not as well studied or understood. In addition, though the psychological impact of abortion on women has been widely debated, the vast majority of high-quality scientific evidence indicates that pregnancy termination does not pose mental health risks for most women. Two groups performed broad reviews of available scientific literature in 2008 – the American Psychological Association Task Force on Mental Health and Abortion and Johns Hopkins University – and both groups concluded that elective pregnancy termination is not associated with an increased risk of psychiatric sequelae (Charles, Polis, Srihara, & Blum, 2008 and Major et al., 2008). In fact, the best predictor of a woman's mental health after an abortion appears to be her mental health prior to the procedure.

Family medicine; Family practice; General practice; Primary care

Definition

Family practice/medicine or primary care is the medical specialty that provides continuing and comprehensive health care for the individual and the family. It is the medical specialty that integrates the physical, clinical, and behavioral sciences. The scope of family medicine encompasses all organ systems, every disease entity and covers the life span.

Primary care is health care that is accessible, coordinated, comprehensive, and continuing. It is provided by physicians specifically trained for and skilled in comprehensive first-contact and

continuing care for persons with a diagnosed illness or those with an undiagnosed symptom, or health concern. In addition to diagnosis and treatment of acute and chronic illnesses, primary care includes health promotion and maintenance, disease prevention, and patient counseling/education in a variety of health-care settings, including private practice offices, the inpatient setting, critical care, and long-term care facilities, as well as in-home care. Primary care is performed by a personal physician, with consultation or referral to other health professionals as necessary.

Family practice/medicine encompasses the following functions:

1. It is first-contact care, serving as a point of entry for the patient into the health-care system.
2. It is highly personalized and assumes responsibility for individual follow-up.
3. It is comprehensive and includes continuity by virtue of caring for patients in sickness and in health.
4. It serves a coordinative function for the various health-care needs of the patient.
5. It assumes continuing responsibility for community health problems and concerns.

The term general practice is synonymous with the term family medicine in many countries. The Royal New Zealand College of General Practitioners emphasizes that a general practitioner provides care that is "anticipatory as well as responsive and is not limited by the age, sex, race, religion, or social circumstances of patients, nor by their physical or mental states." They argue that the family practice physician must be the patient's advocate; be caring, competent, and compassionate; and be willing to recognize limitations and refer when necessary (Richards, 1997).

Family Social Support

Elana Graber and Ryan M. Beveridge
Department of Psychology, University of Delaware, Newark, DE, USA

Synonyms

Social network; Social resources

Definition

Broadly defined, social support is information, clarification, aid, and emotional reassurance that an individual receives from others. Research has differentiated between perceived support (i.e., availability of support in one's environment) and received support (i.e., support one reports having received, often in response to a specific event). Perceived support, particularly in the early family environment, is associated with beneficial health outcomes, better (i.e., proactive) coping skills, and thus is associated with better health behaviors and outcomes. Perceived support is typically stable over time and is thought to develop from one's own early family structure and attachment through one's ability to develop and sustain close relationships with supportive others. As will be discussed further below, the benefits of received support are mixed and have been associated with both positive and negative health consequences.

Social support can also be further divided into practical and emotional support. Practical support includes giving advice, providing

information, or tangible assistance for another person (e.g., washing the dishes for a sick spouse or financial assistance from a family member). Emotional support can include physical affection and discussing one's thoughts and feelings showing warmth and nurturance to indicate the individual is valued and cared for. The degree to which practical and emotional support are helpful often depends on the particular stressor context in which they are occurring, including timing of support and phase of medical illness. Informational support may be needed to make medical decisions, and emotional support may help one cope with a medical diagnosis or treatment difficulties. Based on the matching hypothesis, what is important for individual outcomes is that the received support compliments the needs of the individual undergoing the stressor.

Description

As social beings, humans benefit from their connection to others through social support that they receive and provide, and in no greater context is this process observed than within the family system. Social support in a family context has been consistently linked to incidence of disease and recovery and coping responses to acute and chronic illness. The family context is one of the most common places individuals both seek and receive social support, and early life experiences within the family system shape one's ability to seek and benefit from social support in one's larger social network later in life. Children who develop secure attachments to their caretakers and perceive caretakers as available and attentive to their needs are better able to interpret and perceive supportive acts from others.

Negative Effects of Social Support

Interestingly, receiving social support from close others is not always beneficial. Indeed, patients who receive help from their family members may feel unable to reciprocate that support, creating a sense of inefficacy and bring awareness of one's lack of autonomy and control. Some research has found that received tangible support is even associated with higher mortality rates, while perceived support availability is associated with lower mortality rates.

Associations with Health Outcomes

Social support has been reliably linked with the development and progression of illness, for example, cardiovascular disease, diabetes, and lung disease, and has even been associated with lower risk for developing the common cold. The availability of support and the provision of "invisible support" (i.e., support that is provided but is not perceived) can have beneficial effects on health behavior and health outcomes. Specifically, perceived support can accelerate recovery from disease and improve mortality rates even after controlling for physical health status and demographic factors. Some of the mechanisms explaining the benefits of perceived support on health outcomes include greater proactive coping strategies, lower stress exposure, and healthier behavior choices in terms of diet and medical adherence. There are multiple theories on the utility of social support in alleviating the effects of stress. The stress-buffering hypothesis posits that social support is particularly important when individuals are undergoing large stressors, such as acute or chronic illness, but of relatively little import during periods of low stress. During periods of high stress, the availability of social support attenuates the negative effects of stress and allows the individual to cope more effectively. The direct effects hypothesis suggests that social support is beneficial during periods of high and low stress, making the family system and the general availability of support important at all times. As described above, the matching hypothesis of social support suggests help is likely most beneficial when the type of support provided matches the needs of the patient. A patient who desires emotional reassurance from their family but receives informational help is less likely to benefit from the social support and may even generate negative feelings of incompetence or dependency.

Support interventions have been shown to promote positive health outcomes. Creating supportive home environments early in life will likely place children on better health trajectories that will influence their susceptibility to disease as well as their ability to benefit from a social support network during acute or chronic illnesses.

Definition

Family stress can be defined as any stressor that concerns one or more members of the family (or the whole system) at a defined time, which impacts the emotional connection between family members, their mood, well-being, as well as the maintenance of the family relationship.

Description

While stress has been described as an individual phenomenon for many decades (e.g., Dohrenwend & Dohrenwend, 1974; Lazarus & Folkman, 1984; Selye, 1974), family stress has been conceptualized independently from individual stress theory.

Family stress theories first emerged in the 1930s and 1940s (Angell, 1936; Koos, 1946). The most influential family stress theory (ABC-X theory) was proposed by Hill (1958), and was further developed by Burr (1973) and McCubbin and Patterson (1983). The ABC-X theory includes three interacting variables: the event (A) that interacts with the family's resources (B), which allows the family to create their meaning and definition of the event (C). These three variables then produce the crisis (X). Although the ABC-X model is still used by some research groups and its utility is recognized by theorists, it is limited in different ways. First, the model explicitly deals with major stressors (critical life events) and crisis, and is not appropriate for understanding everyday stress processes in families. Second, the model claims to have a perspective on the whole family, but usually only partners/parents (or even more often only one partner/parent) are targeted while contributions of children are not considered.

Important theoretical additions of the ABC-X model were made by Burr (1973) and Burr and Klein (1994) by including the concepts of family vulnerability and regeneration. These authors focused more systematically on resources within the family and the use of different types of coping according to specific phases in the stress process. Subsequently, the complications the family faced in dealing with the stressor are addressed in the revised family stress model.

In the last two decades, marital research has provided new and stimulating input to the discussion of family stress. This line of research has led

to the development of theoretical models of dyadic stress and research activity (Bodenmann, 2005; Story & Bradbury, 2004, Randall & Bodenmann, 2009). Dyadic stress represents a distinct form of family stress, involving both partners directly or indirectly. According to Bodenmann (1997, 2005) dyadic stress is defined as a stressful event or encounter that always concerns both partners, either directly when both partners are confronted by the same stressful event, when there is stress within the relationship (e.g., disagreement with one's partner), or indirectly when the stress of one partner spills over to the close relationship and affects both partners. In both cases, dyadic stress *elicits* joint appraisals (in addition to individual appraisals) of the stressful situation that extends the primary and secondary appraisals in Lazarus' (1966) approach. These joint coping efforts, or cooperative use of common resources within the couples, are referred to as dyadic coping (Bodenmann, 2005).

Although the definition of dyadic stress has been used primarily in the focus of close relationships, it can be easily expanded to family systems. Specifically, this approach focuses on the following aspects of family stress (see Randall & Bodenmann (2009) for a review):

1. *Locus* of the stress
   (a) *External*: Stress that comes from outside the family, such as: (1) financial stress or (2) stress with regard to the extended family members, such as parents-in-law (grandparents) or other relatives. For example, if a grandparent is sick it may be the primary responsibility of their child to take care of them; subsequently, the mother or father may exhibit a stressful response and may be emotionally affected.
   (b) *Internal*: Stress that originates within the family. Examples would be conflicts and tensions between parents, parents and children, or siblings. For example, if parents have severe marital problems and if they often engage in disagreements, this may affect the family climate and the well-being of all family members.
2. *Intensity* of the stress
   (a) *Macro*: Stressors that can be common (e.g., critical life events). Examples would be (1) severe illness, (2) handicap, (3) unemployment, (4) death of a family member, or (5) important phases and changes, such as the birth of a child or an empty nest.
   (b) *Minor*: These are "everyday" stressors, such as (1) being late for an appointment or school, (2) having to get children to their extracurricular activities, or (3) stress at work, for example, both parents are working, one child is sick, and the family has to reorganize their work schedules to care for the child.
3. *Duration* of the stress
   (a) *Acute*. These stressors tend to be temporary and may be associated only with a single instance, for example, forgetting something at the grocery store or moving to a different house or city.
   (b) *Chronic*. These stressors are stable and can last a long time, for example, having a child that is ill or a partner that is unemployed.
4. *Affected person* of the stressor. Is it only one partner/parent, parents, one child or several children, or is the whole family affected by the stressful encounter? For example, the severe illness of a partner/parent affects the whole family system, whereas one daughter staying home sick may only affect her (the daughter) and perhaps the partner who is staying home with her.

Stress has been shown to have detrimental effects on health and well-being on all family members (see Randall & Bodenmann (2009) for a review). Recently, studies have shown the link between stress and behavioral medicine, specifically with respect to taking care of patients with dementia (Mitrani et al., 2006), and when the child is suffering from a chronic illness (Lewis & Vitulano, 2003). In addition, studies have shown increased family conflict when one child was diagnosed with Type 1 diabetes (Williams, Laffel, & Hood, 2009).

Families operate as a system and each member of the family is an interconnected entity that functions as a whole. Specifically, individuals cannot be understood without taking into account the family as a whole (Segrin & Flora, 2005). Thus, family stress impacts each member of the family and may have detrimental effects on their closeness, emotional connectedness, communication, and, ultimately, their well-being.

Family Studies (Genetics)

J. Rick Turner
Cardiovascular Safety, Quintiles, Durham, NC, USA

Definition

Family studies are fundamental tools in the discipline of behavioral genetics (Turner, Cardon, & Hewitt, 1995) and can provide information of great interest in Behavioral Medicine. They permit assessments of degrees of familial resemblance, or aggregation, of physical, psychological, and behavioral characteristics.

Description

Pairs of siblings resemble each other more than do randomly chosen pairs of individuals, and children resemble their parents, on average, to a greater degree than they resemble randomly chosen adults. Such degrees of resemblance can be assessed in terms of correlation coefficients for continuous quantitative measurements, such as blood pressure and weight, and in terms of concordance rates for discretely defined characteristics, such as having or not having a specific disease state or psychiatric diagnosis.

In clinical studies, the proband is defined as the individual affected by a disease or condition of clinical concern that causes a family to be

included in a study. The probandwise concordance rate is then defined as the probability that a relative of a given type will also be affected. An important point to note is that in the absence of family resemblance, the concordance rate should be equal to the prevalence of the disease or condition. Therefore, for commonly occurring conditions (such as ever having smoked a cigarette), the baseline concordance rate might be as high as 80% in some populations. Family resemblance would then be indicated by concordance rates that were higher than this. In contrast, for conditions that are relatively infrequent, such as a psychiatric condition like schizophrenia with a 1% prevalence, a concordance rate as low as 10% might indicate substantial family resemblance (Hewitt & Turner, 1995).

It is typically found that there is a positive family resemblance for many characteristics, and the resemblance becomes more strongly positive as the degree of family relationship becomes closer. An important confounding factor, however (at least for the conventional nuclear family), is that the degree of genetic relationship is confounded with the degree of environmental or social relationship. Such families tend to eat the same food, for example, a factor that can influence blood pressure and weight. (Individuals who become married, and who perhaps ate relatively different diets, may in time come to eat a more similar diet, which can lead to various other characteristics becoming more similar.) Therefore, the mere observation of familial aggregation of a characteristic or condition of clinical concern is not sufficient to allow the inference of a genetic or environmental etiology. Instead, we need to study pairs of relatives in whom the degree of genetic relationship differs when the environmental resemblance is kept the same or, alternatively, pairs for whom the degree of environmental resemblance differs when the degree of genetic relationship is held constant.

The "natural experiment" of the birth of twins affords a good approximation to the first type of situation, and the adoption of children to be reared apart from their biological parents provides the second type. There are certainly other types of family relationships and study designs of relevance, for example, those involving half siblings and stepfamilies, but it is typically the case that both the statistical power and the conceptual clarity are greatest for research studies that start with a nucleus of either twins or families involved in adoption.

Definition

Family systems theory is one of the major theories in behavioral and social sciences. The foundation of this theory is that all systems, human and mechanical alike, strive toward growth, development, and stability and that individual behavior cannot fully be understood without taking into account the context of the family system (Nichols, 2010a).

There are numerous models within family systems theory, and numerous associated therapeutic techniques designed to help families and individuals with relationship and mental health issues. In brief, Bowenian theory, named for Murray Bowen, focuses on intergenerational issues and family triangles. Strategic family therapy, pioneered by Jay Haley and others, focuses on understanding the function of symptoms and family communication patterns that relate to an individual patient's difficulties and creating strategies to change communication patterns.

Structural family systems theory and therapy, developed by Salvador Minuchin, is concerned with the hierarchical structures within families, positing mental health issues in individual family members when relationship structures are dysfunctional. Additional models include experiential, psychoanalytic, cognitive behavioral, solution-focused, narrative, and integrative approaches to both family systems theory and therapies (Doherty & McDaniel, 2010).

Family Violence

Jason Jent
Department of Pediatrics, Mailman Center for Child Development, University of Miami, Miami, FL, USA

Synonyms

Domestic violence; Intimate partner violence

Definition

Family violence refers to any acts of violence that occur between family members, including but not limited to child maltreatment, intimate partner violence, and elder maltreatment (American Medical Association, 2011).

Description

Types of Family Violence

Child Maltreatment includes any act(s) of commission or omission by a caregiver that results in harm, potential harm, or threat of harm to a child (Leeb, Paulozzi, Melanson, Simon, & Arias, 2008). Child maltreatment is most broadly categorized as child abuse and child neglect. Child abuse consists of three different forms of acts of commission including physical abuse, sexual abuse, and psychological/emotional abuse. Acts of omission or neglect can also be characterized as family violence in specific instances where a caregiver knowingly fails to protect a child from maltreatment perpetrated by another caregiver or knowingly does not take appropriate measures to protect a child from being exposed to pervasive violence (e.g., intimate partner violence) or dangerous conditions (e.g., selling drugs out of the home). Both ▶ Child Abuse and ▶ Child Neglect are discussed in more detail in separate entries.

Intimate Partner Violence, a term that is often used interchangeably with domestic violence, includes acts of commission by a current or former partner or spouse that results in physical, sexual, or psychological harm (Saltzman, Fanslow, McMahon, & Shelley, 2002). Intimate partner violence occurs among heterosexual and same-sex couples and exists on a severity continuum. Intimate partner violence includes four types of behavior: physical violence, sexual violence, threats of physical or sexual violence, and psychological/emotional violence. In addition, stalking is often considered a type of intimate partner violence (Tjaden & Thoennes, 1998).

Elder Maltreatment includes any abuse and neglect of a person age 60 and older by a caregiver or another person in a relationship involving an expectation of trust (Center for Disease Control and Prevention, 2010). Forms of elder maltreatment include physical abuse, sexual abuse or abusive sexual contact, psychological or emotional abuse, neglect, abandonment, and financial abuse or exploitation.

Definition

Family caregiving is not a new phenomenon and is considered a norm of the family based on family and societal obligations. According to a survey conducted in 2009 by the National Alliance for Caregiving, 65.7 million caregivers make up 29% of the United States adult population and 31% of all United States households. Of these 65.7 caregivers, 48.9 million care for adult recipients only, 3.9 million care for child recipients only, and 12.9 million care for both child and adult recipients. Family caregivers provide an estimated $375 billion worth of uncompensated care to loved ones annually, making them the backbone of long-term care. Caregivers are predominantly female (66%), are an average of 48 years old, and frequently take care of two or more people. The top two care recipient conditions are old age and Alzheimer's disease or dementia. Other conditions frequently mentioned include mental/emotional illness, cancer, heart

disease, and stroke (National Alliance for Caregiving, 2011).

On average, family caregivers spend 20.4 h per week providing care, though this number increases dramatically when the care recipient is living with the caregiver or when the recipient is under the age of 18. Caregiver time is predominantly spent helping loved ones complete activities of daily living. This may include helping the care recipient get in and out of beds or chairs, personal care tasks (getting dressed, assisting with bathing or showering, helping the recipient to and from the toilet, and helping deal with incontinence), and feeding. Additionally, caregivers are involved with instrumental activities of daily living, such as transportation, housework, grocery shopping, meal preparation, managing finances, and arranging or supervising outside services. Many caregivers also spend a significant amount of time advocating for the care recipient with care providers, government agencies, and performing medical therapies or treatments. Caregiving for a child with special needs requires a number of additional time-consuming support activities (NAC with AARP, 2009).

Prior to making the decision to become a family caregiver, it is imperative to make a realistic appraisal of the situation. Over half of all caregivers are married and more than 1/3 of caregiving families have children or grandchildren under the age of 18 living in the home (NAC with AARP, 2009). The entire family system is disrupted with the advent of caregiving, and many family members, including the care recipient, frequently experience significant adjustment and coping difficulties (Agosta & Melda, 1995). While many support services focus on the individual caregiver, the total family context is often overlooked. Caregivers who are employed must work to balance the competing demands of employment commitments and family responsibilities. The majority of caregivers who work outside of the home report having gone in late to work, having left early, or having taken time off during the day to deal with caregiving issues. One in five caregivers ultimately takes a leave of absence from work at some point. The Family Medical Leave Act (FMLA) was created in 1993 in order to help caregivers balance work and family responsibilities. This act provides certain employees with up to 12 weeks of unpaid, job-protected leave per year (United States Department of Labor, 2011). Despite changes in employment ability, it is important to note that caregiving can be an expensive endeavor. Not only do many caregivers decrease their work hours, there are a number of potential out-of-pocket expenses that must be addressed (NAC with AARP, 2009). Finally, studies of family caregiving have consistently demonstrated that a host of negative emotional and physical effects develop as a function of assuming responsibility for the care of a dependent family member. Vulnerability factors that may increase caregiver distress include the degree of care burden (both mental and physical), restricted activities, fear (not knowing what will come next), insecurity (feelings of loss of control over life or concerns regarding one's competency), loneliness (decreased partnership and less time to spend outside the home with others), facing death, and lack of support (from the patient, other family members, and health care providers) (Proot et al., 2003).

Despite the risks for distress, there are actions the caregiver can take to boost coping and decrease caregiver strain. It is beneficial for the family caregiver to receive caregiver training. By seeking out educational resources, the caregiver can help avoid serious injury to him/herself and the care recipient, as well as reduce the risk of recipient hospitalization for chronic sores or infections. Learning all one can about the care recipient's condition, its treatments, and the prognosis will help the caregiver and the caregiver's family have a better idea of what to expect in the future and how best one can help. Maintaining precise, up-to-date medical records and learning how to communicate with health care professionals allows caregivers to better advocate for their loved ones (NAC with AARP, 2009). Knowing how to ask for help, delegating duties, and getting friends and family involved in caregiving can also alleviate caregiver strain. Most importantly, however, the caregiver must learn how to manage his/her time and take care of

him/herself. Though time away from caregiving is often associated with fear or guilt, it is imperative that caregivers schedule time away from caregiving obligations. Recharging oneself ultimately makes for a better caregiver. Caregivers can regain control by setting limits about what they will and will not do, then voicing these boundaries to health care professionals. Finding satisfaction in the care one is providing may also decrease vulnerability to strain. Seeking good support, professional, instrumental, and emotional, is also a necessity for all caregivers. Professional support is associated with caregiver inclusion in education and decision-making by the care recipient's health care team. This decreases caregiver burden, fear, insecurity, and may provide realistic hope and facilitation of control. Instrumental support includes practical assistance in the daily care of the patient, which relieves care burden and facilitates the continuing of the caregiver's own activities. Finally, emotional support involves respect for the choices the caregiver must make, acknowledgment of the care they give, and provides someone to listen to the caregiver's concern. Emotional support generates satisfaction and may decrease fear, insecurity, and loneliness (Proot et al., 2003).

Household income

Definition

Family income is a measurement of economic position of individuals who are considered to be part of one familial unit. Income is broadly

inclusive of wages, pensions, investments, governmental assistance or benefits, rent earnings, and any other source of finances. In sociodemographic and epidemiological research, family income is often used interchangeably with household income. However, household income denotes all individuals who are living in the same home, regardless of whether they are blood relatives, legally-bound, or neither. On the contrary, family income typically refers to individuals who are related by blood or by law, especially in societies in which there is a large emphasis on nuclear family compositions (e.g., father, mother, and minor children) (see ► Family, Structure). Consequently, household income and family income are not always equivalent.

Description

There is significant evidence to suggest that income is associated with health outcomes. The income and health gradient demonstrates that, in general, higher income is associated with greater health (see ► Health Disparities). Some plausible mechanisms for this relationship may include the influences of income on access to health care services or education, and health promoting assets and environments, such as grocery stores to obtain fresh food or having places to exercise. Income distribution of neighborhoods or environments can vary greatly, which can result in differential consequences on health.

There is little consensus as to what constitutes family income and how best to measure it, but most researchers agree that a combination of household and neighborhood levels of income should be taken into consideration. At the most basic level, family income can be measured directly by surveying or interviewing members of a family unit to learn how much income they each generate. It is important to consider that family income is determined in part by the number of employed individuals in a household as well as by the number of family members dependent on that income. As such, income should be measured to include all sources (e.g., wages, investments, and benefits), denoting disposable income, and be weighted to different family compositions such that larger families are considered to have lower disposable income given the greater number of people dependent on that income (Galobardes, Lynch, & Davey Smith, 2007). Measurement of family income is becoming more complex as family structures have changed dramatically in recent years and the definition of a "family unit" continues to evolve.

Family income can vary considerably across one's lifespan as individuals may change jobs or lose employment several times during their working life. Education and occupations of family members can provide a more stable estimate of family socioeconomic status, and can be used as proxies for estimating income level. Education and occupations should be obtained for all household members to estimate family income thoroughly, especially in the context of immigration and intergenerational differences in educational opportunities. A higher educational level can reflect knowledge-related assets as well as lifestyle choices, and can be predictive of better jobs, higher income, and safer housing. Occupation is another proxy for income as it links educational experiences with actual income earned (Shavers, 2007). When using educational level or occupation as proxies for income, it is important to consider that occupational status may change during one's lifetime with new jobs or careers and may more readily capture income variability. However, educational level, once attained, tends to remain the same throughout a lifetime and is a more static proxy for income. Of note, the income associated with an educational level or occupation is not always equivalent across race and gender (Shavers, 2007). For example, women and minorities tend to earn less than white male counterparts; therefore, utilizing educational level or occupation as proxies for income may actually overestimate income levels for women and minorities compared to white males of similar educational background or occupational standing (Krieger, Williams, & Moss, 1997).

There may be situations in which individuals or families cannot be asked directly about their economic status, such as when conducting retrospective reviews of health data or when looking

at regional differences in health outcomes. In these circumstances, neighborhood levels of income can be examined as proxies for family-level income. For instance, census tract variables help to estimate median family income and household income levels based on large geographical units such as zip code areas. A combination of variables can be used to estimate neighborhood socioeconomic status, such as percentage of homeownership, percentage of a population with health insurance, or percentage of single-parent households. Neighborhood income is suspected to be closely related to health outcomes because it may reflect environmental factors that impact health, such as neighborhood safety, parks and places to exercise, social services, and access to healthy foods, as well as social capital – the social resources available to families and individuals. One should be cautious when interpreting results from neighborhood-level income estimates; while the estimates can serve as proxies for family-level income, they may not reflect the economic realities of each family.

The significant impact of income on health outcomes points to the importance of accounting for economic factors in behavioral medicine research. While there is no current consensus on how best to measure family income, researchers agree that multiple measurements of individual, family, and neighborhood levels can provide a more comprehensive understanding of family income factors for health research.

Definition

Family relationships have long been a focus of researchers interested in exploring how the social context relates to health. Researchers have shown that differences in family relationships are associated with the development of acute and chronic illnesses, as well as to how individuals and their families adjust to ongoing health problems. Several explanations for the family's impact on health and disease have been proposed. These explanations include the following: the family's role in buffering or exacerbating the physiological stress responses of individuals, the modeling of appropriate health behaviors, and the social control that family members may have on one another's health behaviors. Furthermore, because of the central role most families play in the development and maintenance of stress responses, as well as health behaviors and beliefs, psychosocial interventions are often implemented at the family level.

Description

Research has consistently indicated that the nature of parent-child and spousal relationships associates with the etiology of health, illness, and disease. For example, stable and supportive family relationships are related to long-term health outcomes. Individuals who perceive that their parents were warm and supportive during their childhood are less likely to develop coronary artery disease, hypertension, and alcoholism, than individuals who report less support from their families. Furthermore, being married and having children in the home is related to positive health outcomes such as lower mortality rates, especially for men. Conversely, parent-child relationships characterized as interpersonally hostile, critical, overly controlling, and highly conflictual relate to several health problems in adulthood including lung disease, cardiovascular disease, some types of cancer, diabetes, and drug and alcohol abuse. Furthermore, marital relationships characterized by high levels of conflict as well as interpersonally hostile behaviors are associated with the development of myriad diseases, including cardiovascular disease, which is the leading cause of death in the United States. Indeed, spouses who appraise their partner as collaborative (versus controlling or uninvolved) and who are interpersonally warm and encourage autonomy are less likely to develop coronary artery disease. Marital conflict can also confer negative outcomes on children, including mental health, social, and physiological functioning. Children from families characterized by hostility show increased physiological reactivity when exposed to couples arguing in the laboratory compared with children from less conflictual and hostile families.

In addition to research indicating a link between family relationships and the etiology of health and disease, strong findings indicate that families play a role in how well individuals and families adjust to living with an illness. Specifically, different types of family involvement in coping with chronic illnesses are an important aspect of understanding physical and psychosocial adjustment to illness. Research supports the notion that chronic illnesses are experienced within a social context and that the family environment is significantly impacted by living with a family member's illness. Oftentimes, individuals and families must learn to adjust their diet, exercise practices, daily routines, and other health behaviors in order to successfully manage the illness. Therefore, understanding how family members relate to one another to manage illness demands has been a prominent focus of interest for researchers and clinicians. For example, individuals with type 1 diabetes and cardiovascular disease who appraise their families as being involved in their illness by brainstorming, negotiating, engaging in problem solving, working as a team, and providing helpful suggestions or advice have better psychosocial and physical outcomes than those who perceive their family members as uninvolved or overly controlling. In addition, treatment adherence is generally greater when family members are collaboratively involved in the everyday stressors associated with chronic disease management. Furthermore, when family members provide emotional support, informational support, or tangible support (e.g., money, food, and supplies), individuals, and family members, often have more positive outcomes.

However, family involvement is not always associated with positive outcomes for individuals with illnesses or their families. Specifically, when family members perceive others in their family as being intrusive or causing feelings of dependency, this type of family involvement is associated with poorer treatment adherence, physical outcomes, and higher levels of family conflict. Furthermore, family members may underestimate the physical and psychological resources that an individual with an illness may have, leading to overcompensation and a lack of self-efficacy in the individual with the illness. Additionally, family members providing support may become distressed over providing support and higher levels of depression may be seen in caregivers (although some research indicates that providing support can be beneficial to family members as well). Therefore, understanding the family context in which coping with a chronic illness occurs provides insight into how well individuals, and family members, adjust to living with a disease.

Several researchers, drawing from psychophysiological research, have found interesting mechanisms by which family relationships may associate with the etiology of health and disease, as well as how individuals adjust to living with a chronic illness. First, researchers have posited that parent-child relationships provide a context in which an individual's stress system may be affected for better or worse across the lifespan. Specifically, children who are chronically faced with familial stress may develop increased sympathetic reactivity to stress and exaggerated cortisol and catecholamine responses. Indeed, research suggests that the neuroendocrine stress response system may become deregulated under chronically stressful conditions, creating the potential for diseases such as cardiovascular disease, among others. Furthermore, chronic stress occurring in the context of hostile, critical family environments may dampen killer T-cell activity, and relate to other markers of compromised immune system functioning. This process can relate to the development of chronic health problems, as well as more acute difficulties when coping with a chronic disease. Specifically, family relationship conflict can have direct and indirect effects on immune system functioning. For example, proinflammatory cytokine secretion can be affected by family stress via central nervous system and endocrine system activation as well as indirectly through relationships with emotional distress, depression, anxiety, and poor health behaviors.

Family relationships also provide a key context in which health behaviors, beliefs, and habits form, all of which can have profound associations with health outcomes. Research has shown that family social norms are an important predictor of health behaviors such as proper diet, treatment adherence, smoking, drug and alcohol abuse, and breastfeeding. Family members may provide a model that individuals within the family utilize to form health habits that influence their overall well-being. Some health behaviors, such as healthy diets, are highly related to family norms and are quite stable by early adolescence, indicating the need to intervene early within the family context. Social control, wherein family members' beliefs about health influence individuals health behaviors such as following treatment regiments, going to the doctor, or exercising more regularly, is also an important predictor of health. Furthermore, in some cultures (e.g., Asian, Latino, or Black), individuals may engage in healthy behaviors for the good of the family. Therefore, family relationships can have an important impact on health through both direct and indirect processes.

As a result of the myriad studies that show the importance of family relationships for health, clinical interventions that focus on the family have been successfully developed. Typically, family interventions within health settings include an emphasis on the modeling and education of healthy behaviors. Furthermore, families are provided strategies on how to integrate healthy behaviors into the structure of families' daily routines. Additionally, family members are taught effective problem-solving skills that provide strategies to solve daily hassles, as well as major difficulties that may arise when coping with an illness. Also, families are taught effective communication skills, such as listening to one another, reflecting what others have said, praising appropriate health behaviors, and negotiating when there are different opinions of how to manage health-related decisions. In summary, family functioning and relationships have become an important focus of intervention in health settings.

Definition

Family structure reflects the organization of individuals who may be related by blood or legally bound (i.e., marriage, adoption) that are considered of the same relational unit.

Description

The most basic family structure within Western culture comprises of the "nuclear" family, which includes father, mother, and any children under the age of 18. Information about family structure is often asked of parents or children involved in biopsychosocial research and often documented retrospectively or at the time the information is assessed. However, it can be argued that family stability and family structure are fluid and evolving influences on health, socioeconomic resources, and family dynamics and is more accurately assessed longitudinally.

In health research, family structure is often dichotomized into "single-parent households" and "two-parent households." Data regarding parental structure is of importance as single-parent households have been associated with lower income (see ▶ Family, Income) and poorer health outcomes. However, the definition of family structure is becoming increasingly complex and extends beyond the traditional dichotomy of single versus two-parent households.

For example, single parenthood can include numerous possibilities such as a single biological, adoptive, foster, or stepparent parent due to life transitions including death of a parent, remarriage, divorce, adoption, and advances in assisted reproductive technology (ART, see ▶ Infertility and Assisted Reproduction: Psychosocial Aspects) allowing single adults to conceive without an identified partner. In the most simplistic form, two-parent households may comprise of intact biological parents or stepparents who are legally defined as being married and of the same family unit. However, children are increasingly born to unmarried partners or those who are cohabiting. These families do not conform to legal definitions of marriage in the traditional sense. Furthermore, some unmarried partners may share the same residence while others do not, maintaining residences with children and previous partners. Consequently, the measurement of family structure can be ambiguous and influenced by the context in which the family relationships are defined.

Furthermore, sibling relationships can be highly variable in current-day family structures as stepfamilies and blended families often result from the dissolution of marriages or changes in cohabitation. Biological, half, and stepsiblings can influence family cohesiveness and stability, which can either ameliorate or exacerbate the difficulties of family structure changes. The ages of children in families as well as their developmental and social needs (e.g., children with disabilities) can increase the financial and emotional strain in recently combined families.

In some non-Western cultures, extended family members such as grandparents, aunts, uncles, and cousins are considered part of the core family unit given emphasis on interdependency and collectivism. Collecting information about family members beyond the "nuclear" family may be particularly important in some cultures given the additional social resources that extended family members can provide. For example, assistance from grandparents, in particular grandmothers in certain cultures may be critical to understanding how families and youth cope with chronic illness or other health demands. Extended family members can provide practical support (e.g., providing transportation to doctor appointments, reminding one to take medications, etc.) as well as emotional support to deal with health-related stressors.

Fasting Glucose

Fasting sugar

Definition

Fasting blood glucose refers to blood glucose concentrations after an overnight fast. Normal fasting blood glucose is $\leq$100 mg/dL. Impaired fasting glucose is an intermediate stage between normal glucose homeostasis and overt diabetes. Impaired fasting glucose is between 100 and 125 mg/dL. Fasting blood glucose greater than 125 mg/dL indicates diabetes. Diabetes signifies a failure of glucose regulation. Normal fasting blood glucose is maintained by multiple mechanisms, as described below (Gardner & Shoback, 2007; Kronenber et al., 2008).

Mechanisms that prevent hypoglycemia by raising blood glucose during fasting begin when glucose falls below 85 mg/dL. Initially, pancreatic beta cells sense glucose levels and suppress insulin secretion. Decreasing insulin levels decreased glucose utilization by insulin-sensitive tissue such as skeletal muscle. Lower insulin levels also increase hepatic glucose production. Endogenous glucose production mainly via glycogenolysis is also stimulated by increased glucagon levels. Glucagon is secreted from the pancreatic alpha cells in response to decreasing blood glucose. Glucagon levels begin to rise when blood glucose is less than 70 mg/dL. Glucagon increases hepatic glucose production within minutes via gluconeogenesis and to a lesser extent gluconeogenesis. Epinephrine can also acutely increase blood glucose when blood glucose decrease below 70 mg/dL. Adrenal chromaffin cells in the adrenal medulla secrete epinephrine in response to declining blood glucose. Epinephrine increases blood glucose by stimulating hepatic glucose production and decreasing glucose utilization. Epinephrine acts directly to increase hepatic glycogenolysis and enhance glucagon secretion by activating β_2-adrenergic stimulation. Gluconeogenesis is increased by epinephrine through mobilization of precursors and fatty acids. Insulin secretion is limited by α_2-adrenergic stimulation of epinephrine. Epinephrine decreases glucose utilization in insulin-sensitive tissue through β-adrenergic stimulation. Glucose utilization and endogenous glucose production can also be augmented by

long-term elevation in growth hormone and cortisol. Acute increases in growth hormone have insulin-like effects, but after several hours increase hepatic gluconeogenesis and decrease glucose uptake. Increased cortisol levels for 2–3 h increase hepatic gluconeogenesis and decrease peripheral glucose utilization. After 24–48 h, gluconeogenesis becomes the only source of glucose production. Lipolysis and ketogenesis provide alternative substrate for brain metabolism. Suppression of insulin secretion and secretion of counterregulatory hormones increase endogenous glucose production and decrease glucose utilization during fasting (Sperling, 2008).

Insulin sensitivity

Definition

Fasting insulin levels are primarily used to assess insulin sensitivity. Impaired insulin sensitivity precedes glucose intolerance in the development of type 2 diabetes. Elevated fasting insulin is a compensatory mechanism to prevent glucose intolerance and diabetes. Insulin resistance is defined as the impaired ability to promote peripheral glucose disposal and suppress hepatic glucose production.

The primary site of glucose disposal is skeletal muscle. The gold standard for measuring skeletal muscle insulin sensitivity is the hyperinsulinemic-euglycemic insulin clamp. This is an invasive and time-consuming test that involves infusion of a fixed rate of insulin and a variable rate of glucose to maintain normoglycemia; therefore, alternatives have been proposed. Calculations of fasting insulin and glucose can be used to measure insulin resistance. The most common are fasting glucose to insulin ratio, homeostasis model assessment of insulin resistance (HOMA), and quantitative insulin sensitivity check index (QUICKI). The HOMA and QUICKI models are mathematical estimates of beta cell function and insulin resistance (Gardner & Shoback, 2007; Lifshitz, 2007; Wallace, Levy, & Matthews, 2004).

Fasting insulin levels can also be evaluated during hypoglycemia. An insulin level greater than 2 μU/mL when serum blood glucose is less than 50 mg/dL suggests hyperinsulinism (Gardner & Shoback, 2007).

Fat Absorption

Dietary lipids absorption

Definition

The absorption of the fat begins in the intestine with the help of several enzymes which is closely regulated by local hormones.

Description

More than 90% of dietary fat is in the form of triacylglycerol (TAG). The remainder of the fat is in the form of cholesterol, cholesteryl esters, phospholipids, and free fatty acids, which are unesterified. The mechanism of fat absorption includes degradation by the local enzymes, mediated by the hormones in the gastrointestinal system.

The digestion of the lipids begins in the stomach, when the food content is mixed with salivary lipase produced in the mouth. The gastric lipase is produced by the stomach and salivary lipase, which are resistant to gastric acidity, helps the breakdown of short- and medium-chain TAG molecules. Once the lipid-rich food reaches the duodenum, which is the first part of small intestine, the process of emulsification begins with the addition of bile salts and mechanical peristalsis. With the emulsification, the surface area of the lipid molecules is increased and also prevents their coalescing with other lipid molecules. Eventually, pancreatic enzymes play a major role in the absorption of dietary lipids. TAG is initially a larger molecule when it enters the intestine, and the pancreatic lipase removes the fatty acids from TAG to make it a smaller molecule, which is then taken up by intestinal villi.

Dietary cholesteryl esters in the form of cholesterol are in the nonesterified (free) form. Cholesterol esterase, a pancreatic enzyme, degrades cholesteryl esters into free fatty acids and cholesterol. Phospholipids in the food are degraded by the phospholipase, another pancreatic enzyme.

The lipid digestion is controlled by two important hormones in the intestine. Cholecystokinin (CCK) is a local hormone produced by jejunum and duodenum after the partially digested fat-rich food. CCK contracts the gall bladder to release bile and also act on the cells of pancreas to produce the pancreatic digestive enzymes. Bile fluid is produced from the liver and stored in the gall bladder, and it is rich in bile salts, phospholipids, and free cholesterol. Bile salts help in the emulsification process as mentioned before. Secretin, another small peptide hormone produced by the intestinal cells, act on the liver and pancreas to produce the watery solution rich in bicarbonates and this helps to alkalinize the gastric acidity when the food enters the duodenum. This helps to maintain the optimum pH for the action of all the above-described enzymes.

Free fatty acids, free cholesterol, and 2-monoacylglycerol are the final products of lipid digestion in the intestine. These end products along with bile salts and fat-soluble vitamins form mixed micelles. The micelles are disk-shaped clusters with water-soluble components located outside and water insoluble components located inside their surface. These mixed micelles are absorbed from the brush border of intestinal mucosal cells. Short- and medium-chain length fatty acids are directly absorbed without the assistance of micelles.

After the absorption of these lipids in the intestinal cells, the longer-chain fatty acids are further taken up by the endoplasmic reticulum of intestinal cells where the synthesis of complex lipids

takes place. The longer fatty acids are activated by the enzyme, fatty acyl Co A synthetase, and are transformed into TAG with the help of TAG synthase. The small and medium-chain fatty acids are directly released into the portal circulation to the liver after binding to albumin.

Absorbed lipid components either go to liver through the portal vein or directly in to systemic circulation to the rest of the body through the lymphatic system.

Definition

Dietary fat is broken down into glycerol and fatty acids in the stomach and intestine when ingested. The glycerol and fatty acids are then altered in a process called emulsification in order for fats to be held in the digestive fluids long enough to be digested. Once digested, the fat is transported by the body's cells via the bloodstream and lymphatic system. If the fat is not required immediately, glycerol can be converted into glucose and either used for energy, stored as glycogen (short term) or stored as ▶ body fat (long term).

Given that fats are higher in calories than carbohydrates or protein, all dietary fats should be ingested with moderation. The American Heart Association recommends that approximately 20–35% of daily ▶ caloric intake should come from fats. Depending on height, weight, and activity level, recommended intake ranges from 45 to 75 g of fat a day for women and 60 to 105 g of fat a day for men. The amount of fat recommended for children and adolescents depends on height, weight, gender, and activity level.

Unlike carbohydrates and proteins that have one major function, dietary fat has a number of important roles in the body. These include forming the structure of cell membranes, helping absorb vitamins, lubricating joints, providing insulation for nerves (myelin sheath), supporting strong bones, and supporting a strong immune system.

Description

Fats are constructed from a combination of carbon and hydrogen atoms that are chemically bonded together. The structure of this chemical bond determines the type of dietary fat. There are four main types of dietary fat: saturated, monounsaturated, polyunsaturated, and ▶ trans fats.

▶ *Saturated fats (saturated fatty acids) (SAFAs):* All carbon atoms are bonded to hydrogen atoms in the chemical structure of a saturated fat. These fats have the highest

melting point of all the natural fats and therefore remain solid at room temperature. Saturated fats increase levels of both HDL and LDL ▶ cholesterol; therefore, moderate consumption is recommended for healthy individuals. These fats are found primarily in animal products such as fatty meats, full-fat dairy products, butter, lard, coconut oil, and palm oil.

▶ *Monounsaturated fats (monounsaturated fatty acids) (MUFAs):* In the chemical structure, monounsaturated fats contain one double bond between carbon atoms. Thus, the carbon atoms are bonded to hydrogen atoms everywhere but at the double carbon bond and are therefore only saturated with hydrogen atoms at this single point. Monounsaturated fats have a lower melting point than saturated fats and a higher melting point than polyunsaturated fats. Unsaturated fats increase HDL ▶ cholesterol levels while reducing LDL ▶ cholesterol levels and are therefore highly recommended for consumption. Ingesting foods high in MUFAs may also benefit ▶ insulin levels and blood sugar control. Foods rich in MUFAs include avocados, nuts, and olive oil.

▶ *Polyunsaturated fats (polyunsaturated fatty acids) (PUFAs):* In the chemical structure of polyunsaturated fats, there are two or more double bonds between carbon atoms. Thus, they are not fully saturated with hydrogen atoms at two or more points in the structure. Polyunsaturated fats have the lowest melting point of all dietary fats and remain liquid at low temperatures. The two main types of polyunsaturated fats are ▶ omega-3 fatty acids and omega-6 fatty acids. Omega-3s are found in coldwater oily fish, such as salmon, whereas omega-6s are found in vegetable oils. Both are ▶ essential fatty acids, meaning they cannot be produced by the body and must be acquired from PUFA-rich foods or ▶ dietary supplement. Unsaturated fats increase HDL ▶ cholesterol levels while reducing LDL ▶ cholesterol levels and are therefore highly recommended for consumption. Omega-3 s appear to decrease the risk of ▶ coronary artery disease and may also protect against blood clotting, reducing the risk of stroke, and lowering triglycerides.

▶ *Trans fats (trans-isomer fatty acids) (TFAs):* Trans fats involve adding hydrogen atoms to a fat that was originally unsaturated. These fats are created naturally when a hydrogen bond on an unsaturated fat gets twisted. However, the vast majority of trans fats are man-made in a process called hydrogenation. Man-made trans fats, called industrial or synthetic trans fats, are found in processed foods such as partially hydrogenated margarine, many commercially baked products, and deep-fried foods. TFAs have a high melting point and remain solid at room temperature, making them easier to cook with and less likely to spoil compared to naturally occurring oils. Synthetic trans fats increase unhealthy LDL ▶ cholesterol and lower healthy HDL ▶ cholesterol, increasing risk for ▶ cardiovascular disease and therefore should be avoided. Synthetic trans fats are believed to have no health benefits.

Research indicates long-term consumption of a high-fat diet contributes to increased mortality and morbidity. Consumption of a high-fat diet is a contributing factor to the development of obesity. ▶ Obesity and excessive body weight are associated with various diseases, such as ▶ cardiovascular disease, diabetes mellitus type 2, certain types of cancers, ▶ obstructive sleep apnea, osteoarthritis, and ▶ metabolic syndrome (a combination of disorders including diabetes mellitus type 2, high blood pressure, high blood cholesterol, and high triglyceride levels). As a specific example, a diet high in fat may contribute to the development of ▶ atherosclerosis by activating elevations in blood pressure, which can lead to further risk of other cardiovascular events. While a high-fat diet contributes to negative health outcomes, a change in diet including an increase in the consumption of certain fats, like ▶ omega-3 fatty acids, in combination with a reduction in the consumption of saturated fats can have protective and therapeutic health benefits. These benefits may include a reduction in overall ▶ cholesterol levels and blood pressure, reduced risk for chronic illness, as well as improvements in mood. It is generally recommended daily intake of dietary fat should be limited to 30% of daily ▶ caloric

intake, with the majority of these calories coming from monounsaturated fats or polyunsaturated fatty acids.

Definition

Fat is an energy source derived from food. There are four types of dietary fat: saturated, trans, monounsaturated, and polyunsaturated fat (U.S. Department of Agriculture & U.S. Department of Health and Human Services, 2010).

Description

Fat is an essential dietary element because it supplies calories, helps insulate the body, aids in the absorption of fat-soluble vitamins (i.e., A, D, E, K) and keeps hair and skin healthy. Dietary fat also provides the body with essential fatty acids that aid in controlling inflammation, blood clotting, and developing the brain (U.S. National Library of Medicine & National Institutes of Health, 2011a).

Types of Fats

Based on their composition, the four fats are grouped into two subgroups: saturated fatty acids (saturated fat) and unsaturated fatty acids (which includes trans, monounsaturated, and polyunsaturated fat). However, trans fat is structurally different and not healthy like the other unsaturated fats, so for clarity it will be helpful to use the groups unhealthy (i.e., saturated and trans fat) and healthy fats (monounsaturated and polyunsaturated fat) (Mayo Clinic, 2011; U.S. Department of Agriculture & U.S. Department of Health and Human Services, 2010; U.S. National Library of Medicine & National Institutes of Health, 2011b). Sometimes, unhealthy fats are called solid fats and healthy fats are called oils (U.S. Department of Agriculture & U.S. Department of Health and Human Services, 2010).

Unhealthy Fats

Saturated fats. Saturated fats are grouped under the unhealthy fat category because they can raise

total cholesterol and LDLs (low-density lipoproteins – which are also called "bad" cholesterol). Diets high in saturated fat can result in occluded or narrowed arteries and increased risk for cardiovascular disease (Mayo Clinic, 2011; U.S. Department of Agriculture & U.S. Department of Health & Human Services, 2010; U.S. National Library of Medicine & National Institutes of Health, 2011a). Some examples of saturated fat include: ice cream, butter, cheese, whole milk, coconut oil, palm oil, and most animal fats (U.S. Department of Agriculture & U.S. Department of Health and Human Services, 2010; U.S. National Library of Medicine & National Institutes of Health, 2011a). The body makes enough saturated fat; therefore, it is not a dietary requirement (U.S. Department of Agriculture & U.S. Department of Health and Human Services, 2010).

Trans fats. Trans fats are unhealthy because they can raise LDL (bad) cholesterol and lower HDLs (high-density lipoproteins – which are also called "good" cholesterol). Excessive trans fat consumption can lead to increased risk for cardiovascular disease (Mayo Clinic, 2011; U.S. National Library of Medicine & National Institutes of Health, 2011a). Some examples of trans fat include: processed foods, fried foods, and commercially baked foods (U.S. National Library of Medicine & National Institutes of Health, 2011a). Trans fats are also not essential dietary fats (U.S. Department of Agriculture & U.S. Department of Health and Human Services, 2010). Sometimes trans fats are also called partially hydrogenated oils (Centers for Disease Control and Prevention [CDC], 2010).

Healthy Fats

Monounsaturated fats. Monounsaturated fats are grouped under healthy fats because replacing unhealthy fats (i.e., saturated and trans fats) with monounsaturated fats can lower LDL (bad) cholesterol (U.S. National Library of Medicine & National Institutes of Health, 2011a). Monounsaturated fats also provide essential fatty acids that are not produced by the body; these essential fatty acids are needed for physiological and structural functions (Centers for Disease Control and Prevention [CDC], 2011; U.S. Department of Agriculture & U.S. Department of Health and Human Services, 2010). Some examples of monounsaturated fat include: canola oil, olive oil, and avocados (CDC, 2011).

Polyunsaturated fats. Polyunsaturated fats are grouped under healthy fats because replacing unhealthy fats (i.e., saturated and trans fats) with polyunsaturated fats can lower LDL (bad) cholesterol (U.S. National Library of Medicine & National Institutes of Health, 2011a). Polyunsaturated fats also provide essential fatty acids that are not produced by the body; these essential fatty acids are needed for physiological and structural functions (CDC, 2011; U.S. Department of Agriculture & U.S. Department of Health and Human Services, 2010). Additionally, there are two subgroups of polyunsaturated fats, omega 6 polyunsaturated fats, and omega 3 polyunsaturated fats. Some examples of omega 6 polyunsaturated fats include safflower oil and corn oil whereas some examples of omega 3 polyunsaturated fats include flaxseed, canola oil, walnuts, trout, and salmon (CDC, 2011).

Recommendations

Generally, it is advised that most fat intake should come from healthy sources of fat (i.e., monounsaturated and polyunsaturated fat) and unhealthy sources of fat (i.e., saturated and trans fat) should be limited. Total fat intake should range from 30% to 40% of calories for children 1–3 years of age, 25–35% of calories for those 4–18 years of age and 20–35% of calories for adults over the age of 19 (U.S. Department of Agriculture & U.S. Department of Health and Human Services, 2010). The recommendations suggest healthy Americans over the age of 2 consume less than 1% of daily calories from trans fat, less than 7% of daily calories from saturated fat, and replace remaining fat calories with healthy fats (American Heart Association, 2012).

Further, the recommendations suggest limiting unhealthy fat and replacing it with healthy fat.

However, regardless of the type of fat (i.e., healthy or unhealthy) fat intake should be limited because dietary fat provides 9 calories per gram which is more than double the amount of calories other nutrients provide (e.g., carbohydrates provide 4 calories per gram) (U.S. Department of Agriculture & U.S. Department of Health and Human Services, 2010; U.S. National Library of Medicine & National Institutes of Health, 2011b). Therefore, eating a diet of more fat than recommended (healthy or unhealthy) can lead to overweight or obesity and its associated risk factors (U.S. National Library of Medicine & National Institutes of Health, 2011b). Most Americans consume more total fat and more unhealthy fat than recommended and less healthy fat than recommended (U.S. Department of Agriculture & U.S. Department of Health & Human Services, 2010).

Fatalism

Karla Espinosa de los Monteros
Clinical Psychology, SDSU/UCSD Joint Doctoral Program in Clinical Psychology, San Diego, CA, USA

Definition

Fatalism refers to the general belief that events, such as the actions and occurrences that form an individual life, are determined by fate, and, thus, beyond the capacity of human beings to control. When applied to health, fatalism can be conceptualized as the belief that the development and course of health problems is beyond an individual's personal control (Straughan & Seow, 1998). Research on the relationship between fatalism and health has generally focused on fatalistic beliefs about specific diseases, the most commonly studied being cancer. Powe and Johnson (1995) defined cancer fatalism as a situational manifestation of fatalism where an individual feels powerless in the face of cancer and views its diagnosis as a struggle against insurmountable odds.

Description

The shift from ▶ acute disease to chronic disease as the major cause of morbidity and mortality in developed countries has highlighted the importance of lifestyle factors in the prevention of

disease. This paradigm shift has fostered efforts to understand how ▶ cognitive factors, such as fatalism, influence an individual's decision to adopt health-promoting behaviors. Fatalism's influence on behavior may stem from its impact on an individual's perceived ▶ self-efficacy to control life events, the outcomes attributed to a behavior, and overall motivation to change, maintain, or adopt behaviors (Freeman, 1989; Powe & Johnson, 1995; Straughan & Seow, 1998). For example, an asymptomatic individual who believes that cancer is unavoidable regardless of personal action is likely to perceive few benefits to cancer screening, particularly in light of the material losses (e.g., time, money) and aversive experiences (e.g., discomfort, anxiety) associated with the behavior. Indeed, cancer fatalism has been associated with the underutilization of cancer screening services, delay of care, smoking, physical inactivity, and poor dietary practices (Espinosa de los Monteros & Gallo, 2010; Niederdeppe & Levy, 2007; Powe & Finnie, 2003). Research focusing on fatalistic beliefs about diseases other than cancer is more limited, but preliminary evidence suggests that the construct may also be associated with high-risk sexual behavior and diabetes management.

Cultural differences in the endorsement of fatalistic beliefs about health and illness have been reported. For example, in the United States, cancer fatalism is more common in African American and Hispanic American populations than in non-Hispanic Whites (Abraido-Lanza et al., 2007; Powe & Finnie, 2003). While this pattern may in part be attributed to variation in the dominant worldviews of different cultural groups, generally, fatalistic beliefs about health and illness are most prominent in older adults and less educated populations, as well as in groups that have historically experienced significant social disadvantages (Abraido-Lanza et al., 2007; Davison et al., 1992; Powe & Johnson, 1995). Given these differences, fatalism has at times been studied as a means to understand the factors contributing to socioeconomic, racial, and ethnic ▶ disparities in health behavior, and many studies have called for the development of culturally sensitive interventions to address fatalistic perceptions about health within high-risk groups.

However, theories on the development and maintenance of fatalistic beliefs in regards to health and illness stress the importance of considering certain points. First, care should be taken in interpreting fatalistic beliefs as irrational before considering the social and physical barriers to health that are faced by certain populations. For example, poverty, ▶ discrimination, and limited access to health-promoting resources such as health education and medical care represent tangible barriers to disease prevention and treatment (Freeman, 1989). Therefore, for certain individuals, fatalistic beliefs about health and illness may be grounded on realistic appraisals of individual control and may more accurately represent a balance between the almost universally valued goal of good health, and the recognition that some barriers to health may not be overcome through personal effort (Davison et al., 1992).

Second, while all or none categories are often used to describe the nature of fatalistic beliefs – i.e., individuals are either fatalistic or they are not – empirical evidence shows that people rarely embrace either extreme (Davison et al., 1992). Thus, a more accurate conceptualization of fatalistic beliefs about health and illness is that they fall within a spectrum ranging from high to low, and where an individual falls within that spectrum will likely depend on the disease or behavior in question, as well as the context in which fatalism is assessed.

Finally, while fatalistic beliefs about health and illness may be more prominent in certain populations, they are not exclusive to any one group. As Davison et al. (1992) pointed out, as long as people continue to witness health outcomes that are inconsistent with their current biomedical understanding of disease, there will

always be a place for the notion of fate to help people make sense of what cannot be easily explained.

Fatigue

Fred Friedberg
Psychiatry and Behavioral Sciences, Stony Brook University Medical Center, Stony Brook, NY, USA

Synonyms

Chronic fatigue; Chronic fatigue syndrome; Energy; Exhaustion; Illness fatigue; Self-management; Tiredness; Treatment of fatigue

Definition

Fatigue is a subjective sense of tiredness or exhaustion. Although "fatigue" is a general term intended to encompass both tiredness and exhaustion, it can also refer to the midrange intensities between (milder) tiredness and (more severe) exhaustion. Tiredness is a normal time-limited response to sustained physical, mental, or emotional effort. More persistent states of fatigue and exhaustion may arise from behavioral and environmental stressors, or be a symptom of physical or psychological disorders. A number of physiologic mechanisms for fatigue have been proposed, and some correlations have been identified, but clear biologic markers have yet to be established.

Description

The nearly ubiquitous experience of tiredness in daily life may devalue the symptom of fatigue as

a potential concern to health professionals. As such, the complaint of fatigue is often regarded as non-serious by physicians, but is considered one of the most important symptoms by patients.

Self-report fatigue severity in the population is normally distributed with pathological fatigue represented at higher levels on this quantitative continuum. However, fatigue may also be qualitatively and biologically different depending on its origins (e.g., disease, occupational). For instance, mental and physical fatigue are empirically distinguishable constructs. Persistent fatigue may impact physical and cognitive functioning as well as emotional well-being and quality of life.

Useful distinctions can be made on a severity dimension of tiredness, fatigue, and exhaustion. Similar to Selye's general adaptation syndrome (alarm, resistance, exhaustion), individuals with normal tiredness experience loss of energy in proportion to the amount of energy expended, whereas individuals with (persistent) fatigue experience loss of energy sooner than expected and out of proportion to the amount of energy expended. Finally, individuals with ongoing exhaustion experience sudden and unpredictable losses of energy, often without any identifiable energy expenditure.

These three states of fatigue are also linked to increasing cognitive difficulties, reduced sleep quality, and lessened ability to engage in social interaction. The relative places of tiredness, fatigue, and exhaustion in the adaptation process have implications for the types of interventions that are most appropriate. For example, mild exercise, which might be appropriate for someone experiencing fatigue, might be an additional stressor (and therefore harmful) for a person experiencing exhaustion. This piece will focus on persistent fatigue with respect to diagnosis, lifestyle factors, illness conditions, medication side effects, and treatment.

Diagnosis

Persistent fatigue is a common symptom in health care and is usually not due to an identifiable disease. Definitive physical conditions are found in less than 1/10. In those people who have a clear diagnosis, musculoskeletal and psychological problems are the most common. If a person with fatigue decides to seek medical advice, the overall goal is to identify and/or rule out any treatable conditions. This is done by considering the person's medical and psychosocial history and other symptoms that may be present, conducting standard laboratory tests, and evaluating the qualities of the fatigue itself.

Lifestyle Factors

Behavioral and psychosocial factors linked to persistent fatigue include physical inactivity, overwork, poor ▶ sleep, affective distress, and poor diet/overweight.

Physical inactivity. In modern sedentary societies, occupational, social, and leisure activities typically involve little physical effort. This often indicates a lack of exercise or physically active hobbies. Persistent fatigue may be generated by such physical inactivity. In addition, general inactivity, both physical and mental, may trigger boredom and apathy which can further increase fatigue.

Overwork. In work-focused cultures, near-continuous engagement in goal-directed mental and intellectual activities (often in combination with mild to moderate sleep deprivation) may result in persistent fatigue.

Sleep difficulties. Disrupted ▶ sleep, a significant contributor to fatigue, is related to sleep quality, amount of sleep, the hours set aside for sleep, and the number of times that a person awakens during the night.

Affective distress. Emotions including anxiety, discouragement, and depressed mood may be accompanied by the symptom of fatigue.

Poor diet/overweight. Western diets – typically high calorie, high sugar, and high fat – are linked to overweight and obesity. Self-reported fatigue is associated with higher body mass index and a higher waist circumference.

Illness-Related Fatigue

Chronic illnesses both psychiatric and medical often feature the symptom of persistent fatigue. Psychiatric conditions that commonly exhibit fatigue are clinical depression and generalized anxiety disorder. Medical conditions linked to significant fatigue include anemia, low thyroid, diabetes, cardiovascular disease, arthritis, HIV/AIDS, autoimmune diseases, cancer, fibromyalgia, and traumatic brain injury. Sleep disorders such as ongoing ► insomnia, ► obstructive sleep apnea, and narcolepsy exhibit fatigue as well.

In cancer patients, fatigue has emerged as one of the most prevalent, troubling, and undertreated of all symptoms. In addition, subjective reports of fatigue after activities in the elderly have been found to be a strong independent predictor of functional decline, disability, and death.

Finally, chronic fatigue syndrome (CFS) is an illness defined by medically unexplained fatigue of 6 months or more plus 4/8 secondary symptoms (e.g., post-exertional fatigue, muscle and joint pain symptoms, flu-like symptoms) and significant impairments in physical and role functioning. The fatigue in CFS is only partially alleviated by rest and is qualitatively different from ordinary tiredness. In addition, exercise that was easily tolerated before illness onset may worsen fatigue-related symptoms. Biomedical and behavioral factors have been found in CFS, but no definitive etiology or pathophysiology has been identified.

Drugs and Medication Side Effects

The use of alcohol, ► caffeine, or illegal drugs, such as cocaine or narcotics, especially with regular use or abuse may result in persistent fatigue. Fatigue may also be a side effect of certain medications, e.g., antihistamines, sleeping pills, and lithium salts; blood pressure medicines such as beta-blockers, which can induce exercise intolerance; and many cancer treatments, particularly chemotherapy and radiotherapy.

Treatment of Fatigue

Given the current limitations of medicine in treating fatigue, self-management is an essential clinical issue because sufferers have options ranging from doing nothing to actively seeking help. Early intervention (e.g., individuals with persistent fatigue of less than 12 months) is most likely to be beneficial. However, if the patient has already reached a stabilized level of persistent fatigue, more powerful interventions may be necessary to restart the self-management process.

Non-pharmacological treatment options include patient education about fatigue and its relation to stress and lifestyle. Diary-keeping to track activities, stressors, and sleep patterns and their relation to fatigue and energy are important first steps in designing a self-management program.

Self-management. Self-management techniques for unexplained persistent fatigue, CFS, and illness fatigue in general have shown efficacy in various combinations that include pacing of activities, low-level exercise, low-effort pleasant experiences, sleep improvement techniques, and cognitive coping skills to reduce both illness catastrophizing and over-focusing on symptoms. It should be noted that low-level exercise, typically walking or stretching, is initially prescribed as a stress reduction activity rather than a physical fitness program. Relaxation techniques are particularly helpful for affective distress linked to fatigue. In general, the goal of an effective self-management program is to learn to balance activity and rest in order to avoid the extremes of too little or too much activity. This approach to self-management will lessen fatigue, but probably not eliminate it.

Medications. Medical practice includes corticosteroids as a short-term therapeutic option for relief of fatigue in palliative care. Given limited evidence, no specific drug can be recommended for the treatment of persistent fatigue, although amantadine in multiple sclerosis and methylphenidate in cancer patients have shown promise. Selective serotonin reuptake inhibitors, such as fluoxetine, paroxetine, or sertraline, may improve energy in some patients with comorbid depression. Modafinil, a wakefulness-promoting agent

that is pharmacologically different from other stimulants, has not been adequately tested as a treatment for fatigue.

Alternative treatments. Regarding alternative treatments, acupuncture and several types of meditative practice show the most promise for future scientific investigation. Likewise, magnesium, L-carnitine, and *S*-adenosylmethionine are non-pharmacological supplements with potential in further research. Chinese medicinal herbs for persistent fatigue and CFS lack evidence from controlled studies.

Summary

Fatigue is a commonly experienced symptom that is associated with inactivity, overwork, affective distress, physical and psychiatric illnesses, and drug side effects. In contrast to normal tiredness, the persistent state of fatigue can impact physical and role functioning and quality of life. Medical treatment of fatigue is not well-established. By comparison, self-management of debilitating fatigue through behavioral interventions such as pacing, low-level exercise, and exposure to low-effort pleasant activities can lead to reduced fatigue, increased functioning, and improved quality of life.

Fatty acids-unesterified

Definition

Free fatty acids are unesterified, long-chain carboxylic acids. After esterification, fatty acids are found in the complex molecules like triacylglycerols. Usually, low levels of free fatty acids are seen in all tissues, but the substantial increase in the plasma is seen during fasting state. Free fatty acids are transported by albumin. Free fatty acids are oxidized mainly in the liver and muscle cells to provide energy. Fatty acids are also structural components of membrane lipids such as glycolipids and phospholipids. Fatty acids are also the precursor of prostaglandins. After esterification, fatty acids are stored as triacylglycerol in the adipose tissue, and this serves as a major reservoir of energy during fasting.

Fatty acids are called as "unsaturated" if they have at least one double bond in their chemical structure and "saturated" if they have none. Humans can only produce few unsaturated fatty acids in the body, and remaining fatty acids are

obtained from the dietary intake, and these are called essential fatty acids. Two important essential fatty acids are linolenic and linoleic acids.

Omega numbering system is used for unsaturated fatty acids, and it depicts the position of double bond relative to the end of chain. Dietary intake of omega-3 fatty acids (e.g., linolenic acid) in the diet is associated with a reduced risk of cardiovascular disease events.

Fear and Fear Avoidance

Yori Gidron
Faculty of Medicine and Pharmacy, Free University of Brussels (VUB), Jette, Belgium

Definition

Fear is an unpleasant negative emotion usually rising due to or in association with a specific source or stimulus. Fear avoidance would take place by a behavior which reduces the probability of exposure to the fear-eliciting stimulus or situation. A negative reinforcement process takes place where the lack of elicited fear reinforces the behavior which reduced its probability – normally the avoidance. This is often seen, for example, in the context of chronic pain, where patients fear a situation that in the past increased their pain (e.g., going for a walk). Remaining at home and avoiding activity (disability) is negatively reinforced by the lack of further increases in pain from walking outside. This process could then increase the patient's disability levels. This process is at the core of the fear-avoidance model of pain (Leeuw et al., 2007; Vlaeyen & Linton, 2000). Additional variables that are thought to play roles in this model include cognitive variables such as catastrophizing (severely negative appraisals about anticipated pain), psychophysiological (e.g., elevated muscle reactivity, high sympathetic arousal), and emotional (subsequent fear and anxiety). Numerous elements of the model have been validated. Indeed, one study found in a large sample of back pain patients that baseline fear avoidance predicted high rates of long-term sick leave (Boersma & Linton, 2006). However, one review of nine prospective studies in low back pain patients found that fear and fear avoidance were not consistently predictive of pain. There was some evidence that such fears do play a role in predicting future pains when pain has become consistent (Pincus, Vogel, Burton, Santos, & Field, 2006). It is possible that disability may be more influenced by fear avoidance than pain. Importantly, the clinical application of the fear-avoidance model was tested in a small-scale study with chronic back pain patients. All patients received either first in vivo exposure to individualized fear-eliciting movements (to reduce fear avoidance) or to general graded physical activity, or the reversed order. Only during in vivo exposure to fear-eliciting movements were there reductions in pain-related fears and in catastrophizing (Vlaeyen et al., 2002). This model could be applicable to other health contexts – patients may avoid attending oncology clinics where they

receive chemotherapy which elicits nausea and vomiting, at the possibly grave price of not treating adequately their cancer. Fear and fear avoidance are also of much relevance to anxiety disorders. Thus, fear avoidance is a prevalent problem in medical settings, and its treatment could possibly result in improved health outcomes. Treating fear avoidance could be done by behavioral or cognitive-behavioral methods.

Feasibility Study

J. Rick Turner
Cardiovascular Safety, Quintiles, Durham, NC, USA

Definition

A feasibility study is undertaken to determine whether there is a sufficiently high (acceptable) likelihood that a research study being considered can be successfully executed.

Description

When planning a large and complex research study (particularly an experimental study such as a randomized clinical trial of a behavioral intervention), it is wise to conduct a feasibility study once the study protocol has reached a relatively final stage of development. At that point, the researchers have a good idea of the number of subjects they will need to participate in the trial (the sample size) and many other methodological requirements. The question then becomes: Is there an acceptably high likelihood that it is actually feasible to conduct the trial? Phrased in another manner, the question is: Can the trial be executed as currently laid out in the protocol? A feasibility study is undertaken to answer this question. If the answer is "no," the researchers can consider making changes to the protocol before its finalization to improve the likelihood that the trial is capable of providing a meaningful answer to the research question being asked.

If the research team has done a previous (smaller) trial, they will have information on investigational sites used, principal investigators, and subject recruitment rates. This will help to answer the following questions:

- Where were the investigational sites used in the previous trial(s) located?
- How easy was it to recruit and retain the required number of subjects for the previous

trial, and did ease of recruitment vary across geographic locations within the country? (For some large trials, where investigational sites were located in more than one country, and potentially more than one continent, the answer to this question becomes more complex.)

- How similar is the study design on this occasion? We know that the study size (size of the subject sample) is going to be larger, but are there any other factors that might impact subject recruitment and retention? Such possibilities include more extensive measurement schedules. In cases where more blood samples are to be taken, or more invasive assessment procedures are to be used (all of which information will be in the study's informed consent form), it is possible that the subject recruitment and retention rates could be impacted.

An additional way of collecting relevant feasibility information is to create a survey that is sent with the draft study protocol to behavioral medicine specialists at various clinical and medical centers, i.e., potential investigational sites, at which the trial may be conducted. Such a survey asks a series of questions targeted at understanding if the specialists would be able to recruit certain subjects into the trial, and the timeline by which enrollment will be completed.

When the research team receives back the completed surveys, they need to consider the feedback carefully. It is widely acknowledged that physicians and clinicians interested in participating in clinical trials often inflate (unconsciously or consciously) the number of subjects they say they can recruit. They may also make overly ambitious statements about the suitability of their facilities and their abilities to operationally execute any particularly complicated aspects of the protocol. While such rose-tinted self-appraisals may initially make the physician's site look attractive for inclusion in the trial, subsequent site underperformance has a cascade of unfortunate consequences. Overall subject recruitment is negatively impacted, impacting completion of the trial. From the patients' perspective, this could mean that it takes a (much) longer period of time before a new intervention is available to them.

Fibrinogen

Definition

Fibrinogen is a glycoprotein that plays a critical role in blood clotting and has been also identified as a novel risk factor for acute coronary syndromes and strokes. Fibrinogen is produced by the liver and upregulated in the setting of physiologic stress. It is used clinically in the identification of disseminated intravascular coagulopathy, a serious dysregulation of blood clotting as well as diagnosis of rare bleeding disorders such as congenital hypofibrinogenemia.

A key component in the clotting cascade, fibrinogen functions in creating the platelet plug that creates hemostasis in an injured vessel. Fibrinogen is converted to fibrin via thrombin, a serine protease. Fibrin then undergoes further protein-based cross-linkages to create the plug for the vessel wall. Glycoprotein IIb/IIIa is a receptor for fibrinogen found on platelets that functions in platelet aggregation. Glycoprotein IIb/IIIa is a target for several drugs used to avoid thrombosis in cardiovascular disorders (Maron, Ridker, Grundy, & Pearson, 2010).

Fibrinogen's relevance in behavioral medicine centers on its potential importance as a marker of the stress reaction. The relationship of fibrinogen to other known inflammatory mediators such as IL-6 suggests a cascade of endogenous procoagulant proteins that may be associated with situations of psychosocial stress.

Fibrinolysis

Definition

Fibrinolysis is the process of dissolving the protein known as fibrin, after an injured vessel has healed and no longer requires a plug to achieve hemostasis. It is a complex cascade of enzymatic processes tightly orchestrated by a shifting balance of bloodstream procoagulant and anticoagulant factors (Boyle & Jaffe, 2010). Intravenous fibrinolytic agents have been utilized in the treatment of myocardial infarction. As an alternative to invasive procedures such as primary coronary interventions (PCI), medical approaches such as fibrinolysis are appropriate for certain patients who may not access to primary PCI.

Fibromyalgia

Definition

Fibromyalgia is a chronic rheumatoid disorder/syndrome characterized by widespread pain in the body. It affects 2–4% of the American population and is disproportionally higher in women compared to men (ratio 9:1). While it was once thought to be a psychosomatic problem (this belief was only recently dispelled), fibromyalgia is presently thought to be a condition associated with the body's central neuromodulators. The American College of Rheumatology classification criteria for fibromyalgia (released in 1990) include a history of widespread pain in the body for at least three months and pain from digital palpation in 11 of 18 tender points.

Description

According to the 1990 American College of Rheumatology (ACR) classification criteria for fibromyalgia, a patient can be diagnosed with fibromyalgia if the patient has a history of widespread pain in the body as well as in the axial skeleton (neck or back) for at least three months and must have pain from digital palpation in 11 of 18 tender points, these points being located bilaterally at the suboccipital muscle attachments on the occiput, at the anterior aspects of intertransverse spaces between the C5 to C7 vertebrae, at the midpoint of the upper border of the trapezius muscle, at the supraspinatus muscle near the medial border of the spine of the scapula, at the level of the second rib at the costochondral junctions, slightly distal to the lateral epicondyles, in the upper outer quadrants of the buttocks, at the greater trochanters, and at the medial aspect of the knee at a level slightly proximal to the joint line. More recently (2010), the ACR proposed a new set of diagnostic criteria which require patients to fulfill the following three criteria: widespread pain index (WPI) $\geq$7 and symptom severity (SS) scale score $\geq$5 or WPI 3–6 and SS scale score $\geq$9. Symptoms have been present at a similar level for at least 3 months, and the patient does not have a disorder that would otherwise explain the pain. However, it should be noted that these criteria have not yet been validated with independent samples.

One of the major problems in recognizing and categorizing fibromyalgia is that it presents in a similar fashion to other muscle pain disorders, fails to present specific features, and presently has no clinical diagnostic test. Pain in fibromyalgia is described as throbbing, stabbing, or burning and as such may be confused with arthritis; however, unlike arthritis, fibromyalgia does not have associated joint or inflammation damage. Fibromyalgia pain may also cause paresthesia and mimic nerve root compression, despite no evident change in the peripheral nervous system. Further complicating the issue, patients with fibromyalgia also have normal results in blood tests and diagnostic imaging exams such as computed tomography (CT) scans, magnetic resonance imaging (MRI), and electromyography (EMG). Due to these difficulties, fibromyalgia has earned the nickname of the "invisible disability" of chronic pain syndromes.

The causes of fibromyalgia remain unknown, but it has been reported that the onset of fibromyalgia has a tendency to follow a physical or psychological traumatic event. Presently, central sensitization is considered one of the more likely causes for fibromyalgia and is supported by the demonstration of altered pain processing pathways via functional MRI (fMRI) and by the presence of allodynia (pain from usually nonpainful stimuli) in patients with fibromyalgia. Other models for the pathogenesis of fibromyalgia have also been developed; one such model suggests that fibromyalgia results from stress and abnormalities in the hypothalamic-pituitary-adrenal (HPA) axis. Though the underlying pathophysiology remains to be outlined in great detail, research has generated some consistent findings. One such finding is the elevated level of the substance P neuromodulator in the cerebrospinal fluid (CSF) of patients with fibromyalgia. Substance P is known to participate in nociception and is thought to augment an individual's sensitivity to pain. In addition, research has shown that serotonin inhibits the release of substance P by afferent spinal cord neurons and that in patients with fibromyalgia, levels of

serum serotonin and CSF serotonin metabolites were reduced.

