Income Inequality and Health

Douglas Carroll
School of Sport and Exercise Sciences, University of Birmingham, Edgbaston, Birmingham, UK

Synonyms

Income distribution

Definition

Income inequality is usually defined as the proportion of national income and benefit enjoyed by a specified proportion, say 50%, of the least well-off in society. Occasionally, it has been measured using something called the Gini coefficient, which is a statistical measure of dispersal. Applied to national or state income distribution, a Gini coefficient of 0 would reflect total equality, whereas 1 reflects complete inequality. Egalitarian countries such as Japan and Sweden have Gini coefficients ca. 0.25, whereas more unequal countries like the UK and USA have coefficients ca. 0.36 and 0.41, respectively.

Description

That health varies with socioeconomic position in Western societies is now commonplace. Irrespective of how socioeconomic position is measured, by occupational status, income, level of education, or neighborhood deprivation, it shows a consistent negative association with most measures of ill health, all-cause mortality, cardiovascular and cancer (with the exception of breast cancer in women) mortality, various major

morbidities, and subjective ill-being. The association, however, is not a matter of the very poorest in society suffering from very poor health while the rest enjoy uniformly good health. Rather, there is a continuous gradient linking health outcomes to fine gradations in socioeconomic position. The intimate relationship between sociodemographics and health is nowhere better illustrated than by studies showing that as societies becomes less egalitarian, i.e., the socioeconomic ladder gets steeper, so the contingent health inequalities increase.

Recently, this link between the socioeconomic inequalities and health has taken a step further, as a result of studies examining overall health indices in societies and how egalitarian or unequal those societies are. Studies have used two sorts of comparisons: income inequalities and health outcomes in Western countries (including Japan), such as life expectancy and mortality rate, and income inequalities and health outcomes in the USA. The leading academic players in these two enterprises are Richard Wilkinson in the UK and George Kaplan in the USA. Income inequality is variously measured in these studies, but the outcome is the same regardless.

Whatever the measure used, income distribution has been shown to be strongly associated with differences in population life expectancy and mortality rates among Western countries and states in the USA. Put simply, the populations of more egalitarian countries and states live longer. Egalitarian countries, such as Japan and the Scandinavian countries, also enjoy a host other benefits such as less obesity, lower teenage pregnancy rates, less violent crime, and higher childhood literacy rates; more equal countries even recycle more. Egalitarian states in the USA, such as New Hampshire, Vermont, and Utah, experience less violent crime and have lower rates of smoking and sedentary behavior than more unequal states, such as Alabama, Louisiana, and Mississippi.

Why might more equal countries and states apparently do so much better than unequal ones on a range of health and behavioral outcomes? Two notions have attracted consideration. The first is the idea of social capital, i.e., that more equal countries and states invest more and/or invest more inclusively and effectively in those aspects of the social infrastructure that are health promoting, such as education, health care, safe roads and transport, and so on. The other idea is that of social cohesion. It would appear that less egalitarian societies are less cohesive, engendering among their populations poorer social support and greater psychological distress, factors that have been linked to poorer physical health outcomes. Whatever the case, it is clear that not only does income inequality have a powerful effect on population health, but as income equality changes over time, so too does population health,; i.e., there are relative health benefits in a society becoming more egalitarian. Undoubtedly, the best summary of the recent research on income inequality and its consequences is by Wilkinson and Pickett (2009).

Individual Differences

Austin S. Baldwin and Valerie G. Loehr
Department of Psychology, Southern Methodist University, Dallas, TX, USA

Synonyms

Differential psychology

Definition

Individual differences in behavioral medicine include demographic, psychological, and/or behavioral dimensions that are shared by all people, but upon which individuals differ in ways that influence their health. For example, evidence suggests that five personality traits (openness to experience, conscientiousness, extraversion, agreeableness, and neuroticism) are shared among all people, but differences people exhibit on some of these traits (e.g., conscientiousness) account for differences in healthy behavioral practices, and even mortality rates.

Description

Overview

Individual differences that are known to influence health include demographic factors (e.g., race, gender, SES), psychological traits (e.g., conscientiousness, neuroticism), and behavioral dispositions (e.g., anger/hostility, coping styles). These types of individual differences influence health outcomes in a variety of ways. For example, individual differences are known to moderate how people respond to stress, account for differences in the prevalence rates of chronic illness (e.g., coronary heart disease), account for differences in healthy behavioral practices (e.g., dietary habits, regular medical screenings), and even for differences in mortality rates.