In addition to widespread pain and allodynia, fibromyalgia often presents with a variety of other symptoms, the most common of these being chronic fatigue, nonrestorative sleep, or sleep disturbances, the latter of which is thought to be problematic and contributing to pain perception by preventing the secretion of growth hormone (which helps to fix muscular microtears) in the third and fourth stages of sleep. Fibromyalgia also frequently presents with irritable bowel syndrome, migraines, and decreased cognitive functioning. For example, one study found that cognitive function in individuals with fibromyalgia was comparable to control participants who were 20 years older (Glass, 2008). In addition, a large portion of patients with fibromyalgia have been found to have associated psychological conditions, such as anxiety or depression. It would seem that the combination of comorbid psychological issues and fibromyalgia worsen the pain perception in fibromyalgia.

While there is presently no cure for fibromyalgia, many treatments have been shown to be effective in the management of fibromyalgia-related pain, sleep disturbances, and psychological conditions. The US Food and Drug Administration (FDA) has approved two drugs to date for the treatment of fibromyalgia, these being pregabalin and duloxetine (a serotonin-norepinephrine reuptake inhibitor). In addition, many studies have shown that tricyclic antidepressants such as amitriptyline have been associated with improvements in a number of fibromyalgia-related outcome measures. In general, a multidisciplinary approach, which may include interventions such as patient education, cognitive-behavioral therapy, and exercise, is also indicated for the management of fibromyalgia.

Definition

The five-factor model (also referred to as "The Big Five") is the most widely used and empirically supported model of normal personality traits. It consists of five main traits: Neuroticism, Extraversion, Openness (to experience), Agreeableness, and Conscientiousness.

Description

The five-factor model (FFM; Digman, 1990), or the "Big Five" (Goldberg, 1993), consists of five broad trait dimensions of personality. These traits represent stable individual differences (an individual may be high or low on a trait as compared to others) in the thoughts people have, the feelings they experience, and their behaviors. The FFM includes Neuroticism, Extraversion, Openness, Agreeableness, and Conscientiousness. Neuroticism is the tendency to experience negative emotions (e.g., sadness, anxiety, and anger) and to have negative thoughts (e.g., worry, self-doubt). In general, Neuroticism represents the predisposition to experience psychological distress. It has been linked to the negative affectivity/negative emotionality dimension from other trait models (Digman, 1990; Goldberg, 1993; John, Naumann, & Soto, 2008; McCrae & Costa, 2008). In contrast, Extraversion is the tendency to be sociable, energetic, assertive, lively, and to experience positive emotions (e.g., happiness), and have positive thoughts (e.g., optimism) (Digman, 1990; Goldberg, 1993; John et al., 2008; McCrae & Costa, 2008). It has been linked to the positive affectivity component of other trait models. Although it was originally thought that Neuroticism and Extraversion were strongly related, they are actually quite independent from one another.

Openness consists of intellectual curiosity, creativity, aesthetic sensitivity, and having nondogmatic attitudes (Digman, 1990; Goldberg, 1993; John et al., 2008; McCrae & Costa, 2008). Agreeableness can be defined as how well one gets along with others. It includes being prosocial, altruistic, trusting, warm, and sympathetic (Digman, 1990; Goldberg, 1993; John et al.; McCrae & Costa, 2008). Finally, conscientiousness encompasses being responsible, dependable, disciplined, and organized. In addition, Conscientiousness represents a disciplined striving after goals and a strict adherence to principles (John et al.).

The five factors of the FFM were independently discovered by several different researchers; all utilizing slightly different methods (see Digman, 1990). The FFM was initially identified in structural investigations of the human language in the mid-1900s. In the mid-1980s, McCrae and Costa (2008) documented that the FFM could be found in psychologically developed self-report questionnaires as well. Moreover, they documented that the FFM subsumed the vast majority of competing personality trait models (McCrae & Costa, 2008). Since that time, the FFM has become most widely

utilized and empirically supported model of personality (John et al., 2008; McCrae & Costa, 2008). The FFM is often referred to as "universal" model of personality as it replicates across gender, language, and culture (McCrae & Costa, 2008; John et al.). In addition, there is substantial self-other agreement on all five of the FFM traits (John et al.; McCrae & Costa, 2008). Furthermore, FFM traits are moderately heritable, with heritability estimates of approximately 50% for each of the five traits (McCrae & Costa, 2008). Moreover, the traits of the FFM have been linked to childhood temperament.

The FFM demonstrates impressive stability over time even across intervals of several years and that stability increases as individuals grow older (McCrae & Costa, 2008; Roberts & DelVecchio, 2000). However, the FFM is less stable over longer periods of time (e.g., 20 years vs. 3 years), indicating that people can and do change on their trait levels, given sufficient time and motivation (Roberts & DelVecchio, 2000). This suggests that environmental factors, life experiences, and gene by environment interactions can and do play a role in the development of FFM traits, although there remains disagreement on this point (McCrae & Costa, 2008; Roberts & DelVecchio, 2000). Women consistently report higher Neuroticism and Agreeableness, and men often report higher Extraversion and Conscientiousness (McCrae & Costa, 2008). There is also evidence of a maturation effect: on average, levels of Agreeableness and Conscientiousness typically increase with age, whereas Neuroticism and Openness tend to decrease.

Taken together, research consistently underscores the import of the FFM for such life outcomes as (but not limited to) relationship quality, adaptation to life, psychopathology, functional impairment, occupational success, happiness, health, and even mortality (McCrae & Costa, 2008). At high levels, Neuroticism has been linked to negative life outcomes including most psychological disorders, medical illness, and negative social experiences (e.g., interpersonal conflict and other life stressors). In general, high Extraversion is a protective factor against many negative life outcomes (e.g., psychological disorders). High Openness has been linked to political liberalism and intelligence. Finally, high Agreeableness is linked with having more positive social experiences with friends, family, and colleagues.

Group interview

Definition

Focus groups are group interviews that facilitate focused communication among research participants and generate qualitative data about specific populations. Focus groups range in size from very small (e.g., four people) to as many as 12 participants in a larger group (Krueger, 1988). Whatever the size, groups should be small enough so that all members can share insight, while still remaining large enough to facilitate diverse ideas. Groups should also be composed of people who are not familiar with each other.

Focus groups have several uses, which include gathering information for questionnaire development, assessing community needs, testing new programs, and discovering customer preferences. These types of groups are also widely used to examine people's experiences and concerns with health services. Focus groups may be exploratory to generate ideas, or they can be used to pilot test new materials and interventions.

Focus groups are helpful to researchers wishing to understand the population with whom research will be conducted. For example, the group format allows researchers to observe different forms of communication (e.g., anecdotes, jokes) that are used in the population of interest. Other forms of data collection (e.g., questionnaire self-report) are not well suited to measure these subtleties of communication.

Within behavioral medicine research, focus groups have been used extensively. Data have been gathered regarding quality of life, psychosocial issues, health beliefs, and preferences for various types of interventions among diverse patient populations. Focus groups have been especially useful in gaining understanding of these issues within minority populations. By looking within minority groups, researchers can gather information about shared experiences as well as important within-group differences (Kitzinger, 1995). A number of focus groups are generally conducted until the point of saturation is reached, i.e., the point when there are no longer new ideas being generated. Data generated from focus groups is analyzed qualitatively to identify themes, and this is typically done with the use of qualitative data analysis programs.

In addition to the benefits of focus group research, there are several limitations that researchers should be aware of. At times, the group setting may inhibit some members from participating and sharing their opinions. Additionally, participant confidentiality is compromised by the presence of other research

subjects (Kitzinger, 1995). However, these concerns may be mitigated by the skill of the focus group facilitator.

Follow-up Study

Lynda H. Powell and Imke Janssen
Department of Preventive Medicine, Rush University Medical Center, Chicago, IL, USA

Synonyms

Cohort study; Incidence study; Longitudinal study; Prospective study

Definition

A follow-up study, more commonly called a cohort study, has three basic components: exposure, time, and outcome. A group of individuals (the cohort) is assembled and then assessed at baseline on the *exposure* of interest (a risk or protective factor), other risk factors known to influence the outcome of interest, and the prevalence of the outcome of interest. The cohort is followed over *time* to determine development of the *outcome*. To determine incidence of the outcome, subjects who have the outcome at baseline are excluded. Then subjects with and those without the exposure are compared, controlling for extraneous confounders.

Description

Follow-up studies have various names derived from either study group (cohort studies), the timing of observation (follow-up, prospective, or longitudinal studies), or the disease outcome (incidence studies). They begin with the assembly of a cohort which is any group of individuals ranging from the very diverse (e.g., a general population) to a defined geographical area (e.g., Framingham), a defined occupation (e.g., nurses), a defined high-risk subgroup (e.g., homosexual men), or a group defined by logistical ease of follow-up (e.g., health insurance beneficiaries).

Exposure. In contrast to randomized controlled trials (RCTs), exposure to the putative causal agent is not under the researcher's control but simply based upon history. Therefore, the exposure (i.e., risk/protective factor) could simply be correlated with a true risk factor and result in the problem of confounding. A confounder is a third variable that is correlated with both the exposure and outcome and is not part of the causal path. For example, education could confound the relationship between depression and heart disease because it is correlated both with depression and with heart disease and is not part of the causal path by which depression links to heart disease. Thus, an assumed relationship between depression and heart disease could actually be a true relationship between education and heart disease. To guard against confounding, baseline assessment should not only include the exposure of interest but also potential demographic, medical, occupational, and psychosocial confounding factors. Since exposure status can change over time, many follow-up studies feature repeated assessments of exposure status and confounders beyond baseline. These updated changes are handled in various ways in statistical analyses.

Time. One criterion for making causal claims is temporality; that is, the risk/protective factor precedes the disease. The strength of these studies is that they permit an inference about this temporal relationship. For incidence studies, any subject with prevalent disease is excluded from the cohort at baseline. The non-diseased subjects

are then assessed for exposure and followed over time until disease occurs, they are lost or withdraw, or the study ends. Since exposure assessment predated the observed occurrence of disease, it is possible to argue that the exposure predated the outcome. For example, to make the inference that depression *predicts* heart disease, depression (1) must be more common among those who subsequently develop heart disease and (2) heart disease (the outcome) must not have been present before the onset of depression (the risk factor). It is crucial to maximize complete follow-up of the original cohort. Losses and withdrawals should not exceed 10% or the true incidence of the outcome in the cohort will be underrepresented. Comparisons of baseline characteristics between those who were lost/withdrew and those who completed determine whether missingness was random or nonrandom. If missingness was nonrandom, comparisons of risk in exposed vs. unexposed may be biased (over- or underestimated). For example, if more depressed than non-depressed subjects withdraw, any increase in events in the depressed will be weakened and the study could underestimate the importance of depression as a risk factor for the outcome.

Outcome. Outcomes can include diseases, preclinical diseases, risk factors, or other health-related events and can be categorical or continuous. Periodic follow-ups of the cohort permit a rigorous assessment of the outcome. This assessment must be conducted by individuals who are blinded to the exposure assessment to prevent bias. Outcome incidence and/or pattern over time is then compared, respectively, between those who do and those who do not have the exposure of interest.

Statistical Analyses

Risk associated with an exposure is handled in several ways. The (average) incidence rate of a disease over a specified time interval equals the number of new cases during the interval divided by the total amount of time at risk for the disease accumulated by the entire population over the same interval and is reported as the number of events per person-years. To compare the incidence of disease between two groups (exposed and not exposed), data are usually summarized in a 2×2 table and compared with a χ^2 *test*. The *relative risk* is calculated as the ratio of the proportion of exposed who develop the disease to the proportion of the unexposed developing it. The *odds ratio* (OR) is similarly defined as the ratio of the odds of developing the disease. If either the disease is rare or the time interval is short, the relative hazard is approximately equal to the relative risk and the odds ratio. This odds ratio, transformed by natural logarithm, is the outcome in *logistic regression* models. *Confidence intervals* for these log odds can be derived from normal theory and then transformed back to the original scale to yield confidence intervals for the odds.

With long follow-up time intervals, there is often interest in examining the pattern of events over time. In *time-to-event analysis*, the hazard function (or its integral, the survival function) presents events as a function of time. Under the assumption of *proportional hazards*, that is, that the hazard rates in the exposed and the unexposed groups are the same over time, the hazard can be modeled as a function of covariates (*Cox regression model*). If the proportional hazards assumption does not hold, then parametric survival curves (e.g., accelerated failure time (AFT) models) may provide a better fit. These models allow for *time-varying covariates* where exposure status is updated periodically.

When the outcome is continuous, growth curve models (linear regression in its simplest form) are the preferred method of analysis, modeling the trajectory of the outcome over time. This approach allows separating aging effects (i.e., changes over time within individuals) from cohort effects (i.e., differences between subjects at baseline). These models allow, for example, for different patterns over time between treatment groups.

All of the models just discussed belong to a class of generalized mixed models. Potential covariates such as demographic, medical, occupational, and psychosocial confounding factors are added as a linear function in these *multivariable analyses* (Hedeker & Gibbons,

2006). Time-varying covariates including the change in risk factors can be included in these models.

Missing data in follow-up studies can cause serious problems. Therefore, every effort should be made to avoid missing values and to document the reason for missingness for the unavoidable cases, for example, deaths. The usual assumption is that data are missing at random. If that is not true, that is, if depressed patients are more likely to drop out of the study than not depressed patients, the missing process can be modeled separately and incorporated into the analysis (Little & Rubin, 2002).

In summary, the key strength of follow-up studies is their ability to establish the timing and directionality of exposure and outcome events. Bias in ascertainment of exposure is impossible because neither subject nor observer is aware of future outcome status. Bias in ascertainment of outcome is minimized if outcomes assessors are kept blinded. These studies are more difficult and costly than a cross-sectional study, but the gain in inferential strength and minimization of bias is worth the effort.

The key weakness of these studies is the difficulty in making causal claims since temporality does not imply causality. The problem of confounding can never be completely eliminated for there will always be unknown, and thus unmeasured, confounders that could be the true causal agent. The art of these studies is in a careful review of the literature to determine predictors of the outcome, with a particular eye to those predictors that are also related to the exposure, and in ensuring that this full array of predictors is included in baseline assessment. A common problem in the use of convenience follow-up studies (e.g., the Framingham Study, the Nurses' Health Study) is that they often do not have all potential covariates of interest in their assessment batteries.

Although these studies cannot make conclusive claims for a causal relationship between exposure and outcome, their ability to disentangle temporality can strengthen the chain of evidence by which causal claims can be made. They provide valuable support, or nonsupport, for justifying a rigorous RCT which is the strongest basis for claiming that an exposure causes a disease.

To increase the quality of the reporting of observational studies, several prominent medical researchers issued the Strengthening the Reporting of Observational Studies in Epidemiology (STROBE) statement.

Definition

Food safety refers to all efforts done to monitor and overcome temporary or long-lasting hazards that may make food have adverse effect to the health of the consumer. Food hazards include microbiological hazards, pesticide residues, misuse of food additives, chemical contaminants, including biological toxins, adulteration, as well as genetically modified organisms, allergens, veterinary drug residues, and growth-promoting hormones used in the production of animals. The food hazards can be present along the entire food chain; therefore, it is important that all sectors in the chain operate in an integrated way, and food control systems address all stages of this chain to guarantee food safety. This monitoring from primary producer through consumer is often described as the farm-to-table continuum. However, it is difficult and expensive to test for food hazards and quality loss at each point in the food chain. Especially in many developing countries, the resources are limited, food control laboratories are frequently poorly equipped, there is no suitably trained analytical staff, and the management is poor. This leads to an inadequate food control infrastructure. Therefore a well-structured, preventive approach which controls processes is the preferred method for improving food safety and quality. Factors, such as improper agricultural practices, poor hygiene at all stages of the food chain, lack of preventive controls in food processing and preparation operations, misuse of chemicals, contaminated raw materials, ingredients and water, inadequate or improper storage, which contribute to potential hazards in foods, should be taken into account (Food and Agriculture Organization/World Health Organization [FAO/WHO], 2003).

Food safety is an increasingly important public health issue, both in developing and industrialized countries. The emergence of food-borne illnesses is influenced by factors such as large genetic variability of microorganisms, environmental factors, human actions, and behavior (e.g., traveling), urbanization, raw food production, new technologies, human risk factors such as age, illness, and others (Hall, 1997).

The food-borne illnesses, when focusing on the microbiological hazards, are caused by bacterial agents (e.g., Salmonella or *E. coli*), viral agents, or parasites. The microbiological safety of food is a dynamic situation influenced to a great extent by multiple factors contributing to changing trends in food-borne illnesses. Examples of these factors are rapid population growth, an increasingly global market in vegetables, fruit, meat, and ethnic foods, and changing eating habits, such as the consumption of raw or lightly cooked food, climate change, and others. However, the list of factors influencing the prevalence of food-borne diseases is long and their relative importance is largely unknown (Newell et al., 2010). From a behavior medicine perspective, one may examine, for example, how certain psychological traits such as risk-taking or low conscientiousness affect the prevalence of food hazards in a food-producing company, of importance for prevention.

Forgiveness

Yori Gidron
Faculty of Medicine and Pharmacy, Free University of Brussels (VUB), Jette, Belgium

Definition

Forgiveness refers to the purposeful decision by a victim of wrongdoing to relinquish anger and the desire to punish an offender responsible for inflicting harm (e.g., Enright & The Human Development Study Group, 1991). Forgiveness may go beyond mere indifference, to express goodwill toward the offender. This concept is commonly pertinent to daily social interactions, and it constitutes a basic social process which maintains interactions and relationships. Various scales exist for assessing forgiveness. For example, the Heartland Forgiveness Scale (Thompson et al., 2005) is an 18-item scale assessing forgiveness of oneself, others, and situations. These three subscales demonstrate the importance of this concept to one's personal and interpersonal lives. Investigators have examined the psychosocial correlates or determinants of forgiveness. For example, perceptions of severity of the offense, the intentions of the offender, sincerity of apology, and empathy have been investigated as factors possibly affecting forgiveness (Kearns & Fincham, 2004). In the context of traumatic events, difficulty forgiving others is significantly correlated with depression and posttraumatic stress symptoms (Witvliet, Phipps, Feldman, & Beckham, 2004), implicating a possible relationship and resemblance with the term "rumination." Interventions aimed at inducing forgiveness have resulted in reduced anxiety, depression, and anger in various populations (reviewed by Kearns & Fincham, 2004). In a groundbreaking experimental study, vanOyen, Ludwig, and Vander Laan (2001) asked people to imagine a real person who they either held grudges toward or they had an empathic perspective and imagined themselves forgiving. Compared to baseline levels, the forgiving group evidenced significantly lower psychological (aversive emotions) and physiological (heart rate, skin conductance, etc.) changes, while the first group evidenced worsening of those psychophysiological responses. These studies together point at forgiveness as an important variable in social interactions, which has short- and possibly long-term health implications, since forgiveness can be in question for very long periods of time in people's lives.

Framingham Heart Study

Definition

The Framingham Heart Study is a longitudinal cohort study that began in 1948 with 5,209 participants to examine how lifestyle choices and psychosocial elements impact cardiovascular health. It had helped coin the term "risk factors" in identifying clusters of variables, such as poor diet, lack of physical activity, and negative psychological factors, that contribute to cardiovascular disease.

Description

In 1948, the Framingham Heart Study ventured to better understand cardiovascular disease (CVD) in that little was known about the etiology of heart disease and stroke despite their epidemic proportions due to their steadily increasing rates since the 1900s. A joint project of the National Heart, Lung, and Blood Institute (NHLBI) and Boston University, the Framingham Heart Study sought to longitudinally track a large cohort of participants who initially had no outward CVD symptoms, heart attack, or stroke. Initially, 5,209 participants aged 30–62 were recruited from Framingham, Massachusetts; this was one of the first studies to administer extensive physical exams accompanied by lifestyle interviews over multiple assessments. Participants have returned for assessments every 2 years since the study's inception.

The Framingham Heart Study helped mainstream the concept of preventive medicine in the context of stopping CVD before it starts by promoting health behaviors beneficial to future cardiovascular health. Framingham helped dispel past theories of CVD progression that were heavily reliant on diastolic blood pressure (Kannel, 1995a, 1995b). Importantly, the Framingham Heart Study established the concept of clusters of risk factors rather than one single factor detrimental to CVD (Kannel, 2000); the study is the origin of the term "risk factor."

The Framingham Heart Study has been instrumental in identifying now commonly known primary risk factors of CVD such as increased blood pressure, cholesterol, smoking, obesity, diabetes, and lack of physical activity over long-term follow-up observations (Kannel, D'Agostino, & Cobb, 1996). Additionally, the study also acknowledged secondary risk factors of CVD such as blood triglycerides and HDL

cholesterol along with demographic factors such as age and gender (Kannel & Eaker, 1986); more recently, increased plasma homocysteine has been identified as a risk factor for CVD (Sundström & Vasan, 2005).

Importantly, the Framingham Heart Study's work has published research that specifically gives weights to individual risk factors as predictors of CVD progression through regression models. Risk of CVD can be calculated based on variables such as age, gender, blood pressure, smoking status, parental CVD history, blood markers such as cholesterol and triglycerides, and BMI. Collectively, this equation has been termed the Framingham Risk Score that estimates the 10-year risk of CVD; NHLBI provides an online calculator at http://hp2010.nhlbihin.net/atpiii/calculator.asp.

The Framingham Heart Study helped establish diabetes mellitus type 2 as a risk factor for CVD (Fox, 2010; Kengne, Turnbull, & MacMahon, 2010). In that type 2 diabetes is primarily due to lifestyle choices, this finding helped shape health psychology in addressing prevention of diabetes through weight control and diet.

Specific to behavioral medicine, the Framingham Heart Study has reported increased incidence of CVD in those with greater negative psychosocial factors, such as greater depression, anxiety, perceived stress, anger, hostility, and social isolation. Importantly, the Framingham Heart Study's psychosocial findings controlled for other variables that may have influenced the relationship; in other words, links between psychosocial factors and CVD outcomes were independent of the common risk factors of CVD worsening attributable to demographics and lifestyle.

Additionally, the Framingham Heart Study was one of the first studies to help define Type A personality. Type A behavior is generally defined by high levels of daily stress, emotional lability, tension, anger, and ambitiousness (Haynes, Levine, Scotch, Feinleib, & Kannel, 1978). Framingham established one of the early links between Type A personality and CHD prevalence in women and higher incidence of myocardial infarction (MI) in men (Haynes, Feinleib, Levine, Scotch, & Kannel, 1978) after controlling for age, blood pressure, smoking status, and cholesterol.

Examining longitudinal outcomes with respect to psychosocial factors, 20-year incidence of MI or coronary death in 749 females free of initial coronary disease was predicted by greater tension, anxiety, and loneliness after controlling for age, systolic blood pressure, total/HDL cholesterol Ratio, diabetic status, smoking status, and BMI (Eaker, Pinsky, & Castelli, 1992).

While these psychosocial factors alone did not necessarily account for a majority of the variance in the CVD health outcomes in deference to lifestyle factors such as health behaviors, psychosocial factors have been shown to be an effective complementary treatment target for supplementing lifestyle changes and medication regimens.

Among the other studies that have stemmed from the original study, the Framingham Heart Study has expanded to examine the children and grandchildren of the initial cohort using the same techniques of longitudinally assessing health and lifestyle; this study is aptly named the Framingham Offspring Study. Future directions for the Framingham Heart Study include examination of genetic factors in CVD outcomes using participants' cell lines (Govindaraju et al., 2008).

Definition

In 1971, the Framingham Offspring Study recruited 5,124 of the original Framingham Heart Study's participants' children and their spouses; this new generation were similarly biennially assessed on physiological and psychological measure. The Framingham Offspring Study sought to epidemiologically study CVD in younger adults (Feinleib, Kannel, Garrison, McNamara, & Castelli, 1975).

The Framingham Offspring Study included more physiological variables than its parent study, such as specific dietary measures, neuropsychological measures to assess cognition and reading performance, and MRI to directly measure brain volume. The introduction of cognitive function measures lead to the finding that cardiovascular risk factors and the presence of CVD mediated the association between left ventricular mass and cognition (Elias et al., 2007).

Additional blood marker risk factors of CVD were identified; one of the first reports on high-density lipoprotein (HDL) and low-density lipo-protein (LDL) cholesterol levels in relation to CVD was from the Framingham Offspring Study (Wilson et al., 1980). Other risk factors identified as increasing CVD risk included increased adiponectin (Ai et al., 2011), lipoproteins, and serum albumin and bilirubin. Greater levels of extracellular matrix turnover, specifically matrix metalloproteinase (MMP)-9 and tissue inhibitors of MMPs (TIMPs), were associated with greater internal carotid artery stenosis in the Framingham Offspring Study (Romero et al., 2008). Higher von Willebrand factor (vWF) was found to be a risk factor for CVD in participants with type 2 diabetes (Frankel et al., 2008).

Socioeconomic factors were also recorded. Researchers found that longitudinally, education impacted health: mean systolic blood pressure over 30 years was higher in participants with less than 12 years of education compared to those with more than 17 years of education (Loucks, Abrahamowicz, Xiao, & Lynch, 2011). Additionally, life course socioeconomic status influenced type 2 diabetic status in women and was primarily associated with participants' education levels and occupations (Smith et al., 2011).

From a health psychology perspective, the Framingham Offspring Study helped establish guidelines for healthy eating behavior by suggesting an increase in whole grain food consumption and a decrease in dietary glycemic index to reduce the risk of metabolic syndrome and insulin resistance (McKeown, Meigs, Liu, Wilson, & Jacques, 2002; McKeown et al., 2004).

Psychosocially, anger and hostility were predictive of atrial fibrillation development over a 10-year follow-up in males after controlling for age, diabetes, hypertension, history of myocardial infarction, history of congestive heart failure, and valvular heart disease (Eaker, Sullivan, Kelly-Hayes, D'Agostino, & Benjamin, 2004); trait anger related to total mortality in men. Taken together, the Framingham Offspring Study has expanded the knowledge of the mechanisms of CVD progression through repeated assessments of extensive physiological, behavioral, and psychological factors.

Free-Radical Theory of Aging

Carrie Brintz
Department of Psychology, University of Miami, Coral Gables, FL, USA

Definition

The free-radical theory of aging was formally proposed by Denham Harman in 1956 and postulates that the inborn process of aging is caused by cumulative oxidative damage to cells by free radicals produced during aerobic respiration. Free radicals are atoms or molecules with single unpaired electrons. They are unstable and highly reactive, as they attack nearby molecules in order to steal their electrons and gain stability, causing radical chain reactions to occur. Free radicals are generated in vivo primarily within mitochondria during mitochondrial electron transport as well as by other physiological processes. Harman later extended the free-radical theory of aging to incorporate the role of mitochondria in the generation of free radicals and other reactive oxygen species. The theory proposes that the rate of oxidative damage to mitochondrial DNA primarily determines life span.

While free-radical reactions are implicated in the normal aging process, free-radical damage may occur in varying patterns across individuals, modulated by genetic and environmental factors, and in some individuals may be implicated in a number of disorders. These so-called free-radical diseases include cancer, atherosclerosis, Alzheimer's disease, essential hypertension, the immune deficiency of age, and a number of other disorders. The process of aging by free-radical damage may be slowed by a calorie-restricted diet that includes essential nutrients and antioxidants derived from dietary fruits and vegetables. It is theorized that the prevention or slowing of certain "free-radical" diseases such as cancer may be achieved through dietary intervention with antioxidant supplementation, although evidence supporting this hypothesis in humans is mixed.

Functional Capacity, Disability, and Status

Definition

Functional capacity refers to one's ability to perform the activities and tasks necessary to live independently. These tasks change throughout the life span; children, adults, and the elderly each have their own unique set of activities necessary to maintain their independence. Age, however, is not the only factor that can determine functional capacity or status: specific disease or injury states each bring their own physical limitations. The interactions among age and injury or disease state determine one's functional capacity.

Description

There are two types of tasks that are usually evaluated to determine functional capacity: activities of daily living (ADL) and instrumental activities of daily living (IADL). ADL refer to activities that are involved in basic human survival such as mobility, eating, using the washroom, dressing, and grooming (Besdine, 1988). The inability to perform these tasks severely inhibits one's ability to live independently and maintain health. IADL tend to refer to activities that are necessary to live independently, but disabilities in these areas do not result in serious health implications. IADL can include housekeeping, cooking, shopping, banking, driving, or using public transportation (Besdine, 1988). A functional disability or impairment is defined as the decreased ability to meet one's own needs in either or both of these areas.

Through the life span, the tasks that determine one's functional capacity change to fit the requirements of daily life. As children, activities such as participation in family life and chores, learning at school, and the ability to participate in extracurricular activities can be considered an assessment of functional capacity along with the basic ADL and IADL. In adulthood, functional capacity often describes the ability to perform work-related tasks. Following injury, assessment of functional capacity commonly determines a person's ability to return to the work force or the injured person's ability to participate in modified duties. In elderly populations, functional capacity generally refers to an individual's ability to meet their own survival needs, which can be determined using ADL and IADL assessments.

Since functional capacity is specific to an individual's ability to perform a given task, there is a broad spectrum of tools that are available for

functional assessment. The original assessments of functional capacity examined hip fracture patients during their rehabilitation. Patients were classified as either independent or dependent based on six daily activities of daily living including bathing, dressing, using the washroom, transferring in and out of beds or chairs, continence, and eating (Katz et al., 1963). The current assessment of functional capacity or functional disability in the elderly often occurs through large-scale interdisciplinary assessment of ADL and IADL such as the Geriatric Functional Assessment (GFA) (Besdine, 1988). Functional capacity can also be assessed through cardiovascular fitness tests, frequently used in populations with compromised aerobic function, such as cardiac patients (Clini & Crisafulli, 2009). These tests may use maximal oxygen consumption measurements or VO_{2max} assessments, commonly performed on the bike or treadmill. Indirect measures of exercise capacity can also be used to predict VO_{2max} such as the 6-min walk test, which estimates maximal oxygen consumption without the use of expensive equipment (Rostangno & Gensini, 2008). In the workplace, job-specific functional assessments can also be used to determine if an individual is capable of performing work-related tasks.

The ability to improve functional disability is dependent on the cause of the functional impairment. Following functional disability resulting from injury or a specific disease, rehabilitation may aid an individual to return to his/her functional capacity from prediagnosis. If functional disability results from disabling chronic illness or simply through aging, it may not be possible for the individual to regain his/her ability to live independently. However, for aged individuals or those with disabling chronic disease, rehabilitation may allow individuals to maintain certain aspects of independence. Functional capacity is specific to each individual and the daily tasks that a person performs. The determinants of functional capacity change over the life span and vary depending on disease and injury status. The appropriate measures of functional capacity must address an individual's unique needs and daily tasks.

Functional Magnetic Resonance Imaging (fMRI)

Yoshiya Moriguchi
Department of Psychophysiology, National Institute of Mental Health, National Center of Neurology and Psychiatry, Kodaira, Tokyo, Japan

Definition

Functional magnetic resonance imaging (fMRI) is a technique for measuring neural activity, by

detecting the hemodynamic changes in blood oxygenation and blood flow in response to neural activity, based on blood-oxygenation-level-dependent (BOLD) effect.

Description

Blood-oxygen-level dependent (BOLD) effect is the MRI contrast originated from blood deoxyhemoglobin in the tissue, first discovered by Ogawa, Lee, Kay, and Tank (1990) (Ogawa, Lee, Nayak, & Glynn, 1990; Ogawa et al., 1992). This method depends on the differential susceptibility between deoxyhemoglobin and oxyhemoglobin. Hemoglobin is diamagnetic when oxygenated but paramagnetic when deoxygenated (=deoxyhemoglobin). Therefore, magnetic resonance (MR) signal of blood is slightly different depending on the level of oxygenation. Higher BOLD signal intensities arise from increases in the concentration of oxygenated hemoglobin since the blood magnetic susceptibility more closely matches the tissue magnetic susceptibility. Since deoxyhemoglobin is paramagnetic, it alters the T2*-weighted magnetic resonance image signal to decrease. This deoxyhemoglobin is referred to as an endogenous contrast-enhancing agent and serves as the source of the signal for fMRI. With MRI sequence parameters sensitive to the changes in this differential magnetic susceptibility, changes in BOLD contrast can be assessed. Here, when a brain region is more active, more oxygen is consumed and blood flow increases to the activated region to meet the increased oxygen demand. Actually, increases in cerebral blood flow to the local vasculature that accompanies neural activity in the brain far overtake changes in oxygen consumption, which will lead to relative decrease of deoxyhemoglobin and increased BOLD signal.

The relationship between oxygenation change with increased activity and change of the BOLD signal is in fact a little more complex. There is a momentary decrease in blood oxygenation immediately after neural activity increases, known as the "initial dip" in the hemodynamic response. This is followed by the blood flow increases, not just to a level where oxygen demand is met, but overcompensating for the increased demand. This means that blood oxygenation actually increases following neural activation. The blood flow peaks after around 5–6 s and then falls back to baseline, often accompanied by a poststimulus undershoot.

The fMRI technique has been increasingly used to produce activation maps showing which parts of the brain are involved in a particular mental process or state. While lying in the MRI scanner, a subject experiences some mental states or does some task (e.g., visual stimuli on a screen, response to some cue in a certain manner). Meanwhile, the MRI scanner tracks the signal throughout the brain or some specific part of interest. In brain areas, the BOLD signal is changing as the stimulus or task condition is varying. The hemodynamic change is measured by BOLD contrast in a "voxel" (a volume pixel; a small unit consisting of three-dimensional part of the brain image). The activity in a voxel is defined as how closely the time course of BOLD signal from that voxel matches the hypothesized time course. If the signals from a certain voxel match and correlate the hypothesized time course, this voxel is given a high statistical value, that is, a high activation score. These statistics in voxels can then be translated into a statistical brain map that shows the extent of "activation."

Compared with earlier neuroimaging techniques like positron emission tomography (PET), the advantages to fMRI as a technique to image brain activity related to a specific task or sensory process are the following: (1) fMRI does not require injections of radioactive isotopes, (2) the total scan time required is shorter, (3) the spatial resolution of the obtained functional image is higher (typically several mm, although high resolutions less than 1 mm are now possible technically), and (4) the temporal resolution of time course data is much higher than PET (highest resolution is ~0.5 s; typically ~1–4 s is used) so that it enables to analyze finer hemodynamic changes accompanied with short event-related neural events (called event-related design).

On the other hand, fMRI has disadvantages versus PET: (1) fMRI is loud, and its noise is

over ~90 dB, (2) quite sensitive to movement artifact because fMRI uses sequential excitation method by radio-frequent pulses across multislices of the brain, (3) fMRI causes signal distortion and loss because of susceptibility artifact in orbitofrontal and inferior/medial temporal areas which are important for emotional processing or social cognition, and (4) behavioral and physiological measurement inside the scanner is hard without specially designed MRI-compatible hardware because of a very strong static magnetic field or rapidly changing gradient magnetic field.

Nowadays, researchers started to combine the imaging techniques to determine brain activity and concurrent measurement of various physiological indexes. For example, measurements of the autonomic nervous system, such as pulse/skin conductance/electromyogram, are used in the scanner to detect dynamic associations of the bodily states with neural states. EEG has been also used simultaneously with fMRI, to utilize the advantages of the high spatial resolution of MRI and high temporal resolution of EEG. The transcranial magnetic stimulation method (TMS) is also used with fMRI as a noninvasive method to temporarily suppress the neuronal activity in a local region by electric stimulation by a coil outside the head.

Recently, a movement has arisen that attempts to understand the function of the brain both comprehensively and integratively as a network: This evolved from the point of view that the various sites of the brain and the wide variety of information from the body dynamically form a complicated web of consciousness, recognition, and feelings in a mutually influenced manner. For this purpose, connectivity between different brain regions has been assessed using correlation or multivariate analyses. Furthermore, there is a new direction of neuroimaging studies that includes a wider context than that of specific studies focusing only on a certain disease or nervous system. For example, a new field called "social neuroscience" is spreading rapidly in which neuroscience has begun to be applied to probing highly advanced cognitive functions, such as what kind of role a neuronal system plays in human social interactions.

A unique technique called "real-time fMRI" (rtfMRI) has been recently used in some neuroimaging studies (deCharms, 2007). This method resembles the "biofeedback" therapy that has conventionally been used in clinical settings to therapeutically give patients feedback on their distal physiological signs. The rtfMRI can be called "neurofeedback" in which fMRI simultaneously feeds back to the subjects the regional neural activity of the brain so that they can learn to directly control activation of localized regions by themselves – self-control. The rtfMRI has possibilities for use in rehabilitation through training by noninvasive and non-pharmacological means. A trial has just started into the clinical applications for chronic pain/drug dependency/depression and the ability to support psychotherapy.

Despite the great advantages of fMRI, there are some "pitfalls" to use this kind of neuroimaging technique like fMRI (Bennett & Miller, 2011; Logothetis, 2002). The BOLD response can be affected by a variety of factors, including drugs/substances, age, brain pathology, local differences in neurovascular coupling, attention, amount of carbon dioxide in the blood, etc. The images produced must be interpreted carefully, since correlation does not imply causality, and brain processes are complex and often nonlocalized. Statistical methods must be used carefully because they can produce false positives (Vul, Harris, Winkielman, & Pashler, 2009). One team of researchers studying reactions to pictures of human emotional expressions reported a few activated voxels in the brain of a dead salmon when no correction for multiple comparisons was applied, illustrating the need for rigorous statistical analyses. The BOLD signal is only an indirect measure of neural activity and is, therefore, susceptible to influence by non-neural changes in the body. This also means that it is difficult to interpret positive and negative BOLD responses. BOLD signals are most strongly associated with the input to a given area rather than with the output (Lauritzen, 2005). It is therefore possible (although unlikely) that a BOLD signal could be present in a given area even if there is no single unit activity. fMRI has poor temporal

resolution. The BOLD response peaks approximately 5–6 s after neuronal firing begins in an area. This means that it is hard to distinguish BOLD responses to different events which occur within a shorter time window. fMRI has often been used to show activation localized to specific regions, thus minimizing the distributed nature of processing in neural networks. Several recent multivariate statistical techniques work around this issue by characterizing interactions between "active" regions found via traditional univariate techniques.

The attractions of fMRI have made it a popular tool for imaging normal brain function – especially for psychologists. fMRI is also being applied in clinical and commercial settings. At the moment, there are no clinical applications immediately available, but in the near future, the progress of neuroscience shows promise for its clinical utility.

Functional Somatic Syndromes

Tetusya Ando
Department of Psychosomatic Research, National Institute of Mental Health, National Center of Neurology and Psychiatry, Kodaira-shi, Tokyo, Japan

Synonyms

Functional somatic symptoms; Medically unexplained symptoms; Somatoform disorders

Definition

Several related syndromes that are characterized more by symptoms, suffering, and disability than by disease-specific, demonstrable abnormalities of structure or function (Barsky and Borus, 1999).

Symptoms that cannot be explained in terms of a conventionally defined medical disease (Wessely, Nimnuan, & Sharpe, 1999).

Description

Concern about symptoms is a major reason for patients to seek medical help. Many of the somatic symptoms, such as pain of different location (back, head, muscles or joints, abdomen, chest), fatigue, dizziness, edema, dyspnea, insomnia, and numbness, often remain unexplained by identifiable disease even after extensive medical assessment. Terms such as somatization, somatoform disorders, abnormal illness behavior, functional symptom, and medically unexplained symptom (MUS) have been used to describe these symptoms. The term functional symptom assumes only a disturbance in body function but no psychogenesis of the symptom.

Concept of functional somatic syndromes (FSS) was first proposed by Barsky A.J. and others in 1999. They defined FSS as several related syndromes that are characterized more by symptoms, suffering, and disability than by structural or functional abnormality which include specific somatic syndromes such as multiple chemical sensitivity, the sick building syndrome, repetition stress injury, the side effects of silicone breast implants, the Gulf War syndrome, chronic whiplash, the chronic fatigue syndrome, the irritable bowel syndrome, and fibromyalgia. Patients with FSS have self-diagnosis, and their symptoms are often refractory to reassurance, explanation, and palliative treatments of symptoms. Although individual functional FSS may present with some organ-specific symptoms (e.g., gastrointestinal symptoms in irritable bowel syndrome) and may differ in its lead symptoms, the various FSS have similar symptoms that are diffuse, nonspecific and ambiguous, and very prevalent in healthy, non-patient populations. Symptoms common to the FSS include fatigue, weakness, sleep difficulties, headache, muscle aches and joint pain, problems with memory, attention, and concentration, nausea and other gastrointestinal symptoms, anxiety, depression, irritability, palpitations, shortness of breath, dizziness, sore throat, and dry mouth.

The concept was soon followed by Wessely S and others who postulated that the existence of specific somatic syndromes is largely an artifact of medical specialization on the basis of literature review because they found considerable overlap and similarities in definition, diagnostic criteria, symptoms and non-symptom characteristics, and response to treatment between individual syndromes as described later. This evoked debates regarding commonality and individuality of the specific syndromes and advantages and disadvantages of the concept in understanding and treatment of these illnesses.

Though an objective criterion of general FSS does not exist, epidemiological studies of individual specific syndromes have indicated that FSS are very common in all countries and cultures. For example, the prevalence of irritable bowel syndrome, chronic fatigue syndrome, and fibromyalgia are 10–20%, 0.01–0.3%, and 1–6%, respectively.

The syndromes are strongly associated with emotional distress and disorders such as anxiety and depression, and sufferers are often severely disabled. Costs to patients and to medical resources are substantial with repeated investigation and treatment.

Each single or specific functional syndrome is signified by current lead symptoms or implied cause. But overlap in case definitions of specific syndromes has been suggested. Patients with one functional syndrome often meet diagnostic criteria for other syndromes, for example, temporomandibular joint disorders and nonspecific facial pain, fibromyalgia and tension headache, and non-cardiac chest pain and hyperventilation syndrome are reported to be frequent combinations. Functional somatic symptoms are generally more common in women than in men.

Although, the causes of functional symptoms and syndromes are not fully understood, biological, psychological, interpersonal, and

health-care factors are considered to be all important. Dualistic, single factor view such as whether symptoms are psychological or physical will be unhelpful.

The symptoms of FSS are exacerbated by psychosocial stress and strongly associated with psychological distress, anxiety, and depression. History of childhood maltreatment and abuse has been reported to be frequent in FSS as they have been in psychiatric diseases.

Difficulties in doctor-patient relationship are quite usual. Because symptoms are not explained even after extensive medical assessment and conventional medical therapies are fairly ineffective, physicians are frustrated and patients are dissatisfied. Raising fear of disease, performing unnecessary investigations and treatments, and encouraging disability are adverse effects of medical consultation. Denying the reality of patients' symptoms may damage the doctor-patient relationship. Those iatrogenic components are important in the maintenance of FSS.

As biological mechanisms, altered functioning or abnormality of central nervous system, especially serotonergic system and neuroendocrine system, and immunological disturbances have been implicated, in addition to peripheral functional abnormalities in specific organ systems.

Barsky A.J. recommended medical management of FSS in six steps: (1) ruling out the presence of diagnosable medical disease, (2) searching for psychiatric disorders, (3) building a collaborative alliance with the patient, (4) making restoration of function the goal of treatment, (5) providing limited reassurance, and (6) prescribing cognitive behavioral therapy for patients who have not responded to the aforementioned five steps.

Peripheral or organ-oriented pharmacotherapy primarily aimed at peripheral physiological processes (e.g., bowel function, muscle tension, inflammation, pain, etc.) is also applied. Antidepressants (tricyclic antidepressants and SSRI) are often effective whether or not patient is depressed.

Functional Versus Vocational Assessment

Definition

Function is an individual's use of his/her best capabilities for performing daily activities and

work and for participating in social contexts and present environment. The concepts of functioning and disability are closely related. These make ends of a continuum and are viewed as a complex interaction between the health condition of the individual and the contextual factors of the environment as well as personal factors (WHO, 2011).

Work is the effort people expose themselves to with the aim to produce products or render services that are valuable to other people. *Vocational* is related to a specific job task, a work, or a profession. A work or a job task requires specific *work demands* to be fulfilled with acceptable quality and quantity (Perry, 2007). One of the following methods is chosen to stipulate the work demands, i.e., to perform a job-task analysis for a specific work: (a) the worker's depiction of the job circle, (b) description of a situational work-place assessment documented by video-films and a valid schema for observation (Söderback, 2011; Stein, Söderback, Cutler, & Larsen, 2006), (c) use of the Revised Handbook of Analyzing Jobs (RHAJ) including 60 criterion-referenced factors (U.S. Department of Labor, 1991), and (d) use of the computerized Occupational Information Network Numerical Index (O*NET) (Information Technology & U.S. Department of Labor, 2011; The Work Suite, 2011), as based on the Dictionary of Occupational Titles (DOT) (Information Technology & U.S. Department of Labor, 2011; U.S. Rehab. A division of the VGM Group, 2011). DOT classifies thousands of works into nine occupational categories. Using DOT the demands that a work requires on a worker are stated in the *worker qualification profile* including the following: (a) work performed (the work functions, the work fields, machines, tools, equipments, and work aids (MTEWA)), (b) materials, products, subject matter services (MPSMS), and (c) the *worker characteristics needed to perform the work*. These are stated as follows: (c^1) General Educational Development (GED) including reasoning, mathematical, and language development; (c^2) aptitudes, which is physical or mental competency, knowledge, understanding, or atti-64 tude to do a certain work at a certain level. This competence is innate or acquired, or learned and continuously developed; (c^3) physical activity demands, which means rating of strength and movement, i.e., standing, walking, sitting, carrying, pushing, pulling, lifting, raising; (c^4) temperaments, i.e., personal traits that are required by the worker in specific job-worker situations (U.S. Rehab. A division of the VGM Group, 2011); (c^5) Specific Vocational Preparation (SVP), which is the amount of time required by a typical worker to learn the techniques, acquire information, and develop the facility needed for average performance in a specific job-worker situation; (c^6) worker interests are stated in the Guide to Occupational Exploration (GOE); or the Holland codes, which classify occupations as realistic, i.e., outdoors and hands-on; investigative, i.e., scientific; artistic, i.e., creative; social, i.e., counseling and teaching; enterprising, i.e., management and sales; and conventional, i.e., clerical (Holland, 1985). The results of GED, physical demands, aptitudes, and temperament assessments reveal a person's capability level, but the results of worker interests and attitude inventories reveal which job or occupation a person wants.

Assessment is the process by which an individual is evaluated using specific, reliable, and valid instruments, tools, and procedures. In this process, data is gathered, hypothesis formulated, and decisions and recommendations for future measures stated (Stein et al., 2006; Söderback, 2009).

Description

Investigation: *Functional assessments* investigate a person's level of his/her body functions (mental, cognitive, sensory, speech, and neuromusculoskeletal), activities and participation (learning and applying knowledge, general tasks and demands, communication, mobility, self-care, domestic life, interpersonal interactions and relationships, major life community, and social and civic life areas), behavior (ability, competence, and performance) in interaction with the present environment, health, quality of life, and personality characteristics (ICF, 2011),

sometimes related to specific diagnoses like rheumatoid arthritis, multiple sclerosis, dementia, etc. The results are referred to *standardized norms*, i.e., a person's result is compared with the results of people with similar prerequisites.

For example, a *functional capacity evaluation* (*FCE*) investigates a person's *general* capability to perform a range of physical activities that might be required to be able to successfully fulfill simulated work tasks without any relation to a specific job (Australian Government CRS & Department of Human Services, 2011; Gibson, 2009). These results are referred to *standardized norms*.

Vocational assessment investigates a person's potential to perform a *specific work* and his/her *work* functioning with emphasis on health and wellness at work. It is a tool for finding the optimal match between the demands of a specific work and the person's current work capacity, skills, and experiences. The result is *criterion-referenced*, determining how well the work demands of a specific work produced with a normal performance of a product or service *correspond to* the individual worker's physical, psychological, intellectual capacity and skills, and actual social and environmental circumstances. A vocational assessment should focus on identifying the person's abilities and strengths (Australian Comprehensive Psychological Assessment Centre, 2011; Matthews, 2010; Michaels, 2011; Rich, 2011). An example is the Criterion-Referenced-Multidimensional Model for Vocational Assessment (CMVA), including investigation of (a) the demands on a specific work and (b) the worker's contribution for finishing the job (personal characteristics, job performances, personal prerequisites, and psychosocial work environment), which is valid for people with long-term musculoskeletal pain (Soderback, Schult, Jacobs, 2000; Söderback, 2011).

Aims: *Functional assessments* are used for determining a person's level of body function/dysfunction and how these levels influence his/her performances of personal-home-work activities and participation in the actual environment. Moreover, it is used to estimate a person's perception of his/her health and well-being and for description of personal characteristics. Functional assessments are aimed to determine facts useful for supporting a plan for guiding an objective intervention and for preventing ill-health. It is worth to underline that a *FCE* should *not* be used as the only tool for determining a person's capacity for work.

Vocational assessments are used for determining an appropriate occupational match between the job and the worker. The assessment results determine the following: (a) the worker's readiness for work, and if so, to set a vocational goal and identify a range of suitable employment options, either connected to the ordinary or to a new job; (b) the worker's ability to continuously perform a specific job; (c) a suitable occupational rehabilitation program; (d) amount of health insurance for employment and supporting allowance claims; and (e) used for preventing the worker's long sick leave.

Target groups: *Functional assessment* may be used for people who need response to what is intended to be investigated. For example, it may concern people of all ages, in risk for or living with chronic diseases and/or impairments, disabilities, and restricted participation in social life including those who are outside the labor market.

Vocational assessment is used for career decisions and decisions about return-to-work (Ahlers et al., 2003; Lombard, 1994; Perry, 2007). *Career decision assessments* are used in healthy adolescents, young adults, and unemployed people who need advices with their careers and for young adults who need support for their school-to-work transition (Nel & van der Westhuyzen, 2009). The examinations concern which occupations best fit a person's interests, abilities, and personality.

Return-to-work is used in the injured or disabled people who need rehabilitation, i.e., vocational therapy before return-to-work (ICD-9CM: 9385) (MDGuidelines, 2011). The examinations concern the following: (a) *readiness for work* (i.e., medical and health status and prognoses, a realistic job goal, ability for transporting, manage money, understand the job requirements,

appropriate work habits) (O'Neill & Wolf, 2010) and need for technical aids and adaptation of work environment; (b) *worker meets the work demands*, i.e., if the level of a person's medical and health status showing incapacity, adaptability, ability, work skills, and personality matches a certain job criteria as defined by a job-task analysis essential to successfully fulfill job requirements; and (c) *effects of recruitment and job placement*. Here the train-and-place model is commonly used, i.e., the person participates in a rehabilitative process of vocational assessment, work training in work shops or work hardening, and placement to a job on a supported employment sometimes assisted with a job coach.

Content of the Assessments: Functional and vocational assessments are conducted using a great variation of standardized or non-standardized tools and techniques. Examples are self-assessment inventories, standardized psychometric paper and pencil tests, checklists, structured interviews and observations. In addition, conducting a vocational assessment includes criterion-referenced tests, work samples (e.g., VALPAR component work sample (VALPAR International Cooperation, 2011)), ERGOS® II™ Work Simulator System (Rich, 2011), BTE work simulator (BTE Technologies, 2011), performance-based tasks, examination of records of work experiences and educational certificates, situational assessments of work tasks, and a vocational exploration used. There are enormous number of tools for functional and vocational assessments and the preferable used tool differs according to a country's culture and social system. However, the ultimate demands on actual assessment must be that its psychometric functions are scientifically proved for its validity and reliability.

Providers of *functional assessments* may be professionals working in health or school or social services that have required knowledge in psychometric theories and are certified for the specific assessment to be conducted. However, standardized tests are mainly conducted by a psychologist. Providers of *vocational assessments,* aimed for a career decision, should be conducted by authorities like *vocational consultants*, or *licensed professional counselors*. However, *vocational assessments*, aimed for return-to-work, are often conducted in cooperation between a *vocational rehabilitation consultant* and a *multidisciplinary team*, including specialists from various professional fields, such as occupational therapy, rehabilitation medicine or psychiatry, psychology, social work, schools, and employers. The constitution of these teams depends on the client's disability.

The requirements for working as vocational consultants, vocational rehabilitation consultants, or licensed professional counselor (Career Org, 2011; wiseGEEK, 2011) vary extensively around the world. In Australia (e.g., The University of Sidney, 2010), Hong Kong (e.g., Vocational Training Council (2010)), and the USA (e.g., Lebednik, 2010), these practitioners should have obtained a state license and have master degree in rehabilitation counseling or rehabilitation services (4-year) or doctorate degree in counseling or psychology. In EU, a report on standards of Training for Vocational Rehabilitation Services (2011) has recently been published. However, most employment officers in Sweden have a bachelor degree in behavioral science, social work, occupational therapy, etc. (The Swedish Public Employment Service, 2011), but a specific master degree in vocational counseling cannot yet be obtained and therefore not required.

Current Best Practices and Evidence

The current best practices for conducting functional assessments and FCAs follow the manual of the assessment tool and for vocational assessments the guiding principles stated (e.g., by Smith et al., 2011). However, improvement of the assessments' evidence and effectiveness is required by use of repeated quality assurance measures. Here the goals and objectives should be directly linked to employment outcomes (Ahlers et al., 2003).

Vocational assessments include a great variation of normative and criterion-referenced assessment instruments and tools. This mix is ordinarily a part of vocational rehabilitation (VR) services.

Therefore, the clinical evidence of vocational assessment is so far sparsely documented. Available information might be sought as an embedded part among random controlled studies of VR services. Pruett, Swett, Chan, Rosenthal, and Lee (2008) stated that VR services have "empirical evidence to support the efficacy, clinical utility, and cost effectiveness in returning people with disabilities to competitive employment" (p. 9), if conducted by graduated rehabilitation counselors. However, random controlled studies are strongly requested as results of vocational assessments influence decisions about people's private economy and quality of life.

Summary

Functional assessments differ from vocational assessments in terms of aims, target groups, content, the way of conducting the assessments, and requirements of the providers, and should, therefore, be used with appropriate quality.

Gamma-Aminobutyric Acid (GABA)

Elizabeth Galik
School of Nursing, University of Maryland, Baltimore, MD, USA

Definition

Gamma-aminobutyric acid (GABA) is the primary inhibitory neurotransmitter in the central nervous system of humans and other mammals. GABA is a highly polar and flexible molecule that is formed from glutamate in enzymatic reaction that causes its release into the synapse where it is inactivated by reuptake into glia cells (Chebib & Johnston, 1999). GABA transmission within the central nervous system modulates noradrenergic, dopaminergic, and serotonergic neurons which ultimately influences behavior and mood (Brambilla, Perez, Barale, Schettini, & Soares, 2003; Emrich, von Zerssen, Kissling, Moller, & Windorfer, 1980). A deficiency of GABA has been associated with a variety of neuropsychiatric disorders, including mood disorders, anxiety, panic, addiction, and schizophrenia, and neurological disorders such as Alzheimer's disease, Parkinson's disease, and Huntington's chorea. More recently, GABA has been studied as a mediating factor in the transmission and perception of pain (Enna & McCarson, 2006). GABA is also directly associated with the regulation of muscle tone. Pharmacologic agents that act as agonists of GABA receptors result in relaxation and sedation and have anticonvulsant properties.

Definition

A gastric ulcer is a disease of gastric mucosal damage, caused by impaired mucosal defense and/or increasing gastric acid. Gastric acid consisting of hydrochloric acid and pepsin helps to digest intragastric contents, but they may also damage the gastric wall.

Description

Signs and Symptoms

The symptoms of gastric ulcer are the following: piercing or burning pain in the upper abdomen, poor appetite, nausea, vomiting, loss of weight, and feeling tired and weak. Tarry stool is the alarm sign of a bleeding, which suggests damage of the blood vessels in the submucosal or muscular layers of the gastroduodenal wall.

Causes

A type of bacteria called *Helicobacter pylori* (*H. pylori*) is responsible for most peptic ulcers. *H. pylori* is a common gastric pathogen and often begins to infect in childhood. Most people do not show any symptoms by *H. pylori* infection, but it sometimes causes chronic gastritis, peptic ulcer, dyspepsia, gastric adenocarcinoma, and B-cell mucosa-associated lymphoid tissue (MALT) lymphoma. *H. pylori* is motile and attaches to gastric mucosa through specific adhesion mechanisms. *H. pylori* urease, which produces ammonia on the gastric mucosa, increases the local pH and protects itself from acid. It may produce damage to the mucous coating and local inflammation. Another cause is the long-term use of nonsteroidal anti-inflammatory drugs (NSAIDs). NSAIDs can cause damage to the gastric and duodenal mucosa via some mechanisms, including block cyclooxygenase (COX)-1 and COX-2 inhibition. These two enzymes produce prostaglandins, substances that help to maintain blood flow and facilitate the repair of injury in the stomach. Cigarette smoking does not cause ulcers by itself but can make them worsen and delayed the healing.

Stress

Stress may not cause ulcers but can make them worsen. Patients with posttraumatic stress disorder (PTSD) showed higher prevalence of gastric ulcer than those without trauma. After the Hanshin-Awaji earthquake in Japan, the number of patients with gastric ulcer increased more than the previous year. This study also reported that *H. pylori* infection was a strong predisposing factor of the development of peptic ulcer. Stress sometimes induces psychological and physiological disorder and also closely relates to the central sympathetic activity. Spinal cord transection rat showed hypovolemia and higher prevalence of gastric ulcer. Brain angiotensin II AT1 receptors, which response the stress-induced hormone, relate to the stress-induced ischemia and inflammation in the gastric mucosa.

Diagnosis

First, taking a detailed history of symptoms and risk factors including medications, smoking, and drinking habits and if anyone in the patient's family has had ulcers. Physician will check of the patient's abdomen and chest as well as a rectal exam to look for any sign of bleeding. An abdominal X-ray is to rule out perforation (check free air under the diaphragm), and a blood test is to assess anemia. If a patient complains of sudden upper abdominal pain, it is important to rule out acute coronary syndrome by electrocardiogram. The diagnosis is confirmed by upper gastrointestinal (GI) endoscopy or upper GI series. If peptic ulcer is detected, biopsy of ulcer edge is recommended to rule out malignancy and check *H. pylori*. Noninvasive tests to detect *H. pylori* in a patient's blood, breath, or stool are also available.

Treatment

If acute bleeding is suspected, emergent gastrointestinal endoscopy or, in some cases, surgery is needed. Medication that reduces gastric acid secretion includes proton-pump inhibitors (PPIs) and histamine H2 receptor blockers (H2 blockers). PPIs cannot kill *H. pylori* but some study reported that it helps to eradicate *H. pylori* infection. *H. pylori* testing, therefore, should be done before PPIs medication, or after stopping

PPIs for a month at least. Patients with confirmed *H. pylori* infection should receive 1-week triple therapy consisting of PPIs and the antibiotics clarithromycin and amoxicillin, which can cure 80–90% of patients with peptic ulcer. After *H. pylori* eradication is completed, patients still have a higher incidence of gastric carcinoma than uninfected people. Patients with peptic ulcer therefore should be followed for a long time.

Gastrin-Releasing Peptide (GRP)

Yori Gidron
Faculty of Medicine and Pharmacy, Free University of Brussels (VUB), Jette, Belgium

Definition

Gastrin releasing peptide (GRP) is a peptide with multiple roles which primarily regulates and stimulates secretion of gastric acid (Schubert, 2008). GRP also has other biological roles. For example, in the respiratory system, it causes bronchoconstriction on one hand and vasodilatation on the other hand. Indeed, GRP plays a role in pulmonary diseases leading to asthma, and its blockade serves as a therapeutic target in such conditions (Zhou, Potts, Cuttitta, Foster, & Sunday, 2011). GRP also has a role in several cancers. In neuroblastomas, for example, it acts as a tumor growth factor. The blockade of GRP augments the effects of chemotherapy (Paul, Gillory, Kang, Qiao, & Chung, 2011). Furthermore, GRP also plays a role in the circadian rhythm and in stress. GRP appears to mediate in part the stress response. In rats given corticosterone, higher GRP levels were seen in the amygdala and the medial prefrontal cortex during stress compared to control animals exposed to stress alone (Merali, Anisman, James, Kent, & Schulkin, 2008). Thus, it is possible that GRP alters brain activity upon exposure to chronic stress and to its neuroendocrine concomitants. Finally, GRP and its receptor are distributed in several brain regions and play a role in psychiatric and neurodegenerative disorders (Roesler, Henriques, & Schwartsmann, 2006). For these reasons, it has been suggested that GRP may serve as a therapeutic target in several health conditions (Roesler et al., 2006). Due to the complex and vast roles of GRP in psychological and biological processes and outcomes, it appears that this peptide deserves much attention in the field of behavior medicine as it may partly mediate effects of stress on somatic systems and health conditions.

Gate Control Theory of Pain

Definition

The gate control theory (GCT) of ▶ pain was introduced in 1965 by Ronald Melzack and Patrick Wall. It was the first theory to introduce the concept that pain experience is not simply the result of a linear process that begins with the stimulation of pain pathways in the peripheral nervous system and ends with the experience of pain in the central nervous system. Rather, neural impulses that potentially signal pain from the peripheral nervous system are subject to a number of modulations in the spinal cord by a "gatelike" mechanism in the dorsal horn before the experience of pain is transmitted to the central nervous system (Melzack & Wall, 1965). It also proposes that the gate mechanism is modulated by emotions, cognitive state, and past experiences. While this theory is based on physiology, it explains both sensory and psychological aspects of pain perception.

Description

The gate control theory of ▶ pain was first introduced by Canadian psychologist Ronald Melzack and British physician Patrick Wall in the 1965 *Science* article titled "Pain Mechanisms: A New Theory." The theory proposed that physical pain is not a direct result of activation of pain receptor neurons, but rather its perception is impacted by the interaction between different neurons. It proposes the existence of neural structures in the spinal cord and brainstem that modulate the experience of pain. These structures function like a gate, swinging open to increase the flow of transmission from nerve fibers or swinging shut to decrease the flow. With the gate open, signals arriving in the spinal cord stimulate sensory neurons which relay the signals upward to reach the brain and trigger pain. With the gate closed, signals are blocked from reaching the brain, and no pain is felt.

Gate Mechanism

According to the gate control theory of pain, three main types of nerve fibers are involved in the process of pain perception: A fibers, C fibers, and the "gate" interneurons. The diameters of these fibers vary in size. A-beta fibers have a large diameter and are myelinated, resulting in quick transmission of impulses. C fibers are smaller in diameter and are not myelinated, resulting in the slower transmission of impulses. A-delta fibers, another form of A fiber, are also small in diameter and have a function similar to that of C fibers.

The gate through which the pain pathways send signals to the nervous system is located in the dorsal horns of the spinal cord. The dorsal horns are composed of several layers, called laminae. Two of these layers make up the substantia gelatinosa, the hypothesized location of the gate mechanism. Both the small-diameter A-delta and C fibers and the large-diameter A-beta fibers travel through the substantia gelatinosa. The interneurons, located in the substantia gelatinosa, are the hypothetical gating mechanisms.

Activity of the large-diameter A-beta fibers produces an initial burst of activity in the spinal cord, followed by an inhibitory response. If the interneurons of the substantia gelatinosa are stimulated by activity in the large A-beta fibers, the interneurons produce an inhibitory response and do not allow pain sensations to be relayed up to the brain. Therefore, when the interneurons are stimulated by large fiber activity, the gate closes and no pain is experienced. Activity of the small-diameter A-delta and C fibers produces prolonged activity in the spinal cord. This type of activity promotes sensitivity and subsequently increases sensitivity to pain. If the interneurons are inhibited by the action of the small-diameter C fibers or A-delta fibers, or if they are not stimulated at all, the interneurons allow pain sensations to be sent up the brain. Thus, if the interneurons receive activity from small-diameter fibers, the gate remains open and results in the experience of pain.

In short, when the gate is open, impulses flow through the spinal cord toward the brain, neural messages reach the brain, and pain is experienced. When the gate is closed, impulses are inhibited from ascending through the spinal cord, messages do not reach the brain, and pain is not experienced. Therefore, the status of the gate depends on the balance of activity between the larger A-beta fibers and the smaller A-delta fibers and C fibers. This arrangement of neurons provides a physiological basis for the modulation of incoming sensory impulses.

Influence of the Brain on Pain

Although the gate may be closed by neural activity in the spinal cord, it may also be controlled by messages that descend from the brain. Melzack and Wall proposed the concept of a central control trigger consisting of nerve impulses that descend from the brain and influence the gating mechanism. They hypothesized that this system consists of large neurons that conduct impulses rapidly. These impulses from the brain affect the opening and closing of the gate in the spinal cord and are affected by cognitive processes. That is, the experience of pain is influenced by beliefs and prior experience. According to the gate control theory then, pain has not only sensory components but also motivational and emotional components. The theory explains the influence of cognitive aspects of pain and allows for learning and experience to affect how pain is experienced. ▶ Anxiety, ▶ worry, and ▶ depression, can increase pain by affecting the central control trigger, thus opening the gate. Distraction, ▶ relaxation, and ▶ positive emotions can cause the gate to close, thereby decreasing pain. The gate control theory is not specific about how these experiences affect pain but helps in the understanding that the sensation of pain can be dampened or aggravated by cognitions. For example, the theory helps explain how some people are able to withstand a large amount of pain through sheer willpower.

This theory provided a new way of thinking about pain and pain management and paved the way for current definitions of pain (e.g., International Association for the Study of Pain (IASP) pain terminology).

Impact and Critique

Prior to the gate control theory, pain was thought to be a direct response to a stimulus. Pain theories could not explain how two different people exposed to the same painful stimulus may have different reactions, nor did it explain phenomena such as phantom limb pain, defined as the sensation of pain in a limb that was previously amputated or removed. Melzack and Wall's theory was the first to suggest that psychological factors such as past experiences, attention, and emotion may have an impact on pain responses and perception. In addition, by highlighting the role of spinal and brain mechanisms on pain perception, the gate

control theory triggered an explosive advance in pain research and therapy. Today, it is considered the most influential theory of pain. It forced the medical and biological sciences to accept the brain as an active system that can modulate, filter, and select inputs. It has inspired several clinical techniques for controlling pain, including transcutaneous nerve stimulation (TENS), that involves the artificial stimulation of the large pain fiber system.

The gate control theory represents an important advance on previous simple response theories of pain. It introduced a role for psychology and described a multidimensional process rather than a simple linear one. However, the theory has received several criticisms. Although there is evidence illustrating the mechanisms to increase and decrease pain perception, the location of the gate itself is unknown. Another critique of the theory is that although the input from the site of physical injury may be moderated and mediated by experience and psychological factors, the model still assumes an organic basis for pain. This integration of physiological and psychological factors can explain individual variability and phantom limb pain to an extent, but because the model still assumes some organic basis for all pain, it is still foundationally based upon the flawed stimulus response process. Finally, the gate control theory attempts to depart from traditional dualist models of health by integrating the mind and body. Today, however, the mind and body are still seen as separate processes, although there is an attempt at some integration. The model suggests that physical processes are influenced by psychological processes, yet the two processes remain distinct.

Despite these criticisms, the gate control theory of pain is still the inspiration for the dominant theory of pain today, the ▶ biopsychosocial model of pain, and has stood the test of time remarkably well for a theory that triggered much research on relatively previously understudied health issue.

Gay Men's Health Crisis

Jennifer Pellowski
Department of Psychology, University of Connecticut, Storrs, CT, USA

Definition

The Gay Men's Health Crisis (GMHC) is a volunteer-based, nonprofit organization that provides health, employment, and legal services to people living with HIV/AIDS in New York City. GMHC is an advocate for both public and private research concentrating on HIV/AIDS care and prevention and provides information about such issues as safer sex, testing and substance use through their community awareness campaigns (Gay Men's Health Crisis [GMHC], n.d.).

Description

GMHC was founded in 1981 by six men, including playwright and activist Larry Kramer, who were all concerned about the lack of information and services available to people living with a mysterious disease which is now known as HIV/AIDS. These men aimed to spread the word about "gay cancer" as well as raise money to fund research (Kayal, 1993). Among the first volunteers was Roger McFarlane who played an integral part in the establishment of the organization, particularly with the creation of the first

AIDS information hotline from his own home phone which evolved into the GMHC helpline. McFarlane became the first executive director of GMHC in 1982 (Hevesi, 2009).

One of the first major goals of the Gay Men's Health Crisis was to raise money to support research concerning HIV/AIDS. Within the first year, it raised $50,000 (Kayal, 1993). Currently, GMHC is an advocate for both public and private research, working with a yearly budget of nearly $20 million. In addition to conducting its own research, GMHC publishes several quarterly magazines/journals free of charge focused on health research and policy issues written in a widely accessible manner.

Since its conception, GMHC has been a major force in the dissemination of information regarding HIV and sexual health to the lesbian, gay, bisexual, and transexual (LGBT) community in New York City. It also works to educate people in the larger community, and despite its name, this organization serves people of all sexual orientations and genders (Reinfeld, 1993). In addition to sexual health information, it also provides a wide range of services to People Living with HIV/AIDS (PLWHA) and those at risk of contracting the virus (GMHC, n.d.).

One of their most extensive services is their multidisciplinary mental health clinic. It provides both short- and long-term counseling for individuals, families, and couples. Additionally, it conducts topic-based support groups focused on issues ranging from depression and anxiety to newly diagnosed individuals to living well with HIV (GMHC, n.d.).

GMHC also provides its clients with various services aimed at helping people living with HIV/AIDS like a healthy, normal life as well as reaching out to those who may be a risk for contraction the disease. These services include a hot meal program, nutritional information, an HIV and sexually transmitted infection (STI) testing clinic, legal support, and many different types of career services (GMHC, n.d.).

In addition to support for community members, GMHC is also an advocate for city, state, and federal policies concerning LGBT health care, youth services, and testing. The Gay Men's Health Crisis is integral to not only the LGBT community but to the New York City community at large. This organization works to bridge the gap between public health, government, health-care services, and the community. This, coupled with its support of HIV research, makes GMHC a key organization for the acquisition and dissemination of sexual health knowledge which is a key goal of the field of behavioral medicine.

Gender Differences

Definition

Gender refers to the identity humans tend to develop around their biological sex. While gender may be related to biology, gender identity is significantly influenced by culture and social learning. Gender differences refer to the observed differences in behavior displayed by females and males (or another gender). Specifically, differences in behavior can be observed between genders because society imposes a different set of appropriate activities and behaviors for females and males.

It is important to make a distinction between the biological differences between sexes (sexual dimorphism) and the way in which their behavior differs (gender differences). This difference is exemplified by the relationship between testosterone and aggression. For example, the serum level of testosterone in humans is sexually dimorphic; males tend to have higher blood levels of testosterone than females (Torjesen & Sandnes, 2004). It has also been found that higher levels of testosterone are associated with more aggression (Mehta & Beer, 2009). However, we refer to higher rates of aggression in males than in females as a gender difference because testosterone (biology) is not the only factor influencing aggression (behavior).

It is important to note that because gender is a social construct, the roles of each gender vary across culture as each society has a particular prescription of appropriate behavior for females and males. Although not without some controversy, Margaret Mead in the book *Temperament in Three Primitive Societies* (1963) discussed the influence of culture over aggression in three societies, one in which both females and males were gentle, one in which both females and males were aggressive, and one in which females were dominant and males were more emotionally dependent. The author's findings highlight the influence of socialization on the expression of aggression. Similarly, Bandura (1977) found that both girls and boys were able to learn and subsequently express aggressive behavior by observing others (a model) behaving aggressively, supporting the idea that individuals can be socialized to express more or less aggressiveness.

Many gender differences between males and females have been found. However, very frequently these differences are very small and the variation within genders tends to be much larger than the variation between genders. For example, it has been found that girls tend to do better in verbal tasks and boys in abstract problem solving skills such as those required in math (Hyde & Linn, 1988; Linn & Hyde, 1989). However, while the difference between boys and girls on either task is very small, big differences in verbal skills can be found among girls and in abstract problem solving among boys.

The literature offers many examples of the ways in which females and males are socialized differently and the influence of socialization is so profound that it seems to start even before birth. For example, Smith (2005) observed a series of changes in the way she related to her fetus during pregnancy once she learned it was a boy. For example, she observed that her voice became lower and firm and she stopped "nibbing clockwise" her belly when talking to the fetus and started patting it. She also noticed

her language use accommodated the "prescribed stereotypes" for males (e.g., referring to the fetus as "strong"). After birth, socialization seems to continue throughout the person's life in the form of rewards when gender-appropriate behavior is exhibited and punishment when gender-inappropriate behavior is chosen.

Definition

Gender roles are the socially constructed patterns of behavior ascribed to men and to women. Gender roles encompass concepts about masculinity and femininity, and determine what behavior is expected or appropriate for men and women in a given situation. Gender roles are a social (rather than biological) definition of what it means to be a man or a woman. They may differ by society, culture, socioeconomic class, age, and period in history.

Gender roles are created and reinforced through social institutions such as family and intimate relationships, schools, religious institutions, industry and private enterprise, legal and medical systems, and the media. Not only do gender roles result in differential expectations of behavior, they also assign differential prestige to masculine and feminine behavior. To the extent that they reflect inequalities between men and women in access to resources or control, gender roles may contribute to unequal power relations between men and women (Connell, 1987; Sen, George & Ostlin, 2002).

Gender roles are of importance to behavioral medicine because they can affect an individual's health-related decisions and behaviors. Gender roles are considered particularly important in sexual health, as they can affect sexual practices, selection of partners, experience of pleasure, as well as contraceptive use and reproduction. *Masculine gender roles* typically define maleness through independence, aggressiveness, and exploration. Men may be expected to initiate sex early in life, have multiple sexual partners, and maintain control over their sexual partners. Masculine gender roles may therefore condone or encourage risky sexual behaviors (such as sex without a condom, anonymous sex, and sex with sex workers). Furthermore, in many societies, men are expected to be knowledgeable and experienced in sexual matters. *Feminine gender roles*, on the other hand, often dictate that "good" women lack sexual knowledge or experience, particularly prior to marriage. Feminine gender roles also frequently

assume that women have more control over their sexual desires than men. They may include the expectation that women act as "gatekeepers," limiting sexual access. In contrast to the masculine role of initiator of sexual activity, traditional feminine gender roles confine women to a reactive or passive role. Taken together, these gender roles may encourage behaviors that place both men and women at risk for unplanned pregnancy, sexually transmitted infections, and HIV.

The gender role perspective, while a useful framework for understanding social influences on behavior for men and women, is not without criticism. First, there is some debate regarding how deterministic or fluid gender roles are. Although awareness of and conformity to gender roles is influenced by an individual's childhood upbringing and ongoing experiences, several authors argue that individuals can be active agents in creating or challenging masculine or feminine gender roles. Second, public health scholars have questioned the utility of examining gender roles, as opposed to the more pervasive ways gender is interwoven into the structure of social institutions. As Sen et al. note, "...[E]xclusive or excessive emphasis on roles leads to a focus on behavior change at the individual level, rather than on policy change at the societal level" (2002, p. 6).

Definition

The gene is the fundamental unit of heredity, passing genetic information from parents to offspring. It is an ordered DNA sequence, which encode (a locus on a chromosome) that is involved in producing a protein. It is therefore an ordered sequence of nucleotide bases, which encode the necessary information to produce a specific functional product.

A gene includes regions that precede and follow the coding regions (the nucleotide bases that create a protein). In the mid-1970s, it was generally accepted that genes existed as continuous segments within a DNA molecule. This view changed radically with the discovery in 1977 that in higher organisms (eukaryotic cells), an individual gene can comprise several DNA (exons) segments separated by chunks of noncoding DNA (introns) (see Roberts, 1993). After the DNA sequence within a gene gets transcribed into messenger ribonucleic acid

(mRNA), an elegant process called splicing removes the introns and connects the exons to form the mRNA sequence that will get ultimately translated into a sequence of amino acids. These amino acid sequences make proteins, which are therefore made from the genetic instructions encoded in the DNA molecule.

The human genome contains approximately 20,000–25,000 genes (Human Genome Sequencing Consortium, 2004), a remarkably lower estimate than the figure of 100,000 genes that was commonly used before the Human Genome Project was finished. Human DNA contains approximately three billion base pairs, but the 20,000–25,000 genes comprise only a small percentage (on the order of 2–5%) of these base pairs. Taylor and Bristow (2006) commented as follows: "The "genes" themselves are only a modest part of the whole genome. It is clear that some of the "non-translated" DNA is required for genes to function normally, but the function of large portions of our DNA remains enigmatic. Equally remarkable, perhaps, is that humans do not use all of their genes at any one time, so far less than 25,000 genes are utilized on a day-to-day basis." As noted earlier, necessary genes are transcribed by being translated in to mRNA intermediates, which are subsequently translated into functional proteins.

Finding genes is not an easy task. Watson (2006) commented that "protein-coding regions are but strings of As, Ts, Gs, and Cs embedded among all the other As, Ts, Gs, and Cs of the genome – they do not stand out in any obvious way." Additionally, as noted already, the base pairs that comprise a gene are not arranged in an uninterrupted linear sequence. A typical human gene has eight introns that lie between the exon coding sections. For example, the gene dystrophin is spread across approximately 2.4 million base pairs, but only less than 1% of the total base pairs encode the actual protein. The other 99% are 79 introns located throughout the coding region. Given these difficulties in identifying human genes, knowledge of other genomes has proved remarkably helpful. Comparison between genomes leverages the fact that functional regions are preferentially conserved between specifies and can be used to identify novel genes. Thus, "looking for similarity in sequence between the human and mouse data is therefore an effective way of identifying functional areas, like genes" (Watson, 2006) (See also Table 1).

Definition

The process by which information from a gene is used to synthesize a functional gene product. These products are often proteins, but some gene code to functional (noncoding) RNAs, such as rRNA, tRNA, and miRNA. The process of gene expression is used by all known organisms – eukaryotes, prokaryotes, and viruses – to generate the macromolecular machinery for life. Gene expression process may include several steps of regulation – transcription, RNA splicing, RNA stability, translation, and posttranslational modification of a protein – that determine the expressed product/s from each gene and control the timing, location (cell type), and amount of gene expression. Gene expression is tightly modulated and therefore serves the basis for cellular differentiation and morphogenesis, the versatility and adaptability of any organism, and evolutionary change.

In genetics, gene expression is the most fundamental level at which genotype gives rise to the phenotype. The genetic code is "interpreted" by gene expression, and the properties of the expression products give rise to the organism's phenotypes, such as appearance, behavior traits, and diseases.

A number of human diseases are known to result from the disruption of gene expression, including cancer, neurological diseases, etc. Thus, research of gene regulation is of high relevance to human health.

Definition

Gene-environment interaction refers to the fact that the effects of genes on a disease often depend on the environment or that the effect of environment depends on the genotype (Dick, 2011).

In genetic studies of interest in Behavioral Medicine, gene-environment interaction is often used to describe the effect of genes modified by environmental exposure, including behavioral, nutritional, infectious, chemical, and physical factors, or any other nongenetic factors. It has been increasingly accepted that most common diseases involves not only genetic and environmental causes but also interactions between the two, which may account for a significant proportion of the heritabilities of a complex disease (Ober & Vercelli, 2011). The study of gene-environment interaction has faced some challenges, such as the environmental measurement errors or lack of true full range of environments (Dick, 2011), the need for large sample size (Hunter, 2005), the study methodologies, and the underlying biological mechanisms of gene-environment interaction.

Definition

In genetics, gene-gene interaction (epistasis) is the effect of one gene on a disease modified by another gene or several other genes. Biological epistasis, i.e., the gene-gene interaction has biological basis, is in contrast to statistical epistasis that describes deviation from additivity in a linear statistical model (Gilbert-Diamond & Moore, 2011). Epistasis can be contrasted with dominance, which is an interaction between alleles at the same gene locus. Gene-gene interaction is a common component of genetic architecture of human complex diseases; however, it is difficult to detect. The multilocus genotype combinations for gene-gene interaction increase exponentially and require larger sample size as well as more computation burden. The commonly used linear models have limited ability to detect nonlinear patterns of gene-gene interaction. Multifactor dimensionality reduction (MDR) has been developed to detect gene-gene interaction as a nonparametric method by pooling genotypes from multiple SNPs without assuming genetic model (Moore & Williams, 2009). Another alternative to linear models is combinatorial partitioning method (CPM) (Nelson et al., 2001). The biological interpretation of gene-gene interaction identified from a statistical model may be the most important and most difficult to understand the disease etiology.

General Adaptation Syndrome

Responses to stress; Stress reactivity

Definition

The general adaptation syndrome (GAS) is a theory of stress responding proposed by ▶ Hans Selye. It refers to the nonspecific, generalized responses of the body in response to stress and provides a framework for the link between stress and chronic illness (Selye, 1956). This syndrome is divided into three stages: alarm reaction, resistance, and exhaustion.

Description

▶ Hans Selye (1907–1982), known as "the father" of the stress field, was a Hungarian endocrinologist who emigrated to Montreal, Canada, in 1932. He pioneered research on the biological effects of exposure to "noxious agents," or stress, subsequently developing the concept of the general adaptation syndrome.

Development

▶ Selye first wrote about the general adaptation syndrome in the British journal *Nature* in 1936 when he was an assistant at McGill University's Biochemistry Department in Montreal. In an experiment designed to discover a new hormone, he injected laboratory rats with ovarian extracts in hopes of uncovering changes in the organism that could not be caused by any previously known ▶ sex hormones. He found that following injection of the extract, the adrenal cortex of the rats became enlarged; the thymus, spleen, and lymph nodes all showed signs of deterioration; and deep bleeding ulcers were formed in the stomach and duodenum which eventually lead to death. Interestingly, ▶ Selye discovered that each of these symptoms could be increased or decreased in severity by adjusting the amount of extract injected into the animals. To ▶ Selye, these symptoms appeared to be the workings of a previously unknown hormone. However, later experiments with placental, pituitary, kidney, spleen, and numerous other organ extracts, all resulted in the expression of the same symptoms, causing ▶ Selye to reject the idea that these symptoms were being produced by a specific substance.

Further animal experiments conducted by ▶ Selye with rats demonstrated that if the animals were damaged by acute nonspecific noxious agents (e.g., cold exposure, surgical injury, excessive exercise, and injection of toxic drugs), a typical syndrome appeared, with symptoms that were independent of the type of noxious agent, representing instead a general response to the stimulus. ▶ Selye noted that this syndrome developed in three stages. The first stage began 6–48 h after the noxious agent was administered and involved several key changes in physiological functioning, including a rapid decrease in the size of the thymus, spleen, lymph glands, and liver, disappearance of fat tissue, and a drop in body temperature. The second stage began 48 h

after the initial administration of the noxious agent and was characterized by an overall decrease in general parasympathetic activity, including a cease in general body growth, a deterioration of the gonads, discontinued milk production in lactating animals, and an increase in general sympathetic activity, including enlarged adrenal glands and hyperplasia of the thyroid. Upon continued treatment with the noxious agent, the animals would build up resistance such that by the end of the second stage, the appearance and function of the organs returned to normal. However, with further administration, after a period of approximately 1–3 months and depending on the severity and dose of the noxious agent, the animals eventually lost their ability to resist, and physical symptoms, similar to those seen in the first stage, began to reappear. This apparent exhaustion of the ability to resist was labeled as the third stage.

▶ Selye compared his findings in the laboratory to clinical experiences with humans. Similar to animals, ▶ Selye noticed that physical and emotional stress in humans induced a specific, predictable pattern of health outcomes that, if left untreated, would lead to infection, illness, disease, and eventually death. He noted that the recommended treatments for almost all of these complaints were those that were useful to patients suffering from almost any illness, including rest, changes in diet, and temperature regulation. Given that there was only one recommended treatment for such a wide range of generalized complaints, ▶ Selye thought that there may be a mechanism in the body whose response to external noxious agents was general. He proposed that certain changes take place within the nervous and endocrine systems within the body during stress that can disrupt normal physiological mechanisms, triggering disease or illness. This specific pattern of changes is now known as the general adaptation syndrome, which occurs in three generalized stages (Selye, 1956).

General Adaptation Syndrome Stages

Stage 1, the *alarm reaction*, occurs when the body's defenses against a stressor are mobilized through activation of the sympathetic nervous system. This reaction is known to activate body systems involved in the fight-or-flight response. ▶ Epinephrine (▶ adrenaline) is released, heart rate and blood pressure increase, respiration becomes faster, blood is diverted away from the internal organs toward the skeletal muscles, sweat glands increase production, and gastrointestinal system activity is suppressed. These physiological reactions were believed by ▶ Selye to be adaptive for acute emergency situations. However, many modern stress situations involve prolonged exposure to stress and typically do not require an alarm response. The magnitude of the alarm reaction may also depend on the degree to which the event is perceived as a threat.

If a stressful situation persists, the body's reaction will progress to stage 2, which ▶ Selye called the *resistance* stage. In this phase, physiological arousal remains high, although not as high as in the alarm reaction stage. The body attempts to adapt to the emergency by replenishing adrenal hormones. The duration of this stage depends on the severity of the stressor and the adaptive capacity of the organism. If the organism successfully adapts, the resistance stage will continue for a longer period of time. During this stage, an organism may appear unaffected, but physiologically, the body's internal functioning is active. Continued stress will lead to a stress-induced neurological changes and a breakdown of the hormonal system, leading to conditions know as the "diseases of adaptation," which Selye defined to include ▶ peptic ulcer, ▶ hypertension, hyperthyroidism, and immune deficiencies. At this point, there is a decrease in the organism's ability to cope with everyday events and hassles, possibly leading to behavior change (e.g., irritability, impatience, and increasing vulnerability to health problems).

If the stressful event persists to the point where resistance is no longer possible, the body enters the final stage of the general adaptation syndrome which ▶ Selye called *exhaustion*. At this point, the body's energy reserves are depleted. This stage is characterized by activation of the ▶ parasympathetic division of the ▶ autonomic nervous system (ANS). Under normal circumstances, activation of this division helps keep the body functioning in a balanced state. However, in the exhaustion stage, ▶ parasympathetic functioning is

at an abnormally low level, causing an organism to become exhausted. If stress persists, the "diseases of adaptation" are present and physical deterioration or even death may occur.

Impact and Critique

► Selye's breakthrough ideas about stress helped build an entirely new medical field based on the study of biological stress and its effects on the body. His research has inspired numerous researchers and continues to make contributions to this day by providing a theoretical framework for connecting stress to illness and leading to the study of methods to help the body effectively deal with life's chronic demands.

The concept of the general adaptation syndrome aids in the understanding of how stress may be linked with an abundant source of health problems. Of specific interest is the role of the ► Hypothalamic-pituitary-adrenal axis activity in response to stress. Early life stress has been linked with malfunctions in the normal cycle and functioning of the HPA axis. Instead of reducing the production of ► hormones once the stress is removed or ended, the cycle may be ongoing, with the ► hypothalamus continuing to signal the adrenals to produce ► cortisol. Eventually, high ► cortisol levels may lead to a suppression of the immune system through increased production of interleukin-6. This increased production may lead to the exhaustion of the stress mechanism, resulting in fatigue and depression, apparent in research findings that suggest that stress and depression have a negative effect on the immune system. As a result of the prolonged attempts to resist the stressor, the body may eventually lose its ability to resist all together. This person may then be at a higher risk to contract a disease related to immune deficiency, such as an infection.

Prolonged stress may also lead to blockages in the arteries by fat and ► cholesterol released by the body as part of the stress response, possibly contributing to a heart attack or stroke. The body's reactions to stress may also manifest itself into a number of other illnesses such as ► depression, sleep disorders, ► hypertension, ulcers, and ► asthma.

The general adaptation syndrome theory has not gone unchallenged, however, by evidence that different stressors or emotional states may elicit autonomic specificity or unique patterning during experimental manipulation. Nevertheless, the theory of general adaptation syndrome is a cornerstone of ► behavioral medicine because it led to the study of the effects of stress and hormones on brain function, including research investigating the biological functioning of ► glucocorticoids.

General Population

J. Rick Turner
Cardiovascular Safety, Quintiles, Durham, NC, USA

Definition

The general population is the entire population of individuals with a characteristic of interest, such as a particular disease or condition of clinical concern. It is differentiated from the subject sample chosen from that population for a particular study.

Description

The general population of interest in a particular case will differ from other general populations defined in other ways. For example, if a researcher is interested in testing a new behavioral intervention to lower blood pressure, the general population would be all individuals with high blood pressure (hypertension). In other cases, it may be all individuals with type 2 diabetes mellitus. It can also be defined by previous experiences, that is, individuals who have ever smoked, regardless of whether they currently smoke.

The reason for differentiating the term "general population" from the subject sample is that a subject sample chosen for a study is (virtually) always smaller than the general population. Since there are tens of millions of individuals in the United States with hypertension, for example, an intervention cannot be tested on all individuals in the general population of individuals with hypertension. A subject sample must be chosen. The key challenge here is one of generalizability. Interest does not actually lie with the treatment's therapeutic benefit for the particular individuals taking part in the study, but rather with how the treatment is likely to work for many more individuals comprising the general population. Therefore, great methodological care is required to ensure (to the greatest degree possible) that the subject sample is representative of the general population.

There are also statistical techniques that allow extrapolation of results from the subject sample to the general population. A useful parameter here is the confidence interval associated with a treatment effect, that is, the degree of therapeutic benefit offered by a treatment. Imagine that a behavioral intervention intended to lower blood pressure (let us just use systolic blood pressure in this example) is tested on 100 subjects, and that the average decrease in SBP is 8 millimeters of mercury (mmHg). The research question becomes: To what extent can this result be generalized to the general population on the basis of this one clinical study? Statistical methodology allows us to place a confidence interval around the treatment effect obtained, which is referred to as a point estimate, since it is an estimate of the "truth" in the general population based on the data collected here. Confidence intervals can be created for any percentage greater than zero and less than 100%, but a common and useful one is the 95% confidence interval. Imagine that this was done for the data from our hypothetical example, and the 95% confidence interval placed around the point estimate of 8 mmHg had a lower limit of 4 mmHg and an upper limit of 12 mmHg (in such cases, the limits will always lie symmetrically around the point estimate). These confidence intervals allow us to make the following statement with regard to the general population:

The data obtained from this single trial are compatible with a treatment effect in the general population as small as 4 mmHg and as large as 12 mmHg, and our best estimate is 8.00 mmHg.

In more formal statistical language, the 95% confidence interval (the interval from the lower limit to the upper limit) is a range of values that is likely to cover, with 95% confidence, the true but unknown general population treatment effect.

It is noted in the entry entitled "▶ Demographics" that when reporting a research study it is necessary to provide a summary of the relevant demographic characteristics of the subjects who

participated in the study. The fundamental goal of an individual research study is to provide information that allows a well-reasoned indication of how the general population would respond to the intervention of interest. If all subjects are younger than 30 years of age, it would be unreasonable to claim that the results of a study provided useful information regarding how individuals older than 60 years of age might respond.

Clinicians constantly face the challenge of assessing, on the basis of research evidence collected on subject samples participating in clinical research studies, how best to treat their individual patients. As a research scientist and a physician, Katz (2001) captured the issues here succinctly and eloquently:

> The inapplicability of some evidence to some patients is self-evident. Studies of prostate cancer are irrelevant to our female patients; studies of cervical cancer are irrelevant to our male patients. Yet beyond the obvious exclusions is a vast sea of gray. If our patient is older than, younger than, sicker than, healthier than, ethnically different from, taller, shorter, simply different from the subjects of a study, do the results pertain?

It is reasonable to acknowledge that the more closely the nature of a study's subject sample reflects the general population to whom one wishes to generalize the information gained from the study, the more likely it is that the evidence can indeed be generalized in a clinically informative manner. However, it must always be realized that the practice of medicine, including behavioral medicine, also requires the clinician to include knowledge of and reasoning about each individual patient. This is discussed further in the entry titled "► Clinical decision-making."

Definition

"Genetic counseling is the process of helping people understand and adapt to the medical, psychological and familial implications of genetic contributions to disease. This process integrates the following:

Interpretation of family and medical histories to assess the chance of disease occurrence or recurrence.

Education about inheritance, testing, management, prevention, resources and research.

Counseling to promote informed choices and adaptation to the risk or condition" (Resta et al., 2006, p. 77).

This definition of genetic counseling was adopted by the National Society of Genetic Counselors in 2006, and it remains the standing definition of the service. The definition expresses the basic nature of the service which is grounded in the science of genetics as well as related sciences and the importance of competence in psychosocial counseling skills on the part of the practitioner. Genetic counseling as a formal, free-standing health-care profession in the United States began in 1969 with the development of the first graduate program at Sarah Lawrence College (Stern, 2009). The service, as an

integral part of the health-care field, is in various stages of formal development in many countries around the world (Transnational Alliance for Genetic Counseling, 2011).

Currently, genetic counseling services are provided to patients and families with genetic concerns that cover a broad range of medical conditions (Hampel et al., 2009). Genetic counseling has become an integral clinical service in the perinatal medicine, oncology, neurology, cardiology, pediatrics, public health, and many more health-care arenas (National Society of Genetic Counselors, 2011).

Assessing and addressing the psychosocial needs of patients and families are essential components of genetic counseling (Fine et al., 1996). The relationship between the counselor and the patient is critical to effective genetic counseling where the major goals of a better informed and empowered patient who is able to use genetic information to make important life and health-care decisions are met (McCarthy Veach et al., 2007).

Genetic Testing, Psychological Implications

Definition

Genetic testing, psychological implications refers to the potential cognitive and emotional consequences of undergoing genetic testing and learning the test result.

Description

Psychological Impact of Genetic Testing

The potential psychological impact of genetic testing can be affected by numerous factors including the purpose of testing and the test result as well as the individual's expectations, perception of the disease in question, and coping style. In general, however, studies appear to indicate that although genetic testing may have an immediate negative effect for individuals receiving "bad news," the long-term psychological impact is often negligible or even slightly positive (Broadstock, Michie, & Marteau, 2000; Cameron & Muller, 2009).

Pretest counseling is an important step to minimize the potential for negative effects. This discussion should include a review of the purpose of testing, potential results, and medical consequences of results as well as patient expectations and plans for dealing with the results. Some genetic tests require an informed consent from the individual. This document may also help guide the pretest counseling discussion.

Purpose of Testing

The purpose of testing can have a significant impact on how the individual responds to the genetic result. Currently, genetic tests can be used for numerous scenarios such as:

- Identifying an underlying diagnosis
- Determining carrier status
- Predicting future disease (e.g., Huntington disease, BRCA 1/2)
- Guiding therapeutic management (e.g., pharmacogenetic testing)
- Estimating risk for common disease

Diagnostic testing in a symptomatic individual may bring a sense of relief or closure to know the genetic cause. In pediatric cases, determining the genetic cause may ease parent guilt about whether they did anything to cause the condition or raise parent guilt if the condition was inherited.

Predictive genetic testing is one of the most well-studied scenarios as the tested individual may live healthy and asymptomatic for many years with the knowledge of their molecular diagnosis and impending condition. Although the potential for negative psychological reactions and reduced quality of life is significant, research has generally demonstrated tested individuals cope well regardless of the test result (Fanos et al., 2011; Lammens et al., 2010; Mariotti et al., 2010). These studies may be positively biased, however, as those who choose not to be tested have been under studied.

Genetic testing to learn one's estimated lifetime risk for common disease utilizes knowledge gleaned from genetic association studies and should be considered within the context of other biometric and family history indicators of risk. Studies have not demonstrated a significant psychological impact from this type of testing (O'Daniel, Haga, & Willard, 2010).

Individual Perceptions, Expectations and Coping

An individual's prior perceptions of a disease or condition can significantly affect not only the information they expect to learn from a test but also what they believe the result means and how they respond to it. Preexisting perceptions may be informed by lived experiences especially in the case of a positive family history, by societal views and/or perceived stigma, and by a personal assessment of resources to deal with the condition. The relationship between these dynamic factors in regards to genetic testing has been described by several models including the Health Belief Model, Model of Stress and Coping, the Common Sense Model of self-regulation, and the Theory of Planned Behavior (Gooding, Organista, Burack, & Biesecker, 2006; Marteau & Weinman, 2006).

Definition

Genetics focuses on heredity and its biological basis (genes). It is the science that examines how traits are passed from one generation to the next.

Various subfields can be identified. Robinson (2010) provided a simple but useful classification system, including the following:

1. Classical, or Mendelian, genetics, which describes how traits, physical or psychological characteristics, are passed from one generation to the next. The name Mendelian refers to Gregor Mendel, who had conducted scientific studies of the inheritance of traits in plants as far back as the 1860s, even though the significance of his work was not appreciated and acknowledged until the early twentieth century (see Edelson, 1999). The name transmission genetics also conveys a similar meaning, focusing on how traits are transmitted from one generation to another.
2. Molecular genetics, which focuses on the physiochemical structure of DNA, ribonucleic acid (RNA), and proteins. Classical genetic studies, e.g., twin studies, can be conducted without any knowledge of molecular genetics: It is not necessary to know the biological basis of inheritance of traits to determine that there is a genetic influence in the inheritance of the trait. DNA is discussed in more detail shortly.
3. Population genetics, which looks at the genetic composition of large groups of individuals. It can be defined as the field studying the genetic diversity of a subset of a particular species. It searches for patterns that help

identify and discuss the genetic signature of a particular group. This includes behavioral components of the genetic signature. Population genetics also provides insights into how the collective genetic diversity of a population influences the health of the individuals within the population, providing a direct link to its importance in Health Psychology and Behavioral Medicine.

4. Quantitative genetics, which employs sophisticated mathematical and statistical models to examine the statistical relationships between genes and the traits they code for, or encode. Quantitative genetics is interested in estimating how much variation in a given trait is due to genetic inheritance and how much is due to the environment (and interactions between genes and environmental influences). Heritability is an assessment of how much influence is due to genetic makeup.

The general familiarity with the acronym DNA (deoxyribonucleic acid) is such that the definition is almost never provided when using the acronym. Every time we watch a contemporary detective show on television we are almost waiting to hear about the DNA evidence that will indicate or refute a suspect's guilt. Nonetheless, the field of genetics existed well before the structure of DNA was proposed and published in 1953 by Francis Crick and Jim Watson (Watson & Crick, 1953) and supportive evidence published in separate papers in the same issue of *Nature* by Rosalind Franklin and Maurice Wilkins (Franklin & Gosling, 1953; Wilkins, Stokes & Wilson, 1953). The word "proposed" is deliberately used since Watson and Crick used the following words at the start of their paper: "We wish to suggest a structure for the salt of deoxyribose nucleic acid (D.N.A.)." They concluded their paper with one of the most beautifully understated sentences in scientific literature: "It has not escaped our notice that the specific pairing we have postulated [specific base pairs bonding to each other – see the ▶ DNA entry] immediately suggests a possible copying mechanism for the genetic material."

It was several years before definitive evidence was collected and published. In more recent years, molecular genetic knowledge has proved extremely helpful in many fields within Medicine, Behavioral Medicine, and Pharmaceutical Medicine.

Definition

Genital herpes is one of the most common sexually transmitted infections (STIs) in the United States. Genital herpes is caused by infection with herpes simplex virus 1 (HSV-1) and herpes simplex virus 2 (HSV-2), with the latter classification being the most common cause. About 1 out of every 6 individuals between the ages of 14 and 49 years old have genital herpes, many of whom are unaware that they are carrying the virus because they have not experienced any physical manifestations (Centers for Disease Control, 2011).

Transmission of genital herpes from one person to another occurs through direct contact with an infected cutaneous or mucosal area, which may include areas with active herpes lesions as well as areas in which herpes lesions are not visible. Once a first or "primary" exposure to HSV occurs, physical manifestations are typically evident within a week and may include painful and pruritic (itchy) lesions on or around the genital area, swollen inguinal lymph nodes, flu-like symptoms, and fever. These lesions typically heal within 2–4 weeks (National Institute of Allergy and Infectious Disease, 2011). Following this acute phase of infection, the virus becomes latent within the dorsal root ganglia of the spinal cord. An infected individual carries the virus for life; however, recurrent or "secondary" outbreaks are typically less severe and less frequent and primarily involve localized lesions.

An infected individual may reduce the risk of transmitting genital herpes to a sexual partner through proper condom use. However, it is important to note that infected individuals may "shed" virus before herpes lesions become visible or in between herpes outbreaks, meaning that sexual contact with proper condom use may still result in the transmission of genital herpes. As a result, individuals infected with HSV are recommended to abstain from sexual activity when symptoms of herpes are present (Centers for Disease Control).

Health care providers typically diagnose genital herpes by inspecting the infected area and taking a swab of the lesion to look for the presence of HSV. Additionally, blood samples may be collected to assess for the presence of HSV-1 or HSV-2 antibodies in the blood in between herpes outbreaks (U. S. Preventive Services Task Force, 2011).

Currently, there is no cure for genital herpes. However, outbreaks can be managed with antiviral medications. These antiviral medications are often effective for controlling the duration of an outbreak and the pain associated with herpes lesions. There is also some evidence that antiviral therapy may reduce the risk for genital herpes recurrence (National Institute of Allergy and Infectious Disease).

People with genital herpes may be at increased risk for contracting human immunodeficiency virus (HIV), the virus that causes AIDS, from an HIV-infected sexual partner. Furthermore, individuals who are immunosuppressed, including individuals living with HIV and those undergoing chemotherapy for cancer, may experience serious physical illness if infected with HSV, because their immune systems are less able to mount a proper immune response to an acute infection (National Institute of Allergy and Infectious Disease).

Finally, pregnant women with genital herpes may be at risk for transmitting HSV to a newborn during a vaginal delivery. Newborns may experience serious or fatal illness following exposure to HSV. As such, mothers with active genital herpes will usually deliver their babies via Cesarean section (U.S. Preventive Services Task Force).

Genome-Wide Association Study (GWAS)

Matthew A. Simonson
Institute for Behavioural Genetics, Boulder, CO, USA

Synonyms

GWA study; Whole-genome association study (WGAS)

Definition

Genome-wide association studies are designed to identify points of common variation in DNA that are associated with particular traits, including diseases and responses to medication (Wang, Barratt, Clayton, & Todd, 2005). By examining the genetic variants associated with traits related to health and disease, it is hoped that a better understanding of the etiology of physical and mental disorders, as well as responses to treatment, will be gained (Carlson, Eberle, Kruglyak, & Nickerson, 2004).

Individual differences between people in traits, such as personality, eye color, and height, are all highly influenced by genetic variation (Yang et al., 2010). The development of rare medical conditions, such as hemophilia and muscular dystrophy, is also influenced by genetic variation, while the same is true for more common forms of illness, such as heart disease, cancer, and obesity (Iles, 2008). Understanding how our genetic architecture influences the development of disease is a very high priority for current medical science. One major ambition of the GWAS approach is leading to the development of better treatments that target illness with increased precision and reduced risks (Carlson et al., 2004).

DNA is a molecule that contains the genetic instructions that regulate cellular activity and ultimately plays a large part in the development of traits in living organisms (Watson & Crick, 1953). The order of nucleotide bases in an organism's DNA determines how genetic instructions are executed, through the direct coding of proteins or through regulatory functions. Genetic variation is caused by differences in DNA sequence between individuals; these variants are referred to as *alleles* (Keller, Howrigan, & Simonson, 2011). When a difference in DNA sequence occurs at a single base position, it is called a single-nucleotide polymorphism, or a SNP (den Dunnen & Antonarakis, 2000). Most of the time, SNPs have no biological effect; however, sometimes a single-nucleotide alteration can change the function of a gene, or the regulation of genes, and have an effect on cellular functioning (Wang & Moult, 2001).

Approximately 10 million common SNPs exist in the human genome (Gabriel et al., 2002). Recent research has demonstrated that the 10 million variants cluster into groups where the states of SNPs are correlated with each other

(haplotypes) (International HapMap C, 2003). By carefully sampling the most informative SNPs from these haplotypes, much of the information on common genetic variants can be ascertained. Using DNA microarrays, the allelic state of hundreds of thousands of highly informative SNPs can be determined rapidly and at a low cost (Oliphant, Barker, Stuelpnagel, & Chee, 2002).

In a genome-wide association study, the association between alleles (states of SNPs on a microarray) and a phenotype of interest is assessed. When a trait is dichotomous (affected or not), the genomes of two groups of people are compared. Subjects with some trait of interest (cases) are compared to people without this trait (controls). When a trait is continuous, such as height, associations between the state of SNPs and the degree of a continuous trait are examined. By examining which alleles are associated with the phenotype (or degree of phenotype), genetic differences between individuals can be identified (Hirschhorn & Daly, 2005). GWAS is a hypothesis-free method of analysis, in the sense that no prior candidate allele is investigated for association with a phenotype; instead, the entire genome is scanned for significant associations (Kitsios & Zintzaras, 2009).

Several factors can influence the validity of GWAS results and must be controlled for through methods of data cleaning. Some of these include:

Admixture/Ancestry. Spurious associations can arise when performing a GWAS on a sample composed of subjects from different ancestral populations. Part of the sample that shares common ancestry could have higher rates of the phenotype being investigated for nongenetic (e.g., cultural) reasons, resulting in alleles indicative of ancestry being associated with the trait in question rather than true risk alleles. By controlling for genetic ancestry, false associations can be avoided (Hirschhorn & Daly, 2005).

Data Artifacts. Due to the large number of SNPs examined on a microarray, technical artifacts are likely to occur at some SNPs and can result in false associations. Several methods of data cleaning and study design exist for detecting and controlling for the effects of technical artifacts that exist in SNP data (Williams & Haines, 2011).

Multiple Testing. The aim of multiple testing correction procedures used in a standard GWAS is to simultaneously maximize the likelihood of detecting a true association, if one exists, while at the same time minimizing false associations that are due to capitalizing on chance (Moskvina & Schmidt, 2008).

Given the standard alpha level of 0.05, one expects to get an average of 5 false associations for every 100 independent tests performed on data where no true association exists. For genome-wide association studies, this fact presents a major problem for two reasons. The first is due to the excess of Type I errors (false positives) that will occur due to the very large number of tests for association between SNPs and disease that are being performed. The second problem is that the simple correction method commonly used to remove multiple testing bias from repeated independent tests, the Bonferroni correction, leads to an excess of Type II errors (failed detection of true associations) when applied to GWAS data, because regions of the genome are not entirely independent. Accepted correction values based on replication of results and permutation procedures have been developed to overcome these problems (Johnson et al., 2010).

Overall, GWAS has been very successful at identifying regions associated with disorders and phenotypes. However, the majority of these associated variants have only small effect sizes individually in terms of risk contribution (Clarke & Cooper, 2010). With increased sample size, GWAS will likely provide further insight into the human genome. As sample sizes increase, the power to detect small effects increases. For example, a recent GWAS involving approximately 180,000 subjects was able to explain approximately 10% of the genetic variance in height while simultaneously identifying each significant locus that contributes to this estimate (Lango Allen et al., 2010).

Definition

The discipline of genomics is described slightly differently by different authorities. Brown (2009) defines it as the use of high-throughput molecular biology technologies to study large numbers of genes and gene products all at once in whole cells, whole tissues, or whole organisms. The Britannica Guide to Genetics (2009) describes it as the study of the structure, function, and evolutionary comparison of whole genomes, where the genome refers to the complete genetic complement of an organism.

The discipline of genetics is itself a relatively young science and is concerned with how traits are passed from one generation to the next. Since the advent of genomics more recently, the term transmission genetics is commonly used to represent what had previously been simply called genetics. The mathematics of transmission genetics were first described by Mendel in 1866 (see Edelson, 1999), approximately 150 years ago. In contrast, while the word genome appeared relatively early in the twentieth century, genomics as a new form of experimental biology is a recent phenomenon. Raw biological information, such as the sequence of nucleotide base pairs in a DNA molecule, is itself complex, and the

discipline of bioinformatics is useful. The next step is to integrate all of this information and to address questions about what is happening in very complex systems when tens of thousands of different genes are interacting simultaneously (Brown, 2009). An understanding of genomes and genomic technologies builds upon the knowledge of transmission genetics (how hereditary information is transmitted from one generation to the next) and molecular biology (how genes function to control biochemical processes within the cell).

Definition

The genotype of an individual refers to their specific genetic constitution. It can apply to the entire genetic constitution of an individual or to the combination of alleles at a specific locus.

All individuals carry two homologous copies of their genome, one copy inherited from their father and one copy from their mother. If the gene or position contains variation, the variants are called alleles. Alleles for each gene contain differences in their nucleotide sequence and may codify proteins with different properties. If the allele inherited from the mother is different from the allele inherited from the father, then the individual is termed heterozygous for that trait or gene. If these two alleles are identical, then that person is termed homozygous for that trait or gene. The genotype for one gene describes its allelic composition.

In diploid organisms, a maximum of two alleles are present for each gene or trait. For instance, in Huntington's disease, an affected individual's genotype consists of at least one allele of the gene that carries a mutation, i.e., a change in the DNA sequence, that leads to a defective protein, called Huntingtin (Walker, 2007). However, in general, more than two alleles can exist depending on the type of variation of interest.

Definition

Geographic information systems (GIS) are a means of visualizing and analyzing spatial data, usually in the form of maps (Longley, Goodchild, Maguire, & Rhind, 2005).

Description

An early example of a GIS was John Snow's work mapping cases of cholera in nineteenth-century London, revealing outbreaks clustered around a contaminated water pump. Modern GIS can be used to analyze a range of material from scanned maps and aerial photographs to topographic models and boundary data. Different forms of quantitative and qualitative data can thus be connected to points and regions within geographic space. The powerful analytical tools offered by desktop systems such as ArcGIS and MapInfo are used by professionals in a wide variety of fields, including urban planning, resource management, epidemiology, surveying, and the military. Even at a quite simple level, the outputs of GIS analysis can be striking. An example might be a choropleth map, where different regions are shaded according to characteristics – such as the level of social deprivation – to reveal areas where these characteristics are concentrated. GIS treats datasets as *layers*, allowing them to be compared by placing one on top of another. Thus, clusters of patients suffering from heart disease in areas with high levels of social deprivation can be examined against public transport corridors to determine the accessibility of specialist treatment centers. In a more advanced vein, it is possible to test whether there is a statistically significant relationship between incidents of respiratory problems and people living downwind of an incinerator or to model different flooding scenarios and weigh the costs of improving flood defenses against likely property damage.

Increasingly, GIS has migrated onto the Web through services such as Yahoo! Maps, Open Street Map, and Google Earth, meaning that many people use GIS daily without even realizing it. While these services lack the advanced analytical capacity of proprietary desktop systems, many allow users to visualize their own data as overlays onto the basic maps provided. This might, for example, be tracks of jogging routes recorded by an individual using their own global positioning system (GPS) device or photos linked to the location where they were taken. As GPS is increasingly embedded in portable devices, especially smart phones, a number of lightweight mobile GIS applications are becoming available. These systems move beyond basic navigation functions to allow collection of field data on a mobile device, tagged to spatial location using GPS. This online mapping revolution enables many more people to use GIS, and researchers are increasingly interested in *crowdsourced* data (Crampton, 2009). Here, nonspecialists gather field data of different kinds and post them to a central database. This has a number of applications, for example, in disaster management, where it can be difficult for survey teams to cover

a sufficiently wide area to accurately determine where best to intervene and thus can benefit from local eyes-on-the-ground. This, of course, raises questions about the accuracy and reliability of the data gathered, but offers tremendously interesting possibilities for research and other applications.

Definition

The Geriatric Depression Scale (GDS) is a self-report instrument designed to assess depressive symptoms in older adults. The GDS was first developed as a 30-item measure by Jerome Yesavage and colleagues at Stanford University (Yesavage, Brink, Rose, & Lum, 1983), in response to concerns that available depression inventories contained many items that overlapped with common aging processes (including dementia, sleep disturbance, and gastrointestinal symptoms). The scale was therefore designed to avoid somatic symptoms (such as psychomotor retardation or pain) as well as questions that the authors believed would create defensiveness in older persons (such as those assessing sexual interest or suicidality). To simplify responding, the authors chose a yes/no scale for each item. In contrast to measures based around criteria for major depression taken from the Diagnostic and Statistical Manual of Mental Disorders, the GDS was not originally intended to be a diagnostic or screening measure, although it is frequently used as such in clinical settings. A 15-item short form of this measure and a 4/5 item ultra-short form have also been developed (the GDS-15 and GDS-4, respectively) (Mitchell, Bird, Rizzo, & Meader, 2010; Sheikh & Yesavage, 1986). Although subscales are sometimes used in research efforts, the scale is generally treated as unidimensional, with the total number of "yes" responses used as the outcome.

The GDS has generally performed well in psychometric and clinical testing. In a recent meta-analysis of 25 studies conducted in medical settings and nursing homes, Mitchell et al. (2010) reported overall sensitivity of the GDS-30 as 81.9% when compared to a structured clinical interview for major depression, with a specificity of 77.7%. Similar results were demonstrated in tests of the GDS-15 (sensitivity = 84.3%; specificity = 73.8%). Although only a handful of studies have examined the psychometric properties of the GSD-4/5, early results are promising, with reported sensitivity of 92.5% and specificity of 77.2% (Mitchell et al., 2010).

Despite the fact that the GDS is one of the only scales to be developed specifically to assess depression in older persons, most studies comparing its performance to "gold standard" measures (such as the Patient Health Questionnaire, the Center for Epidemiologic Studies Depression Scale, or the Beck Depression Inventory II) show it to be equally effective in terms of diagnosing major depression (Laprise & Vezina, 1998; Watson, Zimmerman, Cohen, & Dominik, 2009). However, there is some evidence that the GDS may outperform other standardized measures of depression in older adults for whom there is a significant overlay of medical symptoms (Low & Hubley, 2007; Thompson et al., 2011). It has also been suggested in the literature

that some clinicians prefer the GDS over other measures because they find specific questions to be more clinically relevant to their older patients.

The usefulness of the GDS in cognitive impaired older adults is equivocal. Several prospective studies comparing GDS scores to clinician ratings in older adults with cognitive impairment have demonstrated no (Laprise & Vezina, 1998) or very small differences (Burke, Miller, Rubin, Morris, & Berg, 1988) in sensitivity, reliability, and validity. Other studies have demonstrated that although the GDS is unaffected in those with mild cognitive impairment, it performs poorly in severely affected Alzheimer's patients (Debruyne et al., 2009).

The GDS has now been translated from English into a number of other languages, including Spanish, Korean, Japanese, Cantonese, Portuguese, and Arabic.

Care of older adults

Definition

By definition, geriatrics is a subspecialty of medicine that focuses on proving health care to older adults, generally considered to be those 55 years of age and older. The goal of geriatric care is to focus on health promotion and disease prevention and optimize quality of life versus length of life. Moreover, much of the focus is on use of behavioral interventions to accomplish these outcomes whenever possible.

Geriatric medicine is interdisciplinary, and to be provided at the highest level, it requires input from nursing, social work, physical therapy, occupation therapy, speech therapy, psychology, nutrition, and pharmacy, among others. The focus of care tends to be more syndrome than disease driven and addresses such things as

functional performance, falls, urinary incontinence, frailty, congestive heart failure, and dementia, among others.

Description

Given the central importance of prevention and disease/syndrome management in care of older adults, knowledge of behavioral medicine is critical to the training and practice of those in geriatric medicine. At the same time, the behavioral interventions and approaches used for those who provide care to older adults are different than those used with younger individuals. For example, Stage of Change focused interventions may not be as effective for smoking cessation among older adults compared to those who are younger and motivational interviewing may not be useful for those who are older with cognitive impairment.

The special knowledge and skill set of those who practice geriatric medicine is reflected by the ability to identify disease and the atypical presentation of disease among these individuals. For example, symptoms of an infection in older adults often are vague and nonspecific, and the only indication of a problem may be acute delirium or a fall. Pneumonia, for example, may or may not present with fever, but will often present as dehydration, confusion, or a fall.

The management of disease among older adults is also different and central to geriatric medicine. For example, older adults require specific attention to medications and are at particularly risk to complications from polypharmacy. Those with expertise in geriatric medicine need to decipher the need for and appropriate use of medications for multiple medical disorders and counsel older adults about the safety and efficacy of using over-the-counter medications and herbals. The challenges of frailty, complex comorbidity, different patterns of disease presentation, slower response to treatment, and requirements for social support call for special medical skills.

Those with a knowledge of geriatric medicine understand that the presentations of illness among older adults is often nonspecific and thus any presenting problem may be indicative of an acute medical problem. Geriatricians also address and in fact focus on clinical problems such as falls, immobility, incontinence, and confusion as well as adverse drug reactions. Geriatrics tend to manage a broad range of illnesses, acute and chronic, such as stroke, heart disease, infections, diabetes, delirium, and the dementias.

At its core, geriatric medicine requires comprehensive assessment of older adults. This involves working closely with other members of the interdisciplinary team such as nurses, therapists, pharmacists, dietitians, social workers, and many other health professionals. There is an increased focus and need for interdisciplinary teamwork as the number of older adults increases and those with expertise in geriatric medicine decrease.

Those that practice geriatric medicine do so out of a true dedication to care of older adults and consider it an honor to interact with these individuals. The American Geriatrics Society provides some insight about the wonderful benefit of this type of work on their webpage. Examples of comments made by those include the following: “Often, when you work with older people you stumble into a moment of drama when you’re listening to them tell a story. It’s fine to read history in books, but to talk with someone who’s lived it is precious. That’s one of the joys of geriatric practice;” and “Perhaps the most satisfying aspect of geriatrics for me is the opportunity to meet the people who are the history of our nation.”

United States medical school graduates (USMDs) are choosing specialties other than geriatrics due in part to compensation given for the years of additional training. This will have a major impact on the availability of physicians with expertise in care of older adults. It is anticipated that by 2050 there will be 1.6 geriatricians/10,000 people. To address the increased need for more individuals with knowledge of geriatric medicine, educational programs across all disciplines are attempting to integrate geriatric coursework into programs and

there is a trend toward interdisciplinary educational endeavors to further facilitate training in geriatric medicine.

Definition

Gerontology stems from the Greek words "geron" which means "old man" and "logy" which means "study of." Gerontology is the study of the social, psychological, and biological aspects of aging. Gerontology is often confused with the term geriatrics, which addresses the medical aspects of aging with a focus on disease and disease management.

Gerontology is the study or management of aging-related issues and may include healthy aspects of aging as well as age-related disease. It also includes the study of aging within society and the impact that this has on society. Information learned through the work of gerontologists can be applied to policies and programs and to the development of systems and models of care within communities.

A critically important aspect of gerontology is the interdisciplinary aspect of this work. Gerontology includes and requires input from medicine, psychological, sociology, physiology, etc. The complexity of aging-related issues requires this interdisciplinary approach.

The field of gerontology has grown since the first early gerontologists back in the 1940s. Interdisciplinary gerontology organizations were developed such as the Gerontological Society of America in 1945 and the first academic research center devoted exclusively to the study of aging, the Ethel Percy Andrus Gerontology Center at the University of Southern California likewise was established around this time. Approximately 20 years later in 1967, the nation's first master's degree programs in gerontology were initiated with grants provided by the U.S. Administration on Aging. In 1975 the University of Southern California's Leonard Davis School of Gerontology became the country's first school of gerontology within a university and, shortly thereafter, offered the first Ph.D. degree in gerontology. Since that time, a number of other universities have formed departments or schools of gerontology or aging studies and established interdisciplinary gerontology PhD programs.

The increased interest in gerontology is in response to the rapidly growing number of older adults in the United States. Moreover, it is anticipated that the number of individuals over the age of 85 will increase from 5.3 million to 21 million by 2050 (http://www.answers.com/topic/gerontology#ixzz1bTu2NTaA, Aging Stats: http://www.agingstats.gov/agingstatsdotnet/Main_Site/Data/2008_Documents/Population.aspx). To

best respond and manage the physical and psychosocial health needs of this rapidly growing group of individuals, there is a critical need for more individuals to consider gerontology as a profession whether this be from a clinical perspective or research. The opportunities within gerontology are prevalent within academic settings, in service areas such as retirement housing, assisted living, exercise programs, health care, adult education, travel, and entertainment. Gerontology has helped expand our scientific knowledge base related to aging issues for the older adults and the aging community and the need for knowledge explosion in this area is great.

Gestation

Department of Psychology, University of Zurich, Binzmuehlestrasse, Zurich, Switzerland

Gravidity; Pregnancy

Definition

Gestation is the period of time during which the fetus develops in the uterus of the mother. It begins with conception and ends with birth.

The word originates from the Latin verb *gestare*, meaning to bear. When a mother is carrying more than one fetus, as is the case with twins or triplets, the term "multiple gestation" or "multifetal gestation" is used.

Description

Gestational age is the age of an embryo, fetus, or newborn measured from the time of conception. Knowing the gestational age is essential in monitoring fetal development and determining the treatment of complications during pregnancy.

Embryologists measure the beginning of gestation from ovulation. This typically occurs within 1 or 2 h before conception. However, because most women do not know the exact time of ovulation, it has become practice to calculate the beginning of gestation from the first day of the last menstrual cycle which normally takes place approximately 2 weeks prior to ovulation.

In the past, different methods of measuring the beginning of gestation led to confusion and inconsistent usage of terminology. For this reason, the Committee on Fetus and Newborn (COFN) of the American Academy of Pediatrics (AAP) suggested determining gestational age from the first day of the last menstrual cycle. This method has proven reliable in estimating a normal duration of gestation and adds up to approximately 40 weeks or 280 days. In cases of pregnancy achieved by assisted reproductive techniques (where the precise date of conception can be determined), the length of gestation adds up to 38 weeks or 266 days. In such cases, 2 weeks are added to the conceptional age in order to monitor fetal development and growth outcome in a standardized fashion and to be able to compare results across studies.

The gestational period can be clustered into three equal phases that are approximately of 3 calendar months duration or 13–14 weeks long. Depending on the method of calculation, the first trimester ranges from week 1 to the completion of week 13 (1–14, respectively), the second trimester from week 14 to week 26 (15–28), and the

third trimester extends from week 27 to week 39 (29–42). These three trimesters can be regarded as reference intervals in the progression of gestation and fetal development. When dealing with eventual obstetric problems, the more precise method of calculating gestational age uses completed weeks and days, for example, 28 + 2 weeks of gestation, for 28 completed weeks and 2 days.

The embryonic period is defined as beginning 3 weeks after ovulation and fertilization and extends to week 8 after fertilization or to week 10 after the last menstrual cycle. It is followed by the fetal period which ends at birth.

A Biopsychosocial Approach to Pregnancy

Pregnancy-Induced Alterations of the Endocrine and the Autonomic Nervous System (ANS)

Every female organ system goes through remarkable anatomical and functional adaptation during gestation. The fact that these drastic alterations return to the pre-pregnant state after delivery and lactation is equally fascinating.

The Maternal Hypothalamus-Pituitary-Adrenal (HPA) Axis

The maternal neuroendocrine system undergoes significant changes as well. The placenta becomes an additional source of hormone production. From week 8 to week 10 of gestation onward, it induces a drastic rise of maternal plasma corticotropin-releasing hormone (CRH) which leads to a 1,000-fold higher level than in the nonpregnant state. It is furthermore assumed that placental CRH stimulates the HPA axis and causes an increase in maternal adrenocorticotropin (ACTH) and cortisol levels. Therefore, pregnancy has also been described as a state of hypercortisolism.

In the nonpregnant state, cortisol regulates the HPA axis activity through a negative feedback mechanism. By contrast, during gestation cortisol has a stimulating effect on the CRH production in the placenta. However, the exponential rise of CRH does not lead to an overstimulation of the maternal HPA axis, because CRH is bound to the CRH-binding protein (CRH-BP) thereby reducing its bioactivity. While maternal plasma concentrations continue to rise with progressing gestation, approximately 30 days before birth CRH-BP levels suddenly drop by about 50%. The result is an abundance of free bioactive CRH and a cascade of reactions is triggered leading to the onset of labor and delivery. Findings have linked higher CRH levels in early gestation with a higher risk for preterm delivery. When a certain level of CRH is reached during pregnancy, the onset of parturition (i.e., the process of giving birth) is activated. It has therefore been suggested that CRH functions as a placental clock.

Although gestation induces profound changes of the maternal HPA axis, the circadian rhythm is nevertheless maintained during pregnancy.

After delivery, the placenta is expelled from the body and maternal cortisol levels return to normal. The state of hypercortisolism is followed by a temporary suppression of the CRH secretion from the hypothalamus.

The Interaction Between the Maternal HPA Axis, the Fetal HPA Axis, and the Placenta

In early gestation, a negative feedback mechanism regulates the HPA axis of the fetus. Later, however, placental CRH enters into the fetal circulation through the umbilical vein and begins stimulating the fetal HPA axis. In addition, maternal cortisol is to a certain degree additionally able to cross the placenta and stimulate the fetal HPA axis. One third of fetal cortisol levels are ascribed to maternal levels. Fetal cortisol finds its way through the umbilical arteries back into the placenta and stimulates the production of placental CRH. Thus, by the end of gestation a positive feedback loop is established. The resulting massive increase of cortisol in the fetus is necessary for the development and maturation of fetal organs, such as

the brain and the lungs. An overexposure to glucocorticoids can, however, have detrimental effects on the fetus.

The ANS During Gestation

Maternal blood volume begins to increase during the first trimester. At 32–34 weeks of gestation, it can reach levels of up to 45% above the pre-pregnant values. This expansion in blood volume, also called hypervolemia, results from an increase in plasma and red blood cell volume. It serves the functions of meeting the metabolic requirements of the enlarged uterus, providing enough nutrients to the placenta and fetus, enabling blood flow back to the heart when the mother is in a supine or erect position, and protecting her from excessive blood loss at delivery.

During gestation, the resting heart rate is increased by approximately 10 beats per minute and from week 5 there is an increase in cardiac output. The increase in cardiac output is caused by this heart rate acceleration and a decrease in systemic vascular resistance. The latter originates from a vasodilatory effect of progesterone and prostaglandins. Correspondingly, arterial blood pressure gradually falls. After reaching a nadir at 24–26 weeks, these levels begin to rise again until delivery.

In late gestation, the uterus pushes against the pelvic veins and the inferior vena cava aggravating venous return from the lower body. As a result, heart rate, cardiac output, and blood pressure are influenced by the body position.

Conflicting findings have been reported concerning epinephrine and norepinephrine that range from no changes to decreased or even increased levels during gestation. The diurnal rhythm of epinephrine and norepinephrine, however, seems to be preserved.

With regard to heart rate variability (HRV), the high frequency component reflecting the parasympathetic branch of the ANS seems to be decreased in comparison to nonpregnant women, while the low frequency component representing the sympathetic branch seems to show no differences. Findings indicate no alterations in the balance between the sympathetic and parasympathetic branches during gestation.

Stress Reactivity

Maternal stress and anxiety during gestation is related to dysregulated physiological stress systems as well as pregnancy complications. In order to better understand this association, it is essential to examine the acute maternal stress response of the HPA axis and the ANS under controllable circumstances. In studies using standardized laboratory stressors (the cold pressor test, the mental arithmetic test, or the Stroop color-word test) comparing nonpregnant and pregnant women, the physiological stress reactivity of pregnant women appears to be increasingly attenuated with progressing gestation. It has therefore been assumed that pregnant women become less sensitive to the impact of stress with advancing gestation. Similar results have been found in studies using the Trier Social Stress Test and the cortisol awakening response, the latter of which measures the stress response in a more natural but nevertheless standardized setting.

Emerging findings indicate that psychological factors can alter the stress response of the HPA axis and ANS during pregnancy, providing new insight on how maternal prenatal stress may affect the course of gestation, fetal development, and maternal and child well-being after birth.

Medical Complications During Gestation

Women suffering from obstetric complications often experience anxiety about their own well-being and that of their unborn child. These women can benefit greatly from psychological health treatment.

Following are a few common medical complications during gestation:

- Fetal growth restriction is defined as fetal weight that is at or below the 10th percentile

for gestational age. Intrauterine growth restriction (IUGR) is an often-used synonym.
- Gestational diabetes describes a form of diabetes (high blood sugar) that begins (or is diagnosed for the first time) during gestation. The high blood sugar usually returns to normal levels after delivery.
- Gestational hypertension occurs when the maternal blood pressure rises rather than falls during the second (or third) trimester of gestation. In some cases, it may be a sign of beginning preeclampsia.
- Preeclampsia is characterized by (a) an increased blood pressure, (b) edema, and (c) an excess of proteins in the urine. It can develop after the 20th week of gestation.
- The HELLP syndrome is thought to be a severe manifestation of preeclampsia. The acronym stands for hemolysis (H; breakdown of red blood cells), elevated liver enzymes (EL), and low platelet count (LP). It is a syndrome with a series of symptoms such as headaches, nausea and vomiting, abdominal pain, increased blood pressure, and visual problems.
- Hyperemesis gravidarum is severe, persistent, and uncontrollable nausea and vomiting during gestation that may lead to weight loss, electrolyte disturbance, and dehydration. This condition is not to be confused with morning sickness which occurs in many pregnant women.
- Spontaneous abortion (miscarriage) is defined as the involuntary loss of the fetus before 20 weeks of gestation. Over 80% of spontaneous abortions occur during the first 13 weeks of gestation. Many women do not realize that they are pregnant when this occurs. Both mother and father often experience feelings of bereavement and grief. Psychological interventions can help here as well.
- Preterm birth defines a birth before 37 weeks of gestation. Studies have associated pregnancy anxiety, prenatal depression, and chronic stress with preterm birth and low birth weight (which is defined as birth weight of 2,500 g or less).

Psychosocial and Behavioral Factors Influencing Gestation

Psychosocial and behavioral factors can have a strong influence on the course of gestation and have been associated with pregnancy complications and birth outcome. While the detrimental influence of poor health behavior such as smoking, alcohol and drug abuse, malnutrition, inadequate weight gain, and physical strain are well established, the negative impact of psychosocial stress has recently received increased attention.

Psychological Maladaptation During Gestation

Although pregnancy is ideally expected to be a happy experience in life, adapting to the physical, hormonal, psychological, social, and socioeconomic changes can be challenging. Gestation is, therefore, also a vulnerable phase that can be sufficiently stressful to cause psychological maladaptation. A Swedish study found that every fourth pregnant woman expressed considerable fear of childbirth. Other studies have reported no heightened or even a decreased risk of mental problems in pregnant women compared to nonpregnant women. All in all, the prevalence rates show inconsistent results depending on the country or region in which the study was conducted, the measuring instruments used, whether psychiatric disorders or psychological symptoms were examined, or how the investigated time period was defined (during pregnancy only, postpartum only, or both combined), among other factors. For example, a report of the World Health Organization (WHO) and the United Nations Population Fund (UNFPA) in 2008 states that the prevalence rates of mental disorders during gestation tend to be twice as high in low- and middle-income countries as in high-income countries.

Several studies have called the attention to maternal suicide as the leading cause of death during gestation and the postpartum period with

significant higher rates compared to nonpregnant and nonpuerperal women.

Despite the unresolved question whether prevalence rates of psychiatric disorders are higher during gestation or not, there is general consensus that the rates worldwide are high and that mental health problems during gestation appear to be greatly under-identified and untreated.

Examples of possible risk factors discussed in the literature for psychological maladaptation and psychiatric disorders during gestation are adolescent or unwanted pregnancy, an unsupportive marital or partner relationship, previous stillbirth, or repeated miscarriages. Also, women belonging to an ethnic minority seem to be at an increased risk of experiencing a depressive disorder during the prenatal or postpartum period. Further risk factors for psychological maladaptation include trauma, domestic violence, multiple stressful life events, chronic stress, poverty, and lack of financial resources.

Psychiatric disorders during gestation are associated with adverse birth outcome and poor maternal and infant mental health in the postpartum period.

Prevention of Psychiatric Disorders During Gestation

The fact that psychiatric disorders often remain unidentified and untreated indicates that much needs to be done in the field of prevention. A vital measure would be the correct and early identification of pregnant woman at risk and improving access to psychological health treatment. The WHO and the UNFPA suggest including prenatal mental health care in general antenatal care.

Some studies on the impact of partner support and social support have found a buffering effect of these factors on anxiety and depressive symptoms during gestation. Further psychosocial resources such as self-efficacy and the experience of daily uplifts seem to attenuate the psychological as well as physiological response to acute stress in pregnant women. In one study, a simple intervention instructing pregnant women to avoid stress and increase relaxation in everyday life caused a decrease in the perception of stress, negative affect, and morning cortisol levels.

However, broad systematic studies on the impact of psychological treatment still seem to be scarce, calling for further research in this field.

Strengthening coping strategies in the pregnant woman and enhancing resilience through behavioral medicine interventions may greatly reduce maternal stress and prevent related psychiatric disorders and protect the mother and infant from their detrimental effects.

Ghrelin

Yoshiyuki Takimoto
Department of Stress Science and Psychosomatic Medicine, Graduate School of Medicine, The University of Tokyo, Bunkyo-ku, Tokyo, Japan

Definition

Ghrelin is a 28-amino acid peptide that has the particularity to be octanoylated in the serine in position 3. Ghrelin is a hormone produced mainly by the endocrine X/A-like cells of the stomach submucosa that stimulates hunger. Ghrelin is an endogenous orexigenic peptide and considered the counterpart of the satiety hormone, for example, leptin. Plasma ghrelin is regulated by several factors. A key regulator of plasma ghrelin level is food intake. Plasma ghrelin levels increase under starvation and decrease after meals in response to an increase of glycemia. Ghrelin stimulates appetite by acting on the hypothalamic arcuate nucleus. Ghrelin activates the nucleus of tractus solitaries communicating with ARC through afferent vagal stimulus in the stomach. Moreover, ghrelin modulates gastric acid secretion and motility. Ghrelin

is also secreted in the hypothalamic arcuate nucleus, where it dose-dependently stimulates growth hormone secretion.

Glucocorticoids

Definition

Glucocorticoids are a group of hormones that share steroidal structure and affect every tissue in the body due to the wide presence of their receptors. As indicated by their name, glucocorticoids have a significant role in regulating the metabolism of glucose.

Description

Glucocorticoids are released from the adrenal cortex in response to a cascade of hormonal events initiated by the release of corticotrophin-releasing factor (CRF) from the paraventricular nucleus (PVN). CRF reaches the median eminence of the hypothalamus through the portal circulation where it then activates the release of adrenocorticotropic hormone (ACTH) into the systemic circulation from the corticotrope cells of the anterior pituitary. Upon reaching the cortical part of the adrenal gland, ACTH stimulates the synthesis and release of glucocorticoids – most notably cortisol – in humans.

Glucocorticoids are derived from a common precursor, cholesterol, formed from circulating lipoprotein. The formation of cortisol takes place in the intermediate zone of the adrenal cortex, an area called Zona fasciculata. About 95% of cortisol is usually bound to corticosteroid-binding globulin (CBG), and the remaining free cortisol enters cells to affect their metabolic activity. The liver is the main site for cortisol metabolism, and free cortisol is excreted in urine. The daily secretory rate of cortisol is 20–30 mg/24 h, and its highest level is obtained in the morning (10–20 μg/dl) and lowest level (2–5 μg/dl) is reached in the early evening hours.

Glucocorticoid Receptors. There are two types of receptors, mineralocorticoid receptor (MR) and glucocorticoid receptor (GR). MR has a high affinity for cortisol and is found primarily in the limbic system. When occupied, MR serves as the major receptor regulator of normal activity of the hypothalamic-pituitary-adrenocortical (HPA) axis. GR is more widespread and has a lower affinity for cortisol. GR becomes occupied when there are higher levels of circulating cortisol. When cortisol concentrations are high, such as during diurnal peaks or under conditions of stress, this receptor may be up to 60%

occupied. Because of the wide distribution and different levels of sensitivity of both types of receptors, a wide range of peripheral and central nervous system functions are mediated by their actions.

Effects of Glucocorticoids

Metabolic Effects. Glucocorticoids exert numerous peripheral effects that lead to changes in metabolic activities. For example, one of cortisol's main functions in the periphery is to make energy stores available for use throughout the body. This happens through multiple processes. Cortisol increases the expression of the enzymes that are responsible for a process known as gluconeogenesis, and this occurs primarily in the liver leading to the increased synthesis of glucose. Cortisol also decreases glucose uptake by cells in muscles and adipose tissues while also stimulating the release of fatty acids from adipose tissue leading to further increase in gluconeogenesis. The results are a net increase in plasma concentrations of glucose as well as amino acids.

Immune Effects. As a group of hormones, glucocorticoids are known to suppress the immune response and are used to suppress inflammation. These effects take place because glucocorticoids increase the expression of anti-inflammatory proteins, while they also suppress the expression of pro-inflammatory proteins. The increased levels of cortisol in response to stress have been seen as a mechanism to regulate changes in immune activity caused by stress. This is consistent with the hypothesis that stress-related glucocorticoids activity helps curtail the activity of endogenous cytokines and other stress-reactive immune functions. This action helps prevent the occurrence of harmful effects that may be produced by an unchecked immune response. Because of the immune suppression effects of glucocorticoids, they have been used in the treatment of various conditions that involve increased immune activity.

Central Effects. Glucocorticoids have a wide range of effects on central nervous system functions. These central effects are also implicated in the development of affective disorders. One of the primary functions of glucocorticoids is regulating their own release. For example, cortisol regulates its own secretion through its feedback effects on the pituitary, hippocampus, medial region of the frontal cortex, and central amygdala. Cortisol action includes modifying CRF expression leading to reduced release. Cortisol also decreases secretion of ACTH and pro-opiomelanocortin (POMC) from the pituitary. Because it influences gene expression of adrenergic receptors, it regulates effects of catecholamines.

There has been also evidence that cortisol affects cognitive functions, and studies that involved blocking glucocorticoids activity lead to impairment in the recall of emotionally relevant information. It has also been shown that fear learning associated with high cortisol levels leads to stronger consolidation of this memory and that memory performance materials not related to stress are reduced by glucocorticoids. Studies have also shown that formation of long-term memories occurs efficiently when glucocorticoid levels are mildly elevated. Higher levels or absence of glucocorticoids using adrenalectomy was associated with poor formation of long-term memories. Stress hormones have also been associated with reduced retrieval of stored information.

Research has demonstrated dysregulation in cortisol release usually characterized by high basal levels and low sensitivity to cortisol feedback in patients with depression. There is also evidence that antidepressants help restore the normal pattern of cortisol release. Patients with depression have greater ACTH and cortisol secretion, greater free cortisol in urine, and increased cortisol and CRF levels in cerebrospinal fluid compared with nondepressed controls. This dysregulation is also evidenced by greater incidence of escape from a test called dexamethasone suppression test, which test the feedback effects of cortisol on the brain.

Cardiovascular Effects. Glucocorticoids have various cardiovascular effects. For example,

cortisol may increase cardiac output by its effects in enhancing beta adrenergic sensitivity and increasing the synthesis of epinephrine. The latter effect is caused by cortisol's effect in stimulating phenylethanolamine-*N*-methyltransferase (PNMT), resulting in increased epinephrine synthesis, and by inhibiting the catabolic actions of catechol-*o*-methyltransferase (COMT) on catecholamines. Cortisol may act in the kidneys to increase the plasma volume by causing a fluid shift from intracellular to extracellular compartments increasing volume retention, and contributing to increased stroke volume and cardiac output. In addition, cortisol increases alpha adrenergic sensitivity contributing to increased vascular resistance and leading to increased blood pressure.

Definition

Glucose is a monosaccharide (i.e., simple sugar), which is an essential form of energy for cells and organs in the human body. Glucose is an important carbohydrate that is imperative for the survival of organisms.

Description

Glucose is the usable form of energy in humans. Following ingestion, carbohydrates in the stomach are broken and converted to glucose. Glucose then passes through the stomach and enters the bloodstream. Glucose metabolism triggers insulin secretion from the ß-cells in the pancreas, which are responsible for endogenous insulin production. Insulin circulating in the bloodstream binds to receptors facilitating the uptake of glucose into the red blood cells. Glucose can then be used for energy, or converted to glycogen for storage in the liver, muscles, and fat. Glucose metabolism is a homeostatic mechanism that is essential for human survival.

Blood glucose is measured on a continuum. The normal range of blood glucose is between 4.0 and 7.0 mmol/L, or 82–110 mg/dL. When concentrations fall below the lower bound, it is considered to be a state of hypoglycemia (i.e., low blood glucose). When concentrations surpass the upper bound of this range, it is considered to be

a state of hyperglycemia (i.e., high blood glucose). Among healthy individuals, actions of the pancreas maintain blood glucose homeostasis. When the availability of metabolized carbohydrates is low, resulting in a decline in plasma glucose concentration, the α-cells of the pancreas secrete glucagon. Glucagon is a hormone that facilitates the conversion of glycogen in the liver, muscles, and fat to glucose that is released into the bloodstream to restore euglycemia (i.e., normal blood glucose concentration). In the presence of excess circulating blood glucose, resulting in a state of hyperglycemia, insulin is secreted from the ß-cells of the pancreas to facilitate glucose uptake and conversion to glycogen for storage. Disruption of this metabolic process is a hallmark feature of diabetes (i.e., type 1 diabetes mellitus, type 2 diabetes mellitus, gestational diabetes mellitus).

Glucose Meters and Strips

Department of Pediatrics, University of Miami, Miami, FL, USA

Synonyms

Glucometer; Point of care testing; Self-monitoring of blood glucose

Definition

Glucose meter (glucometer) is a medical device used to determine the approximate level of glucose in the blood. It is used for monitoring at home and in the hospital. Patients obtain a small drop of blood using a fingertip lanceting device. Blood is placed on a disposable test strip, and in less than 20 s on average, a reading is given. Most meters are approximately the size of the palm of the hand. Some meters require the user to manually enter in a code specific to the test strip. If the code does not match the strip, then the glucose reading is inaccurate. The glucose value is displayed in mg/dl (USA) or mmol/l.

Meters have different features such as memory, calculation of average sugar, volume of blood sample required, back light, color, and size. Some meters allow manual entry of additional data, such as insulin dose, amounts of carbohydrates eaten, or exercise. Some link with insulin pumps and send the sugar reading directly to the pump. Information such as all readings for 3 months, average sugar at different times of the day, and percentage of high or low readings may be displayed. The software is available for doctor's offices and patients' home use.

This information is used to adjust the medical regimen (primarily insulin) as well as to monitor adherence. The goal is to obtain tight glucose control and prevent complications of abnormal glucose levels. Patients with diabetes are educated on how to maintain glucose levels within target limits using information from blood glucose measurement.

Glucose is a monosaccharide (i.e., simple sugar), which is an essential form of energy for cells and organs in the human body. Glucose is an important carbohydrate that is imperative for the survival of organisms. A homeostatic process regulates the glucose available in the bloodstream that is used by the cells and organs of the body.

Description

Glucose is the usable form of energy for the central nervous system in humans. Following ingestion (within 3–4 h), carbohydrates in the stomach are broken and converted to glucose. Glucose then passes through the stomach and gastrointestinal tract into the bloodstream. Glucose metabolism triggers insulin secretion from the beta cells of the pancreas, which are responsible for endogenous insulin production. Insulin circulating in the bloodstream binds to receptors facilitating the uptake of glucose into the red blood cells. Glucose can then be used for energy or converted to glycogen for storage in the liver, muscles, and fat. Glucose metabolism is a homeostatic mechanism that is essential for human survival and is influenced by the actions of a variety of hormones, enzymes, and substrates.

Blood Glucose Homeostasis

Blood glucose is measured on a continuum. The normal range of blood glucose is between 4.0 and 7.0 mmol/L, or 70 and 120 mg/dL. When concentrations fall below the lower bound, it is considered to be a state of hypoglycemia (i.e., low blood glucose). Clinically, mild symptoms include trembling, heart palpitations, sweating, anxiety, hunger, nausea, and tingling, whereas severe symptoms include impaired concentration, fatigue, confusion, weakness, vision changes, difficulty speaking, dizziness, or loss of consciousness. When concentrations surpass the upper bound of this range, it is considered to be a state of hyperglycemia (i.e., high blood glucose). Clinically, mild symptoms include excessive thirst, excessive urination, fatigue, itchy skin, and, over time, weight loss. However, extreme states of hyperglycemia can trigger a state of ketoacidosis, during which individuals lose excessive amounts of electrolytes through urine and sweat that can trigger a myocardial infarction if untreated.

Among healthy individuals, actions of the pancreas maintain blood glucose homeostasis. When the availability of metabolized carbohydrates is low, resulting in a decline in plasma glucose concentration, the alpha cells of the pancreas secrete glucagon. Glucagon is a hormone that facilitates the conversation of glycogen that is stored in the liver, muscles, and fat, to glucose, which is then released into the bloodstream to restore euglycemia (i.e., normal blood glucose concentration). In the presence of excess

circulating blood glucose, resulting in a state of hyperglycemia, insulin is secreted from the beta cells of the pancreas to facilitate glucose uptake and conversion to glycogen for storage. Disruption of this metabolic homeostatic process is a hallmark feature of diabetes (i.e., type 1 diabetes mellitus, type 2 diabetes mellitus, gestational diabetes mellitus).

Glucose Intolerance and Diabetes Mellitus

In the majority of cases of type 1 diabetes mellitus (T1DM), an autoimmune process destroys the pancreatic beta cells resulting in insufficient insulin production. With both type 2 diabetes mellitus (T2DM) and gestational diabetes mellitus (GDM), the cellular receptors become resistant to the endogenous insulin produced by the pancreas. Prior to the onset of T2DM or GDM, individuals enter a prediabetic state that is characterized by impaired glucose tolerance (IGT), which is an intermediate step in disordered blood glucose metabolism. In such cases, the cellular receptors become resistant to the insulin produced by the pancreas, resulting in excess glucose circulating in the bloodstream. IGT is assessed using the 2-h oral glucose tolerance test (OGTT). During this procedure, individuals are orally administered 75 g of a glucose solution. Over the subsequent 2 hours, their plasma blood glucose is assessed. IGT is characterized by a 2-h OGTT between 7.8 and 11.1 mmol/L or 140 and 199 mg/dL. If untreated by adaptive health behavior change (e.g., nutritional therapy, increased physical activity) or pharmacotherapy, individuals with IGT will typically progress to a diabetic state. Although the pathophysiology and underlying mechanisms are different for the various diabetes subtypes, all forms of the disease result in chronic hyperglycemia if untreated.

Blood Glucose Management

Among individuals with diabetes, blood glucose control is influenced by four health behaviors including dietary intake, physical activity, medication adherence, and self-monitoring of blood glucose. Specifically, individuals must reduce their carbohydrate intake, frequently participate in moderate physical activity (i.e., 150 min per week, with no more than two consecutive days of inactivity), adhere to their medication regimen (of oral medications that aid in blood glucose metabolism or of exogenous insulin to overcome their beta cell deficiency), and regularly self-monitor their blood glucose before and after meals (particularly in the context of insulin therapy) to inform their future decisions to maintain normal blood glucose levels. Failure to maintain blood glucose in the normal range increases the risk for developing serious short-term and long-term complications associated with this disease process.

A1C is considered to be the "gold standard" measure of blood glucose control. It provides an index of the mean blood glucose levels over the previous 90–120 days. A1C is assessed through a blood sample that is analyzed in the laboratory. Over the 120-day life span of red blood cells, glucose molecules bind to hemoglobin in the red blood cells to form glycated hemoglobin. A concentration of glycated hemoglobin in the red blood cells reflects the average level of glucose that the red blood cells have been exposed to during its life span. This glycated hemoglobin is then expressed as a percentage. Optimal A1C is considered to be $\leq$6%. Higher A1C is indicative of worse glycemic control. Failure to maintain A1C $\leq$6% has been shown to increase the risk of developing serious vascular pathology and premature mortality. Specifically, poor blood glucose control (A1C $\geq$6%) can lead to blindness, renal failure, pain and loss of sensation in the extremities, myocardial infarctions, cerebrovascular accidents, and amputations. Following the assessment of individuals' A1C, these data are then used to inform clinical decision-making regarding pharmacotherapy and self-management practices.

Blood glucose metabolism is a complex homeostatic process. Various states of metabolic dysregulation can occur that require intensive pharmacological and behavioral intervention. Failure to achieve and maintain normal blood glucose levels can result in short-term and long-term complications and potentiate serious morbidity and premature mortality.

Definition

Glycemia refers to the concentration of glucose circulating in the blood plasma. Glycemia is influenced by a metabolic homeostatic process. As carbohydrates are ingested, they are broken down and converted to glucose, which then enter the bloodstream. Glycemia is measured on a continuum. The normal range of blood glucose is between 4.0 and 7.0 mmol/L, or 82 and 110 mg/dL. Glycemia can be assessed in the laboratory using antecubital venipuncture, either in a fasting or nonfasting state. Among patients with diabetes, glycemia may also be assessed by using portable glucometer. With such devices, individuals lance their fingertip to acquire a droplet of blood from the capillaries in

the fingers. The blood droplet is placed on a test strip that is inserted into the device for analysis. These meters provide cross-sectional data on the state of glycemia at a single point in time. However, these devices do not provide data on glycemic variability. For individuals with diabetes receiving insulin therapy, recent technological advances have resulted in the development of continuous glucose monitoring systems (CGMS) that provide a virtually continuous assessment of glycemia. These devices are worn on the abdomen and wirelessly transmit to the receiver (a pager-like device worn on the belt). The abdominal sensors sample the interstitial fluid at a rate of once every 5 s and provide an average blood glucose concentration over a period of several minutes. Although data from CGMS are less accurate than plasma blood glucose, these devices provide information on blood glucose variability that would otherwise be unavailable outside of the laboratory setting. For the surveillance of diabetes self-management outcomes, individuals can provide a blood sample for A1C analysis. A1C is collected by a venipuncture in the medical clinic. It provides an index of the mean level of glycemia over the previous 90–120 days. Optimal A1C is considered to be $\leq$7%. Higher A1C is indicative of worse glycemic control and places individuals at risk of serious long-term vascular complications. A1C is considered to be the "gold standard" measure of achieved blood glucose control among patients with diabetes.