The value of considering the role of individual differences in behavioral medicine is twofold. First, because individual differences are often associated with different patterns of behavioral and physiological responses (e.g., how people respond to stress), individual differences provide a useful framework through which researchers and practitioners can understand how different behavioral and physiological responses influence health. Second, individual differences allow researchers and practitioners to identify dimensions on which different people might benefit from different interventions and treatments.

Associations Between Individual Differences and Health

The sections below include descriptions of how selected individual differences are associated with health. Descriptions of differences in demographic factors, psychological traits, and behavioral dispositions are used as examples.

Demographic Factors

Race/Ethnicity. A variety of health differences exist among different minority race/ethnic groups in the United States, including African Americans, Asian Americans and Pacific Islanders, Latinos, and Native Americans (Whitfield, Weidner, Clark, & Anderson, 2002). Brief descriptions of the differences that exist among each of these groups are provided.

African Americans have higher mortality rates compared to Caucasians, and this difference may be due primarily to higher rates of heart disease and stroke (Potts & Thomas, 1999). Related to these observations, African Americans also show greater cardiovascular reactivity to stress (Clark, Moore, & Adams, 1998). Moreover, there is

evidence that African Americans also manifest higher rates of smoking, obesity (at least among women), risky sexual behavior, and lower rates of physical activity, all of which contribute to the mortality rate.

Compared to non-Latinos, Latinos have higher rates of obesity, diabetes, and hypertension, all of which are risk factors for cardiovascular disease. These higher rates are likely due to diets low in fruits and vegetables and high smoking rates. Latinos also have higher rates of alcohol use compared to non-Latinos, but report less risky sexual behavior. In addition, acculturation among Latino populations in the United States plays an important role in health outcomes. For example, Latinos who are acculturated in the United States (e.g., English is the primary language in the household) are more likely to smoke and to do so at greater rates (Navarro, 1996). More acculturated Latinos are also at greater risk of having stroke (Ontiveros, Miller, Markides, & Espino, 1999).

Asian Americans and Pacific Islanders have the best health profile among ethnic groups in the United States, and the limited evidence suggests that this is due, in part, to lower rates of tobacco and alcohol use. Acculturation among this population is also important to health. For example, new immigrants to the United States often experience stress due to language and employment difficulties (Nwadiora & McAddo, 1996).

Native Americans have higher mortality rates relative to other groups, due to higher smoking rates, poorer diets that lack sufficient fruits and vegetables, higher alcohol use, and lower rates of physical activity. Stress due to acculturation may also contribute to higher suicide rates (Lester, 1999).

Gender. Mortality rates are higher for men than women, and men are more prone than women to nearly all of the leading causes of death (e.g., cardiovascular disease, accidents). There is not strong evidence for biological differences, but there is evidence that men have higher rates of smoking, alcohol use, and accidents. Men also have a higher prevalence of hostility, making them more prone to cardiovascular disease (Weidner & Mueller, 2000), and men cope less effectively with stress than women. Moreover, compared to women, men tend to receive less social support that can act as a buffer against psychosocial stressors.

Socioeconomic status (*SES*). Across racial and ethnic groups, gender, and age, there is an inverse relationship between SES and disease morbidity and mortality. Although it has previously been speculated that SES-related differences in health may be due to the overlap between SES groups and racial and ethnic groups (e.g., African Americans, Latinos), SES has an independent effect on health. This effect is due, in part, to higher rates of smoking, obesity, poorer dietary habits, and lower usage rates of preventive health services.

Psychological Traits

Conscientiousness is one of the five factors in the "Big Five model" of personality and is characterized by the tendency to be dutiful, organized, and industrious. Evidence suggests that conscientiousness is associated with differences in mortality rates. In one study, children who were high in conscientiousness were shown to be more likely to live to old age than those low in conscientiousness (Friedman et al., 1995). There are a number of explanations for this association with mortality rates. Conscientious people are more successful in avoiding situations that could potentially harm them, tend to have high fitness levels and healthy dietary habits (Bogg & Roberts, 2004), and are more likely to follow medical recommendations and guidelines. In contrast, individuals low in conscientiousness are more likely to use alcohol, tobacco, and drugs, and engage in risky driving and sex. (Hampson, Goldberg, Vogt, & Dubanoski, 2006).