Definition

HbA1c, or glycosylated hemoglobin, is a measure of how much glucose is irreversibly bound (glycated) to hemoglobin, and can be used to assess the degree of exposure to glycemia in the preceding 2–3 months (corresponding to the life span of the red blood cell where hemoglobin is contained). In a person with normal blood glucose levels, the amount of glycated hemoglobin is around 4–6%, representing an average blood glucose level between 70 and 120 mg/dl. In individuals with diabetes, HbA1c can be measured every 3 months with a goal of keeping the value as close to normal as possible, or at least under 7% in most patients. The higher the HbA1c, the greater the risk over time (usually measured in years) of developing microvascular complications, such as diabetic retinopathy, nephropathy, and neuropathy. HbA1c remains the best predictor for future diabetes-related chronic complications that is available in the clinical setting.

Goodness of Fit Hypothesis

Yori Gidron
Faculty of Medicine and Pharmacy, Free University of Brussels (VUB), Jette, Belgium

Definition

This term refers to the effectiveness of matching (fitting) a coping strategy to a situation's level of controllability, in relation to adaptation to stress. This matching was proposed by Lazarus and Folkman (1984) and Forsythe and Compass (1987) and is termed the goodness of fit hypothesis (GOFH). According to the GOFH, emotion-focused coping (EFC) is more adaptive for uncontrollable and unsolvable situations, while problem-focused coping (PFC) is more adaptive in controllable and solvable situations. EFC includes denial, distraction, relaxation, or, in negative forms, catastrophizing. In contrast, PFC includes defining the problem, suggesting solutions, and implementing one. The GOFH is a major issue in the field of stress and coping and reveals the complexity of the person-situation fit, in relation to adequate responses to stress.

The GOFH has important implications for behavior medicine as well. For example, Levine et al. (1987) assessed levels of denial (an EFC) in cardiac patients and examined its relation with recovery indices during hospitalization (acute phase) and over 12 months after discharge (long term). Levine et al. found that while greater denial predicted better short-term prognosis in hospital, it predicted poorer prognosis in the long-term. These results can be seen as supporting the GOFH since during the acute phase of hospitalization, cardiac patients have less control over their situation, and hence, the ability to deny may have reduced stress-related excessive sympathetic responses, which may have reduced the risk of further cardiac events. In contrast, during recovery at home, when modifying one's lifestyle is under a patient's control, denial would impede such efforts and, thus, probably contribute to adverse health outcomes. Another more recent example is the study by Rapoport-Hubschman, Gidron, Reicher-Atir, Sapir, and Fisch (2009) that tested the relationship between coping and outcomes in in-vitro fertilization (IVF). This form of medical treatment "bypasses" women's hormonal system and, thus, constitutes a strong example of reduced control by the patient over the procedure and outcome. In their study, women with higher baseline levels of "letting go" (i.e., high EFC) had a significantly higher chance of being pregnant than those with lower levels of "letting go" coping, independent of confounders (age, number of IVF cycles, and cause of infertility). While not all studies have supported the GOFH, it has received quite a bit support, and it has important implications for teaching stress management. Specifically, people can learn to first appraise whether a situation is controllable or solvable or not and then choose to use EFC or PFC. Importantly, Forsythe and Compass (1987) also found that people with both types of coping adapt the best,

suggesting that people need to learn both EFC and PFC, and know when to use or perhaps combine both forms of coping strategies. The GOFH is an important concept and framework in stress, health, and illness.

Definition

Graded exercise testing is a variety of exercise testing where tests are designed to be increasingly more difficult as they progress. A graded maximal exercise test would ideally progress until the participant reaches a level of maximal exertion, while a graded (multistage) submaximal exercise test would progress to a predetermined point.

While graded exercise tests are typically administered to determine a participant's functional aerobic capacity (VO_{2max}), they can also be used to diagnose certain diseases (primarily cardiovascular) when used in conjunction with other diagnostic tools, e.g., electrocardiograms (ECG), echocardiography, or nuclear medicine scanners. Graded exercise tests ideally involve large muscle groups, e.g., the hip and leg musculature, so as to more accurately determine from the results the need, delivery, and consumption of oxygenated blood. As such, the modalities most commonly used in graded exercise tests are treadmills and cycle ergometers. While cycle ergometers generally provide more advantages than treadmills, such as being less expensive, taking up less space, and providing more precise ECG readings due to reduced trunk movement, participants tend to attain higher VO_{2max} values when using treadmills (this is primarily due to the larger number of muscles which are engaged). Though less common, it is also possible to conduct graded exercise testing on equipment designed to assess specific muscle groups (e.g., arm ergometry) or activities (e.g., rowing ergometry).

Maximal and submaximal graded exercise tests have different advantages, and choosing which type of test to administer will depend on the parameter to be determined, the equipment available, and the level of expertise of the test administrators. For example, maximal graded exercise tests are more sensitive in the diagnosis of a number of cardiac problems, though the participant will need to exercise to the point of exhaustion. In contrast, a submaximal graded exercise test will provide a standardized and consistent level of exertion across all participants,

which can be very useful in a research setting. In addition, for all exercise testing, it is usually recommended that a physician be in attendance or available if a participant is at high risk of cardiovascular problems.

Grief Counseling

Bereavement counseling; Bereavement therapy; Grief therapy

Definition

Grief counseling (also referred to as grief therapy or bereavement counseling) is the term used for the nonjudgmental counseling support that is provided for those who are suffering as a consequence of a loss through death of someone close to them. Grief counseling may also be used to assist with adjustment to a range of losses that involve a strong element of grief, such as amputation, loss of role, or loss of one's home. Bereavement therapy is a related term and may be distinguished from bereavement counseling as being provided for those who are having trouble adjusting, rather than being provided more routinely.

Grief counseling developed largely from the 1970s onward to provide support to people following bereavement in the increasingly fragmented societies of the technologically developed world, in which the religious rites,

rituals, and support of more traditional communities had been eroded. Services have traditionally been provided through professionals, volunteers, and self-help groups alike. The process of counseling offers an opportunity for the bereaved to express thoughts and feelings to someone trained and willing to listen, who has an understanding of the impact of grief.

Raphael, Minkov, and Dobson (2001) distinguish four levels of bereavement intervention:

1. Universal primary preventative intervention, that is, grief counseling being offered to all who have experienced bereavement with the aim of facilitating an adaptive response
2. Selective preventive intervention, that is, grief counseling being offered to those who may be vulnerable to difficulty in adapting due to the presence of risk factors related to their prior life, the nature of the death, or their circumstances following the death
3. Indicated preventive intervention, that is, grief counseling being offered to those who have unusually high levels of distress or a disturbing or unusual response, soon after bereavement
4. Treatment, that is, grief therapy offered to those with a complicated grief reaction who present to health services some time after the index event

Research evidence suggests that carefully targeted grief counseling at layers 2–4 of this framework is most effective, since universal provision may disturb a person's way of coping through reliance on their own resources and nonprofessional networks.

A number of scales have been developed which can be used to help in the assessment of whether someone might benefit from grief counseling (see Neimeyer and Hogan, 2001, for a useful review).

Where counseling is indicated, it may be provided at one of a number of levels (group, family, or individual) and using one of a number of approaches (e.g., nondirective or based on enhancing emotion-focused or problem-focused coping). Several approaches to level 4 treatment have been evaluated including behavior therapy, brief psychodynamic psychotherapy, hypnotherapy, and self-help. All appear to be helpful to a modest degree. This may indicate that nonspecific therapeutic factors are the key helpful ingredients in grief counseling or it may reflect individual differences in response to different approaches. Evidence-based factors to take into account in providing grief counseling include consideration of personal preferences; family, cultural, and religious contexts; enabling the person to reflect on both the past and the future; facilitating the person's search for meaning, and encouraging the person to consider both loss-oriented (e.g., feelings of grief) and restoration-oriented (e.g., dealing with the practicalities of day-to-day life without the deceased) stressors.

Bereavement; Grief; Loss

Definition

In a narrow sense, grieving is the term used to describe the experience and expression of the emotional state, of sadness, anguish, and pining, that commonly follows the death of one who was significant in the life of the bereaved, along with the somatic, cognitive, and behavioral facets of this response.

In a broader sense, grieving may be understood as referring to the whole period of time from first news of a death, through to a point when reasonable adjustment has been made; a period which may encompass a wide range of emotions (including numbness, disbelief, fear, anger, guilt, anguish, and sorrow) and a lengthy process of adaptation.

Description

Bereavement, by definition, is the loss of a person through death. However, grieving, the emotional response to bereavement and loss, may start prior to bereavement (anticipatory grief). Thus, facing death and issues of bereavement are closely intertwined.

Grief is often viewed as an individual emotional reaction, and its nature can be understood using ideas from the psychology of attachment and bonding, as the individual experiences irrevocable detachment and separation. However, bereavement affects all who knew a person, and therefore, families and social networks set the wider context for grieving and for support, and religious and cultural factors also influence the ways that grief is expressed and the way the dead are mourned and remembered. In some societies and in relation to some relationships, grief of a particular individual may not be sanctioned, this position being named "disenfranchised grief."

The end point of grief is hard to define with adaptation to life without the person who has died having a range of markers. For most people, life is never the same again, but many people report elements of growth and development through grief as well as distress and pain. However, about 15% of people experience prolonged and very distressing grief, and this is often referred to as "traumatic," "pathological," or "complicated."

A number of descriptive and theoretical frameworks have been used to try and capture the essence of grief. Parkes, in his seminal work, described common phases of response during the period of time following bereavement, usually described as (1) numbness, (2) searching and yearning, (3) disorganization and despair, and (4) reorganization. It should be noted that this framework is not intended to be applied rigidly to each individual case. A related view that places premium upon the active nature of grief is that of "grief work" (Worden). This conceptualizes the bereaved as needing to address four particular tasks: to accept the reality of the loss, to work through the pain of the loss, to adjust to the environment in which the deceased is no longer present, and to emotionally relocate the deceased and move on with life. In recent years, further concepts and models have been proposed. The most predominant at the present time is the dual process model (Stroebe & Schut, 1999) which lays emphasis on the concurrent existence of both loss-oriented stressors (related to the pain of separation) and restoration-oriented stressors (related to living life without the deceased) and considers the necessary oscillation in coping as the bereaved person responds to both of these sources of grief, addressing the emotional *and* the practical consequences. In addition, there is a recognition that rather than needing to let go, continuing bonds with the deceased can be helpful, as long as these are symbolic rather than very literal. It is also recognized that each person has their own grief narrative and that the process of

meaning-making is central to "coming to terms" (Neimeyer, 2000) with grief.

All the frameworks referred to in this entry can be found in the Handbooks of Bereavement Research named below.

Group Therapy/Intervention

Yori Gidron
Faculty of Medicine and Pharmacy, Free University of Brussels (VUB), Jette, Belgium

Definition

Group therapy interventions refer to a format of several individuals taking part in a psychological intervention aimed at helping them change or deal with a long-lasting problem they are encountering, guided by a therapist or counselor. Group therapies have important advantages and are thus suitable for several types of problems, mainly those involving interpersonal issues. These include, for example, stress management, a common medical problem (cancer, heart disease), or addictions. The advantages of group over individual interventions include vicarious learning from others, knowing and being comforted by the fact that others share one's difficulties, and practicing in a safe environment constructive solutions for interpersonal problems. In behavior medicine, studies have used such a format to treat cancer patients (e.g., Andersen et al., 2008), cardiac patients (e.g., Gidron, Davidson, & Bata, 1999), and many other patient samples. In cardiac patients, one review found psychosocial interventions to reduce mortality and cardiac risk factors (Dusseldorp, van Elderen, Maes, Meulman, & Kraaij, 1999). Such group interventions can also take place at a workplace setting, enabling to solve work-related problems, for the benefit of individual workers, the team and the workplace as a whole.

Some studies have also begun to identify patient, therapist, and process variables predictive of positive outcomes following group interventions. In a unique and large-scale study on 40 groups of 266 Israeli children undergoing group therapy for emotional and behavioral problems, child bonding affected group functioning, which, in turn, affected behavioral outcomes. Similarly, therapist variables including encouragement and self-disclosure positively affected outcomes while challenging negatively affected outcomes (Shechtman & Leichtentritt, 2010). Thus, group interventions are an important medium for behavior modification and have been used in medical and health settings as well.

Definition

Guided imagery involves a practitioner verbally leading an individual through the processes of mentally representing situations in their mind. The representation can occur in one or more senses so that the person (or imaginer) experiences the sights, tastes, sounds, smells, and feelings associated with the situation. Details about people, places, and events can also be included to make the experience as realistic and vivid as possible.

To aid the process of generating the mental "images", guided imagery is usually performed with closed eyes, in a quiet environment, while the imaginer reclines in a comfortable position. Instructions on how and what to image can be delivered individually or in groups and are imparted either live or as an audio recording. Similar to hypnosis or meditation, guided imagery is often combined with music and relaxation techniques, such as deep breathing or progressive muscle relaxation, to help clear and focus the mind in preparation for the imagery.

What is imaged depends on personal preference or the technique used, such as Bonny's (1980) Method of Guided Imagery and Music (GIM). The content, however, is predominately determined by the imager's desired outcomes or reasons for using the guided imagery. For example, to feel more positive and reduce anxiety, instructions may direct the person to image a sense of calmness and therefore feel their mood improve. For pain sufferers, the imagery might lead them to focus on numbing and relief from pain or noxious symptoms. Alternatively, they might be guided to escape from the pain by imaging themselves in a pleasant location, such as a beach or the countryside.

Classed as a complementary alternative medicine (CAM), guided imagery is frequently recommended to cancer patients to help maximize pain relief in conjunction with pharmacological regimens; reduce aversion to certain treatments, such as chemotherapy; manage stress; aid in relaxation; and to empower patients to manage issues arising from their treatment. It has also been suggested that using the power of your mind to influence psychological and physiological states can help improve the quality of life and psychological well-being of individuals suffering from respiratory disease (e.g., asthma, chronic bronchitis, and emphysema), chronic pain (e.g., fibromyalgia, chronic headaches, and osteoarthritis), and hypertension. Guided imagery is also recommended as a coping strategy for perioperative patients and end-of-life palliative care to reduce anxiety. It has been used to help increase physical strength and aid in the recovery of motor function following musculoskeletal injuries and for individuals with stroke and Parkinson's disease. Further, guided imagery

has been recommended for changing health behaviors, including physical activity, smoking cessation, and weight management.

To evaluate its effectiveness, guided imagery has been compared to standard care practice in patient populations. For example, an intervention combining relaxation and guided imagery was used to improve immune function by asking patients undergoing surgery for breast cancer to mentally experience immune cells destroying cancer cells (Lengacher et al., 2008). The effects on the immune system were explained by relaxation and imagery reducing stress and leading to the release of neuropeptides and cytokines to improve the immune response. Despite these promising results, much of the available research evaluating the effectiveness of guided imagery for use with patients suffers from poor, inconsistent methodologies combined with small samples that make the efficacy of guided imagery difficult to compare across studies. However, a review of six randomized clinical trials by Roffe, Schmidt, and Ernst (2005) indicates that guided imagery can be psychology supportive and increase comfort of cancer sufferers but not improve their physical symptoms, such as nausea and vomiting. A more recent five-study review by King (2010) found some support for the use of guided imagery as an aid in alleviating the pain associated with cancer. When guided imagery is effective in controlling pain, it seems to provide patients with a source of distraction from the discomfort or serve to stimulate their relaxation. However, the pain characteristics of certain patients (i.e., the intensity of the pain) may make it difficult for them to image, which could explain why the technique is not always effective in managing pain (see Kwekkeboom, Hau, Wanta, & Bompus, 2008).

Another barrier is individual differences in the ability to create and control vivid images. Although everyone has the ability to image, there is considerable variability from person to person. Those who are more proficient in generating, transforming, and maintaining images will more likely benefit from imagery interventions. To identify who would be most helped, the Imaging Ability Questionnaire (IAQ) was developed by Kwekkeboom (2000) as a valid and reliable screening tool for cancer patients. The IAQ measures the ability to generate vivid images using various senses and to be involved or engaged in the imagery experience. Similar questionnaires have been developed for specific use with other clinical populations, such as the Kinesthetic and Visual Imagery Questionnaire (KVIQ; Malouin et al., 2007), to measure motor imagery ability in individuals with physical impairments. Although termed "ability", it is also important to note that individuals become more proficient at imaging following instruction and practice. Those who score low on imagery ability questionnaires therefore might first need training exercises to improve their skills of imaging before receiving a guided imagery program.

Definition

A habit can be defined as a learned behavioral response to a situational cue. The repeated performance of a behavior in a specific context leads to the development of a behavioral habit that is triggered by features of the environment that have covaried frequently with past performance of the behavior. Such features of the environment might include performance locations, preceding actions in a sequence, the presence of particular people, or an internal thought or feeling. As a consequence of repetition in the same cue-contexts, a habit becomes capable of being triggered directly by perception of the cue. This is referred to as cue contingent automaticity. A person might experience his or her habit as something "I cannot help doing."

Habit strength is a function of the frequency with which an action has been repeated in a stable context and has acquired a high degree of habitual automaticity. Verplanken and Orbell (2003) developed and validated a metacognitive 12-item instrument to measure habit strength, the Self-Report Habit Index (SRHI). This is a generic instrument that asks respondents whether their performance of a target behavior occurs frequently; requires conscious awareness, thought, and effort; and is difficult to control.

From an empirical perspective, stronger habits are associated with heightened attention to cues associated with the performance of a habit and an increased likelihood of making an action slip when the cue is detected (Orbell & Verplanken, 2010). Removal of the cue (e.g., by changing one's environment) disrupts the performance of a previous habit (Wood, Tam, & Guerrero Witt, 2005). Strong habits also disrupt the ability to enact a counterhabitual intention. Strong habits may be useful in health contexts where, for example, good adherence is required and may be

promoted by interventions that promote repetition in stable contexts (Orbell & Verplanken, 2010).

Definition

The Hamilton Anxiety Rating Scale (HAM-A) is a widely used 14-item clinician-administered rating tool in the public domain used to measure the severity of anxiety symptoms among individuals previously diagnosed with anxiety disorders (McDowell, 2006). The HAM-A was originally developed by Max Hamilton in 1959 as an assessment tool to evaluate anxiety symptoms among people diagnosed with "anxiety neurosis." Since that time, anxiety neurosis has been reconceptualized and the HAM-A is used among individuals with a variety of anxiety disorders (panic, phobia, and generalized) (McDowell, 2006). The 14 items reflect 13 categories of anxiety-related symptoms including anxious mood, tension, fear, insomnia, intellectual/cognitive symptoms, depressed mood, general somatic (muscular and memory symptoms), cardiovascular, respiratory, genitourinary, and gastrointestinal symptoms, with one item capturing the rater's assessment of behavioral symptoms. The HAM-A takes approximately 15–30 min to administer and score and contains two subscales – psychiatric anxiety (psychological distress) and somatic anxiety (physical symptoms of distress) (Hamilton, 1959).

The HAM-A is not designed to be used as a diagnostic tool and has poor discriminant validity between anxiety disorders and depression. Instead, it is a standard primary outcome measure used to asses the efficacy of clinical interventions for DSM-IV anxiety disorders – most commonly

generalized anxiety disorder – within psychopharmacologic randomized controlled trials and psychotherapeutic clinical trials (Roemer, 2001). It also used for monitoring anxiety symptoms during treatment. The severity of the item is determined on a five point scale (0 = not present, 4 = severe). A computerized version as well as a pen-and-paper format is available (Kobak, Reynolds, & Greist, 1993), and a structured interview guide has also been developed to standardize its administration (SIGH-A), as its administration is not predefined in the initial instrument (Williams, 1988). A six-item abbreviated scale capturing psychic anxiety, tension, restlessness, inability to relax, startle response, worry, and apprehension called the Clinical Anxiety Scale was also proposed by Snaith, Baugh, Clayden, Husain and Sipple (1982). The HAM-A has also been translated into several languages, including Spanish, German, and Polish (Roemer, 2001).

Definition

The Hamilton Rating Scale for Depression or Hamilton Depression Rating scale (HAM-D, HRSD, or HDRS) is a 21-item clinician-administered multiple-choice measure of depression symptom severity. The first 17 of the 21 items contribute to the total score (Hamilton, 1960) and items 18–21 give additional information not part of the scale, such as paranoia and diurnal variation (Hedlund & Vieweg, 1979). Other versions have been developed, ranging from 7 to 29 items (e.g., Hamilton, 1964; Williams, 1988). In all versions, symptoms are defined by anchor point descriptions (ranging from 3 to 5 possible responses), which increase in severity. Clinicians consider intensity and frequency of symptoms based on patient response and observations. A score of ≤ 7 is widely thought to indicate remission on the HAM-D_{17} (Frank et al., 1991).

The HAM-D was first published in 1960 and reviewed subsequently (Hamilton, 1964, 1980). Due to its comprehensive coverage of depressive

symptoms, strong psychometric properties (Hedlund & Vieweg, 1979), and the total score demonstrating high concurrent and differential validity as well as strong reliability (Carroll, Fielding, & Blashki, 1973), the HAM-D is considered by many to be the "gold standard" of assessing depressive symptomatology. However, most individual items demonstrate fair to poor agreement (Cicchetti & Prusoff, 1983). Use of the Structured Interview Guide, published in 1988, increased the reliability of the items (Williams, 1988). Self-report and computerized versions have been developed to improve the psychometric properties of individual items (Williams, 2001).

The HAM-D is primarily applied for research purposes to determine severity of depressive symptoms throughout treatment and in response to psychotherapy or antidepressants (O'Sullivan, Fava, Agustin, Baer, & Rosenbaum, 1997; Williams, 2001). More specifically, in the area of behavioral medicine, the HAM-D is used to measure the severity of depression in people with comorbid chronic illness. As assessment of depression can be particularly complicated in this population due to the co-occurrence of somatic features of depression and physical illness, the HAM-D has been criticized for its sensitivity to somatic symptoms (Maier & Philipp, 1985; Sutton, Baum, & Johnston, 2004). Consequently, researchers have evaluated the utility of the HAM-D for assessing depression in chronic illness. An early study assessing somatic comorbidity in a sample of elderly patients found that eight of the HAM-D scale items rated as positive scores for depression by psychiatrists were rated by internists as being related to somatic conditions (Linden, Borchelt, Barnow, & Geiselmann, 1995). Additionally, researchers compared depression rating scales in chronic fatigue syndrome and found that the HAM-D overestimated the number of depressed patients (Henderson & Tannock, 2005). Nevertheless, a more recent study evaluated the scale in depressed participants with multiple sclerosis and found that the majority of items (12 out of 17) captured depressive symptoms and adequately differentiated from somatic symptoms (Moran & Mohr, 2005). Results suggest that this co-occurrence must be considered when using the HAM-D in behavioral medicine settings.

Handgrip Strength

Definition

This term refers to a common measure used often in rehabilitation medicine to determine the maximum forearm muscular isometric strength. Given that muscle strength has general characteristics, the handgrip strength test may often indicate general muscular strength. The test includes a dynamometer, with a scale in kilogram, where people are asked to perform their maximal press with their hand. Different protocols exist concerning the angle of the arm and hand in relation to the body, the number of pressing trials, and the duration of pressure, normally lasting 3–5 s. This test can be used to indicate various health factors in different populations.

A review of the value of the handgrip strength test in dialysis patients found this test to correlate with general muscle mass, nutritional status (of importance in dialysis), and future complications (Leal, Mafra, Fouque, & Anjos, 2011). A review of 114 studies in the general population and 71 studies with arthritic patients found a strong age-related decline in handgrip strength, and much lower scores among arthritic patients, suggesting a relationship between inflammation and performance on this test (Beenakker et al., 2010). In some pain patients, this test is also helpful in assessment of their condition. For example, handgrip strength is lower in patients with fibromyalgia, and is inversely related to their levels of pain, fatigue, and stiffness (Aparicio et al., 2010). This test was used in several cohort studies to predict risk of death. For example, in elderly French women, a low handgrip test score significantly predicted risk of mortality, independent of confounders (Rolland et al., 2006). In patients with congestive heart failure, low handgrip strength also predicted risk of death, independent of confounders (Izawa et al., 2009). Furthermore, handgrip scores also prospectively predict decline in activity of daily living and in cognitive performance in the elderly (Taekema, Gussekloo, Maier, Westendorp, & Craen, 2010). Thus, the handgrip test is a simple, rapid, and objective test which provides information on important physical factors and has predictive validity in relation to functional, cognitive, and vital status measures.

Definition

Positive emotions (including happiness) arise as the result of pleasurable engagement with the environment and may present themselves in a variety of forms (e.g., enthusiasm, calm, contentment). Traditionally, physical health is defined as the objective absence of disease or illness, but can also include perceptions of wellness.

Description

While the concept that happiness is tied to better health is not novel and is widely accepted by the public, the research in this area remains in its infancy. Due to the surge of interest in positive psychology over the last decade, researchers are beginning to unveil the predictive and protective effects of positive emotions on health. There are however many remaining critical research questions. This section will focus on the most robust and striking findings in the literature on positive emotions and physical health, in addition to a brief discussion on some of the important methodological concerns for the field.

What Is Positive Affect?

While there is some debate in the literature as to what adjectives and precise feelings make up positive affect (PA), it is typically considered to be the general positive emotions or feelings (e.g., happiness, enthusiasm, calm, or contentment) resulting from pleasurable interactions with the environment. These feelings may persist for long periods of time and define an individual's general disposition (often called trait PA) or they may be transient moments of emotion that last for minutes or days, typically referred to as state PA, positive mood, or emotion (emotion being the shorter lasting of the two). Research on PA and health primarily focuses on trait PA given its more likely *long-lasting* effects on physical well-being; however, on occasion, studies will assess the effects of state PA (commonly assessed via a one-time mood assessment asking questions like "How happy are you this week?"). While shorter time assessments of positive feelings are less likely to influence long-term health outcomes, they are known to have transient effects on physiology and are highly correlated with dispositional measures of PA.

Measuring Positive Affect

PA is most frequently assessed via self-report scales asking about the frequency, duration, or intensity of positive feelings. There are a host of different scales to do this with wide discrepancies between them. In the health field, the most frequently used multi-item tool is the 20-item Positive and Negative Affect Schedule (PANAS), which assesses affect by having individuals rate the degree to which each emotion word (e.g., enthusiastic or irritable) describes their typical mood with flexibility in the assessed time period covered. This scale focuses on aroused emotions and is therefore not useful for individuals interested in assessing the health impact of low-energy states (e.g., calm). There are however many other mood adjective checklists that include low-arousal emotions such as those using Circumplex Models of Emotion (Russell, 1980), which includes measures of both arousal and valence, or the extended 60-item version of the PANAS (the PANAS-X)

(Watson & Clark 1999). Studies have also utilized single-item questionnaires (e.g., "Are you happy?"), confederate report, positive items drawn from other scales (e.g., depression measures), or even autobiographical writing samples. Given the known high levels of social desirability and response bias to emotion scales, future research would benefit from greater use of unobtrusive and non-self-report methodologies to determine an individual's level of PA. One other critical measurement concern relates to the role of negative affect (NA) in the PA health association. At the trait level, PA and NA are often weakly correlated; however, they are sometimes considered to be opposite ends of the same spectrum by many researchers. It may be the case that benefits of PA on health are simply attributable to the absence of NA. The majority of studies do not test for the independence of these affect variables in relation to their health impact; however, those that do frequently report that PA is beneficial to health irrespective of NA. Also critical is to better understand what types of PA are beneficial to health. Given the divergent physiological impacts of high- versus low-arousal emotions (e.g., ecstasy versus relaxation), it is not unrealistic to anticipate differential health results. Nevertheless, this is rarely considered and frequently unmeasured due to the choice of affect items within scales.

Associations Between Positive Affect and Health

In their major review, Pressman and Cohen (2005) evaluated the results of over 150 studies on PA and health and physiological outcomes. They consistently found that greater PA was associated with increased longevity in individuals older than 55, in studies with years to decades of longitudinal follow-up. For example, in one creative study by Danner, Snowdon, and Friesen (2001), autobiographical writing samples from 180 young nuns entering the convent were coded for positive and negative emotion word usage. At a 50-year follow-up time point, researchers found that nuns who used higher levels of positive words lived almost 11 years longer than their counterparts who used the fewest positive emotion words. This finding was not attributable to negative word usage. Similar results have been demonstrated in multiple studies of healthy, community-dwelling older individuals revealing that those individuals who report greater amounts of PA at baseline live *years* longer than their less positive counterparts.

There is also consistent evidence that positive emotions are protective against a multitude of morbidity outcomes including decreased falls and injuries, reduced heart attack and stroke incidences, fewer hospitalizations for coronary complications, and improved pregnancy outcomes. An exemplary example of this is the viral challenge work of Cohen, Doyle, Turner, Alper, and Skoner (2003). In this study, PA (determined via interviews averaged over several weeks) was found to prospectively predict the decreased likelihood of developing an objective cold (and cold symptoms) after being experimentally exposed to a novel virus. These results were independent of the influence of trait NA, which was only tied to the *perception* of having a cold as opposed to actual incidence. This finding was replicated, in that positive emotion styles predicted fewer objective flu cases and fewer flu symptoms reported when the flu virus was experimentally administered.

Additional findings from the literature generally show that cross-sectionally, individuals with higher PA report fewer symptoms and generally feel better. What remains unknown is whether this is a true physiological process (e.g., altered opioid levels) or whether PA simply leads to altered attention to or perception of symptoms. Similarly, it may also be true that feeling of health lead to greater positive emotion. Most studies to date do not address these mechanistic and directional questions.

Finally, survival studies of diseased patients have provided *some* indication that PA may lead to improved health outcomes, but not in every circumstance. Research on those with early-stage life-threatening diseases (e.g., HIV, stage I–II breast cancer) indicates that PA may lengthen life. This may be due to physiological changes (outlined below) or due to greater adherence to treatments and/or positive behavioral changes,

but these mediators have not been thoroughly evaluated. To date, there is little and mixed evidence regarding the effects of PA in late stage disease (e.g., stage IV breast cancer, end-stage renal disease). There are several possible reasons for this: high PA during the end stages of life may indicate unusual or inappropriate coping and possible underreporting of important symptoms. It is also likely that the small physiological changes tied to PA may be too weak to alter the course of disease in its late stages.

How Could Positive Affect Improve Health?

Pressman and Cohen (2005) proposed two pathways by which PA might benefit health and prevent disease. The first is the main effect hypothesis, which contends that PA influences health via its positive influences on health practices, physiological functioning (e.g., immune, cardiovascular, endocrine), and social relationships (also known to have health benefits). The second theory indicates that PA may be tied to better health via its beneficial impact on the stress response. Specifically, it may ameliorate the negative impact of stress by altering perceptions of severity, reducing detrimental physiological responses, and by helping individuals build resources (e.g., physical health, social support) to aid in coping and stress recovery. It is likely that both pathways play some role, although to date no one has directly contrasted the pathways in a single study. There is, however, growing evidence for both types of connections.

Critiques and Future Directions

Future research needs to distinguish what *types* of positive factors are most important to health outcomes and when. To date, most studies focus on "happiness"; however, there is equally good evidence for multi-adjective scales in addition to related positive constructs (e.g., optimism, life satisfaction). It is also important for researchers to better understand at what intensity and frequency positive emotions must be felt to show real physiological benefits and to what extent changes are independent from negative feelings. There is also a need to better understand the mediators of the PA health association and to have studies that prospectively test both health and physiological pathways together. Finally, it is an exciting notion to consider the possibility that PA-inducing interventions might improve health in a meaningful fashion, but it is too soon to determine whether or not these types of studies have robust effects.

General Conclusions

Happiness and other positive emotions have been linked to a greater lifespan, reduced disease susceptibility, improved health perceptions, and better outcomes for those with early-stage diseases. Meanwhile, researchers continue to explore the extent to which positive emotion can be beneficial, when it is most important in disease prevention and treatment, and finally the mechanisms by which it is most helpful.

Hardiness and Health

Personality hardiness

Definition

Hardiness is a personality construct composed of three traits – control, commitment, and challenge – that are theorized to make one resilient in the face of stress. Individuals high in hardiness tend to believe and act as if life experiences are controllable (control), to engage meaningfully in life activities and to appraise these activities as purposeful and worthy of investment even in the face of adversity (commitment), and to view change in life as a challenge toward growth and development rather than as a threat to security (challenge). Based on existential personality theory, the combination of these characteristics is believed to provide individuals with the courage and motivation to cope adaptively with life stress, thereby buffering its adverse effects on health.

Description

Hardiness has historical significance because it played a significant role in the re-emergence of research examining the relationship between personality and health, and it foreshadowed the current positive psychology movement that focuses on transformation, growth, and resilience in the face of adversity (e.g., optimism, benefit finding, posttraumatic growth). Hardiness was developed by Maddi and Kobasa (Kobasa, 1979; Kobasa, Maddi, & Kahn, 1982) out of a longitudinal study of executives at Illinois Bell Telephone who were facing work upheaval due to deregulation. Executives were studied before, during, and after deregulation to identify characteristics of those who remained healthy and thrived in this time of heightened life stress versus those who showed signs of strain. Individuals who displayed little strain differed from their high strain counterparts on the characteristics of control, commitment, and challenge.

Associations Between Hardiness and Health

Evidence has accumulated across the decades to suggest that hardiness is associated with lower levels of physical and psychological strain following exposure to stress. Higher hardiness has been associated with lower reports of physical symptoms and psychological distress in both cross-sectional and longitudinal analyses. Such associations have been found across samples experiencing diverse stressors including

school-related stress in undergraduates, work-related stress among business executives, bus drivers and lawyers, and military personnel undergoing stressful military procedures. The characteristics of hardiness have also been consistently associated with better performance under stress as revealed in higher GPAs, athletic performance, and leadership skills.

Research has also examined the biobehavioral mechanisms by which hardiness may attenuate adverse responses to stress. There is compelling evidence that characteristics of hardiness facilitate adaptive cognitive appraisals in the face of stress. For example, high hardy individuals make more positive appraisals when experiencing laboratory-induced threat, and appraise the same life stressors as less threatening and more controllable than do low hardy individuals. Hardiness is also associated with more adaptive coping characterized by higher problem-focused and support-seeking coping, better health behaviors, and lower avoidance coping. Consistent with hardiness theory, these more positive perceptions of stress and active versus passive coping strategies have been found to mediate associations between hardiness and health.

Controversies Regarding Hardiness and Health Associations

Despite such encouraging findings, numerous criticisms of this literature have led some researchers to question the evidence supporting an association between hardiness and health. Concerns have centered on: (a) problems with the measurement of hardiness, (b) problems with the measurement of health outcomes, and (c) inconsistent evidence that hardiness "buffers" the adverse effects of stress.

Measurement of hardiness. Progress in the field has been hampered by a number of problems with the measurement of hardiness. First, the measure of hardiness has gone through multiple iterations and no standard measure of hardiness exists. The use of multiple measures makes it difficult to evaluate findings across studies. Second, the existing measures have not consistently supported the three-factor structure theorized to underlie the hardiness construct, raising questions about whether hardiness should be examined as a single composite variable. Research that has examined the three constructs individually suggests that control and commitment are more consistently associated with lower strain than is challenge. No study has provided compelling evidence that all three components are necessary to promote adaptive responses to stress. Third, the items on the initial hardiness scales were negatively keyed, raising questions about whether the scale was measuring the absence of maladaptive traits (e.g., neuroticism) rather than the presence of adaptive traits. Construct validity studies have demonstrated that hardiness scores are strongly correlated with neuroticism, and that some associations between hardiness and lower strain are reduced or eliminated when shared variance with neuroticism is statistically controlled. The most recent version of the hardiness scale – Personal Views Survey III-Revised (PVS III-R) – appears to have partially addressed these issues. However, the psychometric properties of this scale have not been published in a peer-reviewed journal.

Measurement of physical health outcomes. Another concern with the hardiness and health literature is that health outcomes are commonly measured with self-reported somatic complaints or other subjective signs of strain, rather than with objective signs of illness. Such outcomes are imperfect measures of health; they are heavily influenced by illness cognition and illness behavior processes that occur with heightened distress. The use of such health measures combined with the overlap between measures of hardiness and neuroticism have raised concerns that hardiness-health associations reflect shared variance with neuroticism. Few published studies have examined associations between hardiness and more objective signs of physical health (e.g., psychophysiological reactivity to stress; blood pressure; immune function; mortality), and those that exist have yielded inconsistent findings.

Evidence of stress buffering. Although developed in the context of work-related stress, the question of whether hardiness "buffers" the adverse health effects of stress is not fully answered. If hardiness works by buffering stress,

its associations with health outcomes should be stronger under high versus low stress conditions, as evidenced by a statistical interaction between hardiness and stress. Many studies have not been designed to test this stress-buffering hypothesis (e.g., hardiness is often tested among samples exposed only to high levels of stress), and those that have provide inconsistent support for stress buffering. Nevertheless, the consistent finding of adaptive perceptions of stress noted above suggests that hardiness may reduce one's level of psychological stress even in the face of objectively similar stressful life events.

Conclusion

The construct of hardiness continues to be studied in a variety of settings around the world, and interventions to increase levels of hardiness have been developed. This recent wave of hardiness research has focused on psychological strain and performance-based outcomes more than on physical health outcomes, but may provide answers to some of these ongoing controversies.

Definition

Harm reduction is a public health framework that refers to policies, programs, and practices that focus on reducing potentially adverse health, social, and economic consequences related to engagement in high-risk behaviors. Harm reduction has been controversial as it focuses on preventing or reducing harm and not necessarily on preventing or eliminating risky behavior. Although it has been used in many different settings, harm reduction is most often associated with issues related to substance use and became a more prominent framework in the mid-1980s as a public health response to the HIV epidemic among injection drug users.

In the field of substance abuse, harm reduction provides an alternative to abstinence. The harm reduction framework recognizes that there are many people who are unable or unwilling to stop using illicit drugs. Subsequently, it focuses on reducing the societal and individual harms that may occur as a result of drug use. Needle exchange programs are an example of a harm reduction approach to HIV among injection drug users. These programs focus on providing clean syringes so that individuals who continue to inject drugs do not get infected with HIV. Through a nonjudgmental approach, education, and offering clean equipment, the programs strive to prevent adverse health outcomes (e.g., HIV infection) among injection drug users. These programs do not encourage or promote drug use but instead offer realistic options to individuals who are unable to quit their drug use. This framework has been proven to be effective in reversing and preventing the HIV epidemic among injection drug users (Des Jarlais, 2010).

The harm reduction framework encompasses multiple levels as policy, environments, and individual behaviors can all be targeted and modified to reduce harm. The framework acknowledges that risky behaviors occur along a continuum ranging from minimal risk to excessive risk. The goal is to identify feasible and realistic options along this continuum that can be adopted to reduce risk. Instead of seeking to criminalize or moralize behavior, harm reduction seeks to meet individuals in their current situation and identify ways to reduce the harmful outcomes to society and the individual that may be a result of engaging in risky behavior. According to a recent editorial in the International Journal of Drug Policy, harm reduction started as a public health strategy informed by social justice and over time has increasingly drawn attention to structural issues and the need to reform policy so that disenfranchised populations can avoid harm (Stimson & O'Hare, 2010).

Biographical Information

Laura L. Hayman earned her BSN, MSN, and PhD at the University of Pennsylvania. Her program of research and scholarship focuses on primary prevention of obesity and cardiovascular disease (CVD) in children, adolescents, and families. Her research, in collaboration with colleagues from several disciplines, has included clinical, school, and population-based studies of biobehavioral risk factors for CVD. Her recent work combines both individual/clinical and community-based approaches to identifying children at risk for obesity and cardiometabolic conditions, and theory-based interventions designed to increase physical activity and promote healthy lifestyle behaviors.

Hayman has served on numerous national and international interdisciplinary advisory and expert panels relevant to primary prevention of obesity and CVD in childhood and adolescence. She has also served in leadership roles in the American Heart Association, the Society of Behavioral Medicine, and the Preventive Cardiovascular Nurses Association. She holds fellowships in the American Heart Association, the American Academy of Nursing, the Society of Behavioral Medicine, and the Academy of Behavioral Medicine Research.

A1C; Glycated hemoglobin; Glycosylated hemoglobin; Hemoglobin A1c

Definition

HbA1c, or glycosylated hemoglobin, is a measure of how much glucose is irreversibly bound (glycated) to hemoglobin, and can be used to assess the degree of exposure to glycemia in the preceding 2–3 months (corresponding to the life span of the red blood cell where hemoglobin is contained). In a person with normal blood glucose levels, the amount of glycated hemoglobin is around 4–6%, representing an average blood glucose level between 70 and 120 mg/dl. In individuals with diabetes, HbA1c can be measured

every 3 months with a goal of keeping the value as close to normal as possible, or at least under 7% in most patients. The higher the HbA1c, the greater the risk over time (usually measured in years) of developing microvascular complications, such as diabetic retinopathy, nephropathy, and neuropathy. HbA1c remains the best predictor for future diabetes-related chronic complications that is available in the clinical setting.

Headaches, Types of: Cluster, Migraine, and Tension

Hiroe Kikuchi
Department of Psychosomatic Research, National Institute of Mental Health, National Center of Neurology and Psychiatry, Tokyo, Japan

Definition

Cluster headache, migraine, and tension-type headache are three major types of primary headaches. Primary headaches are headaches with no apparent underlying organic disease process.

Description

The International Classification of Headache Disorders, 2nd edition (Headache Classification Subcommittee of the International Headache Society, 2004), is a widely used classification of headaches, and it contains diagnostic criteria for headaches. Cluster headache, migraine, and tension-type headache are classified as primary headaches, and their diagnosis is based on the pain characteristics and associated symptoms. Generally, neuroimaging is not necessary for the diagnosis; however, it is considered to exclude underlying abnormalities of the brain in some cases. Assessment of psychosocial aspects is also important especially in migraine and tension-type headache because psychosocial factors can be precipitating and aggravating factors of headache and headache may affect psychosocial condition.

In these headaches, treatment consists of acute therapy and prophylactic therapy. Prophylactic therapy is important because frequent use of analgesics places patients at risk for medication overuse headache.

Cluster Headache

Cluster headache is a headache which is severe, strictly unilateral, and orbital, supraorbital, or temporal in location. Attacks usually occur in series for a period of weeks or months which is called a cluster period. Cluster periods are separated by remission periods which are usually months to years. The attack lasts 15–180 min, and its frequency ranges from once per 2 days to eight times a day. The attack accompanies ipsilateral autonomic symptoms such as ptosis, miosis, lacrimation, conjunctival injection, rhinorrhoea, nasal congestion, and forehead and facial sweating. Pain is severe enough to disturb daily activities, and most patients are restless or agitated during attack.

The prevalence of cluster headache is less than 1%, and prevalence is three to four times higher in men than in women (May, 2005).

Pathophysiological involvement of hypothalamus is suggested by time pattern of attacks. Neurovascular factors are also important.

Acute therapy for cluster headache includes inhalation of pure oxygen and triptan. Subcutaneous injection and nasal spray are preferable to oral administration. As preventive therapy for cluster headache, verapamil is established. Lithium, methysergide, and corticosteroids are also used. Non-pharmacological treatment is generally ineffective.

Migraine

Migraine is further classified into two major subtypes: migraine without aura and migraine with aura.

Migraine without aura is recurrent headache disorder whose pain is generally unilateral, pulsating (throbbing), moderate to severe in intensity, aggravated by daily physical activities, and accompanied by nausea and/or photophobia and phonophobia. The attack lasts 4–72 h, and its median frequency is 1.5 per month. Migraine with aura is characterized by a complex of reversible focal neurological signs (visual, sensory, motor, or speech signs) which gradually progresses in 5–20 min and last for less than 60 min generally before headache. Typically, headache of the same quality as migraine without aura follows aura, but sometimes, the quality of headache is different and even headache can be absent. Symptoms such as fatigue, difficulty in concentrating, neck stiffness, sensitivity to light or sound, nausea, blurred vision, yawning, pallor, or emotional lability sometimes occur several hours to 2 days prior to migraine (either with or without aura), and they are called premonitory symptoms. Migraine may be aggravated (i.e., increased in the severity or frequency in a relatively long term) by psychosocial stress, frequent intake of alcohol, and other environmental factors. An attack may be triggered by menstruation, chocolate, etc.

Prevalence has been reported to be between 5% and 25% in women and 2% and 10% in men.

Trigeminovascular theory is now a broadly accepted pathophysiological mechanism of migraine (Silberstein, 2004). Perivascular trigeminal terminals are stimulated by certain causes and vasoactive substances such as calcitonin gene-related peptide (CGRP) are released. Vessels dilate and neurogenic inflammation occurs, which leads to pain and accompanying symptom such as nausea. Central pain modulation is also thought to be involved. Cortical spreading depression is associated with aura.

Acute therapy for migraine consists of specific (triptans and ergots) and nonspecific (analgesics) (Silberstein, 2004). Triptans are $5HT_{1B/1D}$ receptor agonists and have effects of vasoconstriction and inhibition of vasoactive substances release and of neurogenic inflammation. Prophylactic therapy includes calcium channel blocker, beta-blocker, ergots, antidepressants, and anticonvulsants (Silberstein, 2004). Refraining from drinking alcohol and eating certain foods (chocolate, cheese, etc.) may also be effective for prevention of migraine attacks. Relaxation therapy, thermal and electromyography biofeedback, and cognitive behavior therapy are also used as prophylactic therapy.

Tension-Type Headache

Tension-type headache typically causes pain which is bilateral, pressing or tightening, and mild to moderate in intensity, and is not aggravated by daily physical activities. Although anorexia may accompany, neither nausea nor vomiting does. Photophobia and phonophobia can coexist.

Tension-type headache is the most common type of primary headache, and its life prevalence estimates range from 30% to 78%, and tension-type headache is slightly more in women than in men (Headache Classification Subcommittee of the International Headache Society, 2004). Its prevalence is most at 40s (Loder & Rizzoli, 2008).

Increased muscle tension was formerly thought to be a major cause of tension-type headache; however, now it is thought that peripheral factor (hypersensitivity to pain in the head and neck tissue) plays a major role in less frequent headache (i.e., infrequent and frequent episodic tension-type headache), while central factor

(alteration of pain sensitivity in the central nervous system) plays a major role in more frequent headache (chronic tension-type headache).

Acute therapy for tension-type headache is analgesics (nonsteroidal anti-inflammatory drugs (NSAIDs) and acetaminophen). Over-the-counter analgesics are commonly used. As pharmacological prophylactic therapy, amitriptyline is the most widely researched (Millea & Brodie, 2002). With less evidence, other antidepressants such as selective serotonin reuptake inhibitors (SSRIs) and tizanidine are considered as prophylactic therapy. Relaxation therapy, electromyography biofeedback, and cognitive behavior therapy are also used for prophylaxis.

Headaches: Psychological Management

Hiroe Kikuchi
Department of Psychosomatic Research, National Institute of Mental Health, National Center of Neurology and Psychiatry, Tokyo, Japan

Definition

Psychological management of headache includes assessment of psychosocial aspects of headache, screening and treating psychiatric comorbidity, and application of psychological treatments to manage pain.

Description

Psychological management of headache has been researched mostly in tension-type headache and migraine.

When diagnosing headache, assessment of psychosocial aspects is also important because psychosocial factors can be precipitating and aggravating factors of headache and headache may affect psychosocial condition. In both migraine and tension-type headache, 50–80% of patients report that psychological stress is a precipitating or aggravating factor of headache according to some reports. Identifying individual precipitating or aggravating factors is fundamental for the prophylaxis of headache. In both migraine and tension-type headache, anxiety and depressive mood are reported to be higher than healthy controls and social activities are also affected. Overall assessments of those psychosocial conditions are necessary to understand the burden of headaches.

Comorbidity with mood disorder and anxiety disorder is also reported to be high in both migraine and tension-type headache (Holroyd, 2002). In addition, psychiatric comorbidity is reported to be a possible risk factor for chronification of headache. Therefore, screening and treating psychiatric comorbidity is also necessary for headache management.

Representative psychological treatments of headache are relaxation therapy, biofeedback therapy, and cognitive behavioral therapy (Holroyd, 2002).

In tension-type headache, relaxation therapy in the form of progressive muscle relaxation and autogenic training, electromyographic biofeedback therapy (reducing muscle activity in forehead or neck and shoulder muscles), and cognitive behavioral therapy are used. Although relaxation therapy alone is suggested to be effective, it is reported that the percentage of patients

whose headache was improved was increased when biofeedback therapy was added. Cognitive behavioral therapy is also conducted in combination with other therapies as well as alone. Cognitive behavior therapy increases the effectiveness of relaxation therapy when it is added to relaxation therapy.

In migraine, relaxation therapy in the form of progressive muscle relaxation and autogenic training, thermal biofeedback therapy (warming hand), and cognitive behavioral therapy are generally thought to be treatment options for prevention of migraine as psychological treatment. However, it is reported that cognitive behavioral therapy did not appear to enhance the effectiveness of relaxation therapy or thermal biofeedback.

In cognitive behavioral therapy, it is assumed that irrational cognition and maladaptive behavior underlie pain, psychological stress, and mood disturbances and those cognition and behavior are the targets of intervention. Usually, treatment program comprising several components is conducted and relaxation therapy is often included. Treatment aims at achieving adoptive coping behavior to pain as well as approaching psychosocial factors. Psychological treatments have a feature that they all aim at self-control in common. There is not any recommendation about which of these psychological treatment to choose for specific patients.

Psychological treatment is usually used either with or without medication. In chronic tension-type headache, the combination of cognitive behavioral therapy and tricyclic antidepressants are reported to possibly improve outcome relative to monotherapy.

The mechanism of how these psychological treatments improve headache is still unclear. Previous studies that showed the effect of psychological treatment on headache was not limited to patients with psychiatric comorbidity, and it is not likely that the improvement of comorbid psychiatric disorders fully mediates the improvement of headache.

Description

Health anxiety refers to an excessive concern or preoccupation about the meaning and potential

consequences of somatic symptoms. Individuals high in health anxiety are more likely to believe that their physical symptoms are signs of a serious disease than their low anxious counterparts despite medical reassurance indicating otherwise.

Several environmental, biological, and psychological (e.g., behavioral and cognitive) factors have been implicated as causes of health anxiety (Abramowitz & Braddock, 2008; Kirmayer & Looper, 2006). Evidence from research examining the environmental antecedents of health anxiety indicate that individuals, especially females, who have experienced serious illness as children, suffered the death of a loved one from a devastating medical condition, or were victims of physical, sexual, and/or emotional abuse in childhood are at higher risk of developing health anxiety when compared to individuals without a history of traumatic experiences (Stein et al., 2004). Another environmental risk factor is parental modeling of illness behaviors via observational learning (Mineka & Ben Hamida, 1998). For instance, children can learn from overprotective parents that any somatic symptom is a sign of a serious disease which can result in the regular use of emergency and/or primary care clinics to care for nonthreatening symptoms. Finally, informational transmission (e.g., media and Internet) can serve as a trigger for health anxiety and health anxious-related behaviors (Abramowitz & Braddock, 2008; Rachman, 1991). Examples of this include mass psychogenic illness, mass anxiety hysteria, "Koro" in Southeast Asia, and medical student's syndrome.

Family and twin studies suggest that heritability may play a role in the development of health anxiety and hypochondriasis; however, evidence about the specific genes involved is inconclusive (Smoller, Gardner-Schuster, & Covino, 2008). Research on the neurobiological basis of health anxiety suggests that hyperactivity in the amygdala and limbic regions and an inability of higher cortical executive areas to inhibit limbic responses may be involved in initiating and maintaining anxiety episodes (Martin, Ressler, Binder, & Nemeroff, 2010). Additionally, neuropharmacological studies have shown that either decreased inhibitory control utilizing GABA, or an increase of the excitatory neurotransmitter Glutamate, or a synergistic combination of both systems play key roles in the development of health anxiety. It must be noted, however, that these neurobiological antecedents are not unique to health anxiety but rather shared by various anxiety disorders.

The identification and understanding of psychological antecedents of health anxiety have received wide attention from researchers (Marcus, Gurley, Marchi, & Bauer, 2007). Individuals high in health anxiety have been found to: (1) have catastrophic beliefs about their somatic symptoms, (2) be more sensitive to and aware of their somatic symptoms (i.e., somatosensory amplification), and (3) be more likely to interpret their somatic symptoms as signs of a serious disease. Health-anxiety beliefs can be elicited by various triggers such as benign physical symptoms, nonthreatening disease, and hearing or reading about illnesses from different sources (e.g., friends, media). Once triggered, these beliefs are responsible for maintaining a feedback loop that results in automatic hypochondriacal thoughts which, in turn, increase attention to somatic sensations that may confirm illness (i.e., confirmatory bias). Increased somatic vigilance compounded with a confirmatory bias help perpetuate health anxiety.

Health anxiety is best understood as a continuum ranging from mild to severe. Although many people have benign health anxiety, it can become extreme and result in hypochondriasis, a somatoform disorder (Faravelli et al., 1997; Looper & Kirmayer, 2001). The prevalence of hypochondriasis in the general population (0.2%) is low, while nonclinical levels of health anxiety (6%) are more common (Looper & Kirmayer, 2001). To diagnose an individual with hypochondriasis, he or she must believe that his/her somatic symptoms result from a serious disease despite medical reassurance. These symptoms must last a minimum of 6 months and cause significant

distress or interfere with social, occupational, or other forms of functioning (American Psychiatric Association [APA], 2000). Hypochondriasis is typically treated with a combination of cognitive behavioral therapy and psychotropic medication (e.g., SSRI, Pimozide, and Clomipramine).

Health anxiety can be assessed with different tools including self-reports and structured clinical interviews. The most widely used self-reports include the Short Health Anxiety Inventory (Salkovskis, Rimes, Warwick, & Clark, 2002), the Illness Behavior Questionnaire (Pilowsky & Spence, 1994), and the Health Anxiety Questionnaire (Lucock & Morley, 1996). Structured clinical interviews include the Composite International Diagnostic Interview (World Health Organization [WHO], 1990) and Structured Clinical Interview for DSM disorders (First, Spitzer, Gibbon, & Williams, 1995). Clinical interviews should be used when the goal of assessment is the diagnosis of clinical levels of health anxiety.

Health Assessment Questionnaire

Definition

The Health Assessment Questionnaire (HAQ) was developed three decades ago by James F. Fries, MD, and colleagues at Stanford University (Fries, Spitz, Kraines, & Holman, 1980) as a model of patient-reported outcome (PRO) assessment for assessing physical function. Three reviews examined the HAQ's history, its reliability, validity, and applicability (Bruce and Fries, 2003; Ramey, Fries, & Singh, 1995; Ramey, Raynauld, & Fries, 1992).

The HAQ has been administered globally and validated in patients with a wide variety of rheumatic diseases, HIV/AIDS, and in studies of normal aging, in diverse disciplines and different cultures, and in dozens of languages without impacting reliability or validity with properly designed adaptations. The HAQ is usually self-administered. However, it can be administered face-to-face or over telephone by a trained interviewer. Further, the HAQ has been validated for Internet administration (Bruce, Fries, & Lingala, 2011). The HAQ is available online (The Arthritis, Rheumatism, and Aging Medical Information System, 2011).

The original HAQ was developed using classical test theory methodology, is sensitive to change, and a good predictor of future disability and costs. However, it did not benefit from use of modern psychometric approaches. Modern methods, such as Item Response Theory (IRT) (Embertson & Reise, 2000), which quantitatively assess item properties, enable development of more precise instruments (Rose, Bjorner, Becker, & Fries, 2008).

Recently, items in the HAQ, along with the SF-36's PF-10, have undergone extensive revamping using both classical and IRT methods as part of the Patient-Reported Outcomes Measurement Information System (PROMIS) (Reeve et al., 2007). PROMIS is part of the National Institutes of Health (NIH) Roadmap Initiative aimed at re-engineering the clinical research enterprise. Work in PROMIS resulted in a 20-item revised HAQ and the IRT-derived PROMIS PF-20, both of which more precisely measure physical function and are available for use on the PROMIS website (http://www.nihroadmap.nih.gov) (US Department of Health and Human Services, 2011). Investigation of the psychometric functions showed that instruments utilizing these items are more patient-centered, more validly translatable, and have better clarity in diversely educated groups. In addition, they also show responsiveness and precision that is

better than the parent instruments, the original HAQ and PF-10 (Fries, Krishnan, Rose, Lingala, & Bruce 2011).

Health Beliefs/Health Belief Model

Tana M. Luger
Department of Psychology, University of Iowa, Iowa City, IA, USA

Definition

Rosenstock's Health Belief Model (HBM) is a theoretical model concerned with health decision-making. The model attempts to explain the conditions under which a person will engage in individual health behaviors such as preventative screenings or seeking treatment for a health condition (Rosenstock, 1966).

Description

Under the HBM, a person's likelihood for health behavior is assumed to be related to four main variables. First, action is more likely if the person perceives himself to be *susceptible* to or at risk for the condition. For example, if Lucy has a history of breast cancer in her family, she may see herself as more susceptible to developing breast cancer, and thus, be more likely to get a mammogram each year. Second, the likelihood for action depends on the *perceived seriousness* of the condition. Seriousness may be judged based on the amount of emotional arousal produced by thinking about the condition as well as the anticipated physical, social, and psychological consequences of developing the condition. For example, Lucy's mother passed away from breast cancer so she deems it to be a serious condition requiring preventative action. Third, the *perceived benefits* of performing the action are considered. Lucy considers the effectiveness of a mammogram in detecting breast cancer when determining whether to get the screening. Finally, the *perceived barriers* of performing the action are weighed. Lucy knows that a mammogram can be uncomfortable and scheduling an appointment is inconvenient. However, for Lucy, the benefits outweigh the barriers. Additional modifying variables like age and sex have been introduced with the assumption that they influence the above beliefs.

The variables of HBM are intended to measure a person's psychological readiness or intentions to act (Kirscht, 1988), and on the whole, research has found the HBM to be predictive of people's individual health behaviors (Janz & Becker, 1984). Self-reported susceptibility, benefits, barriers, and severity were shown to be correlated with health behavior outcomes such as attending preventative screening, seeking medical care, and utilizing health clinics. However, the HBM has been unable to consistently predict adherence to a medical treatment regimen or terminating an unhealthy behavior such as smoking (Kirscht, 1988). Additionally, while the variables of HBM may measure a person's individual level of readiness, the optimal level of readiness for health behavior change is still unknown.

Further critiques state that HBM ignores self-efficacy (a person's belief that he has control over a particular behavior) which has been shown to play a large role in behavior change (Kirscht, 1988). Thus, while the predictive validity of HBM with regard to health behaviors seems firm, the usefulness of focusing only on HBM factors in interventions has been contested (Davidhizar, 1983; Kirscht, 1988).

Health Care

Peter Allebeck
Department of Public Health Sciences, Karolinska Institute, Stockholm, Sweden

Definition

Health care is a general term comprising services provided to improve health in the general population as well as to cure diseases and relieve symptoms in diseased patients. Health care may denote the organization of services (e.g., private vs public health care), a facility (e.g., hospital or health care center), as well as the actual delivery of care (e.g., to provide health care or to obtain health care). The term may comprise preventive services, such as vaccination, and mother and child care as well as curative services.

Health Care Access

Peter Allebeck
Department of Public Health Sciences, Karolinska Institute, Stockholm, Sweden

Definition

Health care access is the extent to which patients and groups have access to health care. It depends on factors related to general living conditions in society, and to organization of health services as well as factors in individuals. General conditions comprise availability overall of economic resources and how they are distributed, manpower for health care, and availability of health care facilities and transport systems to reach them. Organization of health services comprises how they are organized in primary and secondary care, adequate staff at various levels, geographical distribution, and insurance system to cover costs. Factors in individuals and groups are related to their knowledge about health care services, capacity to pay for fees and transport, and knowledge of the language and other cultural codes needed to access health care.

Health Care System

Peter Allebeck
Department of Public Health Sciences, Karolinska Institute, Stockholm, Sweden

Definition

The concept “health system” has been developed and defined by the World Health Organization (WHO), and is now widely used internationally by scientists and policy makers. The WHO defines health system as “all organizations, people, and actions whose primary intent is to promote, restore, or maintain health.” The concept thus includes not only public and private health care facilities and staff, but also health insurance organization, water control, occupational health, and safety legislation. The WHO has described a health system framework consisting of six building blocks: Service delivery; Health workforce; Information; Medical workforce, vaccines, and technologies, Financing, and Leadership/Governance.

Health Care Utilization

Olveen Carrasquillo
Division of General Medicine, Miller School of Medicine, University of Miami, Miami, FL, USA

Definition

Health Care Utilization is the quantification or description of the use of services by persons for the purpose of preventing and curing health problems, promoting maintenance of health and well-being, or obtaining information about one's health status and prognosis.

Description

Health Care Utilization refers to the use of health care services. People use health care for many reasons including preventing and curing health problems, promoting maintenance of health and well-being, or obtaining information about their health status and prognosis.

Utilization is often reported in a variety of different methods:

1. The number of services used over a period of time divided by a population denominator (e.g., in 2008, there were 320.1 ambulatory Care Visits to Physicians' Offices per 100 persons living in the USA).
2. The percentage of persons who use a certain service over individuals eligible for that service in a period of time (in the USA in 2008, 75% of all women aged 18 years and over reported having a Pap smear in the last 3 years).
3. An aggregate number without a denominator (in 2008, there were 39.9 million discharges from US hospitals).

Health care utilization can vary by many factors. Sociodemographically persons at extremes of age (very old or very young) have higher health care utilization. Women also have higher utilization than men, partially explained by need for obstetric and gynecologic care. By race and ethnicity, members of minority groups have lower utilization of certain health care services. For example, despite a higher burden of cardiovascular disease, after adjusting for factors that predict utilization, African-Americans are less likely to receive invasive cardiac procedures. Latinos are less likely to have colorectal cancer screening tests. By health status, persons with poorer health have higher utilization.

However, of all the factors that drive utilization, perceived need for health care by the patient is probably the single most important independent factor. In addition, since many people may not fully know how medical conditions are prevented, diagnosed, or treated, perceived need also includes the perceptions on what health care is needed for a particular person by their providers and others who make health care recommendations to patients. In addition to need, there are many other factors that also impact utilization. Often these are conceptualized as predisposing, enabling, and need related factors. Examples of predisposing factors include a person's propensity to seek care as well as cultural norms on health care seeking behaviors. Ability to pay or health care coverage is the most important enabling factor. However, other important enablers include accessibility and location of services, language and cultural barriers, and availability of resources to appropriately provide such services.

Data on utilization can be gathered and compiled from various sources. One is administrative or claims data collected from those delivering

health care services or serving as payers of those health care services (such as insurers). An example is data on the number of cardiac catheterizations performed among Medicare beneficiaries which can be examined from the Medicare Provider Analysis and Review (MEDPAR) files. Data can also be collected from providers using surveys. An example of this type of utilization data is the CDC's National Ambulatory Medical Care Survey in which a representative sample of office-based providers are queried to provide data on health care services delivered over a 1-week period. Another example is the Nationwide Inpatient Sample containing discharge abstracts from a 20% stratified sample of US community hospitals (part of AHRQ's Healthcare Cost and Utilization Project). A limitation of these methods is that collecting and compiling accurate such data through these approaches can be resource intensive, particularly in countries with multi-payer and delivery systems. Also, it will not capture services delivered outside the health care sector being sampled. An example is data on alternative medicine.

Another approach used in many countries to collect information on healthcare utilization is through population-level surveys using self-reported data from patients themselves. In the USA, examples are the CDC's National Health Interview Survey and AHRQ's Medical Expenditure Panel Survey. Since these are based on patient self-reports, accuracy is always a concern. Thus, careful attention needs to be paid in design, collection, and analysis of data from such surveys so that the data presented is valid and accurate.

Utilization data is used for a variety of purposes. Cross-sectional data can be used to compare services received across different settings, to relate provider characteristics to patient utilization, to compare utilization rates among subpopulations, and to assess how the health care delivery system is being used and by whom. It can provide interested parties with information to help determine if utilization is appropriate or inappropriate, high or low quality, and expensive or inexpensive, and highlight areas that may warrant in-depth examination. For example, data on a higher than expected rate on cesarean sections or less use of cancer screening tests by certain population subgroups may highlight areas in need of attention. Longitudinally, health care utilization data is also used to monitor changes in the use of health care resources and to forecast future health care expenditures, or as the basis for projecting future healthcare needs such as facilities, personnel, or supplies.

Health Communication

Health education; Health promotion; Social marketing

Definition

In the context of behavioral medicine, health communication is best defined as transmission or exchange of information designed to modify behaviors related to health. This can be envisioned broadly to encompass communication in medical settings (e.g., patient counseling to increase adherence to regimens), in communities and populations (e.g., media and community outreach campaigns to increase condom use), and in the political sphere (e.g., internet messaging platforms designed to spur advocacy to influence policies that affect health).

Description

Modalities include (1) face to face, telephone, and telecommunicated interpersonal communication between individuals and groups; (2) text and graphic messaging in print and electronic form, e.g., newspaper stories, posters, leaflets, websites; (3) audiovisual messaging in mass communication, e.g., television and documentary film; and (4) new media integrating multiple modalities through interactive web-based and mobile applications.

Skills training and guidelines for health communication are widely available online (e.g., U.S. Centers for Disease Control, 2011). Key tasks for effective health communication include assessment of audiences' health literacy, composition of appropriate messages through cultural competency, selection of channels of communication to effectively reach defined audience segments, and creation of message content to influence specified intermediate cognitive or emotional factors to achieve measurable changes in behavior. Audience research is central to effective health communication, as observations, interviews, focus groups, and surveys can be used to prioritize the segmentation of audiences within populations and identify most suitable channels and forms of communication for those audiences, and the knowledge, attitudes, perceptions, feelings, competencies and other factors that will provide the most effective message content for achieving behavior change.

Health communication is an important part of health education and promotion (Glanz, Rimer, & Viswanath, 2008), which also is concerned with changing behavior through both communication and the modification of environmental circumstances to facilitate or incentivize healthy behaviors. However, changing environmental circumstances requires effective media advocacy and related political communication skills. Social marketing (Andreason, 2006), in which techniques and strategies from advertising and sale of consumer products are adopted for noncommercial purposes, has become the dominant professional model for much health communication and been associated with numerous successful behavior change campaigns in both the developed and developing world (Wakefield, Loken, & Hornik, 2010). Alternatives and complements to the marketing model include behavioral journalism (McAlister, 2000) and the use of narrative storytelling (Kreuter et al., 2007), illustrated by reality-based television programs that follow individuals through the process of smoking cessation or weight loss, and edutainment in the form of radio dramas to promote family planning.

The basic theoretical foundation for health communication was articulated by William McGuire (2001) in his classic communication matrix model which considers how channels, sources, and message content influence exposure, attention, comprehension, yielding to persuasion, skill acquisition, trial of new behaviors, and long-term behavior change. This kind of sequential analysis of communication effects on individual behavior change has been elaborated in the transtheoretical model (Prochaska & DiClemente, 2005), which highlights specific processes in particular steps such as emotional arousal in the initial contemplation of change and feelings of self-efficacy and competence in the acquisition and maintenance stages of behavior change. Health communication effects on sequential processes in behavior change on the societal level are described in Rogers' (2003) diffusion of innovation model, which distinguishes between early adopters (who acquire innovations after being exposed to them via

media communication) and later adopters (who are more influenced by peer modeling, interpersonal communication, and conformity pressures).

The integrative model of behavioral prediction (Fishbein & Cappella, 2006) classifies mediating psychological factors that are influenced when communication yields behavior change: (1) modification of belief and expectations regarding behavior outcomes and values, (2) increases in perceived "normative" social pressure and anticipations of social sanctions, and (3) rise in "self-efficacy" expectations regarding personal or collective ability and competence. The latter factor is central to Bandura's (2001) social cognitive theory, which emphasizes a dual link comprised of peer modeling via mass media and social reinforcement in learning to perform healthy behaviors. Social cognitive theory also provides a formulation for self-management training methods widely used in patient education and behavioral counseling. Motivational interviewing (Rollnick, Miller, & Butler, 2007) is another notable theory-based technique for interpersonal communication to change behavior.

Innovation in health communication, while largely based on theoretical foundations noted above, has followed emerging technologies. Computer and web-based interactivity has opened new capacities for communicators to precisely segment differentiated audiences and tailor messages to their observed preferences. Internet and mobile applications for gaming have become notable modalities for health communication (Read & Shortell, 2011). New platforms for interactive social media and mobile messaging are providing opportunities for more compelling communication with patients in behavioral medicine, communities in health promotion, and advocates for policies to strengthen public health (Korda & Itani, 2011).

Definition

A health disparity is defined as an observed difference in health outcomes (e.g., diabetes) or health status between the most advantaged group in a given category (e.g., the wealthiest) and all other groups in that category. Observed differences in the health outcomes are not only limited to differences between better- and-worse-off groups, given they reflect varying levels of social advantage and disadvantage (Braveman, 2006).

Description

The term "health disparity" is often times used interchangeably with the terms "health inequality" or "health inequity." The use of "health disparity" is most common in the United States, whereas the other terms are most often used outside of the United States (Carter-Pokras & Baquet, 2002). The underlying distinction between these terms is that the latter ones distinguish between health differences that are unfair, unjust, and unavoidable. To illustrate, differences in health among men and women that are due to sex-specific problems (e.g., ovarian cancer) would be attributed to biological variation and therefore unavoidable, whereas health differences due to social or environmental factors (e.g., socioeconomic status, unequal access to resources), for example, would be considered unjust and avoidable (Whitehead, 1992). However, the term "health inequality" requires both an ethical and moral consideration regarding what constitutes a difference as "unavoidable" and "unjust/unfair," and therefore leaves its definition open to interpretation (Braveman, 2006; Carter-Pokras & Baquet, 2002).

Health disparities are typically thought of as referring to racial/ethnic disparities in health status. This is partly due to the long legacy of racism and racial inequality in the United States, for example. In fact, it has been consistently argued that health disparities must not be stripped from the social, cultural, political, and historical contexts in which they occur. However, differences in health can be present along other social dimensions, other than those based on race and ethnicity. These may include differences in health indicators with respect to gender, socioeconomic status (e.g., education, occupation, income), disability, age, and sexual orientation, among other characteristics. Several social determinants of health disparities have been identified, including but not limited to socioeconomic status (e.g., education, income, poverty), residential segregation, differential access to resources, lack of health insurance, and differential exposure to different types of stressors. These factors can both initiate as well as sustain health disparities. Further, systematic differences in health outcomes, such as those noted for African Americans across a number of health indicators (e.g., heart disease, certain types of cancer, diabetes, HIV, infant mortality), can further compromise the health status of already disadvantaged social groups (Myers, 2009).

There is no clear consensus on how to best measure health disparities, given the differences that exist in the use of the terms "health disparities," health inequalities," and "health inequities." Likewise, different approaches to measuring health disparities exist given the research question one is trying to answer. Nonetheless, a direct way of measuring a health difference is by comparing the health of one group (the reference group) with the health of another group(s). In general, one could compare the non-minority to the majority population (e.g., non-Hispanic whites compared to Asian Americans); compare a group against the general population; or compare differences among segments of the population. Other considerations include subgroup comparisons; for example, comparing differences within the Latino category (e.g., Mexican Americans against Cuban Americans). However, for any of these approaches, lack of clarity exists in who the reference group should be, although the most widely used approach has been to identify specific social groups a priori and examine differences in health status between them (Carter-Pokras & Baquet, 2002). Additionally, the U.S. National Center for Health Statistics has advocated for using the group with the most favorable rate in a given health indicator as the reference category, since it can potentially avoid dealing with concerns regarding who is considered to be the "most" socially advantaged group (Braveman, 2006; Keppel, Pearcy, & Klein, 2004). Other approaches to measuring health disparities have included obtaining relative indicators of health (e.g., black–white ratios), as well as measuring the distribution across individuals in a population on health status (similar to the measurement of income distribution in a population) (Asada, 2005). Depending on the field and question of interest, any of these approaches may be used, though they all have advantages and disadvantages to them.

Importantly, health disparities do not equate to *health care disparities*. In contrast to a health disparity, the Institute of Medicine, in its report "Unequal treatment: Confronting Racial and Ethnic Disparities in Health Care," defines a health care disparity as a difference in access to and quality of health care treatment between population groups that are not justified by access-related factors, treatment preferences, or the underlying health condition(s) of the population groups. Important to note is that limited access to treatment and good quality health care services play a significant role in observed differences in health status, particularly in producing racial/ethnic health disparities (Institute of Medicine, 2002).

Significantly, although specifying that both a difference in health exists and that they are socially patterned are important first steps to addressing the problem, they alone are not enough to reduce or eradicate health disparities. Indeed, addressing health disparities will require multi- and interdisciplinary research approaches to better understand the causes of specific types of health disparities, as well as multilevel interventions that target social disparities known to contribute to differences in health status (Braveman, 2006; Myers, 2009).

Definition

Health economics applies the principles of economics to address problems of health and health care. It identifies the factors that contribute to the health of individuals and populations and identifies the most productive ways of using whatever resources are available for improving health.

Description

Health economics is an area of economics that applies the principles of the discipline of economics to address problems of health and health care. Both health and health care are commodities with characteristics that make them different from standard goods and services that are bought and sold in private markets. This means they require particular attention from economists in order to consider the use of resources devoted to producing health care and changing health.

Health as a Commodity

Health cannot be purchased directly. Instead it is "produced" by the levels and combinations of health "determinants," that is, factors that influence health and illness. Some of these factors can be purchased directly (e.g., exercise equipment, healthy foods, health care), while others may be in the form of public goods (or bads) such as air pollution. The individual may have little control over exposure to some of these determinants.

Although *health care* is an important determinant of health, other factors might also influence an individual's health, for example, an individual's genes, his lifestyle (Does he smoke?), his places of home and work, his diet and activity levels as well as limitations placed on choices about many of these factors by income and wealth. The relationship between health determinants and health outcomes is often complex and conditional on other health determinants. For example, the improvement in health produced from a heart bypass procedure may depend on the environment in which an individual lives and works (Are there factories close by that pollute the air that he breathes? Is he exposed to unhealthy work conditions?), the lifestyle he follows (Does he smoke?), the skill levels of the doctors treating him, etc. Economics provides a means of analyzing the production of health both at the level of an individual but also in terms of the production of health in populations.

The estimation of health production functions (the relationship between health determinants and health outcomes) enables us to consider the following:

1. The returns to investment in health determinants across a range of *different levels* of investment. For example, is the relationship between the quantity of health care and the health outcome produced constant for all levels of health care or does the change in health produced from health care change with the level of investment in health care? This is similar to the dose–response relationship in clinical research.
2. Whether the returns to investment differ among a range of *different health determinants*.

For example, does investing resources in public health programs to reduce smoking produce more health outcomes than investing the same amount of resources in additional cardiac care services?

3. Whether the return to investment in a particular health determinant is conditional on the levels of other health determinants. For example, is the health outcome associated with a public health program to reduce smoking conditional on the socioeconomic circumstances of the population targeted by the program.

Health Care as a Commodity

Health care represents a range of services aimed at improving health or reducing the risks of health loss. It is often labor intensive requiring the inputs of a mix of skilled professionals (physicians, nurses, dentists, etc.) together with nonlabor inputs such as capital equipment (hospitals, beds, diagnostic and surgical equipment) into a health care production function. The production function represents the particular technology (or production process) used to combine inputs to produce health outcomes. For example, primary care physicians may work independently, or in groups or as part of multidisciplinary health care teams.

Often opportunities arise for substitution between inputs. For example, nurse practitioners are trained to be able to perform services provided by family physicians. The production of primary care services could be changed by deploying more nurse practitioners and fewer family physicians. Decisions about the choice of production function need to be informed by evidence of the difference in outcomes and costs of the different ways of producing primary care services. Substitution can also occur between human and physical capital often as a result of new technologies. Cataract replacement surgery used to involve an inpatient stay requiring considerable inputs of physician time. The introduction of new laser technology has reduced the amount of physician time required, with the procedure now taking only a few minutes delivered in an outpatient clinic.

In addition, health care often involves episodes of care that are made up of a complex series of complementary services (e.g., prevention, treatment, and rehabilitation). The health outcomes of each item of care within an episode may not be simply additive. Failure to provide one element of the package of services may undermine the outcomes of the other elements.

Both the demand and supply of health care are complex issues that cannot be analyzed in the same way as many other commodities. Because of the complex nature of the association between health care use and health outcomes, individuals are unable to determine what services they need to address their health problems. Instead they rely on the advice of their health care provider. In an unregulated market, any individual could set themselves up as an "expert" in diagnosing the cause of an individual's health problem, recommending a treatment and delivering that care. However, changing provider as a result of poor advice would not avoid the potentially profound consequences of poor health care decisions (serious injury, illness, disability, or death). Supply is, therefore, organized through a system of strict licensure that involves restrictions on entry to the market to individuals with defined qualifications as well as professional codes of practice in order to protect the public interest.

Health care is not demanded for its own intrinsic value. On the contrary, individuals would generally prefer to not consume health care since it is often unpleasant, uncomfortable, or painful. Instead, the demand for health care is derived from the demand for the health outcomes it is expected to produce. Providers, in addition to being a major input in the supply of health care, also influence (or induce) the demand for health care through their role as advisor, or agent, of the patient. Supplier-induced demand is not a problem per se because the whole purpose of a licensure system is to have "experts" advising individuals what services they need to improve their health. However, it can become a problem where the earnings of providers respond to the

level and type of health care delivered. As a result changes in levels of services used over time need not reflect (only) changes in need for those services among patients but also responses of providers to income opportunities. This means that the traditional market of supply and demand does not exist for health care and hence market mechanisms fail to achieve the socially optimum allocation of health care resources.

Health care economics is that part of health economics concerned with the supply of health care and the evaluation of health care services and patient uptake of and compliance with treatment. In the context of scarce health care resources, it considers the impact on the health and well-being of individuals and populations of using the available resources in alternative ways by comparing both the effects (outcomes) and costs of different health care interventions (Economic evaluation). Such evaluations are, in isolation, simply descriptive information on the expected rate of return on additional investment (what extra outcome can be produced by investing more resources in this particular treatment?). In addition, consideration needs to be given to the opportunity cost of the additional investment (what has to be forgone in order to provide the additional investment required) and how to ensure the services supported by the additional investment will be produced by providers and consumed by patients in the way intended. Hence, health care economics extends beyond the area of economic evaluation of health care interventions to also incorporate the study of the behavior of providers and consumers. So, for example, there may be interest in introducing a new screening service. Health care economics would involve inter alia the following:

1. Estimating the additional costs and effects of the new service compared to existing practice
2. Calculating the expected rate of return of the additional costs
3. Considering the alternative ways of supporting the additional investment within the existing resource constraint and the forgone effects associated with taking the resources required from these other uses
4. Analyzing the behavior of providers and patients when presented with the opportunity to deliver/use the new service

This final set of challenges involves studying the funding, planning, management, and delivery of health care. Health problems can be caused by problems associated with low income and wealth, and health problems can lead to reductions in income and wealth as they can restrict normal activities. As a result an individual's need for health care is greatest when his ability to pay for health care is lowest. Health economics is, therefore, concerned with addressing this "conundrum" by analyzing alternative approaches for funding provision, allocating resources, and managing performance.

The World Health Organization defines health education as "any combination of learning experiences designed to help individuals and communities improve their health, by increasing their knowledge or influencing their attitudes." Because knowledge alone may not be powerful enough to motivate change, health education works to enhance knowledge, attitudes, and skills to positively influence health behaviors of individuals and communities.

Adult learning theory is an important construct to consider for effective health education. Malcolm Knowles has identified five crucial assumptions about the characteristics of adult learners. These characteristics are (1) self concept, as a person matures, they move from a dependent personality to a self-directed one; (2) experience, an accumulation of experiences are a resource for learning; (3) readiness to learn, an adult's readiness to learn is oriented to the tasks of their social roles; (4) orientation to learning, adult learning shifts from subject-centered to problem-centered; and (5) motivation, an adult learner's motivation to learn is internal.

Health education is provided in a variety of settings and can be targeted at individuals, groups, or larger populations. Although health education is generally considered primary prevention as a health promotion strategy, it can also occur at the secondary and tertiary levels. Health education at the primary prevention level is aimed at educating to promote healthy behaviors and to prevent the occurrence of illness or injury; at the secondary and tertiary levels, health education focuses on teaching strategies to detect problems early by identifying risk factors, and rehabilitation to optimize function and prevent complications of disease.

Health education is a dynamic process that requires planning and evaluation of interventions. Important steps include assessing the need for education of a target population, setting learner-centered goals and objectives, implementing the educational intervention, and evaluating and revising education to meet the targeted goals. Other considerations needed for education to be effective include one's readiness to learn, and personal, cultural, political, and environmental factors that may impact learning.

Health Insurance Portability and Accountability Act of 1996 (HIPAA)

HIPAA is a federal law that addresses a variety of health care subjects in various titles. These address health insurance coverage, enrollment and preexisting conditions, fraud and abuse, administrative simplification, electronic billing and coding for health care services, and the protection of certain individually identifiable health information that is obtained by "covered entities." These titles affect how health care claims are documented and billed and amended laws governing health insurers. Tax laws were amended to establish medical savings accounts and address the deductibility of health insurance premiums by self-employed individual, long-term care insurance, and provide other benefits. With respect to fraud and abuse, HIPAA also, for example, provide for advisory opinions, increased and expanded fraud and abuse investigation and enforcement penalties and tools for regulatory agencies and outline when inducements by health care providers to Medicare and certain other health care beneficiaries are prohibited. The use, disclosure, and retention of protected health information is addressed under both a privacy rule and a security rule. Covered without limitation entities include health care providers such as physicians, nurse practitioners, physician assistants, psychologists, health care facilities such as hospitals, nursing homes and pharmacies, health insurance companies and health plans, and entities that process nonstandard health information they receive from another entity into a standard format (a health information clearing house). There are also regulations governing the sharing and use and accounting of information by business associates of covered entities. Any discussion of HIPAA should also include reference to the statutes and regulations enacted under the Health Information Technology for Economic and Clinical Health (HITECH) Act, enacted as part of the American Recovery and Reinvestment Act of 2009. Subtitle D of the HITECH Act addresses the privacy and security concerns associated with the electronic transmission of health information, in part, through several provisions that strengthen the civil and criminal enforcement of the HIPAA rules.

Definition

The term *health insurance* is generally used to describe a form of insurance that pays for medical expenses of the insured. The main aim of a health insurance is to spread the financial risk arising from ill-health. Health insurance may apply to a limited or comprehensive range of medical services and may provide for full or partial payment of the costs of specific services. Moreover, the insurance could be provided either through a governmental national insurance program, or from private for-profit or non-for-profit insurance companies. Some health care systems rely more on private health insurance than others, for example, the health care system in the United States.

Description

A *health care system* includes all activities and structures whose primary purpose is to influence health in its broadest sense. The goals for health systems are good health, responsiveness to the expectations of the population, and fair financial contribution (World Health Organization (WHO), 2000). *Health care systems* are organized differently, that is, the way health care is provided and how it is financed differs between countries. Most health care systems are characterized by both providers (primary care centers, hospitals), who supply health care services, and purchasers (insurers, health authorities) who buy health care for a certain population. Health care systems can be funded via social health insurance, general taxation to the state, county or municipality, direct or out-of-pocket payments, voluntary or private health insurance, and donations or community health insurance. Most countries' systems constitute a combination of these. One common feature is that all health care systems implicitly *pool* the risks associated with individual health care needs (WHO, 2000). A risk pool allows a large group of people to share the risk that they may become ill and need expensive care. Funds dedicated for health care are collected through pre-payment (e.g., via insurance) and are managed in such a way as to ensure that the risk of having to pay for health care is borne by all the members of a pool and not by each contributor individually.

Since improving access to health care services has been a fundamental objective of health systems in the past 30 years, most countries today have a *national health insurance*, which means that it insures a national population. By having a national health insurance governments ensure that people have access to affordable health services without risking, ending up in financial difficulties. Very often national health insurance systems are established by national legislation. The clear benefit of national insurance is that the pool of pools is very large representing the national population. The contribution from the individual is regulated by the government and paid into the pool over a lifetime. This is different from *private health insurance*, where the price is set in a competitive insurance market and health risks are matched with the price of the insurance.

National health insurance can be administered by the public sector, the private sector, or a combination of both. These insurance programs differ both in terms of how the money is collected, and how the services are provided. Even if several countries raise part of the revenue for health in the same way, they may operate differently in how they pool funds and how they purchase and provide services. This is why the

traditional way of categorizing health financing systems into tax-based or social health insurance is not longer useful (WHO, 2010). In some countries, payment is made by the government (or local governments) directly from tax revenue, for example, Canada and Sweden. In other countries, for example, the UK, an additional contribution is collected for all workers, paid by employees and employers based on their earnings. In both of these cases the collection is administered by the government. The collection of compulsory contributions can also be administered by non-profit organizations like in the case of France. This is sometimes related to as a single-payer health care system. The health care providers may be either publicly or privately owned. The Netherlands, on the other hand, has adopted a completely different funding approach, where competing health insurance funds receive the compulsory contributions. These insurance funds can be either public bodies, private for-profit companies or non-profit companies. They are all obliged to provide a minimum standard of coverage and are not allowed to discriminate between patients by charging different rates according to age, occupation, or previous health status. Other countries' national health insurance plans, for example, Germany and Belgium, are largely funded by contributions by employers and employees to sickness funds. With these programs, funds usually come from three sources (private, employer-employee contributions, and national/subnational taxes). These funds are usually not for profit; institutions run entirely for the benefit of their members.

Some national insurance plans also provide compensation for loss of work due to ill-health, or covering things such as pensions, unemployment, and occupational retraining.

Countries' national health insurance systems also differ in terms of the amount of out of pocket payments that are required. Out-of-pocket expenses are direct outlays of cash made by the patient when seeking care, which may or may not be later reimbursed. Many countries still rely greatly on out-of-pocket payments from individuals to health service providers to fund their health systems. Some countries have abolished out-of-pocket payments completely, for example, the United Kingdom, and the patient is not paying anything when seeking health care, while in other countries patients are expected to pay part of their medical expenses and to pay more for higher level of services, for example, as provided in Singapore. In other countries like France, patients pay medical bills and are later reimbursed by sickness insurance funds. These outlays made by patients, usually just represent a symbolic part of the real cost of services in developed countries, as in the majority of these the government subsidizes basic healthcare. However, in many developing countries these financial outlays made by patients lead to severe financial difficulties as a consequence. A high proportion of the world's poor have no access to health services merely because they cannot afford to pay at the time they need them (Preker et al., 2004).

Separate to national health insurance there is in many countries also the possibility to have private health insurance. Private health insurance schemes are financed through private health premiums, that is, payments that a policyholder agrees to make for coverage under a given insurance policy. A contract is issued by an insurer to the covered person. Commonly private health insurance is voluntary; however, it can be compulsory for employees as part of their working conditions. Premiums paid by the covered person are non-income-related, although the actual purchase of private health insurance can in some cases be subsidized by the government. An important distinction between private and national health insurance is that the pool of financing is not channeled nor administered through the government. Private health insurance can be a controversial form of insurance because of the conflict between the need for the insurance company to make profit versus the need of its customers to remain healthy, which many view as a basic human right.

Some countries' health systems depend greatly on private health insurance, for example, the United States (US) which has a complex health care system. In the USA, public programs (e.g., Medicare, Medicaid, and Veterans Health Administration) provide coverage for health care of those

citizens that meet their eligibility requirements. The US insurance system has made discussions, and in 2010, a new law came into force making it mandatory to have health insurance.

The health sector is extremely complex, and health care expenditure represents a major use of a nation's resources and has been growing during the last three decades. Factors such as an aging population, the increased personal use of health care, and medical advances that have opened the way for more treatment options and diagnostics have contributed to a rise in the demand for health care and increased the costs for health care. At the same time enormous pressure is being put on the health system in terms of their capacity to improve outcomes and ensure consumer satisfaction, in an equitable, efficient, and financially sustainable manner. Health financing is, therefore, an issue of growing importance.

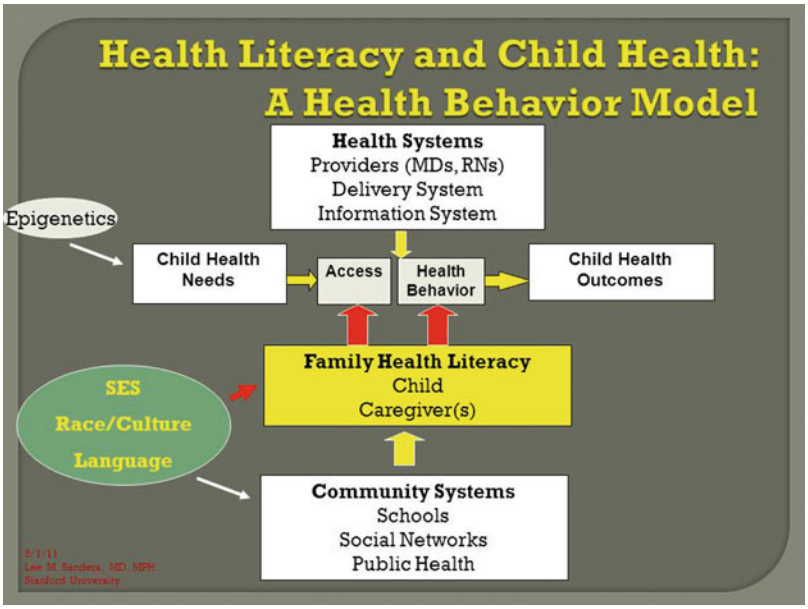
Literacy

Definition

Health literacy refers to an individual's ability to understand and use written and spoken health information. An applied version of the broader construct of "literacy" (i.e., the ability to read and understand all written information), health literacy encompasses the tasks necessary for a patient to navigate the modern medical system. This includes tasks such as dosing medication according to written instructions, interpreting a food label, following an immunization schedule, completing personal health information at the doctor's office, understanding a patient-centered brochure, completing health-insurance forms, or finding health information on the Internet. At least one in three US adults has limited health literacy (Kutner, Greenberg, Jin, & Paulsen, 2006; Nielsen-Bohlman, Panzer, & Kindig, 2004; Yin et al., 2009). According to the 2003 National Assessment of Adult Literacy (NAAL), 78 million US adults (36% of the population) are unable to perform "basic" health literacy tasks, such as using an immunization schedule, following recommendations from a preventive-health brochure, and interpreting a growth chart (Doak, Doak, & Root, 1996; Rich, 2004). Unfortunately, most health information in the USA is written with a complexity of form and language too difficult for most US adults to understand (Davis et al., 1994; Kutner et al., 2006; Rothman, Housam, & Weiss, 2006; Sanders, Federico, Klass, Dreyer, & Abrams, 2009; Yin et al., 2009)

Health literacy is a critical and potentially modifiable factor that influences health behaviors and may help reduce health disparities. Health literacy may contribute to the health-behavior model of health outcomes by attenuating the relationship between social factors and health behaviors. Many of the leading sources of morbidity and health disparities (e.g., preterm birth, obesity, chronic lung disease, cardiovascular disease, type 2 diabetes, mental health disorders, and cancer) are the result of literacy-sensitive health behaviors acquired across the life course (e.g., physical activity, nutrition, smoking,



Health Literacy, Fig. 1 This conceptual model proposes collective health literacy ("Family Health Literacy") and institutional health literacy (the "Health Systems") as modifiable determinants of child health outcomes. Note the contribution of other social determinants (e.g., SES, culture, language) as moderating factors and of health behaviors as mediators

risky sexual behaviors). Recent studies among adults have established an independent association between lower health literacy and decreased access to preventive-care services, increased use of urgent care services, increased risk for depression, and worse chronic-illness outcomes. Controlling for income, gender, and age, several studies have demonstrated that adults with limited literacy skills are significantly less likely than those with stronger skills to receive basic preventive care, including vaccines, weight management, and screening for breast, cervical, and prostate cancer (Bennett et al., 1998; Scott, Gazmararian, Williams, & Baker, 2002; Schillinger et al., 2002). In similarly adjusted analyses, children living with low-literacy caregivers have decreased access to primary preventive care, are more likely to be uninsured, less likely to access needed social services, less likely to be breastfed, and more likely to be exposed to second-hand tobacco smoke (Sanders et al., 2009). Adolescents who read below grade level are at an increased risk for violent and aggressive behavior, substance use, and sexually transmissible illnesses (Abrams & Dreyer, 2009)

As a result of these research findings, leading government agencies and national medical organizations – including the National Institutes of Health, the Institute of Medicine, and the Agency for Research in Healthcare Quality – have developed guidelines that call for more strategic attention to individuals' health literacy as a way of addressing major health disparities and public health challenges in the USA (Kutner et al., 2006; Nielsen-Bohlman et al., 2004; Yin et al., 2009). Experimental, clinical, community-based, and policy approaches to attenuating literacy-related health disparities have been proposed and tested. Evidence suggests that the most effective solutions apply to simplifying systems of care, particularly in the domains of medication delivery, chronic-illness management, and informed consent (Doak et al., 1996; Edwards, Elwyn, & Mulley, 2002; Rich, 2004; Sanders, Thompson, & Wilkinson, 2007; Weiss, Francis, Senf, Heist, & Hargraves, 2006). The most innovative and effective strategies apply interdisciplinary solutions that integrate cognitive behavioral theory, visual images, cultural sensitivity, and new interactive technologies.

Health Outcomes Research

Yori Gidron
Faculty of Medicine and Pharmacy, Free University of Brussels (VUB), Jette, Belgium

Definition

Health outcomes research refers to the entire evaluation of all health professionals' efforts in ameliorating patients' health conditions, in relation to various dimensions of health. Furthermore, it refers to the work not only of health professionals but of health-related organizations and their policies as a whole as well. Thus, in contrast to research on the effectiveness of specific medical or health interventions on specific health indices (e.g., blood pressure, survival), health outcomes research is a broader concept, both on the side of the intervention agents as well as on the side of the outcomes. Health outcomes research thus can guide health policy makers, health economists, as well as specific types of health professionals and clinicians.

The setting or context of health outcomes research includes clinics, hospitals, patients' homes, or even entire regions. The typical measures used in health outcomes research are also broader than those commonly used in medical intervention trials. While in the latter, outcomes mainly include physiological parameters (e.g., HbA1C, tumor markers, pulmonary functioning), health outcomes research additionally focuses on patients' satisfaction with health care, daily functioning, and, more broadly speaking, on their well-being. In addition, health outcomes research uses the method of meta-analysis to summarize and infer from multiple, yet comparable, clinical studies of a given treatment. Measures of functional status include physical (e.g., carrying), role (e.g., being a parent or worker), and social functioning (e.g., taking part in social events) in general or as influenced by a disease. The Brief Pain Inventory assesses the level of interference of pain in these factors. Measures of well-being include dimensions such as mental health, health perceptions, pain, and general life satisfaction. A common measure assessing most of these dimensions is the SF-36 (Aaronson et al., 1992). This measure is also used in health economics studies to assess quality-adjusted life years, a major outcome in health outcomes research, as it encompasses survival time with its quality.

Definition

A nation's, state's, city's, or other community's decisions regarding matters affecting health.

Description

Health policy refers to the systematic and/or organized approach to decision making regarding matters affecting health by a national or regional governmental entity (such as state or city) or other organized group (company, agency, etc.) (Patrick & Erickson, 1993). Most often, the term is used synonymously with health-care policy. However, the latter more narrowly applies to decisions affecting the formal medical system. Ideally the goal of such decision making would

be toward improving the well-being of members of the community (Bodenheimer & Grumbach, 2009; Weiner, Famadas, Waters, & Gikic, 2008). Further, such a decision-making process should be largely informed and driven by factual knowledge and evidence from the natural and social sciences. However, in reality, health policy is heavily influenced by many factors outside the scientific realm such as economic and political forces. In addition, such policies also heavily reflect a region's and society's ethics and values (Bodenheimer & Grumbach, 2009; Weiner et al., 2008). Thus, health policies vary widely around the world.

An example is the ways countries choose to finance their formal health-care sector, for which there are five major approaches: direct taxation; social health insurance, with mandatory premiums; voluntary or private health insurance; out-of-pocket payments; and charitable care (World Health Organization, 2005). In some countries such as Norway, the vast majority of health care is financed through direct government taxation. In Taiwan, social health insurance, financed by a payroll tax, covers nearly all health care. In the USA, a mixed market exists, with the government paying for slightly under half of all costs, and most of the rest covered by private insurance and/or out-of-pocket payments. In extremely poor countries, such as Mali, much of the care is provided by charitable organizations (World Health Organization, 2005).

Health-care policy also includes decisions around how health care is organized and delivered and the amount of money that should be devoted to health care. While it is generally agreed that countries spending less than $60 per person annually on health care have difficulty providing minimal essential services (World Health Organization, 2005), absolute funding levels do not necessarily correlate with health or health-care outcomes. For example, the USA spends nearly twice as much as most other developed countries on health care, yet is often ranked lower than many other countries with respect to measures of health outcomes and access to care. How health-care funding is allocated is also a major focus of health policy deliberations. In many countries, more population-based medical interventions, such as immunization programs, are prioritized as it is felt that these may result in a more efficient allocation of limited health-care resources. In poorer countries, such population level interventions may also be administered by transnational organizations such as the World Health Organization or nongovernmental organizations operating at the national, state, or local levels (World Health Organization, 2005).

Another example of differences in health-care policies across countries is evident with respect to counseling and therapies meant to promote behavior change, such as dietary counseling or counseling to promote tobacco cessation. Given extensive evidence that such programs can reduce complications related to obesity and long-term tobacco use, many countries provide coverage for such services. In contrast, until recently many insurance plans in the USA provided limited or no coverage for counseling directed at shaping health behaviors.

Health policy also includes programs and legislation which may influence health-related behaviors but are not typically considered part of the formal health-care sector. An example is outdoor smoking bans, which not only protect nonsmokers from secondhand smoke but are also associated with decreases in tobacco use among smokers. Laws allowing police to issue tickets to drivers of cars with unbelted passengers are associated with increased seat belt usage and a corresponding decrease in motor vehicle accident-related deaths. Another example is land-use policies that create pedestrian-friendly built environments that promote healthy behaviors, such as walking, and result in lower obesity rates (U.S. Centers for Disease Control). Often times, the health effects of such policies may not even be apparent at the time they are implemented. For example, the intention of a federally mandated decrease in highway speed limits in the 1970s was to improve conservation of fuel, but resulted in fewer automobile accident-related deaths. Thus, while health-care policy often dominates health policy deliberations, interventions

outside of the formal health-care delivery system may also have a major influence on health (Connolly, 2008).

Health Psychology

Definition

Health psychology is a relatively new subfield of psychology that studies psychological factors related to how people stay healthy, why they become ill, and how they respond when they do become ill. The American Psychological

Association's official definition of health psychology comes from Matarazzo (1982): "Health Psychology is the aggregate of the specific educational, scientific, and professional contributions of the discipline of psychology to the promotion and maintenance of health, the prevention and treatment of illness, the identification of etiologic and diagnostic correlates of health, illness, and related dysfunction and to the analysis and improvement of the health care system and health policy formation."

Health psychology emphasizes the biopsychosocial model where physical well-being and disease reflect a complex set of interrelated processes including biological factors (e.g., genetics, hormonal fluctuations), psychological factors (e.g., mood, personality, health behaviors), and social factors (e.g., cultural norms, health policy, social support). Health psychologists may focus their professional activities on consultation, intervention, public health policy and administration, and/or research. They commonly collaborate with other health care professionals in multidisciplinary settings in order to provide optimal care for patients and to improve health care systems, policy, and public health. From its inception, health psychology has had a dual focus on research and practice, reflecting the philosophy of the broader discipline of psychology.

The field of health psychology was formally recognized in the USA in 1978 with the establishment of the Division of Health Psychology (Division 38) within the American Psychological Association. A confluence of factors contributed to the development of the field of health psychology at this time including (a) research demonstrating compelling mind-body associations (e.g., Neal Miller's work on the conditioning of physiological processes), (b) recognition that the leading causes of mortality (e.g., coronary heart disease) could be prevented, delayed, or treated through health behavior change, and (c) the possibility to curb health care costs through prevention and low-cost behavioral initiatives. The mission of Division 38 was – and still is – to advance the contributions of psychology as a discipline to understanding health and illness through basic and clinical research, to promote education and services in the psychology of health and illness, and to inform the psychological and biomedical community of these research and service activities. Parallel movements and related fields have developed over the years but remain distinct from that of health psychology. Behavioral medicine is an interdisciplinary organization devoted to integrating biomedical and psychosocial factors in health and illness, in contrast to the intradisciplinary focus of health psychology; health psychologists engage in behavioral medicine when they collaborate with colleagues outside of psychology (e.g., medicine, nursing, public health, etc.). Medical psychology, or clinical health psychology, is a term most commonly used to describe the work conducted by clinical psychologists who practice in medical settings. Another interdisciplinary field, psychosomatic medicine, which developed somewhat earlier than health psychology and behavioral medicine, focuses similarly on understanding biobehavioral links between psychology, psychiatry, internal medicine, physiology, and other disciplines.

Division 38 (Health Psychology) of the American Psychological Association, the Society of Behavioral Medicine, and the American Psychosomatic Society are organizations that promote research and practice of health psychology and related fields. Many scholarly journals are dedicated to disseminating research generated by health psychologists. The official journal of Division 38 is Health Psychology, but there are also international journals that publish peer-reviewed research in health psychology (e.g., Journal of Health Psychology; Psychology and Health; Health Psychology Review). Health psychology research is also routinely published in journals linked to the interdisciplinary organizations of behavioral medicine (Annals of Behavioral Medicine) and psychosomatic medicine (Psychosomatic Medicine). Finally, consistent with the goal of informing the biomedical community about the research and service activities of health psychologists, health psychologists increasingly publish their research in relevant medical journals.

Health Risk (Behavior)

Peter Allebeck

Definition

Health risk is a comprehensive term covering all phenomena that carry a hazard to health of individuals or communities. Health risks can be divided into social, environmental, and behavioral risks. Another, partly overlapping, division is into health risks at population level, community level, or individual level. However, it is important to understand that health risks operate on various levels, so even if one talks about health risks on individual level, such as an individual's smoking, alcohol consumption, or lack of physical activity, these are often related to social and environmental conditions under which people live. Behavioral health risks, such as those related to eating habits, physical activity, stress, etc., have often been referred to lifestyle risk factors, although more specific terms are usually preferred.

Quality of life

Definition

In 1948, the World Health Organization defined health as "the state of complete physical, mental and social well-being and not merely the absence of disease or infirmity" (World Health Organization [WHO], 1948). Since then, QoL has become increasingly important in health-care practice and research. The term "health-related quality of life" (HRQoL) narrows QoL to aspects relevant to health. However, HRQoL is a comprehensive and complex concept for which no universally accepted definition is available (Fayers & Machin, 2000). Two aspects of HRQoL are central in most definitions. First, it is a multidimensional concept that can be viewed as a latent construct which describes the physical, role functioning, social, and psychological aspects of well-being and functioning (Bullinger, 1991; Calman, 1987; Spilker, 1990). Second, in contrast to QoL, HRQoL can include both objective and subjective perspectives in each domain (Testa & Simonson, 1996). The objective assessment focuses on what the individual can do, and it is important in defining the degree of health. The subjective assessment of QoL includes the meaning to the individual; essentially it involves the translation or appraisal of the more objective measurement of health status into the experience of QoL. Differences in appraisal account for the fact that individuals with the same objective health status can report very different subjective QoL.

HRQoL as an Outcome

It has become clear in the last decade that HRQoL is an important outcome variable on its own independent of medical outcomes. HRQoL outcomes can guide decisions on alternative treatments or effectiveness of interventions at a *patient group level* (Koot, 2001). In clinical research trials in children, HRQoL has long been neglected as an outcome, but this changed rapidly over the last 10 years (Clarke & Eiser, 2004). An important step towards a more structured and frequent use of patient-reported outcomes (PROs) in drug development is represented by the US Food and Drug Administration (FDA) guidance, issued in 2006. This describes how the FDA evaluates PROs, including HRQoL, to be used as effectiveness end points in clinical trials (U.S. Department of Health and Human Services, 2006). This guidance emphasizes the importance of considering HRQoL separate from medical effectiveness. From the *individual patient perspective*, HRQoL can guide the choice of best treatment, made by the patient himself/herself and the health-care professionals (Koot, 2001). Evaluating the impact of diabetes on the adolescents' HRQoL and vice versa can help both the patient and physician decide on the optimal individual treatment (de Wit et al., 2008).

HRQoL in Children

Attention to the QoL of children has evolved rapidly from the 1980s. Advances in medical care have changed the emphasis in pediatric medicine from the diagnosis and management of infectious disease to prevention and control of chronic conditions. This means that health-care professionals should have insight into the child's views and experiences. Early attempts to rate children's QoL were based on data provided by mothers as children are often regarded as unreliable respondents. However, children and parents do not necessarily share similar views about the impact of illness. As children grow older and develop their own life, the HRQoL reports of parents become of less relevance. It has been shown that parents and children agree more on objective domains of HRQoL (i.e., physical functioning) than on subjective domains, like emotional and social functioning (Eiser & Morse, 2001; Janse, Sinnema, Uiterwaal, Kimpen, & Gemke, 2008). Therefore, the child's HRQoL is included more and more in decisions about their care and treatment.

Healthy Cities

Yori Gidron
Faculty of Medicine and Pharmacy, Free University of Brussels (VUB), Jette, Belgium

Definition

The term healthy cities (HC) refers to a policy and activity at the village, town, or city levels to promote health. This follows the World Health Organization's (WHO) conceptualization of health as one's physical, psychological, and social well-being and current health professionals' growing emphasis on people's self-care. Furthermore, HC reflect the emerging need to allocate resources to disease prevention and to the maintenance of health and well-being, beyond treatment of existing illnesses alone. When this is done at the level of a town or city, "peer pressure" becomes positive and can influence people toward more healthy lifestyles including balanced diets, physical activity, smoking cessation, moderate alcohol consumption, and provision of communal social support. Furthermore, recognizing that environmental factors influence health (e.g., crowding, pollution), HC also provide an excellent opportunity to change one's environment in order to foster health and well-being. Such initiatives are supported by the WHO via fostering programs and networks, inside and between countries (Goldstein, 2000). Additional core values in the HC project are equity, community participation, and community empowerment (Tsouros, 2009), particularly fostered by the European Healthy Cities Network (Heritage & Dooris, 2009).

An example of a HC project, which was tested, includes the Minnesota Heart Health Program (MHHP), where three intervention towns/cities were compared to three control towns/cities. The MHHP focused on health education with the aim to reduce cardiovascular morbidity and mortality. It succeeded to mobilize many community leaders, large segments of the adult population, and repeatedly exposed health-education information to residents via multiple channels of communication (Mittelmark et al., 1986). van Oers and Reelick (1992) developed quantitative indicators for evaluating HCs and also showed that such evaluation can feedback into local policy making, thus influencing health-related decisions at the city levels. According to initial findings from the European Healthy Cities Network, 80% of such cities used various forms of community participation, and more than two thirds of cities tried to empower their citizens (Heritage & Dooris, 2009). Empowerment is of

course central to health since it fosters self-efficacy, a major predictor of health outcomes (e.g., Ironson et al., 2005). This term reflects an important area of intervention for behavior medicine, where its theoretical models, methodological rigor, and clinical practice could contribute to societies' health at the "macro" level.

Definition

A healthy diet is one that maintains a state of well-being and reduces the risk of chronic diseases such as obesity, cancer, heart disease, and diabetes. A healthy food intake will have an adequate amount and balance of macronutrients (protein, carbohydrates, and fats), micronutrients (vitamins and minerals), and fluids. This goal can be accomplished with different dietary patterns.

Description

A healthy diet produces an appropriate body weight. Maintaining a healthy weight, with a body mass index between 18.5 and 24.9, is achieved by balancing total calorie intake with calorie requirements. The 2010 report of the Dietary Guidelines for Americans states that too many calories from foods high in solid fats and added sugars are contributing to obesity. These same foods offer few nutrients other than calories. Eating with mindfulness and an awareness of what, when, and how much is eaten is a useful technique for weight loss and maintenance. Limiting solid fats such as butter and lard and using limited amounts of mono- and polyunsaturated fats from plants and seeds support healthy weight and normal blood lipids.

The base of a heart-healthy intake is nutrient-rich plant foods. In addition to essential vitamins and minerals, plant foods provide phytonutrients. Phytonutrients are chemical compounds that occur naturally in plants. Phytonutrients have a beneficial effect on health but are not yet established as essential nutrients. Examples of phytonutrients are lutein and zeaxanthin in dark greens that reduce the risk of cataracts and sulforaphane in broccoli that reduces the risk of cancer. It is recommended that half of the food consumed at a meal be plant based.

The recommendation for dietary fiber is between 25 and 35 g a day. Dietary fiber assists with weight management, control of blood glucose levels, and healthy blood cholesterol levels. Dry beans, whole grains, fruits, and vegetables with skin are sources of fiber. Many different

foods, including breakfast cereals and yogurts, are fortified with extra fiber. The Nutrient Facts Label on all packaged foods lists fiber content.

Dietary protein provides essential amino acids to build body proteins and is also a calorie source. Most Americans are eating the required 0.8 g protein/kg body weight/day. Major sources of protein are lean meats, chicken, fish, dry beans, and soy products. Proteins from dry beans and soy products have the added benefit of fiber.

For a healthy diet, sodium intake should be less than 2,300 mg for healthy adults and less than 1,500 mg for individuals with hypertension, African Americans, and middle-aged and older adults. Seventy-five percent of sodium intake comes from processed and fast food. Increasing plant-based foods, cooking and eating at home, and using low-sodium canned products assist in reducing sodium intake.

Potassium helps to reduce the impact of sodium on blood pressure and is deficient in the average American diet. Most fruits and vegetables are good sources of potassium. Excellent sources are bananas, melon, oranges, spinach, fat-free milk, tomatoes, and vegetable juice.

Most fluid requirements are met through water and beverages, and a lesser amount through food. Adequate fluid is necessary for maintaining body temperature, lubricating joints, protecting spinal cord and other sensitive tissues, and ridding the body of waste. Greater fluid intake is necessary in hot climates, among physically active people, during illness such as a fever, diarrhea, or vomiting. Primary source of fluid should be water and calorie-free drinks.

A healthy meal is one half vegetables and fruits, ¼ whole grains, and ¼ lean meats or high-protein plant foods. The Food Guide Pyramid is a resource for further information about portion sizes, meal plans, and food tracking.

Hearing Impairment (Noise Pollution Related)

Definition

Hearing impairment is the alteration in the perception and interpretation of sound secondary to changes in the auditory system as a result of exposure to noise.

Description

Hearing is a complex phenomenon that depends on the capture, transmission, and interpretation of sound waves from the environment. Ultimately, hearing occurs in the brain where incoming information is synthesized and interpreted. However, appropriate and accurate transmission of sound has to occur for correct interpretation to be possible. Exposure to a single loud noise or chronic exposure to noise above a sound pressure level of 85 dB (decibels) can damage the inner elements of the ear responsible for the translation of sound into signals that can be transmitted by the auditory nerve to the central nervous system. Although other components may be affected, of special concern is the impact that loud noise can have on the hair cells within the cochlea that transform sound into electrical signals that can be transmitted via the auditory nerve to the auditory cortex and related structures The level of noise exposure needed to cause permanent hearing loss may vary with the individual because of genetic or other environmental conditions. The hair cells that are responsive to high-frequency sounds, located near the base of the cochlea, are especially vulnerable. Thus, hearing loss as a result of noise exposure tends to present with a distinct audiogram pattern which usually includes a "notch" at about 4,000 Hz (Hertz; 4 kHz). A "notch" is a drop in hearing acuity at a given frequency, indicating that the sensory receptors responsive to that frequency have been damaged. Current data suggest that the damage from noise may be caused by oxidative stress. Individuals vary in their susceptibility to noise exposure, and other concurrent exposures, such as to certain medications or environmental toxins, may act synergistically with noise to further damage the hair cells. Strategies are being tested to try and protect the sensitive inner ear components before noise exposure and/or to minimize the traumatic response to the noise exposure. However, most current efforts are aimed at preventing exposure to excessive noise or minimizing the level of exposure. For example, the Occupational Safety and Health Administration has established specific requirements for hearing protection in settings where noise exceeds a given level as well as a permissible noise exposure.

Hearing impairment

Definition

A decrease, alteration, or distortion in the perception of sound.

Description

Hearing involves the perception and interpretation of sounds transmitted from the environment and occurs within the central nervous system. Sound waves enter the ear canal and stimulate the ear drum or tympanic membrane. The movement of the tympanic membrane changes the acoustic energy into mechanical energy that can then be transmitted by the three tiny inner ear bones or ossicles to the oval window of the inner ear or cochlea. The mechanical energy transmitted to the oval window initiates movement of the fluid within the inner ear. The sound energy now carried by the inner ear fluid stimulates sensitive hair cells and is transformed into electrochemical energy that can be transmitted by the auditory nerve to the auditory centers of the central nervous system. It is at the central level that sound is perceived and interpreted. Disturbances anywhere in the transmission process can lead to hearing loss. Thus, hearing loss can be conductive (disturbance in transmission from the external environment to the inner ear), sensorineural (involving alterations in the inner ear and/or auditory nerve), mixed conductive/sensorineural, or central. The cause of hearing loss can be multifactorial. Conductive loss can be caused by cerumen or wax in the ear canal which blocks sound transmission. The accumulation of wax is more common in older adults because of changes in its consistency with age. Conductive loss can also occur as a result of changes in the middle ear related to the ossicles or other diseases. Sensorineural losses can be caused by noise, ototoxic agents (e.g., environmental toxins or ototoxic medications), chronic conditions, or age. Chronic conditions such as diabetes mellitus are increasingly recognized as associated with increased incidence of hearing loss, possibly through their impact on the cardiovascular system. Age-related hearing loss is usually called "presbycusis" and is characterized initially by loss in the perception of high-frequency tones. Because consonants (such as s, p, t) are high frequency while vowels (a, e, i, o, u) are low frequency, individuals often feel they can "hear but not understand" or that individuals mumble because they are only hearing the vowels in any given word. This leads to distortion and misinterpretations. For example, "time" and "dime" may be confused. Hearing loss can occur at any time in the life cycle but becomes increasingly common with age. While hearing loss is usually not considered a life-threatening condition, it is associated with multiple negative outcomes including isolation, depression, and altered interpersonal relationships. There is also increasing interest in the relationship between hearing loss and cognition. Approaches to the treatment of hearing loss usually focus on enhancing amplification in the frequencies that are most affected. Newer hearing aids have a greater capacity to be individualized but remain aids. Individuals need to understand that they will need to relearn how to hear and to get use to hearing sounds that they may not have heard in some time. The underlying damage to the ear is

not repaired. In addition to hearing aids, other assistive listening devices are available to facilitate communication or participation in activities or events (510).

The heart is the principle organ of the circulatory system and is responsible for pumping blood through the pulmonary and systemic circulations.

Description

In humans, the heart has four structural chambers: two upper ones, the left and right atria, serving as reservoirs for blood return from the pulmonary and systemic venous vasculature, respectively; and two lower chambers, the left and right ventricles, that eject blood forward into the aorta and the pulmonary arteries. In a typical cycle, peripheral venous blood returns to the right atrium via the superior and inferior venae cavae, and then empties into the right ventricle through the tricuspid valve, both passively and with contribution from right atrial contraction. Contraction of the right ventricle then opens the pulmonic valve and propels the deoxygenated blood through the main pulmonary artery on the way to the lungs. After passing through lung alveoli where gas exchange takes place, oxygenated blood from the pulmonary circulation eventually drains into the left atrium through the four pulmonary veins, and from there fills the left ventricle via passage across the mitral valve. Contraction of the left ventricle then opens the aortic valve, and oxygenated blood is pumped into the aorta to perfuse the other organs of the body. The blood supply to the heart itself is provided by the coronary arteries: the left main artery, arising from the left coronary cusp at the root of the aorta, and giving rise to the left anterior descending and the left circumflex arteries; and the right coronary artery, arising from the right coronary cusp. Venous return from the heart drains into the right atrium via the coronary sinus (Kusumoto, 2005).

Anatomically, the heart lies within the mediastinum and is encapsulated by the pericardial sac, which normally contains small amounts of serous fluid to minimize friction as the heart moves during each contraction. At the cellular level, the heart is composed of myocytes, which contain sarcomere units that form the basic contractile elements. The myocytes also possess gap junctions that allow propagation of electrical impulses from cell to cell. In addition, there are specialized myocytes with unique electrical properties that form the conduction system of the heart. Electrical impulses are typically

initiated in the sinoatrial node (SA node), located within the right atrium, then travel to the atrioventricular node (AV node), which lies along the inferior-posterior aspect of the interatrial septum near the opening of the coronary sinus. The AV node allows conduction from the atria to the ventricles, and its refractory properties help to prevent rapid ventricular response in case of atrial arrhythmias. From the AV node, the electrical impulses travel rapidly down the bundle of His and then the right, left anterior and left posterior bundle branches, eventually arriving at the Purkinje fibers that reach the rest of the heart. It is this carefully timed activation sequence that makes possible the ordered and efficient contraction that occur with each heartbeat (Kusumoto, 2005).

Numerous disease processes are known to affect the heart. Early in life, abnormalities of cardiac development can lead to various forms of congenital heart disease. Disorders of the conduction system can manifest as tachyarrhythmias and bradyarrhythmias, and can present at any age, either in isolation or in conjunction with other cardiac diseases. Valvular heart disease may involve stenotic or regurgitant lesions of any of the four cardiac valves or combinations thereof. The clinical syndrome of heart failure, defined as the inability of the heart to generate enough forward flow except at elevated filling pressures, can occur through diverse mechanisms including ischemia due to coronary artery disease to genetic disorders such as hypertrophic cardiomyopathy. Ischemic heart disease caused by coronary atherosclerosis is currently the most frequently diagnosed cardiac disorder, in part due to the increased life expectancy and changes in lifestyle and diet that occurred in the past century. Taken as a whole, cardiovascular diseases represent one of the most significant global public health burdens of the modern age, accounting for 30% of all deaths worldwide and up to 40% of all deaths in the industrialized world (American Heart Association Statistics Committee and Stroke Statistics Subcommittee, 2010; Gaziano, 2008).

Heart and Estrogen/Progestin Replacement Study (HERS)

Jonathan Newman
Columbia University, New York, NY, USA

Definition

The heart and estrogen/progestin replacement study (HERS) was a randomized, double-blinded placebo-controlled trial of the effect of 0.625 mg of conjugated estrogens plus 2.5 mg of medroxyprogesterone acetate daily on coronary heart disease (CHD) event risk among more than 2,700 postmenopausal with women with known CHD.

Description

The primary outcome of this trial was CHD events (nonfatal myocardial infarction (MI) plus CHD-related death). Secondary cardiovascular outcomes included coronary revascularization, unstable angina, congestive heart failure,

resuscitated cardiac arrest, stroke or transient ischemic attack, and peripheral arterial disease.

Overall, during more than 4 years of follow-up, there were no significant differences between the hormone and placebo groups in the primary outcome of CHD events (nonfatal MI plus CHD-related death) or in any secondary outcomes.

However, post-hoc analyses showed a statistically significant time effect, wherein participants taking hormone therapy experienced more CHD events in the first year of treatment, and fewer in years 3–5. This led the investigators to speculate that the early risk due to estrogen/progestin treatment may be due to a prothrombotic, proischemic, or proarrhythmic effect which was gradually outweighed by the beneficial effects of hormone therapy, potentially mediated by observed changes in low- and high-density lipoprotein cholesterol.

This apparent pattern of an early increase in CHD events followed by a later decrease led to the recommendation that women with CHD should not start hormonal therapy for the purposes of preventing CHD events, but that those who were taking hormones could continue to do so. As reported in HERS II, women in HERS tended to follow this advice and many of those randomized to hormones during the trial continued with open-label treatment. This provided an opportunity to continue outcome surveillance for several years (HERS II).

The HERS II study contained both cardiovascular and non-cardiovascular components. Participants from the initial HERS study were followed for an additional 4 years. The HERS cardiovascular study demonstrated the absence of late benefit of hormone therapy, effectively answering the important question raised by the original HERS study of whether the lower CHD event rate observed during the final years of the trial suggested the presence of a long-term benefit of hormone replacement therapy. The non-cardiovascular component of the HERS study demonstrated an increase in venous thromboembolism and biliary tract surgery over the near 7 years of follow-up and demonstrated unfavorable trends in the incidence of some cancers and incidence of fractures.

The follow-up study (HERS II) has been critiqued because randomized assignment was no longer blinded in HERS II, and event ascertainment may have been influenced by the knowledge of randomization assignment. Regardless, the HERS I/II provided useful information regarding the short- and long-term use of hormone replacement therapy, and supported the larger, more definitive trials on hormone replacement and cardiovascular and non-cardiovascular events, such as the Women's Health Initiative.

Definition

There has been a long-standing notion that exaggerated responses to mental stress are linked to the development of future heart disease (Hamer & Malan, 2010). Although not clinically meaningful in themselves, if heightened responses to stress are elicited on a regular basis, they might become clinically relevant over time. Existing work has largely focused on cardiovascular reactivity to stress as a tool to predict future risk. Blood pressure and heart rate responses to mental stress are largely augmented by the sympathetic nervous system and release of catecholamines. The issue of whether stress reactivity contributes to the progression of underlying disease or only to the incidence of clinical cardiac events has led to research involving indicators of subclinical disease. Several studies have indicated that heightened blood pressure and heart rate responses to laboratory-induced stressors predict future progression of subclinical atherosclerosis and hypertension in initially healthy participants, independently from conventional risk factors such as blood cholesterol, resting blood pressure, and smoking (Chida & Steptoe, 2010). Few studies have examined the association between cardiovascular reactivity and the incidence of clinical cardiac events, and the available evidence is equivocal. Since individuals cannot be randomized to being high or low cardiovascular reactors to stress, it is impossible to prove or disprove beyond doubt that exaggerated reactivity is a causal risk factor in cardiovascular disease. On balance, there is substantive evidence to support the reactivity hypothesis although effect sizes are small and the clinical utility is questionable. Reasons for inconsistencies in the data include variability in the type of mental stressors employed and individual differences in responses that might be influenced by factors such as personality, race and ethnicity, genetics, chronic background stress, and lifestyle habits.

From a mechanistic standpoint, stress-induced blood pressure surges that contribute to increased shear stress in the arteries could promote endothelial damage and inflammatory responses that are thought to play a role in atherogenesis. Endothelial dysfunction plays a key role in the initiation of atherosclerosis because nitric oxide production from healthy endothelial cells has an anti-atherogenic effect by inhibiting cellular adhesion, migration, and proliferation responses. Individual differences in blood pressure reactivity have also been linked with activation patterns in corticolimbic brain areas (e.g., divisions of the

cingulate cortex, insula, and amygdale) that are jointly involved in processing stressors and regulating the cardiovascular system (Gianaros & Sheu, 2009). Thus, this data might provide the vital piece in the missing jigsaw puzzle explaining the interaction between brain and body.

Heart Disease and Emotions: Anger, Anxiety, Depression

Timothy W. Smith
Department of Psychology, University of Utah, Salt Lake City, UT, USA

Definition

The negative emotions of anger, anxiety, and depression exist in several different forms – stable individual differences in negative emotionality (i.e., personality traits), brief emotional episodes, symptoms of emotional distress, and emotional disorders. Each of these emotion constructs has been examined as an influence on the development and course of coronary heart disease, a common cause of death resulting from the progression of atherosclerosis in the arteries that otherwise supply blood to the myocardium.

Description

Negative emotions have been suggested as an influence on the development and course of coronary heart disease (CHD) for centuries since the earliest descriptions of this common and costly medical condition. CHD begins as early as childhood or adolescence, with the development of fatty streaks within the walls of the coronary arteries. Over decades, these progress to more substantial coronary artery lesions, with the buildup of lipids and inflammatory processes at these sites. After decades of asymptomatic or silent progression of coronary artery disease (CAD), the symptoms of CHD appear in mid to later adulthood in the form of angina pectoris (chest pain due to myocardial ischemia), myocardial infarction, or sudden coronary death. Recent research indicates that negative emotion may play a role in CHD at each stage of this decades-long process. However, the various specific negative emotions and forms of these emotion characteristics are closely related, and it is not clear if they have independent or overlapping effects on the development and course of CHD (for reviews, see Smith, 2010; Suls & Bunde, 2005).

Virtually all major conceptual descriptions of basic emotions distinguish among anxiety and related emotions (e.g., fear), depression and related emotions (e.g., sadness), and anger. In contrast to a state of calm, anxiety is characterized by nervousness, tension, and apprehension. In the extreme, it is characterized by dread. Depression is characterized by sadness, sorrow, and unhappiness, and in the extreme by despair. Anger varies in intensity from irritation or annoyance to the extreme of rage. In terms of accompanying cognitive content, anxiety is associated with perceptions of threat and vulnerability to potential harm. In contrast, depression is associated with

a sense of loss, separation from important others, failure, and hopelessness. Anger is associated with thoughts of interpersonal transgression, frustrated goals, and unfair victimization or mistreatment.

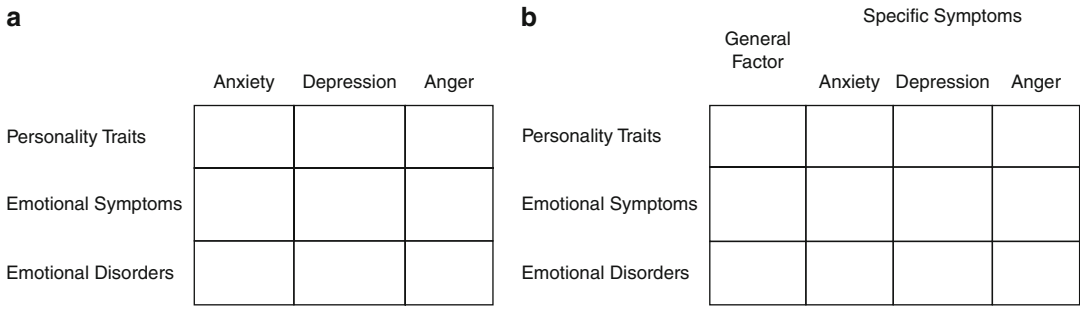
These affective phenomena take several forms, ranging from brief episodes well within the range of normal experience to much more enduring and maladaptive conditions. Episodes of negative emotion (e.g., anger during a pointed disagreement) have been examined as precipitants or "triggers" of acute coronary events (e.g., myocardial infarction, sudden coronary death), and the related findings suggest that these episodes can indeed evoke such life-threatening events, although this is most likely limited to individuals who have advanced CAD (Bhattacharyya & Steptoe, 2007). Episodes of negative emotion can be distinguished from related moods, in that emotions are more intense, briefer, and much more strongly related to physiological changes and the activation of associated behavioral response tendencies.

There are stable individual differences in the tendency to experience negative emotions and moods, such as the Five-Factor Model trait of neuroticism versus emotional stability. This trait contrasts individuals who are prone to anxiety, depression, anger, and related characteristics (e.g., self-consciousness, feelings of vulnerability or inferiority) with individuals who are generally calm. A closely related construct – negative affectivity – differs from neuroticism by including only the affective elements of this broad trait. In these trait models, individual differences in the tendency to experience anxiety, depression, and anger are seen as lower level, more specific aspects or "facets" of the broader trait.

These emotions are also seen in various forms of psychopathology. Anxiety disorders (e.g., generalized anxiety disorder, social phobia) and mood disorders (e.g., major depressive disorder) are common, and intense and destructive anger is the major feature of intermittent explosive disorder. Individuals can report elevated symptoms of anxiety, depression, or anger without reaching the severity, duration, or level of related impairment necessary to qualify for a diagnosed emotional disorder. Such elevations in symptoms are presumed to be less enduring than the negative emotionality seen in related personality characteristics, and diagnosable emotional disorders are seen as qualitatively distinct from personality traits in their severity, related features, and levels of general impairment or dysfunction. Hence, anxiety, depression, and anger are typically conceptualized and studied as distinct emotions, as are their various forms in emotional episodes, symptoms, disorders, and personality traits.

If these distinctions were in fact firm, the common approach of studying one emotional risk factor for CHD at a time would not pose a problem. Unfortunately, these distinctions are quite difficult to support empirically (Smith, 2010; Suls & Bunde, 2005). There is a high degree of correlation among anxiety, depression, and anger, and this is true in each of the various forms. Further, the distinctions between the various forms of negative emotions are problematic. Symptoms of emotional distress are closely correlated with related personality traits, and scores on such symptom inventories are more stable than should be the case if they were unrelated to personality (Suls & Bunde; Watson, 2009). Neuroticism and negative affectivity are closely associated with anxiety and mood disorders (Weinstock & Whisman, 2006), and symptoms of emotional disorders often appear to take the form of continuous severity distributions rather than the discrete structure implied by categorical models of emotional disorder (Haslam, 2007). Emotional disorders co-occur so frequently that alternative diagnostic frameworks involving "distress disorders" have been proposed (Watson, 2009). Hence, when one specific negative affect risk factor is related to the development or course of CHD, this association could easily involve another negative affect and/or another form of negative affect. This lack of specificity complicates the design and implementation of risk-reducing interventions, in that it is not clear which specific negative affect or which form of negative affect should be targeted.

Reviews of the many studies of negative emotional factors and the development and course of CHD suggest reliable associations for depression, anxiety, and anger when these characteristics are



Heart Disease and Emotions: Anger, Anxiety, Depression, Fig. 1 (**a**) Conceptual framework for overlapping negative affective risk factors (**b**) Alternative framework including general and specific aspects of negative affect (Reprinted with permission from Smith (2010) (Fig. 12.1, p. 161))

considered separately (Chida & Steptoe, 2009; Nicholson, Kuper, & Hemingway, 2006; Suls & Bunde, 2005). However, the far fewer studies attempting to parse the potentially overlapping effects of these negative emotional phenomena have produced mixed results. Studies of preclinical, asymptomatic atherosclerosis that have measured multiple negative affective characteristics have sometimes found that depression but not anxiety or anger predicts disease severity (Stewart et al., 2007), whereas others have found that anxiety and anger but not depression are related to CAD (Smith, Uchino et al., 2008). Studies of multiple indicators of negative affect as predictors of the initial occurrence of CHD have produced evidence of the unique or independent effects of anxiety (Phillips et al., 2009; Kubzansky et al., 2006; Shen et al., 2008), depression (Grossardt et al., 2009; Phillips et al., 2009), and general emotional distress (Boyle et al. 2006; Kubzansky et al., 2006). In studies of patients with CHD, the evidence is again mixed. Some studies suggest that anxiety and depression are independent predictors of recurrent cardiac events (Frasure-Smth & Lespérance 2008), whereas others suggest that anxiety but not depression has an independent effect (Tully et al., 2008).

Additional research is clearly needed to sort out the independent versus overlapping effects of the various negative emotions and their various forms, across the multiple phases of the development and course of CHD. The design of future studies must attend to the fact that anxiety, depression, and anger are correlated, and the overlap across various forms of these emotions is considerable. Figure 1 presents two conceptual models that can guide these efforts. In the first (panel A), anxiety, depression, and anger are each considered and assessed separately, as are the various forms of these emotional constructs. In the second, the general factor (i.e., general emotional distress) is considered and assessed directly, as are the unique aspects of anxiety, depression, and anger. For example, depression differs from anxiety and anger in its associated low levels of positive affect and physiological activation (Watson, 2009), and anger involves approach motivation (e.g., overcoming obstacles in frustrated goals, redress social transgressions or mistreatment), whereas anxiety is mostly associated with avoidance motives (i.e., minimize harm). Additional studies that measure these multiple aspects and forms of negative emotion could help define targets for risk-reducing interventions more precisely.

Interventions for CHD patients focused on a specific negative affect (e.g., depression) generally have not been found to be effective in reducing recurrent coronary events (ENRICHD Investigators, 2003). In contrast, more general interventions focusing on stress and negative emotion broadly considered have been found to be effective in improving the prognosis of CHD patients (Linden, Phillips, & Leclerc, 2007). If supported in future research, it is possible that this pattern of intervention results indicates that it is the general or overlapping aspects of negative emotion – rather than the specific aspects – that

are important risk factors and important intervention opportunities. However, much additional research is needed.

Heart Disease and Smoking

Definition

Heart disease is a relatively broad term which refers to many diseases associated with the heart. Coronary heart disease (CHD) refers to a narrowing or even complete occlusion of the blood vessels which supply the heart with blood and oxygen. Cardiovascular disease (CVD) is often used as a synonym for CHD. Smoking is defined as inhalation of smoke from burning tobacco via a cigarette, cigar, pipe, or other smoke delivery device (e.g., hookah).

Description

Approximately 20% of adults smoke in the United States, and this percentage has remained fairly consistent across the last 10 years (Centers for Disease Control and Prevention, 2010). It is currently estimated that over 140,000 individuals in the US will die annually due to smoking-attributable CHD (Centers for Disease Control and Prevention, 2008). There is currently compelling evidence that smoking is causally related to cardiovascular diseases. The most extensive current compilation of evidence supporting a causal link between smoking and CHD is found in the 2010 Surgeon General's Report: *How Tobacco Smoke Causes Disease: The Biology and Behavioral Basis for Smoking-Attributable Disease* (U.S. Department of Health and Human Services, 1994). What follows is a brief overview of the evidence for a causal link between smoking and CHD including a discussion of the biological processes impacted by smoking that are implicated in CHD.

There are numerous studies which demonstrate a clear dose–response relationship between number of cigarettes smoked per day and risk for developing CHD. The recent Surgeon General's Report on Smoking (Centers for Disease Control and Prevention, 2010) indicated that risk for CHD is increased across all levels of smoking and that smoking even a few cigarettes per day (less than five) resulted in increased risk of developing CHD. This report also indicated that duration of smoking is associated with increased risk of CHD-related mortality.

Exposure to secondhand smoke also increases the risk of CHD. One study determined that the relative risk of CHD for smokers is 1.78 as compared with 1.31 in nonsmokers exposed to secondhand smoke. This study also revealed that exposure to secondhand smoking resulted in similar negative circulatory changes to those which occur in smokers. There is also evidence of decreased hospital admissions due to myocardial infarction rates in locations which have banned public smoking (Barnoya & Glantz, 2005)

There are multiple physiological changes which occur in response to smoking which are thought to be associated with CHD. Cigarette smoking results in decreased blood flow to the heart and increased blood pressure and heart rate (U.S. Department of Health and Human Services, 1994). Smoking damages and impairs regeneration of the inner lining of blood vessels (endothelium). Damaged blood vessels increase the risk of developing arterial plaques (atherosclerosis) which consequentially increases the risk of developing blood clots which can lead to myocardial infarct (U.S. Department of Health and Human Services). Cigarette smoking causes inflammation in the circulatory system and also impairs vasodilation of blood vessels, both of which increase the risk for negative cardiac events (U.S. Department of Health and Human Services). Smoking can also cause platelets in the blood to become sticky, and this is thought to increase the likelihood of clot formation (U.S. Department of Health and Human Services). Importantly, similar

physiological changes have been demonstrated in persons exposed to secondhand smoke (Barnoya & Glantz 2005).

Quitting smoking will reduce the risks of developing CHD (U.S. Department of Health and Human Services). The risk for CHD and CHD-related mortality drops in half after approximately 1 year of smoking cessation. After 10 years of smoking cessation, the risk for developing CHD-related issues is essentially equivalent to that of a nonsmoker (U.S. Department of Health and Human Services). Smoking cessation at any age is also clearly associated with increased longevity (Taylor et al. 2002).

Heart Disease and Stress

Peter A. Shapiro
Department of Psychiatry, Columbia University, New York, NY, USA

Definition

Stress is a hard concept to define precisely, but like obscenity (to paraphrase Supreme Court Justice Potter Stewart (*Jacobellis vs. Ohio. 378 U.S. 184, 197, 1964*)), you (sometimes, but perhaps not always) know it when you feel it. For any given system, stress implies a load that challenges the homeostasis and integrity of the system. Stress may be intrinsic to the system, for example, the weight of a suspension bridge's roadway platform, or extrinsic to the system, such as the effect of hurricanes, earthquakes, or traffic jams loading the bridge. Both intrinsic and extrinsic stressors pose the risk of bridge collapse. Whether a stressor is intrinsic or extrinsic, the system must have a capacity to withstand it in order to maintain structural and/or functional integrity. Thus for a suspension bridge, to continue the example, this capacity is built into the tensile strength of its suspension cables and the mass and strength under compression of the towers and buttresses supporting the cables and transmitting force to the surrounding ground. In behavioral cardiology, concern about stress and heart disease has focused on external psychological stressors, and related behaviors and affective and psychophysiological states, associated with

the onset and progression of heart disease, especially coronary artery disease and sudden cardiac death.

Description

For lack of a precise, gold-standard, quantifiable measure of stress as it relates to heart disease, stress is usually defined by subjective measures of perceived stress, by characterization and counts of common life experiences generally regarded as stressful, unwanted, or at least as disturbing homeostasis (e.g., daily hassles, hostile interactions, job strain, job loss, loss of a loved one, divorce, interpersonal conflict, moving to a new city, marriage, promotion to new work responsibilities), by experimental manipulations or ecological measurement of short-term challenges, and by exposures to epidemiologically significant events such as natural disasters, missile attacks during wartime, and terrorism. It is evident that stress is often associated with negatively valenced affective states such as anxiety, depression, and anger, but can also be associated with more positively experienced acute excitement and life experiences.

Evidence for the association of stress with heart disease is overwhelming. Numerous studies demonstrate that earthquakes are associated with a subsequent increase over background rates in myocardial infarction and sudden death. Iraqi missile attacks on Israel during the Gulf War in the 1990s, the destruction of the World Trade Center in New York in 2001, and sports events such as World Cup Soccer matches have been consistently observed to be associated with increased rates of acute coronary syndromes and lethal ventricular arrhythmias, even in individuals not physically endangered by proximity to the events. Acute episodes of anger appear to be an especially potent trigger of acute coronary events in vulnerable patients. In INTERHEART, a very large case–control study of first myocardial infarction involving over 24,000 subjects in 52 countries, chronic exposure to stress, measured by self-reports of problems with family relationships, work, or financial strain over a 1-year period, was associated with increased rate of MI, with population-attributable risk estimated at 12–33%. A dose–response relationship was observed between the number of stressful life events reported and risk of myocardial infarction, with an odds ratio for MI risk of 1.5 for individuals reporting two or more stressful life events compared to those reporting no stressful life events. Thus, epidemiological evidence supports the role of emotional stress both over the long term, in processes contributing to the development of coronary atherosclerosis, and in the short term, as a trigger of acute coronary events in vulnerable patients. Perceived stress is heightened in people with low socioeconomic status, which may also be associated with numerous other behavioral and physiological cardiac risk factors. Conversely, stress effects on cardiovascular risk are moderated by the presence of good social support. Studies comparing heart disease risk in men and women have found that for women, the relationship of stress at work to coronary heart disease risk is less clear-cut than in men, but stress at home and in interpersonal relationships is associated with increased risk of coronary disease-related events.

Stressful experiences result in derangements of autonomic nervous system regulation of the cardiovascular system, with reduced vagal tone and relatively increased sympathetic tone. Heart rate and blood pressure increase in response to acute mental stress; the extent of this increase depends in part on the nature of the stressor and also in part on individual characteristics such as trait anxiety and hostility. Interruption of sympathetic inflow to the left side of the heart by left stellate ganglionectomy reduces stress-induced ischemia and ventricular arrhythmias. Stressful experience is associated with hemoconcentration and increased blood viscosity, which may increase the risk of thrombosis, especially as clotting factors and platelet activation also increase during acute stress. Stressful experiences alter hypothalamic-pituitary axis function, with lasting consequences, such that childhood trauma is associated with elevated circulating levels of corticotrophin-releasing factor in adulthood, and stress in adulthood leads to hypercortisolemia.

Endothelial dysfunction and paradoxical vasoconstriction during acute mental stress are observed in atherosclerotic coronary artery segments. During mental stress, increased heart rate and blood pressure along with coronary vasoconstriction may result in myocardial ischemia, which may be manifest as ST segment changes in the electrocardiogram, reduced left ventricular ejection fraction and regional wall motion abnormalities; stress-induced impairment of left ventricular function is associated with an increase in the risk of recurrent coronary events and survival. Yet, although mental stress–induced ischemia occurs primarily in individuals with exercise-induced ischemia, it is notable that mental stress–induced myocardial ischemia is frequently asymptomatic, and occurs at a level of increased heart rate and blood pressure less than that required to achieve ischemia during exercise. Acute mental stress also induces an inflammatory response, with elevated levels of inflammatory cytokines IL-6 and TNF-alpha, which can destabilize atherosclerotic plaque and promote plaque rupture or superimposed thrombosis. The extent to which each of these mechanisms mediates the effect of stress on heart disease risk is unknown.

Sudden emotional stress can also lead to acute cardiac events in patients who do not have coronary artery disease. Takotsubo cardiomyopathy is a rare syndrome characterized by transient left ventricular dysfunction with apical ballooning and acute heart failure in response to emotional shocks, such as surprise parties or receiving unexpected bad news. The syndrome has been attributed to rapidly increasing sympathetic tone and catecholamine levels in response to the psychological stressor.

Studies of the effects of interventions to reduce stressful experience or improve resilience in managing stress on heart disease outcomes have had decidedly mixed results. Behavioral or cognitive behavioral stress management treatment groups to reduce angry responding and time urgency reduce the incidence of recurrent MI. Inclusion of "stress management" in cardiac rehabilitation programs for post-MI patients is associated with reduced recurrent cardiac events and reduced mortality, but individualized life stress monitoring and problem-solving interventions for post-MI patients resulted in no benefit in men and increased recurrent cardiac events in women in the Montreal Heart Attack Readjustment Trial (M-HART). Cognitive behavior therapy aimed at bolstering social support also had a negative effect on recurrent cardiac events in women in the ENRICHD trial. Overall, however, exercise and stress management programs appear to reduce recurrent cardiac events, improve subjective well-being, and may reduce hemodynamic and other physiological responses to stress.

Heart Disease and Type A Behavior

Yoichi Chida
Research Department of Epidemiology & Public Health, University College London, London, UK

Synonyms

Coronary heart disease (CHD); Type A behavior pattern (TABP)

Definition

A comprehensive meta-analysis of prospective studies between 1966 and 1998 failed to show an association between Type A behavior pattern (TABP) and coronary heart disease (CHD) (Myrtek, 2001), and since then there has been no evidence showing such an association. However, the recent meta-analytic investigation on prospective studies showed that anger and hostility, one of the key dimensions of TABP, are significantly associated with not only increased CHD events in initially healthy populations but also poor prognosis in the patients with existing CHD (Chida & Steptoe, 2009).

Description

Type A behavior pattern (TABP) was first noted by two American cardiologists, Meyer Fredman and Ray Rosenman, in 1959 (Friedman & Rosenman, 1959). They demonstrated that a group of 83 men, mainly executives, had seven times the risk of coronary heart disease (CHD) when compared with that in the other two groups of 83 men from unions and accounting firms and 46 unemployed blind men. The behavior pattern of group A is characterized by intense ambition, competitive "drive," constant preoccupation with "deadlines," and a sense of time urgency. Over time, together with input from psychologists, they refined the notion of TABP with an increasing focus on the elements of aggressiveness and easily aroused annoyance or hostility (Rosenman, 1978). Persons not showing these characteristics are labeled Type B behavior pattern. Data published in 1974 and 1976 from the Western Collaborative Group Study containing approximately 3,000 middle-aged men, exhibited a relative risk of 1.8 for nonfatal myocardial infarction (MI) or angina over 4 years in those were TABP, and a relative risk of 1.9 for fatal CHD, nonfatal MI, or angina over 8.5 years in those who were TABP (Jenkins, Rosenman, & Zyzanski, 1974; Rosenman, Brand, Sholtz, & Friedman, 1976). Nevertheless, as time passed, these original findings were not supported by an increasing number of subsequent studies (Brotman, Golden, & Wittstein, 2007; Everson-Rose & Lewis, 2005). More comprehensively, a meta-analysis of prospective studies between 1966 and 1998 failed to show an association between TABP and CHD (Myrtek, 2001), and since then there has been no evidence showing such an association.

Some researchers, therefore, changed their focus to investigate whether anger, hostility, and related constructs, one of the key dimensions of TABP, would be more closely linked to the development of CHD. Hostility is typically described as a negative attitude or cognitive trait directed toward others, anger as an emotional state that consists of feelings that vary in intensity from mild irritation or annoyance to intense fury or rage, and aggressiveness as a verbal or physical behavioral pattern manifest in yelling, intimidation, or physical assaults. These constructs, these terms often are used interchangeably and their interrelationship remains poorly delineated (Martin, Watson, & Wan, 2000; Schulman & Stromberg, 2007). Over the past 25 years, the body of research investigating associations between anger and hostility and CHD development and progression has grown. The recent meta-analytic investigation on prospective studies showed that anger and hostility are significantly associated with not only increased CHD events in initially healthy populations but also poor prognosis in the patients with existing CHD (Chida & Steptoe, 2009). The harmful effects of anger and hostility were slightly greater in the CHD patients than the healthy population

studies, making it possible that frequent anger episodes related to trait anger and hostility trait might accelerate recurrence of CHD.

If anger and hostility do influence CHD risk, effects might be primarily mediated via behavioral pathways, with anger and hostility promoting high-risk behaviors such as poor diet, less physical activity, smoking, poor sleep, or lower treatment adherence (Scherwitz et al., 1992; Shin et al., 2005; Siegler, Peterson, Barefoot, & Williams, 1992). Indeed, the apparently harmful effects of anger and hostility on CHD were no longer significant in either the healthy or disease populations after fully controlling for behavioral covariates such as smoking, physical activity or body mass index, and socioeconomic status (Chida & Steptoe, 2009). However, other unmeasured factors cannot rule out that could potentially have confounded the associations, and direct physiological pathways might also contribute. Anger and hostility may alter susceptibility to CHD via autonomic nervous dysregulation (Chida & Hamer, 2008; Thomas, Nelesen, & Dimsdale, 2004; Vella & Friedman, 2007), increases in inflammatory and coagulation factors such as interleukin-6, C-reactive protein, and fibrinogen (Markovitz, 1998; Stewart, Janicki-Deverts, Muldoon, & Kamarch, 2008), and higher cortisol levels (Steptoe, Cropley, Griffith, & Kirschbaum, 2000). Furthermore, a number of studies have demonstrated that anger and cynical hostility predict the progression of subclinical atherosclerosis (Matthews et al., 1998; Raikkonen, Matthews, Sutton-Tyrrell, & Kuller, 2004), suggesting that the associations between anger/hostility and CHD may be due to the impact of anger and hostility on the development of coronary atherosclerosis, although acute trigger effects may also contribute (Dimsdale, 2008; Mittleman et al., 1995; Möller et al., 1999).

Taken together, given a recent meta-analysis on randomized controlled trials endorsing the efficacy of psychological interventions in cardiac patients (Linden, Phillips, & Leclerc, 2007), clinical trials focusing on anger and hostility in CHD interventions are necessary for the more effective prevention and treatment of CHD.

Definition

Heart failure is a general term used to describe a clinical syndrome characterized by shortness of breath, exertional dyspnea, paroxysmal nocturnal dyspnea, orthopnea, peripheral and/or pulmonary edema, and exercise intolerance. Since individual experiences of these clinical indicators may vary, it is important to understand how heart failure is classified. The underlying etiology and associated pathophysiology are keys to appropriate diagnosis and management.

Several categories are used to describe, organize, and classify heart failure. Acute versus chronic heart failure are terms used to describe both the onset and intensity of symptoms. Acute heart failure refers to the sudden appearance of symptoms (e.g., usually over hours or days), which have progressed to a point at which immediate or emergency medical intervention is necessary. Chronic heart failure refers to the development of symptoms over a period (e.g., months to years). Chronic symptoms represent the baseline condition or symptoms that an individual lives with on a daily basis. If the cause of the acute onset of heart failure is not reversible (e.g., left ventricular damage from a myocardial

infarction), then the heart failure may become chronic. Other classification categories include left versus right-sided heart failure.

Right-sided heart failure refers to failure of the right ventricle to pump adequately, and is most commonly caused by left-sided heart failure. It can also be caused by pulmonary disease and primary pulmonary hypertension. Left-sided heart failure refers to failure of the left ventricle to fill or empty properly, which leads to increased pressures inside the ventricle and congestion in the pulmonary vascular system. Left-sided heart failure may be further classified into systolic and diastolic dysfunction.