Neuroticism is another of the five factors in the "Big Five model" of personality. It is characterized by the tendency to experience negative emotions, and is associated with fearfulness, irritability, low self-esteem, social anxiety, poor inhibition of impulses, and helplessness. Elevated levels of neuroticism are associated with an increased risk for illness, psychological distress, and an increased mortality risk in patients with chronic medical conditions

(Christensen, Moran, Wiebe, Ehlers, & Lawton, 2002). Neuroticism also affects the perception of physical symptoms. Individuals high in neuroticism tend to recognize and report their symptoms more quickly, and often present an exaggerated picture of their symptoms (Ellington & Wiebe, 1999) that can comprise a physician's ability to effectively gage a patient's condition. They are also more likely to erroneously believe they have a serious disease. For example, up to 30% of those who did not have detectable heart disease after being referred for coronary angiography were high on neuroticism (Pryor, Harrell, Lee, Califf, & Rosati, 1983).

Hardiness is a collection of personality traits that moderate the negative effects of stress. Hardiness includes the tendency (1) for involvement in, as opposed to alienation from, whatever one encounters (commitment), (2) to not feel or act helpless in the face of adversity (control), and (3) to accept change as normal in life and an opportunity for growth rather than a threat to security (challenge). There is evidence that under stressful conditions, hardy individuals are less likely to get sick than non-hardy individuals, more likely to perceive negative situations positively, and show less physiological strain than non-hardy individuals (Contrada, 1989; Maddi, 1998). However, evidence for the associations between hardiness and objective markers of physical health has been inconsistent.

Dispositional optimism is the tendency to believe that good things are likely to happen in one's life. People who are high in optimism have lower blood pressure, less risk of coronary heart disease, higher levels of pulmonary function in older men, less cancer mortality among the elderly, and less illness-related disruption of social and recreational activities among breast cancer patients compared to their pessimistic counterparts. Evidence suggests that optimism leads people to cope more effectively with stress, that in turn reduces their risk for illness and benefits their recovery from serious medical procedures. This may happen in different ways. First, the positive mood associated with optimism may lead to a state of physiological resilience. For example, the tendency to experience positive emotional states has been tied to greater resistance to the common cold (Cohen, Doyle, Turner, Alper, & Skoner, 2003). Second, an optimistic disposition may improve long-term prospects for psychological adjustment and health by promoting more active and persistent coping efforts (Segerstrom, Castañeda, & Spencer, 2003).

Behavioral Dispositions

Hostility is defined as a set of negative attitudes, beliefs, and appraisals of others that emerged from studies of Type A behavior patterns. Individual differences in hostility also include aggressive tendencies and anger. Evidence has found that individuals high in hostility are at a higher risk for coronary heart disease (CHD) and higher mortality rates than people lower in the disposition. Hostility is associated with heightened inflammatory reactions to stress and to metabolic syndrome, likely explaining its link to CHD (Niaura et al., 2002). Differences in hostility are also associated with increased rates of hypertension, stroke, and diabetes. Finally, evidence suggests that individuals high on hostility may take longer to physiologically recover from stress (Suarez et al., 1997).

Coping Styles. Individuals tend to cope with stress differently, through either avoidant or vigilant coping styles. Avoidant strategies tend to minimize the impact of the stressor by denying that a threat exists, suppressing unpleasant thoughts, or refusing to seek or attend to threatening information. In contrast, vigilant strategies involve actively seeking information about the stressor and how to deal with it. Each style has advantages and disadvantages in managing stress and its effects. Avoiding threatening events works effectively with short-term threats; for example, it may be beneficial in some medical procedures, such as blood donation or dental surgery. However, avoidance may not be useful for managing long-term or persisting threats. Evidence shows that a vigilant style allows individuals to engage in cognitive and emotional efforts needed to deal with long-term problems, but they may experience anxiety and heightened physiological reactivity as a result (Smith, Ruiz, & Uchino, 2000).

In contrast, the chronic use of avoidance may heighten the risk of the adverse effects of stressful life circumstances.

Pathways Through Which Individual Differences Influence Health

Various theoretical models suggest that individual differences, such as personality traits, influence health indirectly through their effect on people's appraisal of and coping with stressful circumstances. The differences in stress appraisal and coping then influence people's physiological and/or behavioral responses. It is the physiological and behavioral responses that then have a direct effect on illness and mortality. In other words, personality traits and behavioral dispositions are thought to indirectly effect health through their influence on stress appraisal, coping, and subsequent responses. Although there is some evidence for the individual behavioral and physiological mechanisms through which individual differences affect health outcomes, evidence for the entirety of these causal pathways is incomplete (Smith, 2006).