Systolic dysfunction is usually estimated by ejection fraction, or the percentage of the left ventricular end-diastolic volume (LVEDV) that is ejected from the ventricle in one cycle. For example, if the LVEDV is 100 mL and the stroke volume is 70 mL, the ejection fraction is 70%. Normal ejection fraction is 50–70%. Systolic dysfunction is defined as an ejection fraction of less than 40% and is caused by a decrease in heart contractility. Diastolic dysfunction, which is more common among older adults, is less well defined and more difficult to measure (i.e., left ventricular function is preserved). Although heart contractility is normal or even increased (e.g., normal or even high ejection fractions), diastolic dysfunction is caused by impaired relaxation and/or filling (e.g., fast heart rate, stiff or poorly compliant ventricle, rhythm that is poorly organized).

Diagnosis and management of heart failure begins with a clinical history and physical examination, and confirmatory evidence of cardiac dysfunction on an echocardiogram. Once a diagnosis has been made, it is important to characterize the degree of impairment using the standardized New York Heart Association (NYHA) Functional Classification. The American College of Cardiology (ACC) and the American Heart Association Guidelines (AHA) outline four stages of heart failure that are useful for organizing the prevention, diagnosis, management, and prognosis for patients with heart failure; only stages C and D are applicable to the NYHA functional classification system.

Definition

Heart rate is the number of beats of the heart per unit of time. Typically it is measured in beats per minute (bpm). Heart rate is based on the time interval between one R wave and the next. The R wave is the onset of ventricular depolarization. For further details, see Andreassi (2006).

Definition

Like many organs in the body, the heart is dually innervated. Although a wide range of physiologic factors determine cardiac functions such as heart rate (HR), the autonomic nervous system (ANS) is the most prominent. Resting cardiac autonomic balance favors energy conservation by way of parasympathetic dominance over sympathetic influences. In addition, the HR time series is characterized by beat-to-beat variability over a wide range, which also implicates vagal dominance as the sympathetic influence on the heart is too slow to produce beat-to-beat changes. There is an increasing interest in the study of this heart rate variability (HRV) among researchers from diverse fields. Low HRV is associated with increased risk of all-cause mortality and has been proposed as a marker for disease. In the following, I will briefly describe the nature and assessment of HRV.

Heart Rate Variability

The basic data for the calculation of all the measures of HRV is the sequence of time intervals between heart beats. This interbeat interval time series is used to calculate the variability in the timing of the heart beat. Relative sympathetic increases cause the time between heart beats (the interbeat interval) to become shorter and relative parasympathetic increases cause the interbeat interval to become longer. The parasympathetic influences are pervasive over the frequency range of the heart rate power spectrum whereas the sympathetic influences "roll-off" at about 0.15 Hz. Therefore high-frequency HRV represents primarily parasympathetic influences with lower frequencies (below about 0.15 Hz) having a mixture of sympathetic and parasympathetic autonomic influences. The differential effects of the ANS on the sinoatrial node, and thus the timing of the heart beats, are due to the differential effects of the neurotransmitters for the sympathetic (noradrenaline) and parasympathetic (acetylcholine) nervous systems. The sympathetic effects are slow, on the timescale of seconds, whereas the parasympathetic effects are fast, on the timescale of milliseconds. Therefore the parasympathetic influences are the only ones capable of producing rapid changes in the beat-to-beat timing of the heart.

Measures of HRV

A variety of measures have been used to operationalize HRV. Long-term measures like the standard deviation of all interbeat intervals in 24 h, short-term measures like the standard deviation of 5 min intervals and beat-to-beat measures like the root mean square of successive RR differences (RMSSD) have all been used. Power spectral analysis of interbeat interval time series is frequently used to quantify HRV. The power spectrum of short-term time series contains two major components, a high-frequency

(0.15–0.40 Hz) and low-frequency (0.01–0.15 Hz) component reflecting cardiac vagal influences and a mixture of vagal and sympathetic influences, respectively. RMSSD and the high-frequency component of the power spectrum are closely related and reflect vagal cardiac influence. More recently, measures derived from nonlinear dynamics have been used to describe aspects of HRV. One such measure is approximate entropy (ApEn). It quantifies the complexity or irregularity of time series data.

Hematopoietic Stem Cell Transplantation

Yoshinobu Kanda
Division of Hematology, Saitama Medical Center, Jichi Medical University, Omiya-ku, Saitama, Japan

Description

In general, hematological malignancies show good response to antineoplastic agents. However, less than half of patients with hematological malignancies can be cured with chemotherapy alone. Since some antineoplastic agents show linear dose–response relationship, increasing the dose of chemotherapy may increase the antineoplastic effects, but it is precluded by the adverse effects of antineoplastic agents, so-called dose-limiting toxicities. The dose-limiting toxicity of many antineoplastic agents is myelosuppression. Therefore, hematopoietic stem cell transplantation has been investigated to allow high-dose chemotherapy over the maximum tolerated dose by supporting the hematopoietic system with the infusion of hematopoietic stem cells from a donor (allogeneic transplantation) or the patients themselves (autologous transplantation). In addition to the effect of the high-dose chemotherapy, an immunological antineoplastic effect of donor cells, so-called graft-versus-leukemia/lymphoma effect, can be harnessed after allogeneic transplantation. Currently, the application of hematopoietic stem cell transplantation is extended to solid tumors and nonmalignant hematological disorders such as aplastic anemia.

Previously, bone marrow was the sole source of hematopoietic stem cells. However, in the 1990s, the peripheral blood stem cells, which were mobilized by the use of granulocyte-colony stimulating factor alone or in combination with chemotherapy in autologous transplantation, became widely used as a source of hematopoietic stem cells, since the hematopoietic recovery is faster after peripheral blood stem cell transplantation than that after bone marrow transplantation. In addition, cord blood cells are currently the third source of hematopoietic stem cells. A major drawback of cord blood stem cell transplantation is the longer duration between transplantation and hematopoietic recovery. However, cord blood units are readily accessible, since they are already frozen in cord blood banks and there is no need for time-consuming door coordination.

The procedure of hematopoietic stem cell transplantation starts with a conditioning regimen using high-dose chemotherapy with or without total body irradiation. The major object of the conditioning regimen is to eradicate malignant cells from the recipient. However, in allogeneic transplantation, conditioning regimens are also required to suppress host immune system to prevent rejection of donor hematopoietic cells. The latter is the sole object of the conditioning regimen in allogeneic transplantation for aplastic anemia. After the conditioning regimen, hematopoietic stem cells are infused to the recipients intravenously. In general, hematopoietic recovery is observed within 2–4 weeks. However, supportive managements to prevent or treat transplant-related complications are required at least several months (or much longer in allogeneic transplantation) after transplantation.

The major complications after allogeneic hematopoietic stem cell transplantation include toxicities directory due to the conditioning regimen, infection, and graft-versus-host disease (GVHD). Increasing the dose of chemotherapy or total body irradiation over the maximum tolerated dose may induce toxicities that are not observed after standard-dose chemotherapy. For example, a fatal cardiac toxicity may develop after high-dose cyclophosphamide as a conditioning regimen. To extend the application of allogeneic transplantation to the elderly or clinically infirm patients who cannot tolerate these conditioning regimens, reduced-intensity or non-myeloablative stem cell transplantation has been investigated. Clinical studies of reduced-intensity or non-myeloablative transplantation have shown that the incidence of transplant-related morality was decreased, but the increase in relapse rate was the problem.

Hematopoietic stem cell transplantation recipients experience various infections. In the early phase after transplantation (day 0 to day 30), neutropenia is the primary immunologic defect. In addition, mucosal damage caused by the conditioning regimen adds the risk of infection. Flora of the skin, gastrointestinal tract, and mouth are the primary causes of infection during this phase. The second phase (day 30 to day 100), infectious complications due to *Cytomegalovirus*, *Aspergillus*, and *Pneumocystis jiroveci* are common due to the impaired cellular immunity. The development of acute or chronic GVHD is associated with severely impaired cellular immunity. In the later phase (after day 100), impaired cellular and humoral immunity is the major risk factor for infectious complications, especially in allogeneic transplant recipients with chronic GVHD. The causative organisms of infectious complications in this phase include Cytomegalovirus, Varicella-zoster virus, Epstein-Barr virus, *Aspergillus*, and *Pneumocystis jiroveci*.

GVHD is an immunological reaction of the donor immunological cells targeting host antigens. Clinical manifestations of acute GVHD include erythroderma, diarrhea, and jaundice. On the other hand, chronic GVHD resembles autoimmune disorders such as scleroderma, Sjögren's syndrome, primary biliary cirrhosis, bronchiolitis obliterans, and immune cytopenias. GVHD can be observed even after human leukocyte antigen (HLA) matched transplantation, but both its incidence and severity are increased by the presence of HLA-mismatch between the donor and the recipient. A combination of calcineurin inhibitors (cyclosporine or tacrolimus) and methotrexate is the mainstay of the pharmacological prevention of GVHD, whereas steroid is the first choice of the treatment of acute GVHD. The use of these immunosuppressive agents increases the risk of infectious complications.

In general, the incidence of transplant-related mortality is less than 5% after autologous transplantation, but it exceeds 10–20% after allogeneic transplantation, even from an HLA-matched donor. In addition, transplant-related complications, especially the development of chronic GVHD, affect the quality of life of survivors after allogeneic transplantation. Therefore, the indication of hematopoietic stem cell transplantation should be considered by balancing the risk and benefit obtained after transplantation. Many clinical trials have been performed to evaluate the indication of hematopoietic stem cell transplantation in a variety of hematological disorders. However, information is not yet sufficient to identify patients who will clearly benefit from undergoing hematopoietic stem cell transplantation.

Hemodynamic

Jonathan Newman
Columbia University, New York, NY, USA

Definition

Hemodynamics is a general term referring to the movement or flow of blood. More specifically, this term refers to the measurement of and general principles governing the flow of blood in the human body. Movement or flow of blood throughout the body is dependent upon many factors. Two of the most important of these factors are the pressure differences and resistances between different elements of the circulatory system, such as the cardiac chambers, large arteries, arterioles, veins, and venules. Along with the heart rate (HR), pressure and resistance are major determinants of the amount of circulatory blood flow. Measurement of certain hemodynamic parameters, such blood pressure (BP) and heart rate (HR), can be determined noninvasively. Resistance is a calculated parameter determined by flow and pressure. For example, systemic vascular resistance is equal to the cardiac output divided by mean arterial

pressure. As will be described, cardiac output is determined by heart rate and stroke volume. These measures are important in understanding the pathophysiology of cardiovascular disease diagnosis and treatment. However, more detailed measures of cardiac structure, function, and intracardiac pressures are frequently necessary, and advanced measurement modalities are required.

Description

In the field of cardiology and cardiovascular medicine, hemodynamics are most commonly measured by two different modalities in the clinical setting: two-dimensional/Doppler echocardiography and cardiac catheterization. Each modality has limitations, and these two techniques are frequently used in concert. Importantly, absolute pressures can only be directly measured by cardiac catheterization. In contrast, absolute pressure cannot be measured by echocardiography; only pressure differences can be measured.

Echocardiography measures: Cardiac ultrasound, or echocardiography, uses ultrasonic beams through tissue. M-mode and two-dimensional (2D) echocardiography are used for structural imaging, while Doppler echocardiography uses ultrasound to record the movement of blood, enabling the assessment of hemodynamics and cardiac physiology. Each tissue has different properties that influence the amount of ultrasound beam that is reflected back to the ultrasound machine, generating a very small electrical current that can then be integrated into a composite image of the structure. Doppler ultrasound measures the difference between the scatter of ultrasound by different tissues and the frequency of the transmitted ultrasound beam. Doppler echocardiography is especially useful for the hemodynamic measurement of blood flow across stenotic valves of the heart and for measuring the pressure differences between different chambers. Assessment of blood flow is approximated by measurement of cardiac stroke volume. Stroke volume, in turn, is measured by taking the product of the velocity-time-integral (VTI, measured by Doppler echocardiography) and the cross-sectional area (CSA, measured with 2D echocardiography) between certain chambers. Cardiac output is then determined by the product of stroke volume and heart rate. The change in pressure between two cardiac chambers, a useful principle in cardiac hemodynamics, is frequently assessed using a modified form of the Bernoulli equation, which is itself a derivation of basic principles of conservation of energy in closed systems.

Catheterization measures: During catheterization, a special type of catheter is introduced into either the internal jugular vein in the neck or a femoral vein in the leg. The catheter is advanced into different chambers of the right (venous) side of the heart, the side responsible for collecting and pumping deoxygenated blood from the systemic circulation into the lungs. Typically, these catheters have an inflatable balloon built into the catheter. Inflation of the balloon in a pulmonary artery allows for the measurement of the pulmonary capillary "wedge" pressure (PCWP), which is, in most circumstances, a clinically useful approximation of intravascular fluid balance. To measure pressures in the left (arterial) side of the heart, a similar type of catheter and wire system is introduced into the right femoral artery and advanced retrograde up to and across the aortic valve into the left ventricle. Routine hemodynamic pressure measurements obtained from the right side include right atrial pressure, right ventricular pressure, pulmonary artery pressure, and PCWP. Left-sided pressure measurements include measurement of aortic pressure and left ventricular pressure. Cardiac output can be measured directly with cardiac catheterization using the thermodilution or Fick method. In the thermodilution method, cold saline is injected into the proximal port of the pulmonary artery catheter and mixes with body temperature blood in the right ventricle. As blood flows past the distal port, a small sensor records the change in temperature over time. The area under this curve is proportional to the flow in the pulmonary artery which, assuming there is no intracardiac shunt, is proportional to cardiac output. Stroke volume is determined by dividing this measured cardiac output by the heart rate.

The Fick method of cardiac output uses measures of oxygen consumption measured by either exhaled breath analysis or determined by an age, sex, height, and weight specific nomogram and is dependent on hemoglobin and levels of arterial oxygen saturation.

Hepatitis Types A, B, C

Carrie Brintz
Department of Psychology, University of Miami, Coral Gables, FL, USA

Definition

Hepatitis involves inflammation of the liver and is most commonly caused by a number of viruses. Hepatitis can be an acute or a chronic condition. Hepatitis A is an acute viral infection of the liver due to the hepatitis A virus (HAV), and is the least serious of the hepatitis viruses. Hepatitis B and C are viral infections of the liver due to the hepatitis B virus (HBV) and the hepatitis C virus (HCV). Both hepatitis B and hepatitis C can become chronic infections and result in chronic liver disease.

Description

HAV is the main cause of acute viral hepatitis and is endemic worldwide. The virus is spread by the fecal-oral route, and very rarely by blood transfusion, and is often contracted from a contaminated water or food source. Major epidemics of hepatitis A are uncommon in the United States of America (USA), and most common in regions of the world with poor sanitary hygiene and overcrowding. The severity of the illness tends to increase with age. More than 80% of childhood cases of hepatitis A are asymptomatic, which encourages the spread of the virus. Adults with hepatitis A are more likely to have clinical symptoms such as jaundice (a yellowing of the skin and whites of the eyes). Symptoms tend to appear 2–6 weeks after exposure to HAV, and mild symptoms may last several months, particularly in adults. The virus does not remain in the body when the infection is gone. Vaccination for HAV is available, but there are no specific treatments for unvaccinated individuals who are exposed to the virus or develop the infection.

HBV is also found worldwide. It is spread parenterally and by sexual contact. Hepatitis B infection is most prevalent in sub-Saharan Africa, China, and Southeast Asia. Less than 1% of people in modern Europe, the USA, and Canada carry the virus, and in these areas, horizontal transmission occurs predominantly in younger individuals (ages 15–39) by sexual contact or intravenous drug use. Vertical transmission of the virus from mother to child and horizontal transmission from household members to unimmunized children occurs more frequently in high prevalence countries and helps maintain the virus in these areas. Most cases of hepatitis B are acute, but a small percentage of individuals will not clear the virus from their bodies and develop chronic infection. Hepatitis B infections are typically asymptomatic, especially in infancy through young adulthood, but early symptoms of acute hepatitis may occur such as jaundice, appetite loss, low-grade fever, and nausea and vomiting. Symptoms may not appear for up to 6 months after infection with HBV. Chronic infection with HBV can result in cirrhosis and hepatocellular carcinoma (HCC), also known as primary liver cancer. Up to 40% of individuals with chronic infection die from liver-related causes. A vaccination for HBV is available, and unvaccinated individuals exposed to the virus may be treated with Hepatitis B Immune Globulin. Those who develop chronic liver disease may need liver transplantation.

Like HAV and HBV, HCV is a worldwide endemic. It is primarily spread parenterally, while vertical and sexual transmissions of HCV are much less common than in HBV. Intravenous drug use is the most common cause of the virus. More than 80% of acute HCV cases lead to chronic infection, with long-term infection often leading to cirrhosis and HCC. As with hepatitis A and B, hepatitis C infection is usually asymptomatic, with the possible appearance of symptoms such as jaundice, dark urine, abdominal pain, and others. There is currently no vaccination for HCV. However, there are treatments such as antiviral medications that have a high likelihood of removing the virus from the blood or preventing the development of cirrhosis or liver cancer. Chronic hepatitis C with comorbid alcohol liver disease is the most common reason for liver transplantation in the USA.

Relevant to the field of Behavioral Medicine, the behavioral nature of numerous risk factors for exposure to viral hepatitis has led to research examining relevant psychosocial and behavioral predictors of viral hepatitis and its symptoms, as well as behavioral interventions for the prevention of viral hepatitis. Behavioral interventions researched include those targeting risk factors for viral hepatitis such as intravenous drug use and unsafe sex practices that could result in exposure to viral hepatitis.

Herbal Medicines

Timothy Whittaker
The International Register of Herbalists & Homeopaths, Cinderford, Glos., UK

Definition

Herbal medicine is the use of plants to treat human illnesses and debility. Parts used can be roots, bark, flowers, seed, leaves, or sometimes total aerial parts.

Description

Until early twentieth century, materials required for herbal medicine were collected in the countryside, dried by hanging in a warm room, and cut into small pieces to facilitate infusion in hot water, the resulting liquor being consumed as a dose. Mid-twentieth century saw the introduction of fluid extracts where 1 ml of finished liquid preparation represented 1 g of the starting material (dried herb). The industrial process to make these incurred considerable use of heat, very deleterious to fragile plant chemistry via hydrolysis, and/or oxidation. The last quarter of the century saw a substantial swing to the use of tinctures, aqueous-alcoholic preparations, made by steeping the dried herb in the liquor for a few weeks, cold, and pressing the residue to separate the liquid. Tinctures are typically 1:5, i.e., 1 g herb represented by 5 ml tincture. These products are very versatile for practitioner use, as the dose can be varied precisely from one prescription to the next, as the patient requires.

The herbal practitioner diagnoses and then writes his/her prescription. This will comprise a mixture of tinctures (and sometimes water) to make a 5-ml or 10-ml spoonful dose, using from 3 to about 25 per prescription. Experience teaches that there is a high degree of synergy accompanying the use of many together, with the advantage of an absolute minimum of adverse reactions as far less is used of each.

Some modern teachers have promoted the use of single plant extracts, standardized by assay of a single chemical constituent, dried to a powder, and formulated into tablets. This approach fails to appreciate the wide diversity of constituents in a plant (often several hundred), *all* of which work together therapeutically.

Significant behavior modifiers include hops (*Humulus lupulus*), scullcap (*Scutellaria lateriflora*), valerian (*Valeriana officinalis*), kava (*Piper methysticum*), and vervain (*Verbena officinalis*), as sedatives and hypnotics; St. John's wort (*Hypericum perforatum*) and Rhodiola rosea as antidepressants; and the ginsengs, Chinese or Korean (*Panax ginseng*) and Siberian (*Eleutherococcus senticosus*). The latter group acts as stamina providers, called adaptogens, because of their ability to improve the body's response to stress. Most of the named plants have added support from orthodox clinical trials. There are other less-studied herbs also in this area of therapeutics.

Heritability

Jennifer Wessel
Public Health, School of Medicine, Indiana University, Indianapolis, IN, USA

Definition

Heritability, or h^2, is the fraction of the total variation in a phenotype that can be explained by genetic factors. Heritability is not about cause.

Description

Interpretation

Heritability has values between 0 and 1. A heritability of 0 would be a trait where none of

the phenotypic variance is due to genetic factors, whereas a heritability of 1 would be a trait where all of the variance can be explained by genetic factors.

Heritability is based on measuring the correlations of phenotypes within families. Families share more than their genes; they also share environments. Therefore, the correlations may not simply reflect their shared genetic profiles but also environmental (behavioral) exposures. Heritability can also be affected by other factors such as the population (ethnicity, age, gender, location, etc.) from which it was measured (measurement error) and their environmental exposures.

Calculations

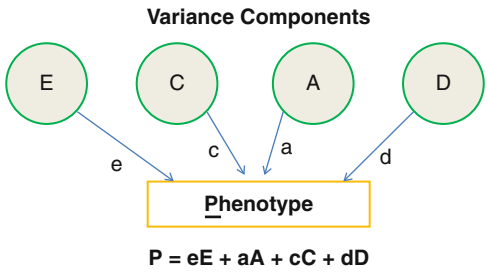
Twin studies are commonly used to measure heritability, as well as family studies. In the classic twin model, heritability is calculated by:

$$h^2 = 2(r_{mz} - r_{dz}),$$

which is the difference between intraclass correlations of a quantitative trait between monozygotic twins and dizygotic twins.

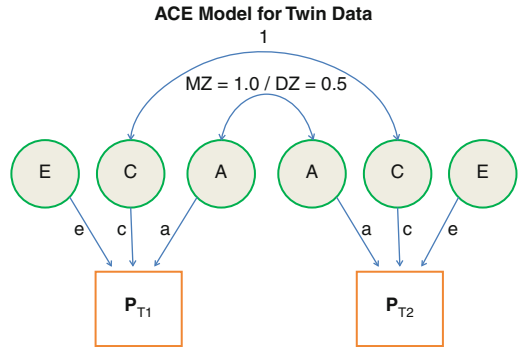
Intraclass correlations are subject to low power and large standard errors, necessitating the development of newer methods which take advantage of variances and covariances.

Path analysis or structural equation modeling estimates the genetic and environmental parameters that give the best fit of the variances and covariances observed in twins or families.



where E is the unique environment of each twin, C is the shared environment within the twin pairs, A is the additive genetic effects, and D is the dominant genetic effects.

Path analysis, or the ACE model, allows a diagrammatic representation between the linear models of the relationships between variables.



where MZ is monozygotic twins that share 100% of their genomes, and DZ is dizygotic twins that share 50% of their genomes, on average. It is assumed that both of the twins in a pair share 100% of their shared environment.

The ACE model can parse the variance of a trait into additive genetic, shared environmental, and non-shared environmental influences on the basis of the trait covariance observed among both monozygotic and dizygotic twin pairs. This model can accommodate hypothesis testing, both continuous and categorical variables, multiple variables, and more complex pedigrees or questions.

Definition

Humans have two alleles on homologous chromosomes for each gene or trait, one from their mother and one from their father. If the allele inherited from the mother is different from the allele inherited from the father, then the individual is heterozygous for that trait or gene. Alleles are variants of a gene and can also lead to a differential manifestation of the trait or disease they codify. Recessive alleles are not observed in the phenotype of heterozygous individuals.

The degree of heterozygosity (proportion of genes that are heterozygous by individual and by population) is used as a measure of genetic diversity in populations. The higher the mean heterozygosity is across the genome and across individuals in one population, the higher the genetic diversity.

Hierarchical Linear Modeling (HLM)

Definition

Hierarchical linear modeling (HLM) is a particular regression model that is designed to take into account the hierarchical or nested structure of the data. HLM is also known as multi-level modeling, linear mixed-effects model, or covariance components model (Leyland & Goldstein, 2001).

Description

HLM has historically been used in educational research where hierarchies occur naturally: students nested within classrooms, classrooms nested within schools, and schools nested within districts (Sullivan, Dukes, & Losina, 1999). Recent advances in statistical computing capabilities have made this model more available to researchers across a variety of disciplines. For example, in organizational psychology research, data from individuals must often be nested within teams or other functional units. For repeated measures or longitudinal data, time can be considered as another level which occurs within subjects (Fitzmaurice, Laird, & Ware, 2004). For assessing differences in mortality rates across hospitals relative to a specific condition or procedure, data are collected on random samples of patients nested within each hospital. In this application, it might be appropriate to adjust for covariates at both the patient level (such as patient age, patient gender, and the severity of the disease) and at the hospital level (such as hospital size and hospital teaching status) (Austin, Yu, & Alter, 2003). These hierarchical data structures are often seen in many medical research applications.

HLM is a more advanced form of traditional linear regression models which were developed making certain assumptions about the nature of the dependency structure among the observed responses. For example, in a simple linear regression model, $y_i = b_0 + b_1 x_i + e_i$, where y_i is the response for individual i; the standard assumption is that the y_i given the covariate x_i is independently identically distributed, that is, the error term e_i is independent among individuals. In many real-life situations, however, one has data structures, whether observed or by design, for which this assumption does not hold.

Suppose, for example, that the response variable is the birth weight of a baby and the predictor is maternal age and data are collected from a large number of maternity units located in different physical and social environments. One would expect that the maternity units would have different mean birth weights so that knowledge of the maternity unit already conveys some information about the baby. A more suitable model for these data is

$$y_{ij} = b_0 + b_1 x_{ij} + u_j + e_{ij},$$

where another subscript j was added to identify the maternity unit and a unit-specific effect u_j was included to account for mean differences among units. If one assumes that the maternity units are randomly sampled from a population of units, then the unit-specific effect is a random variable and the above model becomes a simple example of a two-level model. Its complete specification, assuming normality for random variables, can be written as follows:

$$y_{ij} = b_0 + b_1 x_{ij} + u_j + e_{ij},$$

$$u_j \sim \mathrm{N}\left(0, {s_u}^2\right),\ e_{ij} \sim \mathrm{N}\left(0, {s_e}^2\right),$$

$$\mathrm{cov}\left(u_j, e_{ij}\right) = 0,$$

where ${s_u}^2$ represents the degree of heterogeneity among maternity units (between-unit variance) and ${s_e}^2$ is the pure random error variance (within-unit variance). In this model, the correlation among birth weights in the same unit can be written as ${s_u}^2/({s_u}^2 + {s_e}^2)$, which is known as an intra-cluster correlation. This lack of independence, arising from two sources of variation at different levels of the data hierarchy (births and maternity units), contradicts the traditional linear model assumption, and an HLM is a suitable regression model for this situation.

The above most simple HLM can be elaborated in a number of directions, including the addition of further covariates (both births and units levels) or levels of nesting. An important direction is where the coefficient of covariates is also allowed to have a random distribution, for example, the age relationship can vary across units. This is particularly important for assessing the covariate-by-unit interaction. The regression coefficients b are usually referred to as fixed effects parameter, and the unit-specific effects u_j are referred to as random effects parameter, and the above model is often referred to as a mixed-effects model or random coefficient model.

The parameters of fixed effects and variance components (s_u^2 and s_e^2) in HLM are obtained via a restricted maximum likelihood (REML) estimation method (Cnaan, Laird, & Slasor, 1997; Leyland & Goldstein, 2001). The random effects are estimated using shrinkage estimators, which is referred to as an empirical Bayes estimator or a best linear unbiased predictor (Fitzmaurice et al., 2004). This estimator is essentially an optimally weighted linear combination of the estimated overall mean and unit-level mean. The degree of shrinkage toward the overall means depends on the magnitude of the relative magnitude of s_u^2 and s_e^2. When s_e^2 is relatively large and the within-unit variability is greater than the between-unit variability, more weight is assigned to overall mean. On the other hand, when the between-unit variability is large relative to the within-unit variability, more weight is given to the unit-specific observed response.

There are two major specialized software packages for conducting HLM analysis, one is MLwiN and the other is HLM. MLwiN (version 2.21) can be found via the links provided on the Centre for Multilevel Modelling (CMM), which is a research center based at the University of Bristol, with Internet address http://www.cmm.bristol.ac.uk/. HLM (version 6.08) is available from Scientific Software International, Inc., where HLM has its homepage with Internet address http://www.ssicentral.com/hlm/index.html. HLM analysis can also be conducted using general purpose packages such as SAS or SPSS. SAS (version 9.2) has full-fledged possibilities for HLM analysis, using PROC MIXED or PROC GLIMMIX.

Hierarchy of Evidence

Evidence hierarchy

Definition

The concept of the "hierarchy of evidence" refers to a tabular representation (sometimes presented as a pyramid) of the relative strengths of various investigational methodologies in providing the evidence that is used in evidence-based medicine and evidence-based behavioral medicine.

Byar (cited by Piantadosi, 2005) listed different types of medical studies in terms of the (increasing) strength of the evidence provided by them: case report, case series, database analysis, observational study, controlled clinical trial, and replicated clinical trials (independent verification of treatment efficacy estimates), referring to this progression as a "hierarchy of strength of evidence."

While the concept is simple, there can be disagreement on the order of some methodologies,

particularly toward the top of the pyramid. Randomized controlled clinical trials have typically been placed at the top, and many researchers still agree with this positioning. Others regard systematic reviews and meta-analyses as providing stronger evidence since they combine information garnered from more than one study (although many authors note the considerable care that is necessary when publishing a systematic review or meta-analysis). One such order, therefore, might be:

- Systematic reviews and meta-analyses
- Randomized controlled trials
- Cohort studies
- Case-control studies
- Cross-sectional surveys
- Case reports
- Expert opinions

More detailed accounts of several of these methodologies (listed in the "Cross-References" section) can be found in the encyclopedia.

Hispanic Community Health Study/Study of Latinos

Description

Behavioral, psychosocial, and sociocultural factors pose adverse cardiovascular disease (CVD) risks similar in magnitude to those caused by traditional risk factors such as smoking, high cholesterol, or hypertension. Little research has examined the risk and protective factors that contribute to CVD outcome of Hispanics/Latinos in the United States or that may lead to differential effects across subpopulations of Hispanics/Latinos. Consequently, the Hispanic Community Health Study/Study of Latinos (SOL), sponsored by the National Institutes of Health, was initiated to provide the largest, comprehensive, multicenter, community-based, longitudinal cohort study

of Hispanic/Latino health ever conducted in the continental United States. Objectives of the study include: (a) characterizing the health status and disease burden of the largest minority population in the United States; (b) describing the positive and negative consequences of their immigration and acculturation to the mainstream United States in relation to lifestyle, environmental factors, and access to health care; and (c) identifying likely causal factors of disease in this diverse population.

By June 2011, 16,000 men and women, 18–74 years of age, who self-identified as being Hispanic or Latino completed a 6.5 h baseline clinical exam. The participants were recruited from a stratified random sample of households in defined communities in the Bronx, Chicago, Miami, and San Diego. These communities were chosen so that the overall sample would include adequate representation from Central and South American, Cuban, Mexican, Puerto Rican, and Dominican ancestral backgrounds.

The study assessed risk factors for and prevalence of heart, lung, blood, and sleep disorders, kidney and liver dysfunction, diabetes, cognitive impairment, dental problems, and hearing disorders. Among the physical exam procedures employed were electrocardiogram, blood pressure, comparison of ankle and arm blood pressures to detect evidence of peripheral artery disease, evaluation of pulmonary function, physical activity assessed by activity monitors worn for a week by participants, and disordered breathing overnight to evaluate sleep interruption due to sleep apnea. Questionnaires assessed health histories of participants and their families, information about acculturation, social variables, education, occupation, smoking, nutrition, alcohol consumption, sleep, physical activity, and prescription and nonprescription drug use.

During annual follow-up phone calls, deaths, hospitalizations, and emergency department visits that occurred since the baseline examination are identified and followed up by examining hospital charts and death certificates. These records include documentation of acute myocardial infarction, heart failure, resuscitated cardiac arrest, cardiac revascularization, stroke, transient ischemia attacks, and asthma.

In general, SOL is designed to inform health care providers, the public health community, and the Hispanic/Latino population about the prevalence of impaired health in that population, the likely causes of such impairments as well as the measures needed to improve Hispanic/Latino health in the United States. In addition to the SOL parent study, the NIH has also sponsored ancillary studies that allow expansion of the major objectives of SOL. Thus, for example, an ancillary sociocultural study based on 5,280 of the original SOL participants is examining the influence of such factors as socioeconomic status (e.g., effects of cumulative deprivation during the lifespan), sociocultural factors (e.g., ethnic identity, fatalism), psychosocial risk (e.g., stress, negative emotions), and protective factors (e.g., social resources, family cohesion). In summary, SOL is providing the most comprehensive study of Hispanic/Latino health that has ever been conducted in the continental United States.

Definition

The terms *Hispanic* and *Latino/a* are used to collectively refer to people from Mexico, Central and South America, Spain, and Spanish-speaking or influenced countries. According to the 2010 Census, Latinos comprised 16.3% of the total US population, making them the largest racial/ethnic minority group in the USA (Pew Hispanic Center, 2011). Like other minorities, Latinos have a significant health risk factor profile marked by educational, economic, and disease challenges. Despite these disparities, Latino's appear to live longer than non-Hispanic Whites, an epidemiological phenomenon commonly referred to as the *Hispanic or Latino Mortality Paradox*.

Description

Background

Defining Latinos in the USA

Latinos in the USA are a heterogeneous group representing more than 23 nationalities and speaking at least 12 languages and dialects (Pew Hispanic Center, 2010). Approximately two-thirds (66%) of US Latinos are of Mexican descent followed by Puerto Ricans (8.9%), Cubans (3.5%), Salvadorans (3.3%), and Dominicans (2.8%). Latinos are largely defined and differentiated from other groups by cultural factors. In particular, Latino culture is *collectivistic*, meaning they place an emphasis on the needs of the group over those of the individual. Several specific values including the valuing family (*familismo)* valuing and warm interpersonal relationships (*personalismo)* and valuing interpersonal harmony (*simpatico*) facilitate strong social cohesion (Zea, Quezada, & Belgrave, 1994).

Demographics

Latinos account for approximately 16.3% of the total US population, accounting for 56% of the nation's population growth over the last decade (Pew Hispanic Center, 2011). By the year 2050, the Latino population is projected to triple in size to approximately 29% of the US population. Of the 50.5 million Latinos currently residing in the USA, an estimated 38% are foreign-born (Pew Hispanic Center, 2010). Importantly, foreign-born should not be equated with illegal immigration as unauthorized immigrants account for only 4% of the US population and, thus, a small percentage of the Latino community. Rather, native births are by far the largest source of growth in the US Latino population. Nearly one in five children in the United States is of Latino descent with approximately 89% of those children born in the USA, making them citizens by birth (Fry & Passel, 2009). It is estimated that by the year 2025, 30% of all children born in the USA will be of Latino descent.

The demographic profile of US Latinos differs significantly from other racial/ethnic groups. For example, Latinos are by far the youngest group with a median age of 27 years compared to 41 years for non-Hispanic Whites, 32 years for non-Hispanic Blacks, 36 years for non-Hispanic Asians, and a median age of 36 years for the total US population (Pew Hispanic Center, 2010). Latinos are less likely to have ever been married compared to non-Hispanic Whites (66.3% vs. 76.7%) but more likely to live in a "household" or family unit (81% vs. 69%). Latino households tend to be larger than non-Hispanic White households, and US-born Latinos are more likely to

live with family members than non-Hispanics of any race (Pew Hispanic Center, 2010).

Socioeconomic Profile

Socioeconomic status (SES) is among the most robust psychosocial modifiers of physical health and mortality. Similar to other racial/ethnic minorities, Latinos experience significant SES disparities relative to non-Hispanic Whites and the US population in general. For example, nearly one in five (19.5%) Latinos is classified as living in poverty, a rate comparable to the percentage of non-Hispanic Blacks (21.9%) and significantly higher than non-Hispanic Whites (8.2%; Pew Hispanic Center, 2010). Latinos have the lowest median income for full-time, year-round work relative to other racial/ethnic groups, which may be due in part to their overrepresentation in manual labor jobs and underrepresentation in management and technology (U.S. Bureau of Labor Statistics, 2009).

Education is an important determinant of future earning potential and is an integral part of the conceptualization of SES. Latinos are at a significant educational disadvantage relative to other racial/ethnic groups including other minorities. For example, nearly 40% of Latinos have less than a high school diploma, a rate that is twice that of any other racial/ethnic group and markedly higher than the national average of 15.1%. In addition, the college graduation rate for Latinos is just 12.9% compared to 17.7% of non-Hispanic Blacks, 30.7% of non-Hispanic Whites, and the national average of 27.7%. Together with the economic disparities, Latinos are at or near the bottom of most of the major SES indicators – a profile associated with significant health risk.

Latino Health Status

Perceived Health

Latinos' self-reported health ratings are typically lower than those from non-Hispanic Whites (Perez-Stable, Napoles-Springer, & Miramontes, 1997). For example, in a large survey of California residents, Latinos were less likely than non-Hispanic Whites to rate their health as "excellent" or "very good" (50.2% vs. 30.2%) and more likely to rate their health as "fair" (9.9% vs. 27.5%). This finding is consistent with the challenges of lower SES, although some data suggests that SES does not explain the entire effect.

Diabetes Diabetes is amongst the most common chronic diseases in the USA with an incidence rate of approximately 8.3% and rising (Center for Disease Control [CDC], 2011). Racial and ethnic minorities suffer a disproportionate burden of the diabetes epidemic (CDC, 2011). In general, Latinos are nearly 1.7 times as likely to have diabetes as compared to non-Hispanic Whites (11.8% vs. 7.1%) and are at 50% greater risk of dying from diabetes-related complications. There is considerable heterogeneity in diabetes risk among Latino subgroups with persons of Puerto Rican and Mexican descent twice as likely to have diabetes compared to non-Hispanic Whites (13.8% and 13.3%, respectively) whereas individuals of Cuban descent experience prevalence rates more similar to non-Hispanic Whites (7.6%). End-stage renal disease (ESRD) is a major complication arising from diabetes. Latinos are nearly 1.7 times more likely to initiate ESRD treatment compared to non-Hispanic Whites.

Cardiovascular Disease Cardiovascular disease (CVD) is the leading cause of death in the United States, accounting for approximately 34.3% of all deaths annually (American Heart Association, 2010). Race-related disparities in CVD incidence and mortality are well documented. The CDC and the Office of Minority Health report that African Americans are 1.5 times more likely to have hypertension (high blood pressure) and 1.3 times more likely to die from heart disease compared to Whites. Although far less Latino comparative health data is available, there are important differences to consider. Latinos are more likely to be overweight and have uncontrolled diabetes, two robust risk factors for heart disease. However, the age-adjusted mortality rate from heart disease is significantly lower for Latinos compared to non-Hispanic Whites (165.0 vs. 239.8 per 100,000). Emerging

data suggests that although the incidence rate of heart disease is similar between Latinos and non-Hispanic Whites, the rate at which the disease progresses to critical endpoints, such as heart attacks, is significantly slower for less acculturated Latinos.

Cancer Overall cancer incidence is approximately 30% lower for Latinos relative to non-Hispanic Whites (U.S. Cancer Statistics Working Group, 2011). This advantage is evident among both men and women although there is heterogeneity by cancer type. For example, Latina women are at 33% lower risk for breast cancer and Latino men are 23% less likely to have prostate cancer relative to their non-Hispanic White counterparts. However, Latinos are twice as likely to develop stomach and liver cancer relative to non-Hispanic Whites. In addition, Latina women have an 80% greater risk of being diagnosed with cervical cancer than non-Hispanic women. Unfortunately, the relative survival rate of Latinos following diagnosis is unclear due to a lack of available data. What is known is that relative mortality rates mirror incidence rates with Latinos more likely to die from stomach and liver cancers compared to non-Hispanic Whites.

Infectious Conditions Latinos suffer disproportionate rates of a range of infectious conditions. For example, Latinos account for approximately 75% of newly diagnosed tuberculosis cases and are at twice the risk of hepatitis A, twice the risk for gonorrhea and syphilis, and three times the risk for chlamydia compared to non-Hispanic Whites (CDC, 2009a). With respect to HIV/AIDS, Latinos accounted for approximately 17% of all HIV/AIDS cases despite accounting for less than 15% of the US population in 2008 (CDC, 2009b). Comparatively, Latinos are 3 times as likely to be diagnosed with HIV/AIDS relative to non-Hispanic Whites. Although disparities exist for both sexes, Latina women are 5 times more likely to be diagnosed with HIV compared to non-Hispanic White women. The AIDS-related mortality rate for Latino men is approximately 2.5 times, and for Latina women, 3.6 times the rate of non-Hispanic White men and women, respectively.

Despite their lower SES profile, infant/childhood immunization rates are comparable between Latinos and non-Hispanic Whites (CDC, 2009c). However, there are critical differences in the vulnerable 65 and older age category. At a time when risk increases, Latinos are 20% less likely to get the annual influenza (flu) vaccination and 40% less likely to be immunized for pneumonia (CDC, 2010). Such differences may increase vulnerability disparities in later life.

The Hispanic Mortality Paradox Substantial evidence suggests Latinos live longer than non-Hispanic Whites, an epidemiological paradox given the relative differences in SES and mortality risk factors. This phenomenon was first identified by Markides (1983) who noticed that among community samples in the Southwestern United States, Latino mortality rates were more similar to non-Hispanic Whites than to non-Hispanic Blacks despite substantial SES differences. Subsequent national cohort data consistently demonstrates a Latino mortality advantage relative to other racial/ethnic groups, including non-Hispanic Whites. For example, the 2006 CDC report on mortality by race/ethnicity indicates that the age-adjusted death rate for Latinos is approximately 27.4% lower than for non-Hispanic Whites and 43.7% lower than for non-Hispanic Blacks (Heron et al., 2009). Hence, the Hispanic mortality paradox refers to the epidemiological finding that Latinos appear to live longer than non-Hispanic Whites despite the lower SES of the former relative to the latter.

Multiple explanations have been postulated to explain these paradoxical findings. The most common criticism concerns data reliability. Critics argue that the national cohort data is highly suspect as it is based on representative statistics. For example, the Latino mortality rate is estimated by entering the annualized Latino mortality (determined by number of death certificates indicating Hispanic ethnicity in a given year) in the numerator and the corresponding Latino population size (determined via census estimates) into the denominator. The major

concern is that the numerator relies on accurate recording of Hispanic ethnicity on death certificates and that underreporting biases a more favorable ratio. However, recent data suggests that ethnic misclassification is rare and comparable for Latinos and non-Hispanics (Arias, Eschbach, Schauman, Backlund, & Sorlie, 2010). In addition, two general explanatory hypotheses, the *salmon bias hypothesis* (i.e., Latinos possibly returning to their ancestral country of origin prior to death) and the *healthy immigrant hypothesis* (i.e., biased Latino health in the USA due to better health among those who successfully migrate) have been largely debunked by available data.

An alternative to representative estimates is to examine longitudinal studies where individuals are tracked over time. A recent systematic review and meta-analysis of the longitudinal literature further supports the validity of the paradox (Ruiz, Steffen, & Smith, 2011). Across 58 identified studies involving over 4.6 million participants, Latinos were found to have a 17.5% lower risk of mortality compared to other racial groups. The advantage was most evident in initially healthy samples and in the context of cardiovascular disease. In conjunction with the consistent national cohort data, it may be time to turn the corner on questioning the validity of the paradox and direct efforts to identifying the mechanisms leading to these surprising outcomes.

It is important to note that a mortality advantage is not synonymous with better health. As the risk factor data illustrates, Latinos experience high rates of diabetes, infectious diseases, and several types of cancer. They are less likely to have access to regular medical care, and when they do seek care, it is often in more emergent conditions. Hence, Latinos may live longer but suffer a lower health-related quality of life.

Future Directions

The Hispanic mortality paradox illustrates the heterogeneity in minority health. Despite a risk profile similar to African American/Blacks, Hispanics have significantly different disease incidence, burden, and mortality outcomes. Such differences necessitate research specifically on the health and disease course of Latinos. It is possible that traditional risk factors simply are not the best predictors for disease and mortality among Latinos. It is also possible that Latinos may have resilience advantages at important time points in the disease course such as resistance to initial incidence, slower disease progression, or the ability or resources to more effectively recover from acute incidences. Additional research is also needed to understand the moderating and mediating factors specific to Latinos. Such studies may encompass the role of individual level factors (e.g., personality, experiences of stress), social (e.g., social network size and function) and cultural factors (e.g., cultural values, collectivism), as well as genetic/biological differences that may influence health outcomes. Finally, models are needed to understand the interplay between diverse factors and their impact on Latino health.

Definition

Histamine is a biogenic amine which is involved in a number of biological processes including immune system, gastrointestinal, and nervous system functioning. Histamine is typically released in response to a pathogen or allergen and serves to increase capillary permeability allowing fluid and other immune system cells to leave the capillaries and enter tissues. The fluid will contain white blood cells which can attack and minimize the effect of the pathogen. In response to an allergen, histamine results in typical allergy symptoms of runny nose, congestion, sneezing, and watery eyes. Antihistamines are medications which block receptor sites for histamine and can reduce such allergy symptoms. Histamines are also thought to be implicated in memory, learning, and sleep regulation.

Definition

HIV infection can be characterized as a condition caused by the human immunodeficiency virus (HIV) (National Center for Biotechnical Information [NCBI], 2010a). HIV is a retrovirus that weakens the body's immune system by infecting and replicating in CD4 + T-cells (Morris & Cilliers, 2008). CD4 + T-cells stimulate lymphocytes that assist the body in attacking antigens and fighting off disease. When HIV infection occurs, the virus gains entry to host T-cells by attaching to CD4 receptors via glycoprotein (gp120). gp120 allows HIV to bind to CD4 receptors and kill off helper T-cells. During this process, HIV's genetic material integrates its viral DNA into the cell's host DNA and allows the virus to replicate in the immune system (Morris & Cilliers, 2008).

Description

HIV Infection: Prevalence

Since its co-discovery by Drs. Luc Montagnier and Robert Gallo in 1983, millions of people have been infected with HIV. Current prevalence estimates reveal that there are approximately 33.3 million people living with HIV worldwide (UNAIDS, 2010). HIV prevalence varies greatly by region: HIV disproportionately affects sub-Saharan Africa, a region that accounts for 68% of the global total of persons living with HIV (22.5 million); HIV prevalence has nearly tripled in Eastern Europe and Central Asia (1.4 million) and has risen in North America (1.5 million), Western and Central Europe (820,000), Oceania (57,000), and in the Middle East and North Africa (460,000); HIV prevalence remains relatively stable in South and Central America (1.4 million), the Caribbean (240,000), and Asia (4.9 million); however, there is considerable variation in HIV prevalence within these regions (UNAIDS, 2010).

HIV Infection: Incidence

Advances in HIV prevention have markedly reduced the number of new HIV infections. However, there are noticeable differences in HIV incidence trends worldwide, and incidence patterns vary within countries. Many new cases of HIV infection are concentrated among people who inject drugs, commercial sex workers, and men who have sex with men (UNAIDS, 2010). HIV incidence is particularly high in developing countries (Merson, 2006). However, countries with higher incomes are not immune from the HIV epidemic. In the United States, the epidemic disproportionately affects racial and ethnic minorities and men who have sex with men (MSM), especially in urban areas of the Northeast, West Coast cities, and small towns in the South (El-Sadr, Mayer, & Hodder, 2010). Higher HIV incidence in Western Europe can also be attributed to increases in risky sexual behavior among MSM. Concentrated epidemics, particularly among people using injection drugs and sex workers, contribute to the growing epidemic in Eastern Europe and Central Asia (UNAIDS, 2010). HIV incidence by region is as follows (UNAIDS, 2010):

- Sub-Saharan Africa: 1.8 million
- South and Southeast Asia: 270,000
- Eastern Europe and Central Asia: 130,000
- Central and South America: 92,000

- East Asia: 82,000
- Middle East and North Africa: 75,000
- North America: 70,000
- Western and Central Europe: 31,000
- Caribbean: 17,000
- Oceania: 4,500

Stages of HIV Infection

Within 2–4 weeks after HIV infection, individuals may experience acute retroviral syndrome (ARS) or acute HIV infection. Acute HIV infection can appear flu-like and may be accompanied by a number of symptoms such as sore throat, headache, fever, and swollen lymph glands (National Center for Biotechnical Information [NCBI], 2010b). It may take several months for individuals to exhibit ARS symptoms; however, many people never develop ARS or exhibit symptoms associated with the syndrome. During this phase, the virus is actively replicating and is highly transmissible (NCBI, 2010b). After primary HIV infection, the illness may be asymptomatic in which there are no major symptoms of HIV. Individuals vary in their detectable HIV viral load but can still transmit the virus to others. The asymptomatic stage can last up to 10 years. Over time, the body's immune system weakens from fighting the virus and transitions into symptomatic HIV infection. In this period, individuals exhibit symptoms typical of chronic HIV infection (e.g., diarrhea, fatigue, fever, weight loss). Acquired immunodeficiency syndrome (AIDS) is the final stage of HIV and is defined by <200 CD4 + T-lymphocyte cell counts per microliter of blood (CDC, 1993). The body's immune system is severely damaged and is susceptible to opportunistic infections (e.g., Kaposi's sarcoma). Individuals vary in their progression through these phases. Adherence to antiretroviral medications plays a vital role in suppressing HIV viral replication and the progression of AIDS. There are two types of HIV infection – HIV-1 and HIV-2: both types of HIV weaken the body's immune system; however, HIV-2 has a longer asymptomatic phase with slower and milder immunodeficiency and is predominately found in West Africa (CDC, 2010).

Two classification systems are currently used to assess the progression of HIV infection: the Centers for Disease Control (CDC) classification system and the World Health Organization (WHO) Clinical Staging and Disease Classification System.

The CDC classification system (CDC, 1993) categorizes the progression of HIV infection into three CD4 + T-lymphocyte categories and three clinical categories. These categories are accompanied by particular illnesses or conditions. The corresponding CD4 + T-lymphocyte categories are as follows:

1. Category 1: ≥500 cells/mL
2. Category 2: 200–499 cells/mL
3. Category 3: <200 cells/mL

These categories correspond to CD4 + T-lymphocyte counts per microliter of blood in which an acute HIV infection (≥500 cells/mL) progresses to acquired immunodeficiency syndrome (AIDS) (<200 cells/mL). The clinical categories of HIV infection and corresponding illnesses are as follows:

1. Category A (asymptomatic/acute HIV): Asymptomatic or acute retroviral syndrome/acute HIV infection (acute HIV infection occurs 2–4 weeks after HIV infection, and its symptoms include fatigue, fever, headache, sore throat, and decreased appetite).
2. Category B (symptomatic conditions): Conditions include, but are not limited to, cervical dysplasia, shingles, and pelvic inflammatory disease.
3. Category C (AIDS-indicator conditions): Presence of opportunistic infections such as Kaposi's sarcoma and *Mycobacterium tuberculosis*.

In settings with limited capability to test for CD4 viral loads, the WHO Clinical Staging and Disease Classification System (WHO, 2007) may be used to determine the progression of HIV infection and the appropriate antiretroviral therapy. This classification system is categorized into four stages ranging from primary HIV infection to AIDS-indicator illnesses. The stages of HIV infection and some accompanying illnesses are as follows:

1. Clinical stage 1 (asymptomatic): Asymptomatic, persistent generalized lymphadenopathy

2. Clinical stage 2 (mild symptoms): Unexplained weight loss, fungal nail infections
3. Clinical stage 3 (advanced symptoms): Unexplained severe weight loss, oral hairy leukoplakia
4. Clinical stage 4 (severe symptoms): HIV wasting syndrome, Kaposi's sarcoma

HIV Transmission

HIV is primarily spread through the following modes of transmission (CDC, 2010): unprotected sexual contact with a person who has HIV infection (unprotected oral sex is lower risk for transmitting HIV than vaginal or anal sex; unprotected anal sex is riskier than vaginal sex; unprotected receptive anal sex is riskier than unprotected insertive anal sex; having multiple sex partners also increases risk of HIV infection, especially in the presence of other sexually transmitted diseases during sex), sharing needles or syringes used to prepare illicit drugs for infection, and being born to an infected mother (HIV can be passed from mother to child through pregnancy, birth, or breast-feeding). Less common modes of HIV infection are through blood transfusions. These modes of HIV transmission occur by the transfer of semen, blood, vaginal fluid, or breast milk.

HIV Diagnosis

HIV is typically diagnosed by a set of blood tests (HIV ELISA) that detect the presence of HIV antibodies but can also be diagnosed by tests that identify HIV's genetic material (CDC, 2010). The presence of HIV antibodies marks the body's response to HIV infection. A "window period" between HIV infection and seroconversion (presence of detectable HIV antibodies) can range from 2 weeks to 3 months, in which an individual's immune system may not produce enough antibodies for the antibody test to detect. HIV is highly transmissible during this period even if the virus is not yet detectable. Most people will develop detectable antibodies within 2–8 weeks of HIV infection, and HIV test should be considered positive after a second confirmatory HIV test (CDC, 2010; Puren, 2008).

HIV Treatment

There is no cure for HIV infection. However, antiretroviral therapy can suppress HIV viral replication and the progression of AIDS. These medications help people living with HIV to lead longer and healthier lives. Inconsistent adherence allows HIV to acquire resistance to antiretroviral therapy. There are considerable barriers in HIV prevention and treatment, but global efforts continue to address these challenges.

Definition

HIV prevention is the science of designing, implementing, and evaluating the effectiveness of interventions, programs, and services that aim to prevent an individual from acquiring HIV.

Description

The acquired immune deficiency syndrome (AIDS) was first recognized in 1981 and is caused by the human immunodeficiency virus (HIV) (CDC, 2010). Since the 1980s, science has significantly increased our knowledge about HIV and AIDS. We now know how HIV is transmitted from one person to another, the physiological processes of how the virus replicates once acquired, which medications help stop the virus from replicating, why individuals are more susceptible to opportunistic infections, and how best to prevent HIV transmission between two individuals. As a result, the field of HIV prevention science has emerged to better understand how individuals can help protect themselves from acquiring HIV, and among those who are living with HIV, how best to improve their adherence to treatment and reduce the transmission of HIV to others.

Efforts to reduce new HIV cases are based on how the virus is transmitted. There are three primary modes of transmission, including sexual transmission, transmission through blood, and mother-to-child transmission (Avert, 2011). In detail, an individual may acquire HIV from infected donated blood and organ products, vertically from mother-to-child during labor and/or from feeding the infant breast milk, sexually from having unprotected anal or vaginal intercourse, and from sharing contaminated works when injecting drugs or being stuck with a contaminated needle. Accordingly, HIV prevention interventions, programs, and services are designed to target specific populations based on their primary risk factor(s) for acquiring HIV. For example, self-identified heterosexual individuals who may be more likely to have unprotected intercourse, otherwise known as "high-risk heterosexuals," would be targeted for a particular HIV prevention program that was specifically designed for them. Another HIV prevention program may target HIV-negative men who have sex with men (MSM) to help them sustain from having unprotected anal intercourse (UAI) with multiple sex partners of HIV-positive and/or unknown serostatus. As such, HIV prevention interventions, programs, and services are typically designed and implemented to reach certain populations that engage in behaviors that put them at risk for acquiring HIV.

HIV prevention also has evolved to include individuals living with HIV. For instance, people living with HIV may want help with adherence to their medications, finding appropriate doctors for their treatments, access to care, assistance with disclosing their HIV serostatus, or learning how to help protect others from acquiring HIV from them. In sum, HIV prevention interventions,

programs, and services include two broad types: (1) primary prevention which aims to prevent individuals from acquiring HIV and (2) secondary prevention which helps individuals living with HIV to maintain their health and to reduce the possibility of transmitting HIV onto others (Avert, 2011).

Moreover, the implementation of these interventions, programs, and services is further divided based on the context of the implementation and how many individuals will be targeted. Specifically, interventions are classified as individual-level, group-level, or community-level interventions. Each of these levels describes the population context of the intervention for the primary or secondary HIV prevention services that would be provided to the participants. For example, an individual-level, primary HIV prevention intervention would focus on reducing HIV risk for each individual who participates in that particular intervention.

Many interventions, programs, and services of HIV prevention include an aspect of psycho-behavioral modification and/or a biomedical approach. Several theories of behavior change and models have been developed or modified for the prevention of HIV. For example, many studies and interventions aimed at preventing HIV have used constructs from the health belief model (Rosenstock, Strecher, & Becker, 1994), social cognitive theory (Bandura, 1997), theory of reasoned action (Fishbein & Ajzen, 1975), theory of planned behavior (Ajzen, 1991), transtheoretical model (Prochaska, DiClemente, & Norcross, 1992), AIDS risk reduction model (Catania, Kegeles, & Coates, 1990), and the information-motivation-behavioral skills model (Fisher & Fisher, 1992). Constructs from these theories and models are used to help participants and their networks change their beliefs, attitudes, perceived ability, and norms to lower their risk for acquiring HIV. Scientists and other researchers also use these constructs to better understand individuals' thoughts, actions, and feelings about HIV and/or risk behaviors.

In contrast, the biomedical approach uses a "test and treat" approach that may or may not include a psycho-behavioral component to it. The biomedical approach emphasizes the importance of being tested for HIV. The frequency of being tested for HIV will depend on the individual needs, her or his risk, and access to receiving the HIV test. Because an individual's viral load is highest after initially being infected, the premise of the approach is to link HIV-positive individuals with care as soon as possible and, preferably, before the possibility of transmitting the virus to others. Regardless of which HIV prevention approach is used, only correct and consistent condom use for anal and vaginal intercourse, being in a long-term mutually monogamous relationship with an uninfected partner, or abstaining from anal and vaginal intercourse will significantly prevent an individual from contracting HIV (CDC, 2010).

In addition to testing, consistent condom use, and modifying behaviors to reduce HIV risk, new advances with treatments have led to the development of other promising HIV prevention methods. Current studies are assessing the efficacy and cost-effectiveness of administering a pill or inserting a microbicide (i.e., gel or foam) inside an anus or vagina as additional modes of preventing HIV transmission (AVAC, 2011). These new biomedical advances are still being studied in a variety of populations around the world.

The success of the psycho-behavioral and biomedical approaches to preventing primary and secondary HIV infections is not without debate. Evaluation of HIV prevention interventions is crucial for determining what works best in HIV prevention. For example, the US Centers for Disease Control and Prevention (2007) provides a list of interventions that have been shown to prevent HIV among a variety of at-risk populations. These interventions are called evidence-based interventions (EBIs). Further, new studies that examine the different contexts of HIV are constantly needed in order to address how the epidemic changes with time across the world. The Further Readings section provides additional information about HIV prevention.

Home Health Care

Olveen Carrasquillo[1] and Osvaldo Rodriguez[2]
[1]Division of General Medicine, Miller School of Medicine, University of Miami, Miami, FL, USA
[2]Miami VA Healthcare System, Miami, FL, USA

Definition

Home health care is the rendering of predominantly medically related services to patients in a home setting rather than in a medical facility. The goals of home health care include helping patients recover from an injury or illness and restoring, maintaining, or increasing their ability to tend to their everyday needs at home.

Description

There are a wide range of services that fall under the definition of home health care. These include more skilled care often focused on a particular condition such as wound care for pressure ulcers or surgical wounds, physical and occupational therapy, speech-language therapy, patient and caregiver education such as for daily insulin injections, other intravenous injections, and monitoring serious or difficult to control chronic illness such as diabetes and congestive heart failure. However, it may also include a broader range of services such as social services or assistance from a home health aide. Examples of home health aide services include help with basic daily activities like getting in and out of bed, dressing, bathing, eating, and using the bathroom, as well as help with light housekeeping, laundry, shopping, and cooking for the patient.

In addition to such formalized services, the term can also include informal health-care

services provided by spouses, family, friends, and neighbors often similar in scope to those done by paid home health aides. In some European countries, such informal care is partially funded, while in most other countries, it is typically unreimbursed. One estimate from the USA is that one of every five adults in the United States provides some sort of such informal home care to someone else.

Historically, most health care was traditionally provided in a patient's home. For centuries, midwives, medicine men, and traveling doctors all performed their services in a patient's home. Sometimes, sick people went to a doctor's office, which was usually an extension of the provider's home or a small clinic, but more often than not, the health-care specialists visited the sick in their home. It was only at the start of the twentieth century with the advancement in medical knowledge, treatments, and technology, not feasible to be provided in the home setting, that led to movement of health service delivery for very sick patients to a hospital setting. Of note, in many countries, particularly those with fewer resources where hospital growth and development has been more limited, many very sick patients are still not able to receive hospital-based care and remain in their home, often cared, to the extent possible, by family and friends.

In the latter half the twentieth century, patient preferences and rising hospital care costs have led to initiatives in many advanced countries to shift some care back away from hospitals to a patients home. Thus, governments and other payers began reimbursing for services aimed at fostering home health-care practices. At present, in the USA, where nearly 12 million persons receive home health care at an estimated cost of over $70 billion, the Center for Medicare and Medicaid services is the largest payer for home health care. CMS is also responsible for regulating most home health companies and ensuring compliance. Many states also have additional regulations, licensing and certification requirements, and compliance measures. However, determination of eligibility for coverage and length of services is often a challenge. For example, under CMS, to qualify for reimbursement for home health services, an individual has to be "confined to his home." Operationalizing this definition is often difficult as policy makers need to balance ensuring patients needing services are not denied home care while at the same time limiting potential fraud and abuse. Which services are covered (e.g., skilled or unskilled), for how many hours per day, and for how long are decisions that have tremendous implications and need to be balanced between need and available resources.

Given the extensive evidence that such care is often less costly and sometimes of higher quality than that delivered in an inpatient facility, there will continue to be large growth in the home health-care sector. Particularly given the aging of the population in many countries, governments and policy makers will need to continue to foster, develop, and strengthen innovative programs aimed at facilitating home-based care.

Definition

Tendency and/or ability of a system to strive for and maintain stability of vital internal functions/parameters under unstable, external, or internal circumstances by means of negative or positive feedback.

Description

The necessity of a constant internal stability in face of external instability as a requirement of a free and independent life has first been stated by Claude Bernard, a French physiologist (1813–1878). Walter Bradford Cannon (1871–1945), physiologist at Harvard, then first coined the term "homeostasis," which he based on four propositions: (1) Constancy needs mechanisms to maintain constancy, (2) any change will be automatically resisted, (3) controlling mechanisms are interacting and cooperative, and (4) homeostasis is organized. Thus, homeostasis is the result of a complex interaction of multiple physiological – as well as psychological and behavioral – processes in order to secure and maintain set levels. Formally, the components of a homeostatic system encompass receptors that assess and relay information afferent to a central control which then send efferent signals to subordinated effectors, such as muscles, glands, organs, or systems. The responses are then monitored and controlled by positive and/or negative feedback. Examples for homeostasis can be seen in the regulation of body temperature by redistribution of blood flow (cold feet and hands), activation of muscular (shivers) and behavioral responses (put on a sweater), or in the regulation of blood glucose concentration (release of insulin and glucagon) as well as in more complex interactions between perceived challenges in social situations and emotional, behavioral, as well as neuroendocrine responses and their impact on the situational circumstances. The consequences of the regulatory responses are manifold and encompass permissive, stimulatory, suppressive, as well as preparative actions.

The concept of homeostasis have been extended by the concept of allostasis (McEwen, 1998), which states that stability is not only achievable through regulation, but also through change. Thus, external or internal circumstances are not only met by counterregulatory activation of the respective response but also lead to adaptive changes in the activity and reactivity of the respective system. For example, enduring stress not only leads to enhanced output of adrenocortical steroids, but also to changes in the negative feedback regulation of the affected neuroendocrine system, depending on the duration and the extent of the stressor (for review: Sapolsky, Romero, & Munck, 2000).

Definition

Homocysteine is an amino acid that acts as the intermediary during the synthesis of cysteine from dietary methionine in the human body.

Description

Homocysteine is an amino acid that acts as the intermediary during the synthesis of cysteine from dietary methionine in the human body. Homocysteine is not obtained from the diet but rather formed from the demethylation of methionine. It can then condense with the amino acid serine to form cystathionine, in a step catalyzed by the enzyme cystathionine β-synthase that requires vitamin B_6 as a cofactor. Cystathionine is then cleaved by cystathionine γ-lyase to produce cysteine and alpha-ketobutyrate. Alternatively, homocysteine can be converted back into methionine by donation of a methyl group from methyltetrahydrofolate, which is derived from folic acid. This reaction is catalyzed by the enzyme methionine synthase and requires vitamin B_{12} as an essential cofactor (Konkle, Simon, & Schafer, 2008).

In patients with the medical condition homocystinuria, deficiencies in key enzymes of homocysteine metabolism such as those described above lead to dramatically elevated levels of plasma homocysteine, which then spill over and are detected in urine. In addition to abnormalities of neurological and skeletal development, these patients also suffer from premature atherosclerosis and thrombophilia and have high incidences of venous thromboembolism, cerebrovascular disease, and peripheral vascular disease, beginning as early as the second and third decade of life. Because of this, it has been suggested that elevated homocysteine may play a causative role in promotion of atherosclerotic disease. Both in vitro and in vivo studies have tended to support this hypothesis, demonstrating that homocysteine can increase oxidative stress, cause endothelial dysfunction, promote inflammation, and induce smooth muscle proliferation (Ridker & Libby, 2008; Undas, Brozek, & Szczeklik, 2005). Furthermore, multiple large, prospective epidemiological studies have also concluded that even mildly elevated levels of homocysteine may carry increased risks for both initial and recurrent cardiovascular events (Homocysteine Studies Collaboration, 2002; Wald, Law, & Morris, 2002).

These observations have led to interest in homocysteine reduction as a strategy for cardiovascular disease prevention. Since B-complex vitamins (folic acid, vitamin B_6, and vitamin B_{12}) play a vital role in homocysteine metabolism and are often insufficiently obtained from dietary sources, several large, randomized clinical trials have been carried out to test the efficacy of B-complex vitamin supplementation in patients with cardiovascular disease. Despite uniform reduction of homocysteine levels in the intervention groups, however, none of the trials were able to demonstrate any decrease in incidence of cardiovascular events. Most recently, a meta-analysis was performed by the Cochrane Collaboration in 2009 that included eight randomized clinical trials with a total of 24,210 participants, confirming that homocysteine lowering with B-complex vitamin supplementation does not significantly reduce the risk of fatal or nonfatal myocardial infarction, stroke, or death from any cause (Martí-Carvajal, Solà, Lathyris, & Salanti, 2009). Given the inconsistency between these results and previous experimental and epidemiological data, there remains considerable debate on whether the homocysteine hypothesis is itself incorrect or whether there are other negative effects of B-complex vitamin supplementation

that may have countered the potential benefit of homocysteine reduction (Loscalzo, 2006).

Hopelessness

Yori Gidron
Faculty of Medicine and Pharmacy, Free University of Brussels (VUB), Jette, Belgium

Definition

This is an important reaction to situations involving lack of, or reduced, control. The literature at times confuses helplessness with hopelessness, with the former included in the latter. Hopelessness refers to the belief that one lacks control over outcomes (response-outcome noncontingency or helplessness) and to the expectation of a negative future (negative outcome expectancies or pessimism), as conceptualized by Everson et al. (1996). Hopelessness includes thus two cognitions, rather than feelings. In the general

population, hopelessness is quite a stable phenomenon and is predicted by economic difficulties and unemployment. However, positive changes in one's living condition may protect people from becoming hopeless (Haatainen et al., 2003).

Multiple ways exist to assess hopelessness including a 2-item scale by Everson et al. (1996), the Beck Hopelessness Scale, and other measures.

Hopelessness is a major precursor or depression, particularly in people with a negative attribution style (attributing a negative event to an internal, stable, and global cause; Sweeney, Anderson, & Bailey, 1986). Hopelessness has also been found to be a significant predictor of suicide. Given the difficulty to prevent suicidal behavior, conducting preventative interventions among high-hopeless people may have important preventative value for public health.

Hopelessness is a risk factor of death from coronary heart disease and cancer and significantly predicts progression of carotid atherosclerosis. In Everson et al.'s (1996, 1997), Everson, Kaplan, Goldberg, Salonen, and Salonen (1997) studies, controlling for known cardiac risk factors had little effect on the prognostic role of hopelessness, leading them to conclude that other, not tested factors, could explain these relationships. One model proposes that hopelessness predicts poor prognosis in cancer by its link to brain and systemic interleukin-1 (IL-1) since blocking brain IL-1 prevents helplessness, since brain IL-1 promotes peripheral metastases, and since peripheral IL-1 at tumor sites promotes tumor cell proliferation, angiogenesis, and metastasis (Argaman et al., 2005). Thus, hopelessness could serve as an important predictor and therapeutic target in behavior medicine intervention trials since it is a risk factor of both mental and physical illnesses.

Serum concentrations of the female gonadal sex steroid hormones estradiol and progesterone decrease sharply after ▶ menopause due to the stop of ovarian hormone production. In order to counteract this decline, several forms of hormone (replacement) treatment (or therapy; HT or HRT) have been developed. It has been suggested that this hormone regime can treat menopausal symptoms and could potentially prevent several age-associated disorders. Women with an intact uterus can be treated with a combined regimen of estrogens and progestins. The progestin is added in order to prevent endometrial hyperplasia. Women with a hysterectomy can be treated with estrogen only preparations. Oral route of administration is still the most commonly used route as of today, but other approaches (e.g., transdermal applications) are available.

Sex steroid treatment after menopause has beneficial effects on hot flushes and urogenital atrophy. Moreover it has been shown to prevent osteoporosis, fractures, and ▶ diabetes. Adverse effects include venothrombotic episodes, stroke, and ▶ breast cancer. Negative effects are more pronounced when the combined treatment is administered, when patients are older, and when treatment is continued for longer periods of time (more than 5 years). For reviews see Maki et al. (2010) and Santen et al. (2010).

Due to the widespread action of sex steroids in the brain, beneficial effects of hormone therapy on mood and cognition have been postulated. These could be of relevance for the prevention and/or treatment of menopausal depression and ▶ dementia. Beneficial effects on cognition or mood might occur if treatment is started during or directly after menopause ("window of opportunity hypothesis"). However large randomized controlled clinical trials in this age group are still lacking. In contrast to the postulated beneficial effects, adverse effects were observed in the women's health initiative (WHI) study. In older women, the combined treatment with estrogens and progestins increased the risk for stroke and dementia. More clinical trials with cognitive and affective measures are needed before recommendations can be provided based on solid empirical evidence. For reviews see Maki et al. (2010) and Santen et al. (2010).

As of today, hormone therapy is recommended by the food and drug administration (FDA) for the treatment of menopausal symptoms only. The FDA recommends that hormone therapy be used at the lowest doses for the shortest duration needed to achieve treatment goals.

Definition

Hospice is a specialized form of palliative care; however, whereas palliative care can be provided at multiple stages of illness, hospice care is reserved for patients who are estimated to have less than 6 months to live. The philosophy of hospice care is to provide comfort and control pain symptoms for patients in the last phases of incurable disease while holistically providing for the psychological, social, and spiritual needs of the patient and their loved ones. Hospice care also involves some components of home health care, which focuses on patient rehabilitation and medical management. Home health care focuses on the patient and their physical needs while hospice includes a focus on the family and also addresses emotional and spiritual needs.

Description

History

The word "hospice" stems from the Latin word "hospitium" meaning hospitality, lodging, or guesthouse. The concept of a hospice can be traced back to medieval times when it referred to a place of shelter and rest for weary or ill travelers on a long journey. There is evidence of facilities like modern hospices dating back to the 1800s. For example, Jeanne Garnier founded several hospices in France as early as 1842 and the Irish Sisters of Charity opened hospices in Ireland and England in the 1800s to provide care for dying or incurable patients. The modern hospice movement began in the 1960s when Dr. Cicely Saunders established St. Christopher's Hospice near London to provide pain management and compassionate care for the dying. The hospice movement was propelled by Dr. Elisabeth Kubler-Ross' book, *On Death and Dying*, which was published in 1969 and provided a personal glimpse into the lives of terminally ill patients. During the 1970s the Hospice movement gained attention in the United States when Kubler-Ross testified at the first national hearings on the subject of death with dignity (1972); the first hospice organization was established in the United States in New Haven, Connecticut (1974); and the first hospice legislation was introduced by Senators Frank Church and Frank E. Moss (1974). It was not until 1983 that the Medicare hospice benefit was officially introduced and in 1986 was made permanent by Congress. In the past two decades, hospice organizations have continued to evolve from volunteer-based, grassroots organizations into health care companies with paid staff and quality practices. Today there are more than 4,000 hospice programs in the United States and over one million people in the United States receive hospice services each year. Hospice organizations are also widespread internationally.

Goals and Services

People choose hospice when the disease is not responding to treatment (incurable) or when the treatment has detrimental effects on quality of life. While many hospice patients are diagnosed with cancer (approximately 40%), hospice services are also available to patients with pulmonary disease, heart disease, neurological disorders, Alzheimer's disease, AIDS, and other life-limiting illnesses. The majority of patients who receive hospice services are over the age of 65 (approximately 80%). In the United States, hospice services have historically been more widely utilized by Caucasian patients (greater than 80% of hospice patients in 2005); however, hospice utilization among ethnic and racial minorities has been increasing in recent years. On average, patients spend 69 days on the hospice service before dying (median length = 21 days). In the United States, the majority of hospice services are funded through the Medicare hospice benefit (84% of hospice stays), although private insurers and other medical programs (e.g., Veteran's Administration) offer hospice benefits.

To qualify for the Medicare hospice benefit, a physician and the hospice medical director must certify that the patient has less than 6 months to live if the disease were to run its normal course. Then the patient or a durable medical power of attorney signs a statement declaring that they would like to be admitted to hospice. By signing the statement, the patient agrees to no longer

receive curative treatment related to their terminal illness. Medicare will still pay for covered benefits for any health needs that are not related to the patient's terminal illness. A terminally ill patient may receive hospice care for as long as necessary when a physician certifies that he or she has a life expectancy of 6 months or less; however, recertification of life expectancy is required at regular intervals (approximately 60 days). At any time, patients or their family members have the right to revoke the hospice benefit and resume Medicare coverage of the benefits that were waived when hospice care was elected. The patient can reelect to return to receiving hospice coverage at a later date. The hospice agency can discharge a patient if their health improves and they no longer have a 6-month prognosis.

Hospice services can be provided in multiple settings. More than 90% of the hospice services provided in the United States are based in patients' homes. Home hospice typically requires that a family member or loved one be established as the primary caregiver and be home with the patient at all times. Members of the hospice service will have regularly scheduled visits with the patient and caregiver as well as being available 24 hours a day, 7 days a week by phone to handle emergencies or questions. Hospice services can also be provided in hospitals and nursing homes or other long-term care facilities. These services can be provided on specialized hospice units, by trained nursing staff that can care for hospice patients, or through arrangements made with independent community-based hospice services that provide care inside of the hospital or nursing home facilities. These services can be a good option for patients who want hospice care but do not have primary caregivers to take care of them at home. Finally, many communities have free-standing, independently owned hospices that feature inpatient care facilities as well as home care hospice services.

Hospice affirms the concept of palliative care as an intensive program that enhances comfort and promotes the quality of life for individuals and their families. When cure is no longer possible, hospice recognizes that a peaceful and comfortable death is an essential goal of health care. Hospice philosophy recognizes that death is a natural part of the life cycle and that people have a human right to die in comfort and with dignity. The goal of hospice is not to prolong life or hasten death, but to allow people to achieve high levels of quality of life at the end of their life. Hospice care is also holistic and aims to treat the whole person rather than just focusing on the disease. The expected outcome is relief from distressing symptoms, lower levels of pain, and/or enhanced quality of life. Hospice philosophy is a family-centered approach and aims to assist the family and loved ones with the dying process as much as the patient. Patients and family members are encouraged to be in control of decision making and treatment planning. Finally, hospice philosophy promotes the idea that palliative care should be available to all individuals and their families without regard to age, gender, nationality, race, creed, sexual orientation, disability, diagnosis, availability of a primary caregiver, or ability to pay.

To provide holistic care, hospice services are provided by an interdisciplinary team of doctors, nurses, social workers, counselors, home health aides, clergy, physical and occupational therapists, and trained volunteers among others. Hospice organizations typically become the primary care coordinators during end-of-life care. Services are provided during the last stages of illness, throughout the dying process, and to family members during the first year after the patient's death. Hospice services provide medical treatment to relieve pain and to control other physical symptoms. Patients on hospice can continue to receive palliative radiation and chemotherapy that are designed to reduce pain. Hospice services provide needed medications, medical supplies, and equipment, as well as special services such as speech therapy, physical therapy, or nutritional consultation when indicated. Hospice services also provide assistance with basic needs of daily living by providing limited home health aide and supervision/training for family members. Family coaching and family conferences are common to help patients and their family members understand the illness, how to care for the patient, and improve communication about end-of-life issues.

Hospice staff may assist the patient with unfinished legal or financial business and in making funeral arrangements. Patients who need additional care are able to receive inpatient care as well as brief periods of respite care (up to 5 days), so that caregivers can attend special events or get rest from caregiving responsibilities. Counselors and clergy provide emotional support and address the spiritual needs of patients and their family members. Family members are able to receive bereavement care up to 13 months after the patient's death, which might include counseling, supportive phone calls, referrals to community resources, support groups, and/or memorial services.

Hospital Anxiety

Fear of hospitals; Hospital stress; Nosocomephobia; Operative anxiety

Definition

Hospital anxiety refers to the anxious response and unusual preoccupation about noxious consequences (real or not) that can result from visiting hospitals or from undergoing medical procedures in a hospital.

Description

Hospital anxiety and related concepts (e.g., "fear of hospitals" and "hospital stress") have been widely examined in studies investigating barriers to both seeking medical care (Tod, Read, Lacey, & Abbott, 2001) and blood and organ donation

(e.g., Boulware et al., 2002), and preparation for medical procedures (Johnston, 1980). These fears, if irrational, can lead individuals to avoid appropriate medical care when needed or to disregard medical instructions. Individuals with excessive fear of hospitals (i.e., nosocomephobia) often avoid hospitals which results in skipping or missing appointments scheduled at hospitals and avoid visiting friends/relatives who are hospitalized. These fears are often founded on the belief that visiting a hospital may result in serious illness and even death. Original work focused on nonspecific anxious responses, but recent work has expanded the study of "hospital anxiety" by focusing on specific triggers such as blood, needles, injuries, and medical personnel.

Early studies examined the affective responses that both adult and pediatric patients experienced in hospital settings (e.g., hospital stress). The aim of this work was to understand the effects of anxiety and stress experienced before and/or after undergoing a medical procedure on medical outcomes (e.g., slow recovery post-surgery, increased pain and physical symptoms). Pre- and postoperative anxiety was found to disturb sleep patterns (Kain & Caldwell-Andrews, 2003), reduce adherence to medical recommendations (Mathews & Ridgeway, 1981), and increase pain sensitivity (Chapman & Cox, 1977). Among children, self-report data also showed an association between preoperative anxiety and postoperative negative behaviors (e.g., eating/sleeping problems) (Melamed, Dearborn, & Hermecz, 1983).

Although it is well established that anxiety levels are indirectly and directly associated with physiological and psychological factors that influence health outcomes, the mechanisms are poorly understood (Kiecolt-Glaser, Page, Marucha, MacCallum, & Glaser, 1998). For example, psychoneuroimmunological data suggest that anxiety may delay wound healing by indirectly influencing immune function. Specifically, it has been proposed that individuals who report high levels of anxiety when undergoing medical procedures tend to experience increased pain and may require more anesthesia during surgery and more analgesics during recovery than low anxiety individuals (Maranets & Kain, 1999). This increased use of anesthesia and analgesics, in turn, can result in endocrinological and immunological changes that delay wound healing. Similarly, postoperative anxiety can delay recovery from surgical procedures by influencing adherence to medical recommendations. Existing data suggest that specific anxiety and fear (e.g., fear of pain, cardiophobia, fear of injury) and not general anxiety are the key determinants of maladaptive behaviors (Berlin et al., 1997).

Several individual and situational factors have been implicated as antecedents of hospital anxiety. Although the specific genetic contribution to hospital anxiety is currently unknown, twin studies suggest that genetic predisposition accounts for an important proportion of the variance in anxiety disorders (Hettema, Neale, & Kendler, 2001). Personal experience and learning may lead to specific anxiety/fear. For instance, needle phobia is often the result of an aversive experience with needles involving doctors and/or dentists. These fears can also be the result of watching another individual experience a negative reaction to the medical procedures (Willemsen, Chowdhury, & Briscall, 2002). Other individual factors associated with increases in hospital anxiety include sex (being female), moderate to intense levels of depressive symptoms, and a history of chronic medical conditions (Caumo et al., 2001). Adults undergoing surgical procedures also indicated that they experienced anxiety surrounding uncertainty of the outcomes of the procedure (Caumo et al.). Among situational factors, poor or lack of communication with hospital personnel and health care providers, as well as loss of autonomy and control, are considered some of the most stressful aspects of hospitalization that could lead individuals to experience anxiety (Volcier, 1974).

Assessments of hospital anxiety and related concepts can be conducted in multiple ways. Researchers often explore three main aspects of anxiety, patients' cognitions, emotional state, and situation-specific anxieties. The most commonly used self-report measures of anxiety for adults include Spielberger's State-Trait Anxiety

Inventory and the Hospital Anxiety and Depression Scale (HADS). Spielberger's State-Trait Anxiety Inventory for Children and the Children's Manifest Anxiety Scale have been widely used to assess anxiety among children. Observational tools used often include the Clinical Anxiety Scale, Yale Preoperative Anxiety Scale, and the Palmar Sweat Index. Other instruments that assess specific aspects of hospital anxiety (e.g., the Injection Phobia Scale Anxiety, Blood Injection Symptom Scale, Medical Fears Survey, and the Disgust Scale) can provide important information about the specific triggers that lead to patients' anxious responses.

Interventions to reduce hospital anxiety have a long history. Melamed and collaborators used behavioral modeling to reduce pre- and postoperative anxiety and negative behaviors among children (Melamed & Siegel, 1975). Initial work with adults focused on the reduction of pain and anxiety caused by stressful and painful medical procedures (e.g., endoscopy). Work with adults conducted by Johnson and Leventhal (1974) demonstrated that accurate sensory and procedural information successfully reduced anxiety and pain caused by medical procedures. This type of intervention has been shown to be effective across various types of medical procedures (Suls & Wan, 1989). Principles from these earlier works are at the core of more recent and innovative psychological interventions to reduce pre- and postoperative anxiety. Exposure techniques have been associated with reduction in fear of blood-injection illness in adults (Olatunji, Smits, Connolly, Willems, & Lohr, 2007); whereas behavioral therapies (e.g., modeling) can reduce anxiety levels in children with needle phobias (Willemsen et al., et al., 2002).

Hospital Anxiety Depression Scale

Definition

The Hospital Anxiety and Depression Scale (HADS; Zigmond & Snaith, 1983) is a 14-item measure designed to be used as a brief screen for depression (seven items) and anxiety (seven items) disorders among nonpsychiatric, medically ill, outpatient populations. As a screening instrument, the HADS does not provide definitive diagnosis, but is the first step in a multistage process of selecting individuals at elevated risk for disorder to be evaluated through clinical interview. For example, the HADS does not assess specific symptoms of major depressive disorder (e.g., suicidality, guilt) thought by its authors to be less prevalent in nonpsychiatric populations, functional impairment, or frequency of symptoms, and the time frame assesses the previous 7 days, rather than 2 weeks of mood disturbance. Moreover, five of the seven items in the Depression subscale assess anhedonia-related experiences, and there is no question specifically addressing low mood. The HADS attempts to improve specificity of measurement by reducing physical symptoms that confound physical and psychological disorder (e.g., fatigue, insomnia) and focusing more on behavioral and affective symptoms. Anxiety and Depression subscales can range in score from 0 to 21, with scores of 11 or higher indicating probable caseness for clinical disorders and scores of 8–10 being suggestive of caseness. However, numerous cut-points have been suggested in the literature, as have total rather than subscale scores, though this has not been recommended by the scale authors. The HADS has been used as a measure of symptom severity among individuals with an anxiety or depressive disorder to allow tracking of therapeutic response over time. Both Anxiety and Depression subscales have demonstrated adequate internal consistency (Cronbach's alpha $\geq$0.67 and $\leq$0.93) across numerous translated versions, and adequate sensitivity and specificity for disorder using a score of $\leq$8 (both approximately 0.80; Bjelland, Dahl, Haug, & Neckelmann, 2002), though positive predictive values have been shown to be substantially lower (e.g., 0.17 for depressive disorder) in

medical patients (Silverstone, 1994, cited in Parker & Hyett, 2010).

Definition

Hostility is a multidimensional personality trait with distinct cognitive, affective, and behavioral features. The cognitive component of hostility is evident in the habitual patterns of cynical mistrust and negative, suspicious attitudes and beliefs that hostile individuals have toward their interpersonal network and the community at large. The affective (emotional) component reflects the internal and external expression of anger and contempt, which may vary in degrees from moderate to high. The behavioral component may manifest through mannerisms and actions that perpetuate interpersonal conflicts, such as aggression and irritability. Although distinctions can be made among the cognitive, affective, and behavioral components of hostility, they often are interrelated and co-occur.

Description

The role of hostility and anger in cardiovascular disease (CVD) and more general health and well-being has a long history. For centuries, anecdotal reports and historical observations suggested that strong negative emotions, and particularly feelings of anger, aggressive tendencies, and hostile attitudes, were related to poor health (Everson-Rose & Lewis, 2005; Gallo & Matthews, 2003). These beliefs were supported in early psychoanalytic and psychodynamic reports that identified such personality characteristics in patients with hypertension and heart disease (Everson-Rose & Lewis, 2005). In the mid-1900s, this literature and related observations prompted work on identifying and assessing "coronary-prone behavior"; indeed, hostility, anger, and aggression were identified as critical tenets of coronary-prone behavior, which later came to be redefined as Type A behavior pattern (Friedman & Rosenman, 1971). Type A individuals are described as highly ambitious, competitive, time-urgent, impatient, quick-tempered, and tightly wound. The seminal work by Drs. Rosenman and Friedman in the Western Collaborate Group Study provided clear evidence

identifying Type A behavior as a risk factor for coronary heart disease (CHD) (Rosenman et al., 1975). Indeed, this study and initial empirical confirmation of the study findings prompted the medical community to accept Type A as the first psychosocial factor clearly identified as a risk factor for CHD (Cooper, Detre, & Weiss, 1981). However, the reproducibility of these findings was limited and negative findings on Type A and CHD risk began to appear in the literature. Consequently, researchers began to consider whether one of the components of Type A was driving the adverse effects previously identified for the broader Type A construct. Strong empirical evidence suggests that hostility is the "toxic" component of Type A behavior pattern (Williams et al., 1980), and an independent predictor of CVD (Miller, Smith, Turner, Guijarro, & Hallet, 1996).

Measurement

The development of valid and robust tools for measuring hostile characteristics and traits enabled systematic investigations of the impact of hostility on health. The Cook and Medley Hostility scale (CMHS) (Cook & Medley, 1954) was derived from the MMPI nearly 60 years ago and remains one of the most commonly used measures of hostility. It originally was devised to identify teachers who had poor rapport with their students, but subsequently was adopted as a more general indicator of hostility following its reported association with angiographic evidence of CHD (Williams et al., 1980), and CVD events and mortality (for reviews, see Everson-Rose & Lewis, 2005, and Hemingway & Marmot, 1999). The CMHS consists of 50 true-false items, where 1 point is assigned for each "hostile" response and higher scores indicate greater hostility. Several subsets of items on the CMHS have been used to measure specific components of hostility, the most common among them being cynicism. Other commonly used measures include the Buss-Durkee Hostility Inventory, Multidimensional Anger Inventory, and the Potential for Hostility measure derived from the Type A Behavior Pattern structured interview. Each measure is designed to broadly assess hostility and expressions of anger; however, these scales are not completely overlapping in terms of the dimensions of hostility that they capture (e.g., cynicism, hostile affect, anger expression, anger suppression). The potential for these measures to tap into different components of hostility should be taken into consideration when relating them to health outcomes.

Hostility and Health

The literature on the relationship between hostility and health is expansive, and spans across several disciplines. Most of these observations focus on the relationship between hostility (and its components) and the risk for poor cardiovascular outcomes. The literature relating hostility to non-cardiovascular diseases remains scarce – limited evidence has tied hostile traits to cancer (Tindle, et al., 2009), cognitive function (Barnes et al., 2009), and general health (Adams, 1994). In contrast, numerous epidemiological studies have investigated hostility in relation to various indicators of CVD. Literature reviews summarizing this work (Everson-Rose & Lewis, 2005; Gallo & Matthews, 2003; Miller et al., 1996) highlight significant inconsistencies between study findings. Some of the studies reviewed found that higher levels of hostility are associated with CHD incidence, presence and progression of atherosclerosis, hypertension, peripheral arterial disease, and all-cause and CVD mortality. However, the literature is not unequivocal – other studies have reported marginal and/or null findings between hostility and risk for CHD or CVD (Hemingway & Marmot, 1999). Miller et al. (1996) conducted a meta-analysis of 45 studies relating hostility to CHD, and suggested that variations in the methodology used by these studies may account for the mixed findings in the literature, such as the type of hostility measure, the study design, and the sociodemographics of the study population. Nevertheless, Miller et al. concluded that hostility is indeed an independent predictor of CHD and all-cause mortality. More recent studies, particularly

population-based studies, provide further support for hostility as a significant risk factor for CVD (Everson-Rose & Lewis, 2005); however, among patients with documented CHD, there is limited evidence that hostility or anger predict recurrent coronary events or mortality (Hemingway & Marmot, 1999).

Sociodemographic Characteristics

Hostility is related to a number of sociodemographic characteristics, with some support for differences between groups. Consistent evidence has shown an inverse relationship between socioeconomic status (SES) and hostility. This effect is linear, and suggests that those with the lowest education, income, and occupational status are more likely to express hostile characteristics. Furthermore, there is evidence that hostility may mediate the relationship between SES and CVD (Gallo & Matthews, 2003). In addition to social and economic differences in the expression of hostility, some studies show that hostile traits may vary by race and sex. For instance, growing evidence suggests that blacks and men report higher levels of hostility than their white and female counterparts (Gallo & Matthews); other studies indicate that hostility is higher in younger adults and the elderly and lower in mid-aged adults (Barefoot, Beckham, Haney, Siegler, & Lipkus, 1993). The same study also found that education may moderate the relationship between race and hostility, with more educated blacks reporting lower levels of hostility compared to less educated blacks, and more educated whites reporting higher levels of hostility than less educated whites. Nevertheless, the current literature lacks clear evidence that differences in the expression of hostility by race or sex translate into disparities in the risk for CVD. Several studies have tested this hypothesis and found no association (Everson-Rose et al., 2006) and/or lacked the sampling power necessary to test for these interactions (Iribarren et al., 2000). Future research should include large, balanced, and diverse samples in order to further investigate potential sociodemographic differences in the risk of CVD related to hostility.

Hostility and Pathways to CVD

Hostility may confer independent risk for CVD but also may operate through indirect pathways via its relationship with a number of other psychosocial and biobehavioral risk factors. Hostility is positively correlated with negative emotional states, including depression, anger, and anxiety, and inversely associated with positive psychosocial factors and personality traits, including social support and optimism (Gallo & Matthews, 2003; Tindle et al., 2009). Additionally, a number of studies have identified behavioral risk factors related to hostility. For example, a recent meta-analysis of 27 studies found that the CMHS was significantly associated with several traditional CVD-related risk factors (Bunde & Suls, 2006), including obesity (i.e., body mass index, waist-hip ratio), alcohol consumption, and smoking. Other studies link hostility to physical inactivity and dietary/caloric intake (Scherwitz et al., 1992). Moreover, several studies have identified biological and physiological pathways that may link hostility to disease. For instance, hostility is related to metabolic dysregulation, including impaired glucose metabolism, insulin resistance, and metabolic syndrome (Bunde & Suls, 2006; Goldbacher & Matthews, 2007). Hostile attitudes, emotions, and behaviors are associated with physiological response patterns that reflect activation of several biological systems in the body. Indeed, the physiological responses induced by hostility are characteristic of the "fight or flight" response, including prolonged activation of the hypothalamic-pituitary adrenal (HPA) axis and autonomic nervous system (ANS). For example, research shows that hostile individuals tend to have higher systolic and diastolic blood pressure, higher heart rates, as well as increased levels of stress hormones (i.e., cortisol), catecholamines (i.e., epinephrine, norepinephrine), and pro-inflammatory cytokines (i.e., IL-6 and IL-1) (Everson-Rose & Lewis, 2005). Furthermore, hostility is related to increased platelet activation and aggregation, which together with the other physiological risk factors contributes to increased atherosclerosis, and thrombus and plaque

formation (Markovitz, Matthews, Kiss, & Smitherman, 1996). On the whole, these observations support the fact that hostility clusters with other psychosocial and biobehavioral factors and may increase risk for CVD and other poor health outcomes through both direct and indirect pathways.

Summary

This entry provides a general insight into the history and research relating hostility to CVD and other health outcomes. Hostility is defined by cynical and suspicious attitudes, anger, bitterness, and varying levels of aggression and opposition. The role of hostility in health emerged from the shadow of the classic Type A behavior pattern and has gained momentum as one of the most pathogenic components of Type A. Instruments created to assess hostility have been vital to measuring the impact of hostility on health, and the CMHS stands out as a valid and reliable assessment tool. The literature on the role of hostility in cardiovascular health is somewhat mixed: evidence is more limited for a role of hostility in recurrent events or mortality among persons with existing heart disease, whereas evidence from methodologically sound, population-based studies generally provides support for the hypothesis that increased hostility is associated with excess risk of CVD. Research targeted at addressing these inconsistencies has investigated a number of potential pathways and mechanisms underlying the relationship between hostility and CVD. As a result, it is becoming more apparent that the impact of hostility on health may vary based on an individual's sociodemographic profile, and that hostility may operate through other psychosocial, behavioral, and physiological factors to influence CVD outcomes.

Definition

Hostility is a relatively stable personality trait that is typically characterized as a multidimensional construct with significant affective (e.g., anger), cognitive (e.g., attitudes), and behavioral (e.g., aggression) components. Hostile individuals have a suspicious, mistrustful attitude and often disparaging view of others and generally have a cynical worldview of their environment and social interactions. Thus, this type of personality disposition is often referred to "cynical hostility."

An expansive literature on personality and disease processes and health risks has developed over the past 50–60 years. Hostility has featured prominently in this literature, particularly with regard to cardiovascular disease (CVD) risk (Miller, Smith, Turner, Guijarro, & Hallet, 1996; Everson-Rose & Lewis, 2005). Though some negative studies have been reported, on balance, the available evidence from methodologically strong, population-based studies suggests that hostility is a significant risk factor for myocardial infarction and cardiovascular mortality in healthy populations (Barefoot, Dodge, Peterson, Dahlstrom, & Williams, 1989; Barefoot, Dodge, Dahlstrom, Siegler, Anderson, & Williams, 1991; Everson et al., 1997). Less support has been shown for the role of hostility in recurrent CVD or mortality in patients with diagnosed heart disease (Hemingway & Marmot, 1999). Recent studies in older adult populations have looked at hostility in relation to other health outcomes. Accruing evidence shows that hostility levels are associated with worse metabolic function and glucose regulation (Niaura, Todaro, Stroud, Spiro, Ward, & Weiss, 2002; Shen, Countryman, Spiro, & Niaura, 2008), higher levels of inflammation (Graham et al., 2006), poorer lung function (Kubzansky, Sparrow, Jackson, Cohen, Weiss, & Wright, 2006), and lower levels of cognitive function (Barnes et al., 2009).

Definition

Hostility is defined by a suspicious, mistrustful attitude and cynical disposition toward others. Considered an enduring personality characteristic, hostility is characterized by cognitive, behavioral, and affective or emotional dimensions.

Description

Measurement of hostility can be based on structured interviews, with interviewer ratings of behavioral dimensions and verbal expressions of hostility based on participants' actions and responses within the interview setting. The classic example of this method of assessing hostility is the structured interview for Type A behavior, which was developed by Drs. Meyer Friedman and Ray Rosenman, the two cardiologists who first coined the term "Type A" to describe what they perceived to be coronary-prone behavior (e.g., hostility, aggressiveness, time-urgency, and a need to be hard-driving) among their heart patients (Friedman & Rosenman, 1971). The Type A interview is administered by carefully trained interviewers using a structured format in which scenarios are presented that attempt to elicit behavioral responses consistent with Type A. For example, at varying points during the interview, the interviewer will interrupt the respondent, challenge his or her responses, abruptly change topics, and also appear to be distracted. Interviews are audiotaped for later scoring. A scoring system is used that characterizes respondents on "Potential for Hostility" (PH), among other Type A characteristics, and codes on three dimensions of hostility, including intensity of response, hostile content, and style of interaction (Dembroski & Costa, 1987). As empirical support for the Type A construct in relation to risk for coronary heart disease faltered, investigators shifted focus to what were considered the most toxic components of Type A, and in particular, emphasis was placed on hostility, anger, and aggressiveness. Despite the seeming advantages of having objective ratings of hostile behaviors made by trained observers, such as PH

ratings obtained within the context of the Type A interview, such ratings are uncommon in the current literature on personality and health. Indeed, structured or semi-structured interview formats are rarely used anymore, especially in large community- or population-based studies of health because of the considerable time and expense involved in conducting such interviews. In contrast, a vast majority of such studies typically rely on self-administered or interviewer-administered questionnaires or surveys (i.e., "self-report") to assess hostility and other personality characteristics. Among the most commonly used measures of hostility is the 50-item Cook-Medley Hostility Scale (CMHS; Cook & Medley, 1954), which was derived from the original Minnesota Multiphasic Personality Inventory (Hathaway & McKinley, 1940). Items include such statements as "It is safer to trust nobody," "Most people make friends because friends are likely to be useful to them," "I think most people lie to get ahead," and "Most people are honest chiefly through fear of being caught." Several shortened versions of the CMHS are commonly used as well; most of these versions focus on a subset of 8–13 items that specifically assess interpersonal attitudes characterized by cynicism, mistrust of others' intentions, and anger responses (Barefoot, Dodge, Peterson, Dahlstrom, & Williams, 1989; Greenglass & Julkunen, 1989; Everson et al., 1997). The original CMHS employed a "true/false" response format with 1 point assigned for each "true" response and a hostility score was then calculated by summing across items. Alternate response formats have been used with some of the shortened versions of the CMHS, including a 4-point Likert scale in which respondents are asked to indicate the extent to which they agree or disagree with each statement from completely agree (0) to completely disagree (3). With this format, item responses are reverse-coded and summed to create a hostility score.

Other validated self-report instruments used to assess hostility include the Buss-Durkee Hostility Inventory (BDHI; Buss & Durkee, 1957) and the Multidimensional Anger Inventory (Siegel, 1986). The BDHI includes 75 true/false items; though the items were written to assess seven aspects of hostility, as defined by the creators of the scale, studies show that responses generally reflect two broad categories related to overt verbal and physical expressions of anger and hostility and to angry or hostile thoughts and emotions. The BDHI commonly has been used by psychologists but has rarely been used in epidemiological studies assessing personality or psychosocial factors and health outcomes, largely due to its length and the availability of several shortened versions of the CMHS. Similarly, the Multidimensional Anger Inventory consists of 25 self-report items that tap into four dimensions, only one of which that is specific to hostility and the remainder which are more specific to anger. The dimensions assessed include hostile outlook, mode of anger expression (anger-in and anger-out), anger arousal, and range of anger-eliciting situations. This scale was developed in a convenience sample of college students and though also validated in a community sample of male factory workers, it has not been used widely in population- or community-based studies.

Definition

Hostility has distinct cognitive components, affective or emotional components, and behavioral features. This multidimensional construct most commonly is defined by a mistrustful and suspicious attitude, cynical perceptions of others and their motives, and a negative interactional style characterized by anger, resentment, contempt, antagonism, and suspiciousness. Behavioral expressions of hostility typically include verbally and/or physically aggressive actions. The physiological consequences of hostility and its components contribute to over-activation of neurochemical and biological pathways, consistent with the stress response system, that may contribute to atherogenesis, alterations in glucose metabolism and other bodily systems, and which are harmful to cardiovascular health.

Description

A wealth of research has investigated physiologic responses related to hostility (Everson-Rose & Lewis, 2005). The emotional, behavioral, and cognitive manifestations of hostility are interrelated, although they may operate via different biologic pathways to influence health. This may well be why the literature on hostility's impact on physiological functioning reveals effects on multiple biologic systems, including documented effects on heart rate (HR), heart rate variability (HRV), systolic and diastolic blood pressure (SBP; DBP). One of the well-tested hypotheses that was formulated nearly 30 years ago to understand the linkages of psychosocial risk factors, such as Type A behavior, with coronary heart disease, focused on individual differences in physiologic responding. What came to commonly be called the cardiovascular reactivity hypothesis (Treiber et al., 2003; Smith & Ruiz, 2002) postulated that exaggerated autonomic nervous system and/or neuroendocrine activation occurred under conditions of interpersonal stress in persons with particular psychological traits or under certain emotional states. Hostility is one such psychological trait that has been a focus of the cardiovascular reactivity literature. Although not unequivocal (Suls & Wan, 1993), the vast majority of studies testing this hypothesis with regard to hostility show that, indeed, hostile persons tend to have higher HR (Jamner, Shapiro, Goldstein, & Hug, 1991), reduced HRV (Sloan et al., 1994), higher SBP and DBP (Smith & Allred, 1989; Suarez & Blumenthal, 1991), increased levels of epinephrine and norepinephrine (Zhang et al., 2006), and alterations in cortisol secretion or patterning (Pope & Smith, 1991) particularly under conditions of challenge and/or in ambiguous conditions, which are thought to be interpreted as adversarial by hostile persons (Everson, McKey, & Lovallo, 1995). Furthermore, prolonged and frequent physiological arousal experienced by hostile individuals increase the risk for endothelial injury and damage, a precursor of inflammation, platelet formation, thrombogenesis, and atherogenesis. Nonetheless, the literature on hostility and

risk for cardiovascular disease morbidity and mortality has not clearly shown that this exaggerated cardiovascular reactivity evident among hostile individuals is in fact the primary pathway by which hostility increases cardiovascular risk.

Other biologic pathways are important and also have been associated with hostility. For example, several studies have linked hostility with altered glucose metabolism, central adiposity, and metabolic dysregulation, which additionally may serve as mediators between hostility and CVD and related risk factors. In a recent review of the literature, Goldbacher and Matthews (2007) concluded that negative psychosocial factors, including depression, hostility, and anger, were important contributors to the risk of metabolic syndrome. Specifically in regards to studies investigating the role of hostility on metabolic syndrome, Goldbacher and Matthews found that hostility and its components (i.e., cynicism, aggression) related to increased risk of metabolic syndrome over time, and found longitudinal and cross-sectional evidence supporting the positive association between hostility and visceral adipose tissue, waist-hip ratio, and insulin. For example, one of the studies reported from Niaura and colleagues (2000) found that men high in hostility, as assessed by the Cook-Medley Hostility Scale, have increased insulin resistance and higher fasting insulin levels in the presence of high stress levels, and impaired glucose metabolism than men who are low in hostility. Moreover, there is evidence that ties the combined effects of high hostility and metabolic syndrome to increased risk of myocardial infarction (Todaro et al., 2005). Even so, the review of the literature revealed studies that find no relationship between hostility and metabolic syndrome (Goldbacher & Matthews, 2007), and although steps have been taken to address and conceptualize some of these inconsistencies (Zhang et al., 2006), this work is limited.

Studies also have examined neuroendocrine and genetic biomarkers related to hostility, especially those involved in serotonergic function. Williams (1994) proposed that reduced serotonin levels in the central nervous system may constitute an important brain mechanism by which hostility and related biobehavioral risk characteristics influence risk for cardiovascular diseases. In his hypothesis, he suggested that serotonin dysfunction was the underlying cause of harmful traits (e.g., hostility, anger), behaviors (e.g., excessive alcohol use, smoking), and physiological responses (e.g., heightened sympathetic arousal) which seem to cluster in certain individuals. Justification for his theory is supported by a growing number of studies that identify genetic markers and environmental stimuli that regulate serotonin levels and shape the expression of hostile traits and behaviors. Indeed, more recent studies have provided scientific evidence that individuals with alleles that code for lower CNS serotonin function are more likely to express hostile-like traits (Manuck, Flory, Ferrel, Mann, & Muldoon, 2000; Lesch et al., 1996), including aggression and neuroticism, and other negative psychosocial characteristics like depression (Siegler et al., 2008). In addition, there is some evidence that these genes may vary by race and/or sex; however, this work is limited and requires further investigation. More work is needed to understand the development of hostility and potential biomarkers that may predispose individuals to hostile traits and characteristics.

Hostility is a multidimensional personality trait that functions through several biological pathways to influence health and well-being. The expression of hostile attitudes, emotions, and behaviors are stress inducing, and particularly cardio-reactive. Indeed, the body uses autonomic and neuroendocrine pathways to interpret hostile experiences, which may manifest as heightened cardiovascular stimulation or metabolic dysregulation. In addition, the tendency for hostility to cluster with other negative psychosocial factors and harmful behaviors, led to the growing theory that low CNS serotonin function may predispose individuals to these disease-inducing traits and behaviors. In order to fully conceptualize the mechanisms that shape the relationship between hostility and disease, further research will be required that supports physiological mediators.

Definition

Human factors/ergonomics can be broadly defined as optimizing the relationships between systems and the humans using them. More specifically, it is defined as follows:

"...the understanding of interactions among humans and other elements of a system, and the profession that applies theory, principles, data, and other methods to design in order to optimize human well-being and overall system performance" (Human Factors and Ergonomics Society: About HFES, n d).

In health care, the goal of human factors is to improve patient outcomes by supporting provider performance and by increasing patient safety through the reduction of iatrogenic error. In the context of behavioral medicine, the specific goal of human factors is to promote effective clinical interventions for disease prevention and treatment and to facilitate positive changes in patient behavior. The application of human factors to health care is discussed in more detail below.

Description

In the USA, an estimated 98,000 patients die each year due to preventable medical errors (Institute Of Medicine, 1999). Generally, health care has lagged far behind other industries, notably aviation, for improvements in safety (Leape, 1994). However, some specialties in medicine (e.g., anesthesiology) have made tremendous progress in patient safety over the last decades. For example, by the late 1990s, the risk of death from anesthesia was 1/60th the mortality rate in the 1980s, which translates into a 60-fold decrease in the number of annual deaths in the USA (Kohn, Corrigan, Donaldson, & Institute of Medicine U.S. Committee on Quality of Health Care in America, 2000). This phenomenal accomplishment in anesthesiology patient safety resulted from a combination of changes, most based on the application of human factors principles. Among the changes that increased anesthesia safety were steps toward optimization and standardization of system components (equipment

and training), establishment and implementation of practice guidelines which were widely accepted by providers, hospitals, and professional organizations, and significant advances in technology (Gaba, 2000). In contrast to anesthesiology, other areas in health care have not made as much progress in patient safety. For example, approximately half to two-thirds of all annual patient deaths in the USA are caused by a preventable systemic infection that is associated with a central line (a catheter that is used to draw blood and deliver fluids and medication) placed in a patient (Institute of Medicine, 1999).

A human factors approach that pursues the goal of improving patient safety focuses not only on individual components of the system in isolation, but also takes into account the interactions of these elements with each other. Only such an integrative perspective will result in sustainable change of clinical practice and improvements in patient outcomes and patient safety.

Socio-Natural Systems Perspective of Health Care

Comprehensively addressing patient safety requires considering human performance in a range of different systems while acknowledging the differences between such systems (Durso & Drews, 2010). The safety improvements in anesthesiology were successful because human factors principles were applied to multiple elements (optimization and standardization of equipment and tasks with practice guidelines adopted by providers and organizations), widespread implementation of simulator-based training with feedback, and patient monitoring technology was improved (Gaba, 2000). This combination of interventions improved the transparency of patient outcomes through feedback with better equipment and structured training and education.

Clearly, all of the multiple system components (patients, providers, physical environment, organizational environment, tasks, and equipment/tools; adapted from Carayon, Alvarado, & Hundt, 2007) that are involved in health care need to be included in a comprehensive systemic intervention. In addition, to maximize improvements in performance and safety, it is important to acknowledge the differences and similarities between different systems (e.g., technical systems in aviation vs. socio-natural systems in health care).

For example, health care can be conceptualized by applying a socio-natural systems perspective: patients are, at the core, biological or natural systems, interacting with providers in an organizational environment that constitutes a social system, where often equipment/tools are used to accomplish a goal with the equipment/tools constituting the technical aspect of the system (Durso & Drews, 2010). Interventions to improve safety in aviation and health care are frequently compared, and there are important similarities between the two systems that allow adoption. However, the comparison faces limitations when focusing on a key distinction between the relevant system components in each domain at the microlevel: in health care, tasks are performed on a patient, a natural system. Consequently, feedback on a task, such as treating a patient, is often delayed or not accessible because causality is not directly observable. At the microlevel, tasks in aviation are performed on an aircraft, an engineered system that is designed to provide continuous feedback, making it largely transparent and highly predictable (Durso & Drews, 2010).

In health care, transparency (observation and understanding of a system) of the system component (patients) is partial, at best. One challenge is that the lack of transparency limits the opportunities for learning and reduces the ability to predict the consequences of actions. Another difference between health care and aviation can be found in the approach toward training and distinction in microlevel variability between patients and aircraft. Due to the lack of standardization in health care (Timmermans & Berg, 2003), providers are unlikely to receive detailed training and practice with particular equipment and frequently need to perform the same procedure using different brands of equipment with distinct designs. Whereas in aviation, pilots train and become certified on a specific aircraft, thus they do not encounter differences between aircraft. Furthermore, tasks in aviation are highly structured and therefore predictable, with

checklists (protocols) for routine activities and emergency situations (Wickens, Gordon, & Liu,, 1998). In health care, protocols for every possible situation and patient simply do not exist. Thus, providers perform tasks based on their training, local practices, and the specific needs of patients, because the inter-individual variability of patients is significant. This situation can be contrasted with aviation, where it is one of the most important goals of quality control in aircraft manufacturing to minimize the variability between aircraft.

Other differences between health care and aviation extend to the physical and organizational environment. The work environment in health care has the potential to negatively impact cognition because of frequent error-producing conditions: interruptions, multitasking, suboptimal equipment, and inadequate staffing (Carayon et al., 2007; Nolan, 2000). The work environment in health care sharply contrasts with aviation, where during critical phases of a flight (e.g., takeoff, landing), nonessential conversations in the cockpit are prohibited (sterile cockpit), minimizing interruptions and distractions. Finally, health care is only beginning to establish a safety culture such as that successfully established in aviation. A consequence of this early stage of safety culture adoption is that errors and "near misses" generally go unreported (Leape, 1994), limiting the opportunities for learning because reoccurring patterns are not identified.

To improve performance in a complex system, components such as equipment and training need to be optimized and standardized by applying human factors principles (Nolan, 2000, Wickens et al., 1998). Specifically, this involves reducing the cognitive demands of tasks that are performed. For example, high reliance on perception, memory, attention, and decision-making when performing a task is likely to increase the probability of suboptimal actions and do not promote optimal performance (Wickens et al.). Consequently, reducing the cognitive demand of a task can provide defenses against human error (Wickens et al.). To illustrate the application of human factors in health care, two examples will be discussed in more detail: the development of a drug display (a visual monitor) to improve medication delivery in anesthesiology and tools to improve medication adherence.

Drug Display for Medication Delivery

Delivering correct drug concentrations and doses over the course of administering anesthesia is critical to patient safety. This task has significant cognitive demands because the anesthesiologist must remember the times and amounts of past drug administrations, then use this recalled information to calculate changes in concentration over time, and finally, determine the difference between the calculated current concentrations and the appropriate levels to determine present dosages. The consequences of high cognitive demands are ample opportunities for errors.

Consequently, anesthesia drug delivery performance can be improved with a drug display consistent with human factors principles. Drews, Syroid, Agutter, Strayer, and Westenskow (2006) demonstrated the positive impact of such technology optimized by application of human factors by comparing the display to the standard approach of delivering anesthesia without such information available to the anesthesiologist. The success of this approach can be attributed to the fact that the drug display creates defenses against error by providing "knowledge in the world" which reduces demands on cognition (Norman, 2002). More specifically, the human factors principles that were implemented in the drug display are as follows (Norman, 2002; Wickens et al., 1998):

1. Affordances (perceived functions of objects: intuitive representations of medication doses over time)
2. Chunking (meaningful grouping of related items: different drugs separated, current dose levels for all drugs together)
3. Reduced effort (mental/physical task demands to perform actions: information is provided on the monitor rather than requiring cognition)
4. Structure/guidance (design, layout, and sequence: e.g., time in Western cultures goes from left to right, chunking: information in meaningful units that can be maintained in memory)

5. Visual feedback (visibility: graphical representation depicting patterns of change over time for past, current, and predicted future drug concentration levels)

The drug display is an example of the application of human factors principles to equipment design (or tool design) to increase clinical task performance and reduce human error. However, equipment and tasks are only two of many additional components that are part of health care. Macroergonomics emphasizes such a broad system-based perspective when planning interventions for improvement in performance.

Medication Adherence Tools

A socio-natural systems perspective can be applied to a problem that is highly relevant for behavioral medicine: medication adherence. Lack of medication compliance has negative effects on patient health and produces significant economic costs (Osterberg & Blaschke, 2005). There are a number of causes that can lead to nonadherence, for example, the patient does not understand how to weigh medication benefits compared to the side effects, high access costs (high purchase costs of the medication, difficulty accessing a pharmacy, and other cognitive barriers such as challenges in the complexity of coordinating the timing and dosing of a number of medications) (Osterberg & Blaschke, 2005).

One human factors approach to improve medication adherence is providing cognitive aids or tools to schedule times to take medications (Waicekauskas et al., 2010). Participants scheduled the times to take several medications using a paper or electronic daily calendar, working in pairs (one participant was the "patient" and the other participant was the "provider"). Together the dyads solved examples of scheduling simple and complex sample medication problems. Complexity was increased by adding scheduling constraints, for example, fewer possible times to take a medication because of routine activities on the calendar, requiring the medication to be taken on an empty stomach. Both, the paper and electronic versions of the tool provided support to creating more accurate medication schedules than no aid.

The medication scheduling tool may serve as an example for how human factors approaches can help develop effective cognitive tools that reduce memory and other cognitive demands in coordinating the administration of medications and may also lead to increases in compliance with medication scheduling. However, such a cognitive aid is a technical system component that will likely only raise adherence if the causes for noncompliance were either forgetting to take medication or difficulty in figuring out when and how to take medication. The limitation of this approach is clearly associated with the fact that no improvement in medication compliance can be expected for patients that do not understand how to weigh the benefits of medication versus the medication side effects. For example, blood pressure medication has significant long-term health benefits, but the benefits are not directly visible to most patients, and there are frequent negative side effects (e.g., Osterberg & Blaschke, 2005). The tradeoff between the potentially invisible or less salient therapeutic benefits of medication and noticeable side effects from the perspective of the patient illustrates the challenges associated with a natural system that lacks transparency.

Nevertheless, the efficacy of a medication scheduling tool may be further enhanced by addressing other factors that contribute to noncompliance. For example, a clinical decision support system (a system designed to improve quality of care by providing cognitive support) could be implemented in electronic medical records or paper and applied to the problem of medication compliance (e.g., Drews et al., 2010). Implementing such a support system could prompt providers to: (a) remind patients about benefits versus side effects, (b) discuss medication cost and possible alternatives, and (c) provide pharmacy locations, etc. Although applying human factors to a single system can improve patient care, the example of medication compliance demonstrates both the challenges that are associated with applying an integrative human factors approach to health care and the greater benefits to patients that come with the application of this comprehensive approach.

Definition

The Human Genome Project (HGP) was an international scientific research project to map and sequence the entire human genome. The project goals were to identify all 20,000–25,000 genes and determine the sequences of the three billion base pairs that make up the haploid human genome. The project was started in 1990 and coordinated by the US Department of Energy and National Institutes of Health, and in partnership with the Wellcome Trust (UK). In 1998, Celera Corporation launched a parallel private effort to sequence the human genome. Most of the government-sponsored sequencing was performed in universities and research centers from the USA, the UK, Japan, France, Germany, and China. The public and private efforts succeeded, with a draft sequence published in 2001 (International Human Genome Sequencing Consortium, 2001; Venter et al., 2001), and completion of the HGP in April 2003 (Collins, Green, Guttmacher, & Guyer, 2003; Collins, Morgan, & Patrinos, 2003; Frazier, Johnson, Thomassen, Oliver, & Patrinos, 2003). The HGP also included parallel efforts to sequence select model organisms, such as the bacterium *Escherichia coli*, the fruit fly *Drosophila melanogaster*, and the mouse (*Mus musculus*). Sequencing model organisms served to both help to develop the technology and interpret human gene function. Data from the project are freely available to researchers.

Definition

The human papillomaviruses (HPVs) are members of the Papillomaviridae. These viruses (Papillomaviridae) are specie specific, so they can only infect humans. They are non-enveloped viruses that carry their genetic information on circular, double-stranded DNA. The virus measures approximately 55 nm in diameter. Nearly 200 types of HPV have been identified. While many of them do not produce any symptoms in humans, some strains of the virus can cause warts and in a minority of cases can lead to cancer (Bonnez & Reichman, 2009; Giuliano et al., 2011).

Description

HPV tends to infect skin or mucosal tissue, and while many HPV subtypes do not cause any symptoms, the subtypes that are known to produce symptoms can cause a multitude of skin diseases (e.g., plantar warts, common warts, epidermodysplasia verruciformis, genital warts, cervical and anal carcinoma). Each virus subtype tends to be associated with a specific pathology, for example, plantar warts tend to be caused by HPV-1 or HPV-2, while cervical carcinoma is frequently caused by HPV-16 and HPV-18. However, other HPV subtypes may cause the same diseases, although less commonly (Bonnez & Reichman, 2009).

HPV is easily recognized when it causes symptoms (i.e., clinically apparent infections); however, subclinical and asymptomatic infections are more common. In addition, individuals with past HPV infections represent an even larger group of affected persons. These three types of infections (i.e., clinical, asymptomatic, and past infections) and their relationship to each other make difficult their epidemiological study (Bonnez & Reichman, 2009). HPV is also classified by the location of the infection. For example, a significant distinction is made between infections in genitals and mucosal tissue, and non-genital infections (cutaneous infections).

In the United States, 20 million people are currently estimated to be infected and contagious

(Bonnez & Reichman, 2009), while an additional 6.2 million people between the ages of 15 and 44 become infected with genital HPV annually (Richman, Whitley, & Hayden, 2009). HPV transmission requires skin to skin contact; therefore, most genital infections are transmitted through sexual activity (Giuliano et al., 2011; Richman et al., 2009). Anal HPV infections happen most frequently through anal intercourse, although it is possible to spread the infection from one area to another by contact with hands or objects that have been exposed to infected areas (Giuliano et al., 2011). Nonsexual infections are rare. Most HPV infections (70%) resolve within a year, up to 90% within 2 years. However, individuals who do not clear their HPV infection are at risk for cervical or anal cancer, though the progression to cancer can take 10–20 years (Giuliano et al., 2011).

The three most observed cutaneous manifestations of HPV are *common warts* (71% of all cutaneous infections), *plantar warts* (34%), and *juvenile or flat warts* (4%). Common warts and flat warts are more common in children, while plantar warts are more common in adolescents. The prevalence of common warts in school-age children is estimated to be 4–20% (Bonnez & Reichman, 2009). Since contact with infected skin cells is necessary for transmission, two other vehicles of transmission besides sexual contact are possible, though rare: mother-to-child transmission and exposure to contaminated objects (Giuliano et al., 2011). Infection during birth is rare, but may lead to juvenile-onset recurrent respiratory papillomatosis (JORRP) – an infection that results in warty growths in the upper respiratory tract and can lead to obstruction of the airway in severe cases. JORRP has an incidence of 2 per 100,000 children in the United States (Giuliano et al., 2011). The other uncommon route of transmission is through contact with an object that has residual infected skin cells or with infected hands with a common wart or carrying infected cells (e.g., after scratching) (Giuliano et al., 2011). This means of transmission is more likely if there is trauma to the receiving skin, which may explain the higher frequency of cutaneous warts seen among meat handlers (Bonnez & Reichman, 2009).

Currently, there is no treatment to specifically eradicate an HPV infection; infections have to be cleared by the immune system of the infected person. Treatment of HPV focuses on removing the lesions by chemical or physical means, or by local stimulation of cytokines, to reduce or eliminate the symptoms of the infection (Bonnez & Reichman, 2009). There are two potential methods of preventing HPV transmission. Avoiding skin exposure to infected areas can reduce the likelihood of transmission. However, since HPV can be asymptomatic or subclinical (i.e., an infected individual may not have any visible skin lesions), avoiding contact with infected skin can be difficult or impossible. Condoms provide only limited protection from HPV since they protect only skin that is covered by the condom (Giuliano et al., 2011). A second method of prevention is vaccination against HPV infection, which has been proven to be quite effective (Bonnez & Reichman, 2009; The FUTURE II Study Group, 2007; Trotter & Franco, 2006). The available HPV vaccinations target only up to four HPV subtypes. However, since these HPV subtypes cause the majority of cervical cancers and genital warts, the vaccines can prevent the vast majority of clinically important and cosmetically unpleasant HPV infections (Bonnez & Reichman, 2009).

Human Subjects Committee

Institutional review board (IRB); Research ethics committee

Definition

Ethical conduct of research requires an objective and prospective review and approval by a committee established for the purpose of protecting human subjects involved in research. In the United States, these human subjects committees are usually called Institutional Review Boards (IRBs). They may also be known as Ethics Review Committees.

The main responsibility of the IRB is to conduct a comprehensive scientific and ethical review of the planned research activities. The purpose of this review is to ensure the proposed research meets the federal requirements for ethical research. It determines study feasibility, scientific merit, ethical soundness, strength of study design, balance of risk and benefits, and adequacy of informed consent. The review ensures that the design is scientifically sound and does not expose subjects to unnecessary risk. A sound scientific design is essential, as it is not ethically justifiable to expose subjects to any risk, discomfort, or inconvenience if the research is poorly designed and not likely to obtain meaningful information (Council for International Organizations of Medical Sciences, 1993). The IRB is also responsible for identifying, minimizing, and eliminating conflicts of interests.

Key components of the system include the federal government's regulations, IRBs, the sponsor, and the principal investigators (PIs) conducting the research. Additionally, all investigators and members of the research team and community are charged with protecting human subjects. The federal regulations, issued by the Department of Health and Human Services (DHHS) and the Food and Drug Administration (FDA), are the cornerstone in this system of protection. The DHHS regulates all research it funds and conducts, and the FDA regulates research involving drugs, biologics, and clinical devices.

The criteria for IRB approval are that risks to research participants are minimized; risks are reasonable in relation to anticipated benefits and the knowledge that may result; selection of participants is equitable; informed consent will be sought from each participant or their legally authorized representative and appropriately documented, as required; adequate plans for monitoring data to ensure participant safety are in place; adequate provisions are made to protect the privacy of the participant and the confidentiality of the data; and additional safeguards are provided to protect the welfare and safety of vulnerable participants such as children, prisoners, pregnant women, mentally disabled persons, or economically or educationally disadvantaged individuals (U. S. Department of Health and Human Services, 2009a).

IRBs are responsible for conducting comprehensive prospective and ongoing review of all research activities at least annually. The level of scrutiny and frequency of continuing review depends upon the level of risk posed by the research activities. To best protect human

subjects, an objective review is required by a diverse group of individuals with no direct involvement in the planned research. The Federal Regulations stipulate that the IRB is composed of at least five members. The members must include a scientist, nonscientist, and at least one person who is not affiliated, and is not a family member of an affiliated person, with the institution conducting the research (U. S. Department of Health and Human Services, 2009b). These are the minimal requirements established by the federal guidelines; however, the size and composition may vary depending on the institutional requirements and resources. On occasion, it may be necessary for the IRB to invite an individual to provide expertise in a specific area of research.

The responsible and ethical conduct of research requires that the PI and all team members are appropriately trained and well qualified to conduct research with humans. Responsible for the conduct of the study, PIs must consider the participants' safety and welfare at every phase of the study including initiation, implementation, closeout, and dissemination. Fundamental in providing these protections is ensuring subject privacy and confidentiality (Steneck, 2007). Conducting research in a manner consistent with the established ethical principles is of paramount importance to protect human participants in research. Providing adequate protections requires a broad range of knowledge and a systems approach. Such a system is essential to accomplish comprehensive reviews of planned research activities and to ensure sound ethical interactions between the investigator and participant, especially in the informed consent process. Also important in the system of protection is oversight, including safety monitoring and a robust quality improvement and compliance program (Federman, Hanna, & Rodriguez, 2002).

The Belmont Report and the Protection of Human Subjects

Human subjects who participate in research benefit society by contributing to the development of new drugs, medical procedures, and a greater understanding of how we think and act (Steneck, 2007). Individuals who assume the inherent risks of participating in research deserve to be treated with dignity and respect and to have their rights as humans protected. The federal regulations just discussed are founded upon ethical principles written in the Belmont report. The ethical principles of respect for persons, beneficence, and justice are tightly integrated in the regulations. The principle of respect for persons states that the protection of autonomy and personal dignity requires informed consent of each person before they are involved in research. Special protections, to prevent coercion and undue influence, are required for individuals who are unable to make autonomous decisions, such as children, prisoners, and those with compromised decision-making capacity. Securing the well-being of research participants by minimizing risk and maximizing benefits is essential to ensuring beneficence and protecting subjects from harm. Justice requires equitable subject selection to reduce or prevent overburdening certain populations and providing access to research opportunities for others (The Belmont Report, 1979). While the federal government provides the overarching governance for research in humans, oversight and implementation of the regulations are conducted by the IRB.

Definition

Hyperglycemia is defined as a state of elevated blood plasma glucose ($\geq$7.0 mmol/L, or 120 mg/dL, before meals) and is a hallmark feature of all diabetes subtypes. Hyperglycemia results from disruptions in blood glucose metabolism, insufficient insulin production (in the case of type 1 diabetes), or the cellular resistance to the endogenous insulin produced by the pancreas (in the cases of type 2 diabetes and gestational diabetes). Hyperglycemia can be assessed at home using a portable glucometer, or in the laboratory setting by drawing a blood sample for analysis. Symptoms include excessive thirst, excessive urination, fatigue, itchy skin, and, over time, weight loss. In mild forms, individuals are often unaware of blood glucose elevations. However, in more flagrant episodes, individuals may self-detect these aforementioned symptoms. Hyperglycemia may be managed by a number of self-management behaviors including changes in dietary intake and physical activity. Among individuals with diabetes who are receiving insulin therapy, they may also administer an injection of short-acting insulin. These behaviors, in isolation or combination, will help to restore normal blood glucose levels. However, if unmanaged, extreme hyperglycemia can precipitate a state of diabetic ketoacidosis (DKA), which results in both the production of ketones and metabolic acidosis. DKA leads to excessive urination and loss of both fluid and electrolytes that can result in myocardial infarction and death. Repeated episodes of DKA may be evidence

of poor metabolic control, which potentiates morbidity and premature mortality. Precipitants for DKA include infection, abdominal crises (e.g., gastrointestinal bleeding, pancreatitis), physical trauma, and insulin omission. If unmanaged, repeated episodes of hyperglycemia lead to the development of serious vascular pathology resulting in blindness, renal failure, pain and loss of sensation in the extremities, myocardial infarctions, cerebrovascular accidents, and amputations.

Hyperinsulinemia

Alyssa Parker

Synonyms

Definition

Hyperinsulinemia is an indication of an underlying problem controlling blood glucose levels and is characterized by an excess of insulin circulating in the blood (Shanik et al. 2008). Insulin is produced by the pancreas and helps regulate blood glucose. Hyperinsulinemia may be caused by insulin resistance, a condition in which an individual's body becomes resistant to the effects of insulin and the pancreas compensates by producing additional insulin. Increases in insulin result in a decrease in circulating blood glucose (Buse, Polonsky, & Burant, 2008). Symptoms of hyperinsulinemia are often absent unless hypoglycemia (abnormally low glucose levels) occurs. When present, symptoms may include temporary muscle weakness, brain fog, fatigue, visual problems, headaches, shaking, and/or thirst. Treatment of hyperinsulinemia is directed at the underlying problem and typically focuses on diet and exercise (Diabetes.co.uk Team, 2011). Dieticians recommend a nutritional regimen that is low in sugar and carbohydrates, while high in protein. Additionally, regular monitoring of weight, blood glucose, and insulin is advised. In some cases, typically where obesity is present, treatment with metformin (i.e., an oral anti-diabetic drug) may be used to reduce insulin levels (Glueck, 2007). Though it is often mistaken for diabetes or hypoglycemia, hyperinsulinemia is a separate condition. Left unmonitored and untreated, however, it can develop into type 2 diabetes mellitus. A significant risk factor of hyperinsulinemia is the increased likelihood of developing a cluster of closely related abnormalities known as the metabolic syndrome (Reaven, 2005). Within this syndrome, it is believed that the more insulin resistant a person, the more likely he or she will develop some degree of glucose intolerance, high triacylglycerol and low HDL concentrations, essential hypertension, and procoagulant and proinflammatory states (Reaven, 2006), all of which are known to increase the chance of cardiovascular disease.

Hyperlipidemia

Kelly Flannery
School of Nursing, University of Maryland Baltimore, Baltimore, MD, USA

Synonyms

Lipid disorder

Definition

Hyperlipidemia simply means high blood lipid levels. Lipids refer to cholesterol, cholesterol compounds, triglycerides, and phospholipids. Lipids are carried in the blood by lipoproteins (e.g., low-density lipoproteins (LDL) and high-density lipoproteins (HDL)) (American Heart Association, n.d.).

Description

Hyperlipidemia increases the risk for atherosclerosis (i.e., hardening of the arteries, which is a buildup of plaque in the arteries). Atherosclerosis leads to narrow and stiff arteries that provide a reduced blood flow (Society for Vascular Surgery, 2010) and ultimately an increased risk for high blood pressure, heart disease, stroke, and poor lower leg circulation (Society for Vascular Surgery; U.S. National Library of Medicine & National Institutes of Health, 2011a, 2011b).

Risk Factors

Hyperlipidemia has several risk factors and many are modifiable. Some risk factors include (Mayo Clinic, 2010b; Society for Vascular Surgery, 2010; U.S. National Library of Medicine & National Institutes of Health, 2011b):

- Having certain genetic disorders; for example, familial hypercholesterolemia or familial dysbetalipoproteinemia
- Having a (nuclear) family history of early heart disease (before age 55)
- Age (men >45, women >55)
- Having certain diseases such as diabetes, high blood pressure, kidney disease, hypothyroidism, Cushing syndrome, polycystic ovary syndrome
- Having a body mass index over 25 (also defined as being overweight or obese)
- Drinking alcohol excessively
- Eating diets high in unhealthy fats (i.e., saturated and trans fat)
- Eating diets high in dietary cholesterol
- Lack of exercise

Hyperlipidemia, Table 1 Cholesterol screening summary

	Why the test is important	Desired or optimal value[a]	Some possible modifiable reasons why value is not at desired or optimal value
Total cholesterol	Tells the total amount of cholesterol in blood	<200 mg/dL	Being overweight
			Eating a diet high in saturated and/or trans fats
LDL (bad) cholesterol	When LDL cholesterol is too high, plaque can form in the arteries, which can increase risk for cardiovascular disease	<100 mg/dL	Being overweight
			Eating a diet high in saturated and/or trans fats
HDL (good) cholesterol	High levels can be protective whereas low levels (<40 mg/dL for men and <50 mg/dL for women) are a significant risk factor for heart disease. HDLs also help remove LDL cholesterol	≥60 mg/dL	Smoking cigarettes
			Being inactive
			Being overweight
			Eating a diet high in trans fats
Triglycerides	Unused calories are converted to triglycerides (fat that is circulating in the blood before it is stored)	<150 mg/dL	Eating more calories than working off
			Eating too many sweets
			Drinking alcohol excessively
			Being overweight
			Having diabetes with elevated blood sugar

[a]These are general guidelines and results should be discussed with primary care provider; the table was compiled with information from American Heart Association 2010, 2011; Centers for Disease Control and Prevention, 2010; Mayo Clinic, 2011; National Heart, Lung and Blood Institute, n.d.; U.S. National Library of Medicine & National Cancer Institute, 2011

- Using certain medications such as estrogen, birth control pills, corticosteroids, beta blockers, some types of diuretics, and some types of antidepressants
- Smoking cigarettes

Screening

Hyperlipidemia causes no symptoms; therefore, screening is important (Mayo Clinic, 2010c). To screen for hyperlipidemia a blood sample is obtained and a lipid panel (e.g., total cholesterol, LDL, HDH, triglycerides) is done (Mayo Clinic, 2011). Table 1 summarizes why the test is done, the desired or optimal value, and some possible modifiable reasons why the test is not at the desired or optimal value (American Heart Association 2010, 2011; Centers for Disease Control and Prevention, 2010; Mayo Clinic, 2011; National Heart, Lung and Blood Institute, n.d.; U.S. National Library of Medicine & National Cancer Institute, 2011).

Screening Recommendations

Recommendations for when hyperlipidemia screening should begin differ across organizations but generally testing is recommended to begin for men between ages 20–35 and 20–45 for women and then checked every 5 years. Additionally, screening is recommended when someone develops certain diseases (e.g., diabetes). Guidelines for cholesterol screening for children and/or adolescents vary due to limited evidence. However, some experts say those under age 18 should be screened if risk factors are present (e.g., family history of high cholesterol) while some recommend screening all children (U.S. National Library of Medicine & National Institutes of Health, 2011a).

Treatment

There are two common treatment methods for addressing an abnormal lipid panel. Sometimes only a lifestyle change is needed. A lifestyle

change is often the first step in treating hyperlipidemia. However, if a lifestyle change is not effective (especially if LDLs are still elevated), a combination of lifestyle modification and cholesterol medication may be recommended (Society for Vascular Surgery, 2010).

Possible lifestyle recommendations (Centers for Disease Control and Prevention, 2011; Mayo Clinic, 2010a; Society for Vascular Surgery, 2010; U.S. National Library of Medicine & National Cancer Institute, 2011):

- Eating the recommended amount of fruits and vegetables
- Limiting saturated (e.g., butter, cheese, whole milk) and trans (e.g., processed foods, fried foods, commercially baked foods) fats and replacing them with monounsaturated (e.g., canola oil, olive oil, avocados) and polyunsaturated (e.g., canola oil, walnuts, salmon) fats
- Limiting dietary cholesterol intake
- Eating whole grains
- Engaging in regular exercise
- Losing weight (if overweight)
- Quit smoking cigarettes
- Limiting alcohol consumption

There are five major classes of cholesterol lowering medication, which include: (Agency for Healthcare Research and Quality, 2009)

- Vitamins and supplements
- Statins
- Bile ace binders
- Cholesterol absorption inhibitor
- Fibrates

Definition

Hypertension has been variously defined over the years. However, systolic (i.e., peak) bloodpressure ≥140 mmHg and diastolic blood pressure ≥90 mmHg are now considered indicative of hypertension and of meriting treatment. Blood pressure ca 120/80 mmHg is deemed to be normal (normotensive). Although hypertension may be a secondary consequence of problems elsewhere, e.g., renal failure, the vast majority of cases of hypertension have no proximal and discrete cause. This is called essential hypertension and is a major focus of research in behavioral medicine. This is easy to understand given the prevalence and health consequences of hypertension. It is estimated to affect 15% and 20 % of the adult population in Western countries, with worldwide prevalence being around 10%. Concern with hypertension also reflects its association with coronary heart disease and stroke; the results of many studies testify that as blood pressure rises, so life expectancy decreases. For example, at the outset of the famous Framingham study, some 5,000 of the citizens of that small community in the USA had their blood pressures recorded; around 20% of them were hypertensive. Those with hypertension were three times more likely to go on to have a heart attack and eight times more likely to have a stroke. Given the clinical importance of hypertension, it is perhaps hardly surprising that there are several dedicated scientific journals and many texts devoted to hypertension. My favorite, however, remains Beevers and MacGregor (1995).

Definition

Hypertrophy is a structural response of an anatomic chamber, particularly the right and left cardiac ventricles, to chronically increased volumes or pressures. Left ventricular hypertrophy has been shown to be independently predictive of coronary heart disease onset and is associated with common conditions such as hypertension (high blood pressure) and cardiac valvular dysfunction (Maron, Ridker, Grundy, & Pearson, 2010). While hypertrophy is initially an adaptive mechanism for the heart, the chronic enlargement leads to unsustainable pressures and deformation that impedes contraction and relaxation. Serial

measurements of hypertrophy can be helpful in primary and secondary prevention for cardiovascular events.

Definition

Hypochondriasis is defined by the Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision (DSM-IV-TR) (American Psychiatric, 2000), as preoccupation with fear of having or the belief that one has a serious health condition. Criteria for the diagnosis include that the belief: is often based on the misreading of physical symptoms, is not of intensity better described as delusional, leads to clinically significant impairment in functioning, is of 6 months duration or longer, and is not better accounted for by a medical or psychiatric disorder. A specifier of "with poor insight" may be added to the diagnosis if the individual does not have recognition that the fears of illness are unwarranted and unfounded.

Description

Epidemiology

The prevalence of hypochondriasis is estimated to be between 1% and 5% in the general population. However, the prevalence rates increase to 2–7% within primary care outpatient populations, which is not unexpected given that this population is likely to seek treatment (American Psychiatric, 2000). Hypochondriasis may manifest at any age, but occurrences are commonly noted in early adulthood, with no gender differences noted. The course of hypochondriasis is typically described as chronic in greater than 50% of cases, and likelihood of chronicity is increased by when the individual experiences a number of bodily sensations, believes that one has a serious illness, or has other comorbid psychiatric diagnoses (Taylor & Asmundson, 2006). Cross-cultural differences have been noted among patients diagnosed with hypochondriasis; (Taylor & Asmundson; Asmundson, Taylor, & Sevgur, 2001) for example, gastrointestinal sensations are predominant in the United Kingdom, pulmonary complaints are common in Germany, and concerns surrounding immunology and chemical sensitivities frequently occur in the USA and Canada (Taylor & Asmundson, 2006).

Evaluation

Essential features of an evaluation of hypochondriasis include a thorough medical examination to rule out any potential physiological explanation for the reported symptoms (Taylor & Asmundson, 2006). Following this evaluation, a detailed psychiatric interview should be conducted and include any recent psychosocial stressors and previous history of health-related difficulties of the patient, family member, or significant others. Interviewers should consider in the evaluation that hypochondriasis typically manifests in the forms of disease phobia, bodily preoccupation, and disease conviction. For example, a patient may present with the belief that they have cancer (disease conviction) or may have a preoccupation with gastrointestinal complaints (bodily preoccupation) and insists on laboratory tests and radiological imaging. Although a person

with hypochondriasis may exhibit symptoms in all three of these categories, symptoms that fall within a predominant category can impact patient presentation and treatment (Stewart & Watt, 2001). Adjunctive standardized assessments may be utilized but with cautious interpretation. For example, the Minnesota Multiphasic Personality Inventory-2 (MMPI-2), which has a hypochondriasis scale, does not necessarily measure the fear associated with health complaints but rather measures the degree to which one experiences physical symptoms (Taylor & Asmundson, 2006). Other measures, such as the Structured Clinical Interview for the DSM-IV (SCID), the Structured Diagnostic Interview for Hypochondriasis (SDIH), and other self-report hypochondriasis measures (e.g., Whiteley Index, Health Anxiety Questionnaire, Illness Attitudes Scale, Somatosensory Amplification Scale and Illness Behavior Scale), may be more appropriate tools in gathering diagnostic information within this patient population (Speckens, 2001; Stewart & Watt, 2001).

Treatment/Best Practices

Although there is no evidence to date on combined treatments, there is consistent evidence suggesting that cognitive behavioral therapy (CBT) and medication-based treatments independently for hypochondriasis are effective (Taylor & Asmundson, 2006). Specifically, CBT interventions that focused on exposure and response prevention, psychoeducation, and cognitive therapy were found to improve symptoms in patients with hypochondriasis, and treatment gains continued to be present in a 12-month follow-up (Asmundson, Taylor, & Sevgur, 2001; Fallon & Feinstein, 2001; Taylor & Asmundson, 2006). As an example of CBT with exposure and response prevention for hypochondriasis, a patient with a bodily preoccupation of skin rashes may be exposed to anxiety associated with thoughts of having a skin rash, and resist the typical subsequent responses to that anxiety that would usually follow (e.g., calling a doctor, asking numerous questions about the rash, researching information on the internet/medical books, etc.) until the anxiety is relieved. Finally, while there are self-help and internet resources available, there is a paucity of evidence on the effectiveness of these resources utilized independently and/or as an adjunct to other therapies described (Taylor & Asmundson, 2006).

With regard to pharmacotherapy, selective serotonin reuptake inhibitors (SSRIs) and imipramine, a tricyclic antidepressant, have been shown in both head-to-head trials and randomized control trials to be useful in patients with hypochondriasis. Of the SSRIs studied (paroxetine, fluoxetine, fluvoxamine, and nefazadone), fluoxetine appears to have greater potential for desired treatment effects. However, there are no recent studies on long-term use of these medications with persons diagnosed with hypochondriasis (Asmundson et al., 2001; Enns, Kjernisted, & Lander, 2001; Taylor & Asmundson, 2006).

In addition to these treatment choices, environmental factors may impact treatment effectiveness. For example, the relationship between the patient and treating provider may impact treatment and exacerbation of symptoms (Lipsitt, 2001). If the provider is perceived by the patient as dismissing of symptoms or as not addressing the patient's concerns, the patient may choose to move from provider to provider until such symptoms are addressed. It is also suggested that overreassurance can exacerbate symptoms because the patient may perceive that their symptoms are being dismissed, leading to patient dropout (Starcevic, 2001). Optimally, providers who communicate clearly about guidelines on when to seek treatment and who have regularly scheduled follow-ups may reduce unnecessary treatment visits. Furthermore, patient preference should be weighted heavily into the decision to utilize pharmacotherapy, psychotherapy, or combined treatments (Taylor & Asmundson, 2006).

Definition

Hypoglycemia is characterized by an abnormally low level of blood glucose concentration, designated as less than or equal to 70 mg/dL. Blood glucose serves as the body's main energy source (Pub Med Health, 2011). With hypoglycemia, there is an inadequate supply of glucose to the brain, resulting in impairment of function that requires immediate attention to prevent organ or brain damage, especially when blood glucose is extremely low (Cryer, 1997). Hypoglycemia occurs when an individual's glucose is metabolized too quickly, when glucose is released into the bloodstream too slowly, and when too much insulin is released into the bloodstream (Cryer, Davis, & Shamoon, 2003). Hypoglycemia is relatively common among people with type 1 diabetes, and may occur when too much insulin or diabetes medication is taken, when insufficient amounts of food are ingested, or with sudden increases in exercise. Hypoglycemia is characterized as mild (below 70 mg/dL), moderate (below 55 mg/dL), or severe (below 35–40 mg/dL); and common symptoms include: trembling, nausea, sweating, dizziness, irritability, confusion, seizures, fainting, and coma. Immediate treatment involves quick steps to return blood glucose levels to a normal range. Mild-to-moderate hypoglycemia is treated by ingesting carbohydrates, while glucagon injections, a hormone that blocks insulin and raises blood glucose, are used to treat severe cases (Wysocki, Greco, & Buckloh, 2003). People with type 1 diabetes suffer an average of two episodes of symptomatic hypoglycemia per week, and approximately one episode of severe, at least temporarily disabling, hypoglycemia per year (Cryer, 2010). Careful monitoring of blood glucose levels can help predict or prevent moderate to severe hypoglycemia in at-risk individuals.

Pituitary-adrenal axis

Definition

The hypothalamic-pituitary-adrenal axis (HPA axis) is an interactive neuroendocrine unit comprising of the hypothalamus, the pituitary gland, and the adrenal glands. The hypothalamus is located in the brain and the pituitary at the base of it, whereas the adrenals are on top of the kidneys.

The HPA axis plays key roles in basal homeostasis and in the body's response to stress. The major pathway of the axis results in the production and secretion of cortisol. The hypothalamus responds to basal neural input which follows a circadian rhythm and input as a result of stress by increasing the secretion of corticotrophin-releasing hormone (CRH) from the hypothalamus. This increase in CRH acts upon the anterior pituitary gland to secrete adrenocorticotropic hormone (ACTH), which in turn circulates to the adrenal cortex to stimulate the release of cortisol into the bloodstream. The HPA axis is an example of a negative feedback loop; cortisol can reduce its own secretion via feedback to the anterior pituitary to reduce ACTH and the hypothalamus to limit the secretion of CRH. ACTH also provides negative feedback limiting its secretion via CRH.

The importance of the HPA axis to homeostasis is illustrated through the wide range of functions that cortisol is involved in, including metabolism, vascular activity, and immune and inflammatory responses. Therefore, even in the absence of stress, the production of cortisol via the HPA axis performs vital roles within the human body. In the presence of stress, be it physical, emotional, chemical, or environmental, the HPA axis governs the body's response. An increase in the production of cortisol enhances vascular activity, reduces immune responses, limits inflammation, stimulates gluconeogenesis, and inhibits nonessential functions. These effects serve to protect the body from potential damaging effects of stress, e.g., excessive immune and inflammatory response, but also act to increase resources to cope during the period of stress through changes in metabolism. While the role of cortisol in the stress response is initially protective, long-term stimulation of the HPA axis and over exposure to cortisol can be damaging, leading to immunosuppression and excessive catabolism of body tissue. Dysregulation of the HPA axis has been associated with various illnesses and disorders, both physiological and psychological. More detail on the HPA axis can be found from the following sources: Widmaier et al. (2004) and Greenspan and Forsham (1983) (Fig. 1).

Definition

The hypothalamus is a subcortical collection of nuclei that monitor, modulate, and regulate physiology and behavior including feeding, thirst, reproduction, temperature regulation, sleep, and emotional behavior such as fear and aggression.

Description

This entry describes the hypothalamus in humans. All vertebrates have a hypothalamus, and while there is a high degree of conservation across species and especially in mammals, readers should refer elsewhere for phenotypic and functional details regarding other animals.

The hypothalamus (Latin: hypo: "below" the thalamus) is located below the thalamus on the base of the brain on both sides of the ventral portion of the third ventricle. Three main divisions of the hypothalamus are the anterior, medial

(or tuberal), and posterior regions, each made up of several nuclei. These clusters of neurons coordinate autonomic, endocrine, somatic, and behavioral information to maintain homeostasis and motivate behavior in both the short and long term. Via bidirectional connections throughout many areas of the brain, the hypothalamus regulates a host of physiological processes and related reflexes including feeding, drinking, reproduction, temperature regulation, sleep, and emotional behavior such as fear and aggression.

The hypothalamus receives sensory information from the entire body about conditions in the external world including smells and light cycles and internal information from the visceral somatosensory system. Other sensory cells within hypothalamic nuclei monitor and respond to changes in internal states and biological set points such as temperature, salinity, and glucose, in addition to other factors outside the blood-brain barrier via connections with circumventricular organs such as the area postrema. A change in homeostasis (e.g., increased body temperature) triggers a variety of responses aimed at body temperature reduction, all of which are regulated by the hypothalamus. These include moving blood to the surface of the skin, increased sweating, and increased water conservation at the kidneys.

The hypothalamus controls the endocrine system via the anterior and posterior pituitary gland. The hypothalamus is neural tissue, but it also has specialized neural cells that secrete neurohormones from nerve cell terminals into blood vessels in the pituitary gland. Although the output of these neurosecretory cells is endocrinological, they are morphologically similar to typical neurons and serve to bridge the neural and endocrine systems. Oxytocin and vasopressin are peptides produced in neuroendocrine cells in the paraventricular and supraoptic nuclei of the hypothalamus and released into general circulation directly via projections into the arterial blood within the posterior pituitary gland (also called the neurohypophysis). Other hypothalamic nuclei indirectly control the endocrine system through the production of neuroendocrine factors that inhibit or increase release of various hormones from the anterior pituitary gland (also called the adenohypophysis). For example, corticotropin-releasing factor and growth hormone-releasing factor regulate the release of adrenocorticotropin and growth hormone from the anterior pituitary respectively.

Finally, bidirectional communication between higher cortical regions and the hypothalamus occurs via the limbic system. In the temperature regulation example above, information from the hypothalamus to other limbic areas and the cortex can regulate complex behavior and motivation such as acting on the environment to generate cooling or mobility to a cooler environment. Cognition and emotion related to the situational context can also modulate hypothalamic responses.

Hypothesis Testing

J. Rick Turner
Cardiovascular Safety, Quintiles, Durham, NC, USA

Synonyms

Inferential statistical testing

Definition

Hypothesis testing is the core component of inferential statistics, a branch of statistics that is

employed to provide compelling evidence that two or more groups of numbers (data) differ from each other in a meaningful manner. It is therefore a strategy that facilitates provision of compelling evidence of the efficacy of a new behavioral medicine intervention or treatment.

Description

One of the most efficient ways to acquire new knowledge about any topic (including new behavioral medicine interventions) is to devise questions that guide our investigations. While relatively loosely formed questions can be helpful in early stages of the knowledge acquisition process, refining our knowledge is facilitated by asking more specific questions, and, in turn, acquiring more specific information and knowledge.

The scientific method is one particular method of acquiring new knowledge. In scientific research, our questions need to be asked in a particular manner. These questions are called research questions, and they lead to the development of two research hypotheses in each case. Turner (2007) provided an operational definition of a useful research question:

- It needs to be specific (precise).
- It needs to be testable.

Consider a new behavioral medicine intervention for pain management. To test its efficacy against a standard (existing) treatment, it is planned to conduct a randomized, controlled clinical trial. The research question of interest is:

- Is the new treatment statistically significantly more effective than the standard treatment?

Actually, the "pure" statistical version of this question asks whether there is a statistically significant difference in the efficacy demonstrated by the two treatments. This question allows for the fact that the new treatment could theoretically be statistically significantly ***less*** effective than the standard treatment as well as being significantly more effective. That is, use of a two-sided approach (hypothesis) is, in reality, appropriate here. However, we will proceed here with interest focused on just one of the two directions of differential performance of the new treatment.

The research hypotheses are commonly called the null hypothesis and the alternative hypothesis. In this author's opinion, the term "research hypothesis" is more informative than the term "alternative hypothesis," and so it is used here. The null hypothesis is the crux of hypothesis testing. For our research question, the null hypothesis would be:

- The new treatment is not statistically significantly more effective than the standard treatment.

The accompanying research hypothesis is:

- The new treatment is statistically significantly more effective than the standard treatment.

It is important to note that, whatever the outcome of the trial, the following statements are true:

- It is never the case that neither hypothesis is correct.
- It is never the case that both hypotheses are correct.
- It is always the case that one of them is correct, and that the other is not correct.

A helpful way of remembering which hypothesis is which, i.e., which form the null hypothesis takes and which form the research hypothesis takes, is to conceptualize that the research hypothesis states what you are "hoping" to find, and the null hypothesis states what you are not hoping to find (researchers who have developed a new treatment have an understandable tendency to want it to be better than other treatments). It must be emphasized here, however, that, while helpful, this conceptualization skates on very thin scientific ice. In strict scientific terms, hope has no place in experimental research. The goal is to discover the truth, whatever it may be, and one should not start out hoping to find one particular outcome. In the real world, this ideologically pure stance is not common for many reasons (financial and personal recognition reasons being not the least of them).

Statistical analysis of the data acquired in the trial conducted to compare the two treatments will enable us to decide between the two mutually exclusive hypotheses, i.e., the null hypothesis and the research hypothesis. A measure of pain reduction will be obtained for each person receiving

the new treatment (the test treatment group), and will also be obtained for each person receiving the standard treatment (the control treatment group). The mean (average) pain reduction will be calculated for each treatment group. The focus of attention can be captured by a treatment effect associated with the new treatment, which is calculated as follows: Treatment effect = Mean pain reduction in the test treatment group minus mean pain reduction in the control treatment group.

The concept of statistical significance becomes important here because it is possible for the mean pain reduction in the test treatment group to be numerically greater than mean pain reduction in the control treatment group, but for the difference not to attain statistical significance. To provide compelling evidence that the new treatment is "better" than the standard one, there must be a statistically significant treatment effect. The statistical methodology involved in determining the presence or absence of a statistically significant treatment effect is formulaic: The treatment effect is either of statistically significant magnitude or it is not. If it is, the appropriate test will ultimately produce a result in the form "$p < 0.05$" (see the ▶ Probability entry). If so, given that a randomized study design has been used, this evidence would allow the statement that the difference in magnitude between the mean response in the test treatment group and that in the control group (the treatment effect) is unlikely to have been due to chance, i.e., it is sufficiently great to be declared statistically significant. In this case, the null hypothesis is rejected in favor of the research hypothesis. If the result is "$p \geq 0.05$" statistical significance is not achieved. This result allows the statement to be made that the degree of difference in pain reduction between the two treatment groups could well have arisen by chance alone. In this case, we fail to reject the null hypothesis.

Statistical methodology necessitates a choice being made here: It is a forced choice paradigm. It is always the case that the process of hypothesis testing will result in one, and only one, of these two mutually exclusive actions.

The connection between the terms "hypothesis testing" and "inferential statistics" is a result of the following statement. The ultimate purpose of the results from a single clinical trial (or a group of related trials) is not to tell us precisely what happened in that trial, but to allow us to gain insight into, i.e., to infer in an educated manner, what is likely to happen in a much larger group of patients should the treatment make it into widespread clinical practice.

Iatrogenic Conditions

Nosocomial medical errors

Definition

Iatrogenesis refers to any unintended adverse patient outcome due to a health-care intervention not related to the natural course of an illness or injury (Agency for Healthcare Research and Quality).

Description

Iatrogenic conditions may be both preventable (e.g., medical error, negligence, consumer decisions) and unpreventable (e.g., the side effects of chemotherapy). The study of iatrogenic conditions has largely been in the acute care hospital. Two Institute of Medicine reports describe the staggering prevalence and ramification of medical errors and elevated patient safety as a major concern in health care and among policymakers. The first report, *To Err is Human: Building a Safer Health System* estimated that preventable medical errors resulted in 44,000 and 98,000 deaths per year at a cost of up to $29 billion in unnecessary health-care expenses, disability, and lost income (Kohn, Corrigan, & Donaldson, 1999). The second report, *Crossing the Quality Chasm* emphasized the need to reengineer health-care delivery, and defined six aims of health care. The report called for care to be safe, effective, patient-centered, timely, efficient, and equitable (Institute of Medicine, 2001).

The rate of preventable adverse events continues to increase. In a study published in 2011, the National Center for Policy Analysis estimates that there are as many as 187,000 preventable iatrogenic deaths in hospitals and as many as 6.1 million injuries, both in and out of hospitals (Goodman, Villarreal, & Jones, 2011). Iatrogenic complications, in general, are related to medications (adverse drug events), therapeutic or diagnostic interventions, nosocomial infections, and environmental factors.

Adverse Drug Events

Inappropriate drug prescribing, polypharmacy, administration errors, and suboptimal adherence by the patient are common preventable causes of adverse drug events (ADEs). Medication reconciliation upon admission, transfer, and discharge is a key strategy to maintain medication safety. The use of electronic medical records that provide information (e.g., past diagnoses and lab studies), educational prompts, and warnings

M.D. Gellman & J.R. Turner (eds.), *Encyclopedia of Behavioral Medicine*,
DOI 10.1007/978-1-4419-1005-9,

(e.g., allergy alerts and contraindications) are used to reduce errors in prescribing. The Institute for Safe Medication Practices provides guidelines for the use of well-designed standard order sets, safe automated dispensing, and medication labeling both in acute and community settings (The Institute for Safe Medication Practices Guidelines).

Guidelines for rational drug prescribing, particularly critical in the older adult, are another strategy to prevent ADEs. The Beers criteria address two key areas: (1) medications or medication classes that should generally be avoided in persons 65 and older and (2) medications that should be avoided in older persons with specific medical conditions. The Centers for Medicare & Medicaid Services (CMS) have incorporated the Beers criteria into regulatory guidelines in long-term care. The Joint Commission (TJC) describes prescribing that is incompatible with the criteria as a potential sentinel event in hospitals. While the Beers criteria for inappropriate medications are an accepted guideline for assessing *potential* inappropriate medications, they need to be used in conjunction with clinical assessment of the individual patient's clinical presentation and needs (Swagerty & Brickley, 2005).

Patient understanding of medications needs to be addressed as a potential barrier to medication adherence. The National Quality Forum (NQF) identified the "teach back" method as an essential safe practice to improve health care (National Quality Forum, 2005). Asking the patient to recount what he or she has been told can help gauge the level of understanding and facilitate individualized educational approaches. This method is recommended for all types of provider settings.

Therapeutic or Diagnostic Interventions

Excessive venipuncture increases the risk of anemia, infection, phlebitis, and venous thrombotic embolism (VTE). Another common complication, especially in persons with diabetes mellitus and preexisting renal insufficiency, is nephropathy induced by the use of contrast dye. When a radiocontrast dye is deemed necessary, a low-osmolar agent should be used at the lowest dose possible, with careful hydration before and after the procedure. Medical procedures, such as thoracentesis and cardiac catheterization, have also been linked to preventable adverse effects, such as cardiac arrhythmias, bleeding, infection, and pneumothorax. Aspiration deaths due to barium, emollient laxatives, and contrast medium; colonic perforations due to endoscopy or enema; and complications associated with percutaneous endoscopic gastrostomy tubes are not uncommon.

Older adults in any setting, but particularly the acute care hospital, are at risk for "geriatric syndromes" which can be caused by inadequate care processes and environmental factors. Functional decline, delirium, falls with injury, and pressure ulcers are associated with the use of restrictive devices and immobility, prolonged use of invasive lines, lack of attention to nutrition, sensory deprivation, inappropriate medication use, inadequate pain control, and environments that do not accommodate age-related changes. Bed rest, in and of itself, can have serious negative effects on older patients and is associated with greater risk for venous thrombotic embolism (VTE), orthostatic hypotension, pneumonia, anorexia, constipation, and fecal impaction (Creditor, 1993).

Iatrogenesis can also occur due to misdiagnosis. For example, the older woman who presents to the emergency department with shortness of breath and abdominal discomfort may not receive appropriate evaluation for a myocardial infarction because of her "atypical presentation." She suffers from underdiagnosis due to the provider's lack of knowledge of aging pathophysiology. Similarly, psychological conditions may be underdiagnosed as well as overdiagnosed. For example, a normal bereavement reaction can be pathologized and described as major depression, leading to inappropriate pharmacologic therapy rather than grief counseling.

Nosocomial Infections

Common nosocomial or facility-acquired infections include those of the urinary tract, those

related to intravascular devices, and pneumonia. Potentially preventable and antibiotic-resistant infections include those of the skin (e.g., methicillin-resistant *Staphylococcus aureus*), urinary tract (e.g., vancomycin-resistant *Enterococci*), oropharyngeal (e.g., *Candida* species), and gastrointestinal (e.g., *Clostridium difficile*). Antibiotic resistance is associated with overprescribing of antibiotics, cross-colonization due to poor hand-washing techniques of health-care workers, and the transfer of colonized patients between institutions.

The use of indwelling urinary catheters is associated with urinary tract infections. In addition to aseptic technique during insertion and careful catheter hygiene, providers are advised to avoid their use whenever possible. Also, implementing systems that prompt providers to review the need for the catheter and encourage early removal are warranted (CDC Guidelines for Prevention of Catheter-Associated Urinary Tract Infections, 2009).

Intravascular infections are related to central intravenous or intra-arterial lines. Organizational practices to limit their occurrence include: the use of antimicrobial catheters, proper disinfection of the skin, and prompt removal of the catheter as soon as possible and whenever there is clinical evidence of infection. Factors associated with nosocomial pneumonia include gastric aspiration, fecal-oral spread of pathogens, spread from the hands of health-care personnel, and cross-contamination from other patients. Nosocomial pneumonia is most common in critically ill, ventilated patients. Preventive measures include proper hand-washing and cleaning of respiratory and medical (including stethoscopes) equipment and maintaining the patient in an upright position to prevent aspiration of gastric contents (CDC (Center for Disease Control) Guidelines for Preventing Health-Care–Associated Pneumonia, 2003).

Environmental Factors

The physical environment of health-care facilities, especially hospitals, may pose fall hazards and limit patient mobility and physical activity. Thus, they may actually contribute to iatrogenic outcomes such as fall-related injuries, skin breakdown, and functional decline, especially in older patients or those who are physically or cognitively challenged. Cluttered walkways, hallway glare, beds and toilets not at the proper height to promote safe transfers, noise levels that interfere with sleep, and lack of access to assistive equipment are frequent culprits. Thus, comfort, enablement of physical activity, and safety are important attributes of a health-care environment.

The social environment, particularly the dynamic between the patient and the health-care worker can also contribute to functional and other outcomes. Communication that is encouraging and insightful can motivate patients and facilitate involvement in function-focused care, thus mitigating risk for falls, pressure ulcers, and functional decline. Additionally, collaboration among the interdisciplinary team and inclusion of patients in decision-making is critical. A collaborative relationship between clinicians, health-care workers, and the patient to attain mutually agreed upon goals can foster more patient control, self-care, and autonomy and prevent iatrogenesis (Berntsen, 2006).

Illness Behavior

Health behaviors; Sickness behavior

Definition

Illness behavior refers to any actions or reactions of an individual who feels unwell for the purpose of defining their state of health and obtaining physical or emotional relief from perceived or actual illness. These behaviors include how individuals monitor and interpret bodily sensations, utilize healthcare resources, discuss illness or symptoms with providers, and adhere to prescribed medical regimens.

Illness behaviors can be organized into two broad categories:

- *Self-care behavior* – Any action taken to manage or improve a health condition in the absence of direct medical attention, which includes managing symptoms and caring for minor injuries. Research indicates that a majority of health problems are managed via self-care behaviors and that most individuals will attempt self-treatment prior to seeking medical attention.
- *Healthcare utilization behavior* – Any action that involves direct use of healthcare services (e.g., medical appointments, medical procedures).

Variation in illness behavior is often attributed to psychological and sociocultural factors and can be characterized as a continuum with both ends constituting abnormal illness behavior. On one end of the continuum, illness perceptions and behaviors are disproportionate to objective pathology (e.g., hypochondriasis) and often involve debilitating psychological distress and overuse of health services. Less debilitating

presentations have been termed *hypochondriacal tendencies* or *health anxiety* and can also include overuse of healthcare services, unnecessary medical tests, missed work, and subjective distress. Overuse of healthcare resources has often been attributed to secondary gains (i.e., external rewards associated with illness, such as missed work). On the other end of the continuum, *delay* in seeking medical care or underuse of health services can have life-threatening consequences, particularly when medical conditions require early detection and treatment (e.g., stroke).

Context is important in determining if an illness behavior is functional or potentially harmful. That is, illness behaviors that might be considered maladaptive in one illness context may serve an adaptive function in another context. For example, denial regarding injury severity may be adaptive during early stages of spinal cord injury (SCI) recovery because it may serve to lower anxiety and allow for active participation in therapies necessary to achieve functional gains. In later stages of SCI recovery, however, denial may interfere with long-term adjustment to disability. Therefore, providers are encouraged to consider the context of behaviors with respect to disease characteristics when maladaptive illness behaviors are suspected.

Illness behavior also includes behavioral presentation and communication with healthcare providers. The nature of patient-provider interactions is determined, in part, by the patient's cultural background and psychological characteristics (e.g., personality, anxiety) and can influence subsequent delivery of services, as well as patient satisfaction with medical care. For example, research suggests that ethnic minorities may be less verbally expressive and assertive compared to Caucasians, and physicians may provide more biomedical information to low-anxious patients. Treatment adherence, which includes taking medication as prescribed as well as making recommended lifestyle behavior changes (e.g., weight loss), is another form of illness behavior with obvious consequences for health outcomes. Beliefs in the *cause* of illness and the *effectiveness* of the prescribed treatment are both associated with adherence.

Illness Cognitions and Perceptions

Health beliefs; Illness representations

Definition

The terms *illness perceptions* and *illness cognitions* are used to describe a range of cognitive processes underlying attention, interpretation, and behavior in response to illness-related information. Although often studied in the context of various disease populations (e.g., diabetes, cancer), illness cognitions and perceptions are also relevant in the absence of a diagnosed health condition and have important implications for subsequent illness behavior (e.g., self-care, healthcare utilization, treatment adherence).

Description

Self-assessment of health, which includes symptom perception, interpretation, and reporting, is central to illness-related self-regulatory behavior (i.e., self-care decision making, communication with healthcare providers, commitment to treatment regimens, etc.). Underestimation or overestimation of illness status can lead to inappropriate illness behavior, such as overuse or avoidance of healthcare services. Health self-assessment may have better predictive utility than some objective indicators of health with respect to health outcomes. For example, global health ratings have been found to predict mortality above and beyond objective indicators of health (e.g., documented medical conditions, such as hypertension).

Treatment adherence and health outcomes research often focuses on cognitive and perceptual factors contributing to illness behaviors, examining how individuals define illness and monitor illness status. Various cognitive models have attempted to account for variations in symptom perception and interpretation, though most emphasize information processing.

Information-Processing Models

From a cognitive-perceptual standpoint, input received about physical health status, whether from internal (e.g., body sensations) or external (e.g., healthcare professionals) sources, must be processed and cognitively organized. This organization will then affect how illness is managed. Therefore, information-processing models attempt to understand how subjective interpretations of illness exert influence on illness behavior relative to the objective disease characteristics.

- *Bottom-up Information Processing:* Somatic sensations serve as indicators of potential disease or health risks; thus, interpretations of illness are determined, in part, from somatosensory experiences. In support of this supposition, research suggests that functional difficulties (e.g., shortness of breath) are likely to figure more prominently than medical indicators (e.g., prescribed medication) in subjective estimates of illness severity. Although bottom-up models emphasize somatic experience early in the temporal sequence of unfolding illness perceptions, the importance of previous illness exposure and/or illness beliefs is not entirely discounted.
- *Top-down Information Processing:* Schema-driven, or top-down, information-processing models propose that previously formed expectations influence the perception and interpretation of illness-related information. From this perspective, illness status is evaluated by integrating somatosensory experiences into an underlying cognitive framework. This model presumes that stable mental representations of health-relevant information influence the processing and reporting of physical symptoms. Experimental cognitive research supports this notion, although very little is known about the accuracy of illness-related information processing.

The Common-Sense Model of Self-regulation (CSM)

This prominent model of lay representations of health and illness hypothesizes that illness cognitions function as a filter and interpretive schema for illness information, which subsequently guides illness-related actions and behaviors. *Illness information* is posited to come from three main sources: (1) socio-cultural knowledge and communication related to the illness,

(2) esteemed members of the person's social environment (e.g., doctor, spouse, parent), and (3) direct personal experience. Qualitative, anthropological, and psychological research utilizing patients' accounts of illness has identified five logical themes or dimensions that characterize illness representations:

- *Cause* – beliefs regarding factors responsible for causing and perpetuating the illness or disease, including biological, emotional, environmental, psychological causes
- *Consequences* – beliefs regarding the impact of the illness on functional capacity and overall quality of life
- *Identity* – beliefs about the illness label (e.g., diabetes) and attribution of symptoms to the illness (e.g., extreme fatigue)
- *Timeline* – beliefs about the course of the illness (i.e., chronicity) and timescale of illness symptoms (e.g., acute, chronic, episodic)
- *Cure/controllability* – beliefs about the effectiveness of coping behaviors or treatment on the course of illness

These dimensions are thought to interact to affect illness behavior. For example, research indicates that individuals for whom the illness identity involves high threat and attribution of many symptoms to the identity label are more likely to view their illness as uncontrollable, chronic, and as having serious consequences for their lifestyle. Conversely, patients who view themselves as having greater control over their illness appear to be more likely to view their illness as less chronic and with fewer consequences. In addition, research suggests that the cure/control-consequence relationship appears to be dependent on the timeline dimension, and the identity-timeline relationship appears dependent on the consequence dimension.

Illness Cognitions and Illness Management

The Common-Sense Model explicitly links illness cognitions to coping behaviors, which in turn affect outcomes. Research supports the notion that active self-care behaviors are more likely to occur if they are perceived to be efficacious, and a disease seen as controllable is likely to result in cognitive reappraisal of the illness. Conversely, perceiving the illness as uncontrollable, chronic, and highly symptomatic appears to be associated with coping strategies characterized by denial and avoidance. Cognitive constructs from the *Health Belief Model* have also been examined in the context of illness management behavior. In particular, the perceived threat of a health problem, along with cost-benefit appraisal of available strategies, influences the likelihood that any given illness management strategy will be adopted. Research has also demonstrated in a variety of patient populations that non-adherence is related to doubts about the necessity of prescribed treatment, as well as to concerns about the potential adverse effects of the treatment. For example, an individual who views his or her illness as acute with limited long-term consequences is less likely to adhere to prescribed medical treatment, even if the treatment is viewed as effective and with limited adverse effects.

Abnormal Illness Cognitions and Perceptions

For some individuals, self-assessments of health become a source of preoccupation, emotional distress, and chronic disability. In clinical populations, this is referred to as *hypochondriasis*, which is defined as a preoccupation with the belief that one has a serious disease, based on misinterpretation of bodily symptoms. This belief occurs in the absence of known organic pathology and persists despite appropriate medical evaluation and reassurance. Less debilitating presentations of these characteristics have been termed *hypochondriacal tendencies* or *health anxiety*, which suggests that hypochondriasis may be best conceptualized along the spectrum of anxiety disorders.

Similar to the development of other anxiety-related conditions, health anxiety and hypochondriasis are thought to result from an underlying sensitivity to threatening stimuli (e.g., bodily sensations, illness status). Individuals with health anxiety are more likely to interpret physical sensations as signs of physical

illness, as well as over-attend to health-relevant information (with a bias toward illness-confirming information). Frequent medical consultations or seeking out medical information often follow, which can potentially perpetuate illness concerns.

Individuals with hypochondriacal tendencies have also been found to have catastrophic *interpretations* of somatic information. Consistent with these findings, individuals high in health anxiety have been found to rate themselves at greater risk of medical complications than those lower in health anxiety. Patients high in health anxiety are also more likely to recall medical reassurance as less certain in ruling out serious health problems.

Survey of the extant literature suggests that a combination of risk factors, including temperament, personality, prior experience with illness during childhood, and social development, contributes to likelihood of health anxiety, hypochondriacal tendencies, or hypochondriasis. For example, those most at risk may be high in the personality factor neuroticism and have a history involving significant illness-related events and with parent modeling of overconcern or overattention to bodily symptoms.

Treatment Implications

Understanding illness beliefs from the perspective of the individual is essential for changing maladaptive illness behaviors. For this reason, application of the Common-Sense Model has important implications for healthcare providers. Appreciating an individual's illness representations can introduce outlets for patient education and physician intervention, and these types of discussions may be important for preventing functional disability. Tailoring interventions to specific illness cognitions or perceptions is likely to increase the effectiveness. For example, interventions targeting unrealistic perceived consequences are likely to differ from those targeting unrealistic perception of illness timeline. Effective psychological interventions, such as Cognitive-Behavioral Therapy (CBT), focus on changing illness perceptions, reducing unhelpful perceptions, and improving coping skills, and may lead to enhanced functional ability (e.g., improved health or work outcomes).

Illness Perceptions Questionnaire (IPQ-R)

Jane Upton
School of Sport and Exercise Sciences, University of Birmingham, Edgbaston, Birmingham, UK

Definition

The illness perceptions questionnaire measures an individual's beliefs and feelings about their illness.

The Revised Illness Perception Questionnaire (IPQ-R) is a widely used quantitative measure of the five components of illness representations in Leventhal's self-regulatory model (Moss-Morris et al., 2002). It has been validated for a range of chronic conditions in a wide variety of languages. The five components include:

- Identity in which patients rate the number of symptoms they perceive to be part of the illness
- The cause of the illness
- The timeline of the illness, how long they think it will last
- The consequences of the illness, including whether they perceive it to be a serious condition
- Whether they think the illness can be cured or controlled

These components showed good test-retest reliability, with correlations ranging from .46 to .88 (Moss-Morris et al., 2002).

Definition

Immune function describes the body's response to infection (i.e., the invasion by microorganisms), neoplasms (cancers), and tissue damage.

Description

Successful immune function establishes a state of immunity (Latin: *immunitas*, "freedom from") against infection and disease. Immunity relies on a multifaceted and flexible defense system, the immune system that protects against microorganisms, like bacteria and viruses, and other foreign invaders, like toxins. The immune system also regulates repair processes in response to tissue damage, and it protects against neoplasms (cancers). The immune system does not operate autonomously. It is, among others, influenced by central nervous system processes and their

neurohormonal outflows, which, in turn, are shaped by social and psychological factors. Likewise, activities of the immune system have profound effects on those in the central nervous system, influencing mood, behavior, and cognition.

Immune protection may come at price; the immune system responds in a vigorous manner to perceived threats, which sometimes causes substantial collateral damage to healthy cells and tissues. We experience this as disease symptoms. Damage inflicted by the immune system is also the problem in autoimmune diseases, whereby, for reasons not completely understood, the immune system selects and destroys healthy bodily cells. Hence, the paradoxical observation is that medical treatment often aims to suppress immune system responses, instead of enhancing.

This section provides a brief description of the immune system and its main components in nonjargon terms. The end of this section lists a number of references that provide a more technical and detailed exposition.

The White Blood Cells

Immune function is mediated by an enormous variety of cells and molecules that act together in a dynamic network, whose complexity rivals that of the nervous system. The white blood cells, or leukocytes, are the main effectors of immune responses and are as a collective also described as "immune cells." These cells detect, intercept, and destroy bodily threats. The leukocytes are generated in the bone marrow by so-called hematopoietic progenitor cells and come in three main subtypes: the neutrophils, which make up 70% of leukocytes in the blood; the monocytes (10%); and the lymphocytes (20%). These numbers are somewhat misleading in that the majority of leukocytes (98%) are not in the blood but dispersed in the various tissues, where numbers and proportions of various leukocytes greatly vary from one anatomical location to another and from those in the blood.

The lymphocytes comprise B lymphocytes, T helper lymphocytes, cytotoxic T lymphocytes, and natural killer (NK) cells. The B lymphocytes produce soluble receptors, called antibodies or immunoglobulins, which bind to targets of the immune system, flagging them for destruction. Targets of immune cells and molecules are subsumed under the generic term "antigens," which is an abbreviation of *anti*body *gen*erator. The main function of T helper cells is to orchestrate immune responses via the release cytokines. Finally, the main function of cytotoxic T lymphocytes and NK cells is to destroy infected cells, in particular, cells infected by viruses. They also play an important role in destroying cancerous cells. They do so via the release of toxic substances which induce programmed cell death, or apoptosis. Apoptosis is a process of controlled cellular self-destruction whereby the cell's DNA disintegrates. One of the benefits of this type of cell killing is that the cell dies from the inside, i.e., without rupture (lysis) of its cell membrane, so that infectious viral particles will not leak out and infect other cells.

Innate and Adaptive Immunity

Whereas the immune system consists of many different cell types, each with unique functions in maintaining immunity, these cells are essentially grouped into two classes based on the mechanisms used to detect antigens, i.e., (1) innate immune cells (also denoted as nonspecific or nonadaptive immunity) and (2) adaptive immune cells. The former group of cells utilizes antigen receptors that detect general molecular structures that are common to many microorganisms, the so-called pattern recognition receptors. Examples are receptors that detect double-stranded RNA (ribonucleic acid, which is not produced by human cells and must therefore come from foreign organisms) or receptors that detect lipopolysaccharide (molecules which are only produced by certain bacteria).

By far, most immune cells utilize the above innate immune detection mechanisms, and only the T and B lymphocytes are classed under the adaptive immune system. In contrast to cells of the innate immune system, adaptive immune cells use highly specialized antigen receptors that are capable of recognizing only a single molecular structure. This high specificity, and thus diversity, implies that the number of immune cells expressing a particular antigen receptor

must be low. To generate sufficient numbers of antigen-specific cells needed to eliminate an infection, these adaptive cells divide ("proliferate") upon encountering their cognate antigen, a process that can take up several days. As a result, adaptive immune responses are initially slow, but this disadvantage is compensated by their unique capacity to learn from previous encounters. This immunological memory is established by retaining a reserve of so-called memory cells which perform immune surveillance after the antigen is eliminated. These memory cells respond more swiftly and in greater numbers upon a subsequent reencounter with the antigen, resulting in rapid and effective antigen elimination which prevents the development of disease. This ability to develop immunological memory is exploited by vaccines, whereby small amounts of antigen are injected to produce memory cells against that antigen.

Cytokines: The Messenger Molecules of the Immune System

Cytokines can be regarded as the neurotransmitter and hormones of the immune system and regulate virtually all cellular activities in the immune system and communication among immune cells. Like neurotransmitters, these protein molecules can act in an autocrine or paracrine fashion, or like hormones, act on longer distances (endocrine) via release in to blood stream. Significantly, these molecules also have important regulatory roles outside the immune system. Indeed, many nonimmune cells and tissues have receptors for cytokines which can substantially affect their activities. For example, the effects of cytokines, especially the so-called inflammatory cytokines (see section on The Immune Response and Inflammation below) on the central nervous system is responsible for so-called sickness behavior: a depression-like syndrome characterized by reduced physical and social activity, altered sleep, and negative affect. Likewise, the effect of cytokines on liver, fat, and muscle cells has pronounced metabolic implications, which, depending on the type of cytokine, involves altered glycolysis, fat storage, and insulin resistance. Moreover, many cells and tissues that do not belong to the immune system are themselves capable of producing cytokines. This fact has significant implications for the interpretation immunological data in behavioral medicine research. For example, a short bout of intense physical exercise can elevate the levels of the cytokine IL-6 (interleukin 6) up to 1,000%, which is produced by muscle cells and not by immune cells. Likewise, the oft reported association between depression and elevated cytokine levels in the blood is at least in part accounted for by cytokines released by fat tissue.

The Blood, the Lymphatic System, and the Lymphoid Organs

Most leukocytes continuously traffic into and out of the various tissues in search of antigen and in order to present their finds to other immune cells. The lymphatic vessels and the blood are the transport routes for this trafficking. These routes are also employed to distribute soluble molecules, such as antibodies and cytokines, throughout the body. The lymphatic vessels primarily act as a drainage system, which collects tissue fluid and transfers it into the blood circulation. The lymphatic system does not have a pump, and the drained tissue fluid (lymph) is circulated mainly as a result of muscle activity. Lymphatic vessels pass through lymphoid organs, which are small nodular organs where leukocytes congregate. These local leukocytes interact to exchange antigen that was captured in the upstream tissues and to sample the passing lymph for the presence of antigens. Leukocytes evade the lymph nodes via downstream lymphatic vessels that terminate into the blood circulation; from there, they migrate into the tissues to eliminate infections, cancerous or damaged cells, or they migrate to other lymphoid tissues in further search of antigen. The spleen is a large lymphoid organ that specifically filters the blood, in a manner similar as described above.

The Immune Response and Inflammation

To attract immune cells to sites of infection or tissue damage, the immune system initiates an inflammatory response. This essential part of most immune responses starts with the local

release of cytokines (categorized as inflammatory cytokines, such as TNF-a (tumor necrosis factor-alpha), IL-1b, IL-8) and other chemicals. These messengers are released by tissue cells and local immune cells that have detected molecular signals of infection and tissue damage. The release of these messenger substances has several effects as follows: (1) they attract circulating immune cells into the tissue (a process known as chemotaxis); (2) they affect the local blood vessels by making the vessels leaky, so protective substances from the blood can leak in the tissue, and by making the surrounding blood vessels sticky, via the expression of adhesion molecules that facilitate immune cells to migrate out the blood; (3) they cause local warming of the tissues (pyrogenic effects). These immunological mechanisms underlie the defining symptoms of inflammation: swelling, redness, pain, heat, and diminished tissue function.

Further consequences of the inflammatory response is an enhanced migration of resident immune cells to the draining lymphoid organs (see section above), where they alert other immune cells and hereby initiate larger involvement of the immune system, and the release of inflammatory cytokines into the blood stream. The latter provides a signal for systemic adaptation to inflammation, which involves the release of anti-inflammatory substances that help to keep the inflammation localized (e.g., cortisol from the adrenal cortex and C-reactive protein (CRP) from the liver), metabolic adaptations (e.g., via effects on fat and glycogen stores), and sensory and behavioral adaption (via effects on the nervous system).

Description

Introduction

In 1884, the editor of the *British Medical Journal* noted that at funerals, "the depression of spirits under which the chief mourners labour at these melancholy occasions peculiarly predisposes them to some of the worst effects of the chill." Despite many such anecdotes suggesting a link between psychological factors and immune function, it is only relatively recently that these associations have received widespread acceptance in the scientific and medical communities. In fact, as recently as 1984, an editorial piece in *Nature* proclaimed the persistence of a "stout band of near skeptics" who, while acknowledging that "there is probably a link between the central nervous system and the immune system," still questioned whether "enough is yet known to sustain people's hopes of explanation" (Maddox, 1984). The prodigious development of the field of psychoneuroimmunology (PNI) over recent decades is more thoroughly reviewed elsewhere (Ader, 2000; Fleshner & Laudenslager, 2004); these articles clearly illustrate that, although many mechanisms still require further delineation, the progress of PNI, in terms of the quality, quantity, and impact of the research, has exceeded the expectations of all but its most optimistic forefathers. These endeavors have revealed the complex intertwining of the nervous, endocrine, and immune systems that underpin the effects of stress on immunological health.

What is Stress?

Walter Cannon first coined the term "stress" in this context in 1929, describing it as an emergency mechanism that mobilizes energy for fight-or-flight responses. Richard Lazarus proposed that the initiation of this stress response, be it an emotional (i.e., anger, anxiety), behavioral (i.e., running from threat), or biological response (i.e., cardiovascular changes, immune alterations), is governed by a person's perception of their ability to cope with a particular stimulus. Psychological stress occurs, therefore, when a person's perceived ability to cope with a situation is exceeded by the demands of the perceived stressor (Lazarus & Folkman, 1984). One way of broadly categorizing psychological stress is into chronic and acute forms of stress. Chronic stressors are typically major life experiences, such as bereavement or caregiving for an ill family member, that have a negative impact lasting months or even years. In contrast, acute stressors, such as public speaking or examinations, are short lived, lasting minutes to hours, and typically elicit fight-or-flight responses. In PNI research, chronic stressors can be investigated by comparing the health and/or immune function of a group of participants who have been exposed to a particular stressful life event to a non-stressed matched control group. Alternatively, questionnaires can be used to assess the extent of the chronic stress experienced by an individual, either by indicating how many of a checklist of life events they have experienced in a set period of time or through more subjective measures such as perceived stress. Acute stress exposure can be manipulated experimentally; for example, psychological and immunological measures can be timed to coincide with naturalistic and predictable acute stressors, such as examination periods. In addition, there are a variety of validated laboratory procedures, such as the Trier Social Stress Task and the Paced Auditory Serial Addition Task, which can be used to induce acute stress in order to examine its immunological consequences.

Physiological Effects of Stress

Although a multitude of factors are likely to underpin the effects of stress on health, stress-induced alterations in immune function are clearly an important mechanism. Stress triggers a cascade of physiological responses, which provide a plausible pathway linking psychological factors with immune function and subsequent health. The two neuroendocrine pathways that have received most attention in the PNI literature are the hypothalamic-pituitary-adrenal axis (HPA) and the sympathetic-adrenal-medullary (SAM) axis. HPA axis activation is initiated during stress at the paraventricular nucleus of

the hypothalamus which secretes corticotropin-releasing hormone (CRH). This causes the pituitary gland to release adrenocorticotropic hormone (ACTH), which in turn elicits the production of immunomodulatory glucocorticoids, such as cortisol, from the adrenal glands.

In the SAM axis, activation involves preganglionic sympathetic nervous system (SNS) neurons that descend along the spinal cord from nuclei in the brain stem. The release of the neurotransmitter acetylcholine from these neurons in the adrenal medulla stimulates chromaffin cells to secrete the catecholamine epinephrine. In contrast, postganglionic SNS fibers predominantly secrete the catecholamine norepinephrine upon activation. Therefore, activation of the SAM leads to the release of both epinephrine and norepinephrine. These catecholamines can influence immune cells as all leukocytes express adrenergic surface receptors. In addition, postganglionic nerve fibers directly innervate lymphoid organs including the thymus, spleen, lymph nodes, and bone marrow and therefore come into close proximity with immune cells (Glaser & Kiecolt-Glaser, 2005).

It should also be noted that immune cells can also influence the SAM and HPA axis and subsequently impact brain function and psychological responses. Inflammatory cytokines, released during infection, can access the central nervous system through leaky regions in the blood-brain barrier, via specific transport molecules on the brain epithelium, and through the activation of vagal afferent fibers. These cytokines influence neurotransmitter and CRH function and can induce symptoms of "sickness behavior," including anorexia, anhedonia, and reduced locomotor activity. It has been proposed that these changes in behavior reflect a reallocation of available resources, away from metabolically expensive activities such as foraging, toward behaviors likely to promote recovery from infection (Kelley et al., 2003).

Stress, Immune Function, and Disease

Psychological stress is implicated in the pathogenesis and exacerbation of many diseases and pathologies. For example, there is now evidence that stress can promote tumor growth and progression in a variety of cancers. These effects are likely to be mediated at a number of levels, including changes to local inflammatory signaling supporting initial tumor cell growth and proliferation and stress hormone-induced changes to cancer cell-matrix attachments, cell movement and invasion, angiogenesis, and sensitivity to apoptosis (Armaiz-Pena, Lutgendorf, Cole, & Sood, 2009).

There is also a substantial body of evidence linking psychological factors such as chronic stress, depression, and coping strategies with various markers of HIV progression. Further, behavioral interventions designed to improve psychological functioning have had some success in modifying disease-relevant markers of immune function (Antoni, 2003). It has been proposed that these associations between stress and HIV progression are likely mediated predominantly by changes in sympathetic nervous system activity, leading to alterations in cellular vulnerability to infection and innate antiviral responses (Cole, 2008).

The PNI models of cancer and HIV are both consistent with the model in which stress is associated with decrements in immune function which leave the host vulnerable to tumor growth or infection. However, there is also evidence that stress exacerbates diseases in which the overactivity, rather than underactivity, of the immune system is implicated. For example, stress has been proposed to be an "aggravating factor" in asthma, where those people with asthma exhibit worsened symptoms during periods of psychological stress (Chen & Miller, 2007). These observations are contrary to the intuitive perspective that a stress-induced reduction in immune activity would be beneficial for patients with conditions characterized by excessive inflammation. Instead, research has shown that in asthma, stress accentuates the inflammatory response in the airway induced by allergens and irritants, leading to more severe symptoms (Chen & Miller, 2007). Taken together, there is clear evidence that psychological stress impacts the prognosis in a variety of different diseases via neuroendocrine-immune mechanisms.

Stress and Immune Function in Healthy Populations

Psychological stress can also affect the immune function of otherwise healthy individuals. One of the most dramatic demonstrations of this phenomenon was a series of studies conducted by Sheldon Cohen in which he gave 394 healthy participants nasal drops containing live respiratory viruses. Psychological stress, measured by questionnaire, was associated in a dose-response manner with an increased risk of acute infectious respiratory illness. As the extent and timing of the exposure to the pathogen was controlled, these studies provide compelling evidence that stress impacts the individual's ability to protect themselves against infection. Later studies suggest that this effect is mediated by stress-induced disruption of the regulation of proinflammatory cytokines (Cohen, 2005).

However, a key challenge for scientists investigating stress and immune function in healthy people is choosing an appropriate outcome measure in the absence of the disease-specific indicators. The immune system comprises a complex array of different cell types that are required to orchestrate precise and appropriate responses to a wide range of pathogens, all within the context of a variable neuroendocrine milieu. Not only are these cells required to work together in order to produce an effective immune response, what constitutes "effective" may change depending on the nature of the pathogen. For example, different immunological responses are required for intracellular viruses, compared to bacteria or parasites. As such, it is difficult to establish meaningful measures of "effective immune function" in healthy participants. The wide range of psychological and immunological measures employed by researchers to date is demonstrated in an excellent meta-analysis by Segerstrom and Miller, which examines the results of over 300 PNI studies (Segerstrom & Miller, 2004).

This entry will focus on two in vivo measures of immune function, wound healing and antibody response to vaccination, in which an immunological "challenge" is administered and the subsequent immune response is assessed. These approaches assess the functionality of an orchestrated immune response, generated within the neuroendocrine milieu, and yield clinically relevant outcome measures. For example, the wound-healing process involves a complex series of processes, including inflammation, cellular migration and replication, and connective tissue deposition and remodeling; each stage is regulated by the cellular immune system. Wound healing can be assessed using naturalistic wounds, such as those experienced by patients with venous disease or by examining incisions administered during surgery. A more controlled method that also allows greater investigation of the mechanisms underpinning any stress effects involves administering an experimental wound and assessing the rate of healing over time. A recent systematic review and meta-analysis found that higher levels of psychological stress were consistently associated with impaired wound healing across a variety of different wound types (Walburn, Vedhara, Hankins, Rixon, & Weinman, 2009).

Antibody response to vaccination is another in vivo measure of immune function that has clear clinical implications. The controlled dose of an inactivated antigen induces a complex immune cascade that culminates in the production of specific antibodies; the extent of this response can be used as a measure of the functional status of the humoral immune system (Burns & Gallagher, 2010). There is now considerable evidence that chronic psychological stress is associated with a poorer antibody response to many different vaccinations (Cohen, Miller, & Rabin, 2001). However, more recent research has demonstrated that acute stress can, in contrast, augment the immune response to vaccination (Edwards, Burns, Carroll, Drayson, & Ring, 2007), potentially due to the rapid mobilization of immune cells during acute stress (Segerstrom & Miller, 2004).

Models of PNI

Although early PNI research focused on the immunosuppressive effects of stress, more recently, it has become apparent that the precise implications for the immune system are

dependent on the nature of the stressor. For example, the recent meta-analysis revealed that although chronic stressors were consistently associated with suppression of immune function, acute stressors often upregulated some parameters of immunity. Further, as chronic stress has been shown to affect diseases characterized by both reduced and excessive immune function, it is apparent that it may be the balance of immunological parameters that is critical (Segerstrom & Miller, 2004). As an added layer of complexity, there is also evidence that the effects of stress on immunity are not consistent across individuals, even when the stressor is identical; differences in personality traits and cognitive and affective responses may also account for some variation in stress-induced immune changes (Kemeny, 2009).

In terms of the implications of such changes, it is likely that stress-induced immune alterations are part of an adaptive response to threat that serves to enhance immunoprotection. This model postulates that situations of acute stress are likely, from an evolutionary perspective, to be associated with an increased risk of wounding or infection and, therefore, upregulation of immune function in such circumstances would be beneficial. If, however, this upregulation is directed against harmless allergens or self-antigens, or indeed it is dysregulated through chronic activation, it is likely to contribute to immunopathology (Dhabhar, 2002). An alternative, ecological model of human PNI has recently been proposed, which instead suggests that even chronic stress-induced immunosuppression is part of a coordinated effort to efficiently conserve resources, rather than a sign of dysregulation (Segerstrom, 2010). This ecological perspective emphasizes "phenotypic plasticity," in which the value of a trait, such as robust immune activity, varies according to the environmental circumstances. Thus, immunosuppression during times of chronic stress may simply reflect a change in organism priorities toward the pursuit or protection of resources; the cost of reduced immunoprotection may, in these circumstances, be offset by the longer term health benefits of having these resources.

Conclusion

An array of compelling evidence now indicates that stress is associated with changes in immune function in both healthy and patient populations. Plausible physiological pathways through which psychological factors can influence cells of the immune system have been identified and explored, although there is much still to determine. It is now important to more fully elucidate the clinical implications of these changes and to translate these findings into effective biopsychosocial interventions.

Immunity (Latin: *immunitas*, "freedom from") describes a state of adequate defense against infection, i.e., bodily invasion by microorganisms. Immunity is established by the activities of the immune system (see entry on "▶ Immune Function"). Immunity also used to describe a state of adequate defense against neoplasms (cancers) insofar the immune system is involved. The entry on "▶ Immune Function" provides further details on the main types of immunity (innate and adaptive) and mechanisms by which the immune system establishes a state of immunity. Definition

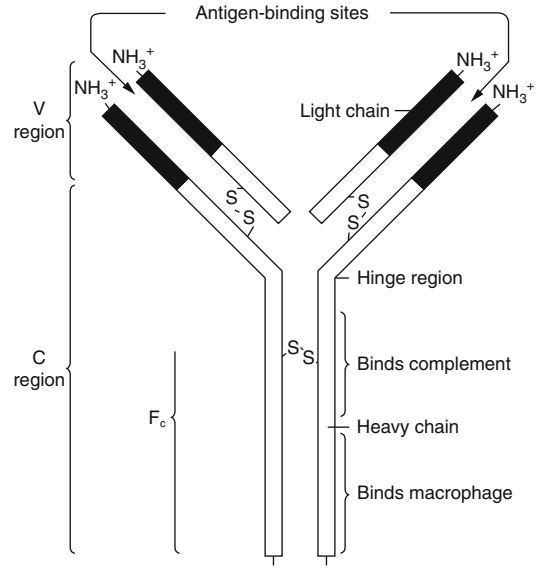
Immunoglobulins (Igs) are a subclass of antibodies which are produced in the early stages of

B-cell development (Abbas & Lichtman, 2006). The structure of Igs can differ between class types; however, they are built from a number of the same basic units known as immunoglobulin domains (Fig. 1). These are formed from 110 similar, but not identical, amino acid sequences which fold to form a globular structure. Each Ig is composed of two identical myosin heavy chain and two identical myosin light chain units, connected by a number of disulfide bonds. The Fab region is where different antigens bind to depending on the Ig subtype and is known as the antigen binding site. The first immunoglobulin domain possesses a large variability of amino acid sequences which determine the antigen-binding specificity of the antibody molecule, thus allowing great diversity of antigen recognition. The hinge region allows some flexibility of the molecule when binding with other cells. The Fc region is known as the constant region which aids modulation of immune cell activity.

Igs are a part of the immune system known as humoral immunity, which involves immunity conveyed by extracellular fluid such as plasma, lymph, and saliva. Basic functions of antibodies include neutralization, opsonization, and complement activation. The myosin heavy chain formation results in the subclass of antibody produced, of which there are 5 major classes: IgA, IgG, IgM, IgE, and IgD. Each isotype is selectively distributed throughout the body and differs in its effector functions. For example, IgG and IgM dominate in the circulation, IgA dominates within epithelial secretions (e.g., mucosa), and IgE is mostly found near the epithelial surfaces (e.g., skin).

Production of Igs within the immune system begins with the naïve B cell. As these B cells mature, they begin to express both IgM and IgD, and after antigenic activation, these Igs often switch to express a different heavy chain constant region. This is known as class switching and results in a change in effector function of the antibody produced. For example, a mature B cell may alter expression from IgM and IgD to IgG or IgE after antigen activation. IgE is formed by attachment to mast cells which are involved during allergic reactions.



Immunoglobulins, Fig. 1 Immunoglobulin structure (Newsholme & Leech, 2010) (Reprinted with permission)

During a primary response to infection, the major Ig subtype used is IgM, as the B cells are immature and not yet specific to a particular antigen. However, during this initial response, memory cells specific to that antigen are created. During the secondary antibody response, these memory cells are activated and secrete primarily IgG, IgE, or IgA. IgG is also secreted earlier during the secondary response, therefore creating a shorter lag period. This occurs for all T-dependent antigens due to B cells requiring costimulation with an activated antigen-presenting cell in order to produce Igs. T-independent antigens do not require the presence of T cells in order to produce an antibody response. However, due to the lack of cell signaling from the T cell, no isotype switching or generation of B-cell memory can occur. Thus, antibody response to T-independent antigens is almost exclusively IgM, and no secondary response occurs (Abbas & Lichtman, 2006).

Prediabetes

Definition

The US National Diabetes Data group (1979) first introduced the term impaired glucose tolerance (IGT) to indicate a state of increased risk of progressing to diabetes. It was defined to reduce the stigma of being labeled with diabetes and was also noted that many individuals with IGT could revert back to normal.

According to the World Health Organization and the International Diabetes Foundation (World Health Organization, 2006), IGT is diagnosed if 2-h plasma glucose levels are between 7.8 and 11.1 mmol/l or 140 mg/dl and 200 mg/dl as measured by the oral glucose tolerance test, or if fasting glucose levels are less than 7.0 mmol/l. Two-hour plasma glucose is the level of glucose or the venous plasma glucose 2 h after ingestion of 75 g of oral glucose load. Blood glucose levels normally rise after eating a meal and then gradually fall as the meal is digested. However, in people with impaired glucose tolerance, these levels remain elevated.

In comparison, the definition of type II diabetes mellitus is 2-h plasma glucose levels more that 11.1 mmol/l (200 mg/dl). Therefore, IGT is not a clinical entity but is a risk factor for future diabetes and/or adverse outcomes and denotes individuals in the range between "normal" and diabetes.

Description

Characteristics

IGT is associated with muscle insulin resistance and defective insulin secretion, resulting in less efficient disposal of the glucose load (World Health Organization, 2006). It has been shown that carrying extra body fat inhibits the effectiveness of insulin therefore any glucose that does reach the muscle will have its journey delayed. If this continues untreated, then blood glucose levels will eventually increase into the diabetes range.

It has also been recognized that IGT is associated with increased risk for cardiovascular disease (Fuller, Shipley, Rose, Jarrett, & Keen, 1980). The Whitehall study found that coronary heart disease mortality was approximately double for individuals with IGT in a population of 18,403 London civil servants aged 40–64 (Fuller et al.).

Prevalence of IGT

The prevalence of IGT varies between populations and across different age groups. For example, in the United States, 15.2% of men and 16.4% of women have impaired glucose tolerance (Harris et al., 1998), and in Australia, the rates were found to be 12% in men and 14% in women (Dunstan et al., 2002). A WHO study found that rates were lowest among some Chinese, traditional American Indian, and Pacific island populations (<3%) and the highest among female Muslim Asian Indians in Tanzania (32%) and male Micronesians in Kiribati (28%) (King & Rewers, 1993).

Prevalence rates of approximately 10% or more are common, and it is typically more common in women than in men. The increasing prevalence with age was illustrated in the DECODE study which showed the prevalence of isolated IGT increasing from 2.9% in 30–39-year-old men to 15.1% in 70–79-year-old men

and from 4.5% in 30–39-year-old women to 16.9% in 70–79-year-old women.

Risk Factors

The prevalence of IGT and diabetes appears to have increased in the last 20 years, and this has been linked to the rise of obesity in many countries. Further, health-risk behaviors such as physical inactivity, smoking, and alcohol ingestion are likely to be important and closely interrelated with IGT. As aforementioned, the risk of IGT is also age related.

Women with polycystic ovary syndrome are also more at risk of IGT as they have profound insulin resistance independent of obesity. Insulin resistance is a major risk factor in developing diabetes mellitus type II.

The American Diabetes Association also listed other risk factors for IGT and diabetes which include having a parent or sibling with diabetes; having a family background that is African American, Alaska Native, American Indian, Asian American, Hispanic/Latino, or Pacific Islander; giving birth to a baby weighing more than 9 lb or being diagnosed with gestational diabetes (diabetes first found during pregnancy); having high blood pressure (140/90 or above or being treated for high blood pressure); having a high density lipo-protein (HDL), or "good," cholesterol level below 35 mg/dL or a triglyceride level above 250 mg/dL; having other conditions associated with insulin resistance, such as severe obesity or Acanthosis nigricans; and having a history of cardiovascular disease.

Prevention and Treatment

People with IGT have a one in three chance of developing type II diabetes within 10 years, but this can be minimized through healthy eating and physical activity as this helps cells respond better to insulin. The Diabetes Prevention Program (Orchard et al., 2005) carried out a randomized control trial to compare an intensive lifestyle modification intervention and the drug metformin. The study found that losing just 5–7% of body weight through a healthy low-calorie, low-fat diet and to engage in physical activity of moderate intensity reduced the incidence of metabolic syndrome (three or more of the following characteristics: waist circumference, blood pressure, levels of high-density lipoprotein cholesterol, triglycerides, and fasting plasma glucose) by 41%. Many participants in the lifestyle intervention group returned to normal blood glucose levels and lowered their risk for developing heart disease and other problems associated with diabetes. In comparison, the diabetes drug metformin reduced the risk of developing diabetes by 17%.

Implementation Intentions

Peter M. Gollwitzer and Gabriele Oettingen
Department of Psychology, New York University, New York, NY, USA

Definition

Implementation intentions are if-then plans that spell out in advance how one wants to strive for a set goal. For the if-component, a critical cue is selected (e.g., a good opportunity, an anticipated obstacle) that is linked to a goal-directed response in the then-component. Implementation intentions are known to enhance the rate of goal attainment. They do so by delegating action control to situational cues thus endowing action control with features of automaticity.

Description

Successful goal pursuit requires solving both of two subsequent tasks: first, strongly committing to goals, and then, effectively implementing them. Accordingly, strongly committing to a goal is a necessary but not sufficient step towards goal attainment. Indeed, effective goal pursuit may be hampered by various problems such as failing to get started and to stay on track as well as overextending oneself. Finally, people may fail to disengage from futile means and unattainable goals. Meta-analytic findings suggest that goals (also referred to as goal intentions) account for no more than 28% of variance in goal-directed behavior (Sheeran, 2002). One remedy to impaired goal pursuit is – after one has strongly committed to a goal – to plan out in advance how one wants to deal with potential critical situations (i.e., by adding implementation intentions to one's goal intentions).

Gollwitzer (1999) highlighted the importance of furnishing goal intentions with implementation intentions. While goal intentions (goals) have the structure "I intend to reach Z!" with Z relating to a desired future behavior or outcome, implementation intentions have the structure "If situation X is encountered, then I will perform the goal-directed response Y!" Thus, implementation intentions define when, where, and how one wants to act on one's goal intentions. In order to form an implementation intention, individuals need to identify a goal-relevant situational cue (such as a good opportunity to act, or an obstacle to goal striving) and link it to an instrumental goal-directed response. Goal intentions merely specify a desired future behavior or outcome. On the contrary, the if-component of an implementation intention specifies when and where one wants to act on this goal, and the then-component of the implementation intention specifies how this will be done. For instance, a person with the goal to reduce alcohol consumption might form the following implementation intention: "And whenever a waiter suggests ordering a second drink, then I'll ask for mineral water!" Empirical data supports the assumption that implementation intentions help close the gap between holding goals and attaining them. A meta-analysis based on close to a hundred studies shows a medium to large effect on increased rate of goal attainment ($d = .61$; Gollwitzer & Sheeran, 2006).

Implementation intentions facilitate goal attainment on the basis of *psychological mechanisms* that pertain to the specified situation in the if-part and to the mental link forged between the if-part and the specified goal-directed response in the then-part of the plan (Gollwitzer & Oettingen, 2011). Because forming an implementation intention implies the selection of a critical future situation, the mental representation of this situation becomes highly activated and hence more accessible. This heightened accessibility of the if-part of the plan has been observed in several studies using different experimental tasks (e.g., cue detection, dichotic listening, cued recall, lexical decision, flanker).

However, forming implementation intentions not only heightens the activation (and thus the accessibility) of the mental presentation of the situational cue specified in the if-component but it also forges a strong associative link between the mental representation of this cue and the mental representation of the specified response. These associative links seem to be quite stable over time, and they allow for activation of the mental representation of the specified response (the then-component) by subliminal presentation of the specified critical situational cue (if-component). Moreover, mediation analyses suggest that both cue accessibility and the strength of the cue-response link together mediate the impact of implementation intentions on goal attainment.

Gollwitzer (1999) suggested that the upshot of the strong associative links between the if-part (situational cue) and the then-part (goal-directed response) created by forming implementation intentions is that – once the critical cue is encountered – the initiation of the goal-directed response exhibits features of automaticity. These features include immediacy, efficiency, and redundancy of conscious intent. As a consequence, having formed an implementation intention allows individuals to act in situ without having to deliberate on whether to act or not. Indeed, there is vast empirical evidence that if-then planners act more quickly, deal more effectively with cognitive demands (i.e., speed-up effects still evidence under high cognitive load), and do not need to consciously intend to act in the critical moment. Consistent with this last assumption, implementation intention effects are observed even when the critical cue is presented subliminally or when the respective goal is activated outside of awareness.

The processes underlying implementation intention effects (enhanced cue accessibility, strong cue-response links, automation of responding) help if-then planners to readily see and to seize good opportunities to move toward their goals. Forming an if-then plan thus strategically automates goal striving. People can intentionally make if-then plans thus delegating control of goal-directed responses to preselected situational cues. This strategic automation hypothesis has recently been supported by studies that collected brain data using either electroencephalography (EEG) or functional magnetic resonance imaging (fMRI), suggesting that by forming implementation intentions, people can switch from top-down control of their actions via goals to bottom-up control via specified situational stimuli. Research on mediating processes has also supported the strategic automation hypothesis, albeit in an indirect way. Numerous studies indicated that neither an increase in goal commitment nor an increase in self-efficacy qualified as potential alternative mediators of implementation intention effects.

But what about *potential moderators* of implementation intention effects on goal striving and goal attainment? First, implementation intentions only benefit goal attainment when goal commitment is high; the same is true with respect to people's commitment to executing the formed implementation intention. In addition, self-efficacy was found to moderate implementation intention effects. Prompting participants to form an implementation intention as to when, where, and how to pursue their most important New Year's resolution (e.g., to engage in regular physical exercise) and in addition reflect on past mastery experiences (i.e., situations in which they achieved a similar goal) led to significantly higher levels of self-reported goal progress compared to a mere implementation intention condition. In a recent study where high versus low self-efficacy was manipulated (by asking participants to solve low- or high-difficulty goal-relevant tasks), it was observed that high-self-efficacy participants showed stronger implementation intention effects than low-self-efficacy participants, especially when the tasks to be solved were difficult rather than easy.

Finally, certain personal attributes have been found to moderate implementation intention effects. For instance, socially prescribed perfectionists (i.e., people who are known to try to conform to standards and expectations of others) show weaker implementation intention effects. Possibly social perfectionists may fail to commit to implementation intentions because they feel that social

expectations and standards will change quickly and unpredictably; flexible responding to such circumstances may be impeded by strong commitments to the preplanned course of action as specified in implementation intentions. Moreover, conscientiousness moderates implementation intention effects. Increases in goal attainment are only found for low conscientious individuals, whereas high conscientious individuals often show perfect goal attainment to begin with and thus goal attainment cannot be enhanced. The moderation of implementation intention effects by conscientiousness is in line with the common finding (Gollwitzer & Sheeran, 2006) that implementation intention effects are generally observed to be stronger for difficult than for easy goals.

Which aspects of goal striving have been found to benefit from forming implementation intentions? The effects of implementation intentions have been demonstrated with respect to getting started, staying on track, disengaging from faulty goals and means, as well as avoiding resource depletion (Gollwitzer & Oettingen, 2011). Implementation intentions were found to help individuals to get started with goal striving in terms of remembering to act (e.g., regarding taking vitamin pills, contraceptive pills, influenza vaccination), not missing opportunities to act (e.g., regarding obtaining a mammography), and overcoming an initial reluctance to act (e.g., regarding undertaking a testicular self-examination). Moreover, goals to perform regular breast examinations or cervical cancer screening and to resume activity after joint replacement surgery were all found to be more readily acted upon by individuals who previously had formed implementation intentions.

However, many health goals (e.g., eating a healthy diet, regular physical exercise, reducing alcohol consumption or smoking, downregulating anxiety) cannot be accomplished by a simple, discrete, one-shot action, because they require that people keep striving over an extended period of time. Staying on track may then become very difficult when certain internal stimuli (e.g., being tired, stressed out) or external stimuli (e.g., temptations, distractions) interfere with the desired goal pursuit. Implementation intentions can be used to protect started goal strivings from interferences stemming from both inside and outside the person. Such implementation intentions may use very different formats. For instance, if a person with the goal to eat healthy foods wants to stay firm with respect to seductive offers of unhealthy snacks, she can form suppression-oriented implementation intentions, such as "And if my colleague approaches me offering a snack, then I will not take the snack!" The then-component of such suppression-oriented implementation intentions does not have to be worded, however, as not showing the critical behavior (in the present example "not taking the snack"); it may alternatively specify a replacement behavior ("..., then I will ask for an apple!"), or focus on ignoring the critical cue ("..., then I'll ignore his offer!"). Recent research suggests that mere negation implementation intentions are less effective than the latter two types of implementation intentions (i.e., replacement and ignore implementation intentions).

Two further types of implementation intentions have been proven effective to master temptations and disruptions. The first one specifies the temptation as a situational cue and links it to thinking of the goal as the response in the then-component. The second one specifies an ongoing activity – that is independent of the temptation – as a situational cue and links it to continuing this activity as the response in the then-component. Using, again, the example of a person who has to cope with a seductive offer from a colleague, let us assume that the person already anticipated receiving the tempting offer during an upcoming encounter with this colleague; she therefore formed an implementation intention stipulating in advance what she will converse about when she runs into him. The interaction with the colleague can then come off as planned as the seductive offer will not have a chance to disrupt the course of action (i.e., the conversation).

Goal striving that is no longer promising may require individuals to disengage from a chosen means or the goal altogether. Such disengagement can free up resources and minimize negative

affect. However, individuals often stick to a chosen goal or means too long thus hurting themselves (e.g., setting a too demanding exercise goal, choosing improper means to reach the goal). Implementation intentions can be used to promote adaptive disengagement by (1) specifying negative feedback as a critical cue and (2) linking this cue to switching to a more promising alternative goal or means. Indeed, when research participants were asked to form implementation intentions that linked negative feedback on the ongoing goal striving to immediately switching to a different goal or means, or to reflecting on the quality of the received failure feedback on the ongoing goal striving, adaptive disengagement from goals and means was found to occur more frequently than for participants who had only formed respective goal intentions or had formed no intentions at all.

Finally, forming implementation intentions can help prevent resource depletion as it enables individuals to engage in automated goal striving and behavior control that does not require effortful deliberation (e.g., forming implementation intentions to ask for available vegetarian dishes when a waiter takes one's order). As a consequence, the self should not become depleted when goal striving is regulated by implementation intentions. Indeed, in studies using different ego-depletion paradigms, research participants who used implementation intentions to self-regulate performance on a difficult first task did not show reduced self-regulatory capacity in a subsequent task.

But how much willpower is actually afforded by forming implementation intentions? Any self-regulation strategy that claims to facilitate goal striving has to prove itself under conditions in which people commonly fail to demonstrate willpower. Such conditions are manifold (e.g., when one's competencies are challenged, opponents interfere with one's goal striving), but self-regulation of goal striving becomes particularly difficult when habitual responses are in conflict with initiating and executing the needed goal-directed responses that are instrumental to goal attainment. Can the self-regulation strategy of forming if-then plans help people to let their goals win out over their habitual responses? By assuming that action control by implementation intentions is immediate and efficient and adopting a simple horserace model of action control, people might be able to break habitual responses by forming implementation intentions (e.g., if-then plans that spell out a response contrary to the habitual response to the critical situation). Still, if the habitual response is based on strong habits (e.g., smoking) and the if-then guided response is based on weak implementation intentions, the habitual response should win over the if-then planned response. However, when weak habits are in conflict with strong implementation intentions, the reverse should be true. This implies that controlling behavior based on strong habits by forming implementation intentions requires that these if-then plans are very strong as well.

The strengthening of if-then plans can be achieved in various ways: One pertains to creating particularly strong links between situational cues (if-component) and goal-directed responses (then-component), for instance, by asking participants to use mental imagery. Alternatively, one may tailor the critical cue specified in the if-part of an implementation intention to personally relevant reasons for the habitual behavior one wants to overcome, and then link this cue to an antagonistic response (e.g., if I feel lonely, then I will put on the music in the living room rather than snack in the kitchen). Also, certain formats of implementation intentions (i.e., replacement and ignore implementation intentions) seem to be more effective in fighting strong habits than other if-then plans (e.g., negation implementation intentions). And finally, stronger implementation intention effects are observed when the respective goals are framed as approach rather than avoidance goals and when goals and plans match in their self-regulatory orientation (i.e., either promotion or prevention). Pertaining to the discussion of whether strong habits can be broken by implementation intentions, one should keep in mind that behavior change is possible without changing bad habits; one may also focus on - building new habits in new situational contexts. With respect to this latter approach,

implementation intentions can guide goal striving without having to outrun habitual responses. The delegation of control to situational cues principle, on which implementation intention effects are based, can then unfold its facilitative effects on goal striving in an undisturbed manner.

Trying to achieve behavior change by solely forming implementation intentions however forgets that effective behavior change demands a change in terms of both setting new goals and preparing the respective goal striving by forming implementation intentions. But how can people best select and commit to new goals? Oettingen (2012) has developed a self-regulation strategy of goal setting, called mental contrasting of future and reality that allows people to strongly commit to achieving desired and feasible future outcomes. Specifically, in mental contrasting, people imagine the attainment of a desired future (e.g., regular exercise) and then reflect on obstacles of present reality that stand in the way of attaining the desired future (e.g., not setting aside enough time). Given that the perceived chances of success (expectations of success) are high, people will actively commit to and strive toward reaching the desired future.

One recent behavior change intervention (called MCII; summary by Oettingen & Gollwitzer, 2010) combines mental contrasting (MC) with forming implementation intentions (II). To unfold their beneficial effects, implementation intentions require that strong goal commitments are in place and mental contrasting creates such strong commitments. Implementation intentions are also found to show enhanced benefits when the specification of the if-component is personalized, and mental contrasting guarantees the identification of personally relevant obstacles that can then be specified as the critical cue in the if-component of an implementation intention. Finally, mental contrasting has been found to create a readiness for making plans that link obstacles of present reality to instrumental goal-directed behaviors.

In recent intervention studies with middle-aged women, participants were taught the cognitive principles and individual steps of the MCII self-regulation strategy. Specifically, in one study, participants were asked to apply MCII by themselves to the wish of exercising more. Participants were free to choose whatever form of exercising they wished to engage in, and they were encouraged to anticipate exactly those obstacles that were personally most relevant. Finally, they had to link these obstacles to exactly those goal-directed responses that personally appeared to be most instrumental. Teaching the MCII technique enhanced exercise more than only providing relevant health-related information (i.e., information-only control intervention). Participants in the MCII group exercised nearly twice as much: an average of 1 h more per week than participants in the information-only control group. This effect showed up immediately after the intervention, and it stayed stable throughout the entire period of the study (16 weeks after the intervention). Conducting the same MCII intervention was also effective for promoting healthy eating in middle-aged women (i.e., eating more fruits and vegetables). The achieved behavior change persisted even over a period of 2 years. Follow-up research targeting the eating habit of unhealthy snacking was conducted with college students. It was observed that MCII worked for both students with weak and strong such habits, and it was more effective than either mental contrasting or forming implementation intentions alone. Moreover, MCII was observed to benefit chronic back pain patients in increasing their mobility over a period of 3 months, whereby physical mobility was measured by objective measures (e.g., bicycle ergometer test) as well as self-reported physical functioning.

In sum, MCII qualifies as a cost- and time-effective self-regulation intervention to enhance healthy and to prevent unhealthy behaviors. It helps to solve the two central tasks of goal pursuit: forming strong goal commitments on the one hand and following up on these commitments by effective goal implementation on the other. Not surprisingly, then, combining mental contrasting with implementation intentions offers additional advantages compared to each strategy alone.

Definition

The meaning of this complex construct is widely debated, including whether it is a stable aspect of personality (trait) or a behavior (state). Most descriptions center on negative aspects and include a reference to behavior executed rapidly without forethought and/or self-control, failure of attention, delay discounting, or probability discounting. There are four main types of impulsivity measures: observer-rated scales (e.g., diagnostic interviews), self-report questionnaires (e.g., Barratt Impulsiveness Scale), behavioral laboratory measures (e.g., reward-choice paradigms), and biological measures (e.g., event-related potentials).

Description

Reacting quickly without forethought can be prudent. For instance, a race-car driver whose split-second decision results in victory is exhibiting functional impulsivity, characterized by rapid response time. However, particularly in psychology, emphasis is placed on the causes and negative outcomes of impulsive behavior. For example, if the same driver skips a race to visit friends, he or she is engaging in dysfunctional impulsivity, characterized by an inability to sustain attention.

The Diagnostic and Statistical Manual of Mental Disorders (DSM-IV TR) defines clinically significant impulsivity in terms of interference in daily functioning. In the description

of attention deficit/hyperactivity disorder (ADHD), impulsivity is referred to as "impatience, difficulty delaying responses,... and frequently interrupting... to the point of causing difficulties in social, academic, or occupational settings" (American Psychiatric Association, 2000, p. 86). Great overlap and confusion exists between the concepts of impulsive behavior (motivated by a desire to release tension and/or feel pleasure) and compulsive behavior (motivated by a desire to alleviate anxiety).

Delay and Probability Discounting

Devaluing an outcome (positive or negative) in relation to the length of time that will elapse before it occurs is known as delay discounting. Research has found that children prone to delay discounting – e.g., preschoolers who opt to have one marshmallow now instead of two after a short delay – are more likely to struggle socially and academically in later years (Madden & Bickel, 2009). Devaluing an outcome (reward or punishment) according to the likelihood of its occurrence is known as probability discounting. Both constructs are hypothesized to play key roles in impulsive behavior.

Evolutionary psychologists point out that these tendencies, which favor present rewards, likely benefited early humans, whose lives were often short and unpredictable. Missing out on a meal or a mate in the short term in hopes of finding a better option later could result in ruin under such circumstances. Research suggests that modern humans in economically disadvantaged or dangerous environments are more likely to engage in impulsive behavior, including delay and probability discounting (Grant & Potenza, 2011; Madden & Bickel, 2009).

Related Health Outcomes

Impulsivity is a key feature in many mental disorders (e.g., ADHD, addictions, mood disorders) and unhealthy behaviors (e.g., drunken driving, overeating). Along with sensation seeking, impulsivity plays a role in risky sexual behavior (e.g., unprotected sex, many partners) and alcohol and drug use, all of which increase HIV risk. It is also theorized that impulsivity may partially account for increased HIV prevalence among those with personality disorders, particularly of the antisocial and borderline varieties (Millon, Grossman, Millon, Meagher, & Ramnath, 2004).

Definition

In vitro fertilization (IVF) is a method of assisted reproductive technology (ART) in which eggs are exposed to sperm in a laboratory, and the resulting embryos are placed into the uterus to achieve a pregnancy.

Description

In vitro fertilization (IVF) is a method of assisted reproductive technology (ART) in which eggs are exposed to sperm in a laboratory, and the resulting embryos are placed into the uterus to achieve a pregnancy. In order to obtain eggs, female patients take medications to stimulate available eggs to move forward toward ovulation. Ultrasound and blood testing monitor the ovarian response. Ultrasound-guided egg retrieval is performed when the eggs are thought to be mature. Once removed, the eggs are exposed to sperm in the laboratory, or in vitro (from the Latin root 'within glass'). Eggs can either be placed with sperm and incubated overnight (conventional in vitro fertilization) or a single sperm can be injected into each egg (in vitro fertilization with intracytoplasmic sperm injection or ICSI). ICSI is usually used to compensate for low levels or poorly functioning sperm. After incubating overnight, embryos are examined to see if fertilization occurred. The fertilized embryos are returned to the incubator for an additional 1–5 days, until they are either transferred into the uterine cavity or frozen for future use. The number of embryos transferred depends largely on the age of the recipient woman and the family planning goals of the intended parents. The American Society of Reproductive Medicine has published guidelines to limit the number of transferred embryos to reduce the likelihood of multifetal gestations. Some countries legislate the maximum numbers of embryos to transfer to reduce the risk of multiple births, instead favoring additional cycles using previously frozen eggs or embryos. Beginning with ovarian stimulation and ending with embryo transfer, one IVF cycle can be accomplished in an approximately 2-week time period; a pregnancy test occurs 2 weeks after the embryo transfer.

Pregnancy rates per IVF cycle vary widely, and clinics have published success rates that range from 10% to 70%. These rates depend, among other factors, on the woman's age, ovarian reserve, medical comorbidities, capabilities of the laboratory facility, and the technical expertise of the laboratory staff. Pregnancy rates can be reported in many ways: pregnancy or live birth per IVF cycle, per egg retrieval or per embryo transfer.

The percentage of IVF cycles that result in the delivery of a viable fetus is called the live birth rate.

Frozen embryos can be thawed for future pregnancies. Women take medications to prepare their uterus for embryo transfer, but do not need to repeat ovarian stimulation. Once a patient or couple completes their family, unused frozen embryos can be donated (to other people or to research) or discarded.

Third Party Reproduction

In vitro fertilization has created opportunities for third party reproduction where another party provides sperm, eggs, embryos, or the use of their uterus so a person or couple can become parents. There are four distinct entities of third party reproduction; some patients require the combination of multiple entities.

Gestational Carrier: A gestational carrier is a woman who agrees to carry, labor, and deliver a child for another person or couple. Gestational carriers assist intended parents who do not have a uterus or in whom pregnancy is medically unsafe. Carriers are usually financially compensated for their services.

Egg Donation: Egg donors undergo ovarian stimulation and egg retrieval to provide an egg for fertilization in the IVF process. The egg can be fertilized with either donated or the intended father's sperm. The resulting embryo is then transferred into the intended mother or gestational carrier. Egg donors can be known or anonymous. Anonymous donors and some known donors are usually financially compensated for services.

Sperm Donation: Sperm donors provide sperm that can be placed inside a uterus to inseminate a woman (intrauterine insemination or IUI) or used to create an embryo by in vitro fertilization that can then be transferred into the uterus of an intended mother or gestational carrier. Generally, sperm donors are financially compensated for their services.

Embryo Donation: Unused embryos from previous IVF cycles can be donated to another patient or couple hoping to become parents. These embryos can be donated in fresh or frozen form and can be transferred into the intended mother or gestational carrier.

The American Society of Reproductive Medicine recommends the routine use of legal and psychological counseling when planning third party reproduction.

Expansions, Controversies, and Disadvantages of In Vitro Fertilization

As cancer treatments have become more successful, IVF has found a role in trying to preserve a woman or man's fertility prior to undergoing cancer treatment. Since radiation and chemotherapy are toxic to egg and sperm, men and women with cancer are often unable to reproduce after undergoing cancer treatments. Eggs, sperm, or embryos can be frozen prior to chemotherapy to facilitate pregnancy after they complete their cancer treatments. This emerging field of science within infertility is called oncofertililty.

Another adjunct to the IVF process is preimplantation genetic diagnosis (PGD) where genetic testing is used to screen embryos for a genetic disease carried by one or both of the parents. Embryos that are continuing to grow in the laboratory are biopsied on the third or the fifth day after egg retrieval. The embryo biopsy is then tested for the genetic difference the couple carries (e.g., mutations that would cause cystic fibrosis or sickle cell disease). Selection of embryos after PGD can prevent delivery of a child affected with a genetic disease. Use of PGD for gender selection or family balancing is highly controversial.

The combination of assisted reproductive technology and third party reproduction has allowed postmenopausal women to become pregnant at any age. The main concerns with pregnancy at greater age are the increased health risks to the mother during pregnancy and shorter time to parent because of her advanced age. Proponents contend that more important than a parent's age is the commitment to a child's well-being. Some countries do not legally allow postmenopausal women to become pregnant which has resulted in some patients traveling abroad to pursue IVF.

Frequently reported disadvantages of IVF and ART include high cost, increased rate of multiple gestations (twins, triplets, etc.), inability to guarantee success, and medications and procedures

that impart medical risk for the female patient. A single IVF cycle can cost upward of US $8,000–$15,000. In the United States, insurance coverage varies between states. A few states have mandated coverage in which insurers providing pregnancy-related benefits must also provide for the diagnosis and treatment of infertility including IVF. This discrepancy between states within one country exemplifies the ongoing debate as to whether or not parenthood is a right and fertility treatments should therefore be paid for with government funding, or a privilege that only the medically insured and/or affluent can afford.