Evidence for Individual Difference–Based Interventions

One of the benefits of considering the role of individual differences in behavioral medicine is the ability to tailor interventions and treatments to different types of people. In the sections below, evidence in support of this approach is briefly described.

Matching Interventions to Coping Styles. Evidence suggests that patients indicate less distress during and after stress-inducing surgical procedures when they are given information and use coping strategies that match their preferred styles. For people who prefer a vigilant coping style, this includes detailed information about the procedure and directions to engage in direct forms of coping. For patients with a preference for avoidant coping, this includes providing minimal information about the procedure and directions to engage in avoidant forms of coping (Martelli, Auerbach, Alexander, & Mercuri, 1987; Miller & Mangan, 1983). Evidence from an intervention targeting mammograms suggests that women were more likely to obtain a mammogram when the message advocating mammography matched their preferred coping style – vigilant messages contained detailed information about the benefits of mammography, whereas avoidant messages contained just main points – than when the messages were not matched to coping style (Williams-Piehota, Pizarro, Schneider, Mowad, & Salovey, 2005).

Hostility-Reduction Interventions. There is evidence that patients with CHD who are also high on hostility benefit from a hostility-reduction intervention such that they reported less hostility and had lower resting blood pressure as a result (Gidron, Davidson, & Bata, 1999). There is also evidence that interventions aimed at reducing hostility and other CHD risk factors can have beneficial effects on heart rate reactivity to anger-inducing situations (Bishop et al., 2005).

A few important conclusions can be drawn from this intervention evidence. First, behavioral and physiological responses that stem from individual differences (e.g., anger/hostility) are mutable and can be changed via intervention. This highlights the importance of understanding the processes through which individual differences influence health, in order to screen for risk factors and target those that may be amenable to change. Second, behavioral interventions can be matched to individual differences in ways that facilitate optimal adjustment (e.g., matching to coping styles). It is not clear, however, whether all types of individual differences (e.g., neuroticism) would be amenable to targeted interventions.

Infant Mortality

Linda C. Baumann and Alyssa Karel
School of Nursing, University of Wisconsin-Madison, Madison, WI, USA

Definition

Infant mortality rate is the number of infant deaths, defined as children under the age of 1 year old, per 1,000 live births in a given year. Infant mortality is used as a major health indicator globally because it is associated with numerous factors that determine a country's overall level of health that include maternal health, prenatal care access, healthcare system quality and access, public health practices, and socioeconomic conditions.

Description

Another indicator used to measure the health status of a country is the under five mortality rate. The under five mortality rate is the probability of a child born in a specific year or period dying before the age of 5, expressed as a number per 1,000 live births. The World Health Organization (WHO) Millennium Development Goals (MDG) has identified the reduction of under five mortality rate by two thirds as goal number 4 to be achieved by 2015.

Variations in infant mortality rates and under five mortality rates are monitored by global regions. Child mortality rates have fallen since 1990 in all country-income groups – with the rate of decline generally faster in high-income and middle-income countries than in low-income countries. Median child mortality fell by almost 50% between 1990 and 2008 in lower middle-income countries, but by only 31% in low-income countries. In 2010, all regions of the world reported infant mortality rates below 200 per 1,000 live births. These numbers reflect a global improvement from 1970, when 40 countries had rates that exceeded this level.

Globally, infant mortality and under five mortality rates are estimated from death registration data that is reported annually to the World Health Organization. Other sources of data come from household surveys and census, especially in countries for which death registration data is not readily available. World regions with the highest infant mortality and under five mortality rates are sub-Saharan Africa and south Asia. Uganda, an example of a country in the sub-Saharan Africa region, had an under five mortality rate of 135 and an infant mortality rate of 84 according to 2008 WHO data. Regions of the world with the lowest rates are western Europe, Australia, high-income areas of Asia-Pacific, and high-income areas of North America. The UK, New Zealand, and South Korea are other high-income countries that lag behind other countries of high-income levels. In 2008, the infant mortality rate in the USA was 7 per 1,000, and the under five mortality rate was 8 per 1,000. The country with the lowest rate was San Marino, a small country located on the European continent, with a rate of 1 death per 1,000 live births. For a list of infant and under five mortality rates by country: http://www.who.int/whosis/whostat/EN_WHS10_Full.pdf.

Reaching MDG 4 will require key interventions, which include access to prenatal and perinatal care, improved child nutrition, vaccines, prevention and management of diarrhea, pneumonia and sepsis, malaria control, and prevention and care of HIV/AIDS. These interventions will lessen the impact of the six conditions for which 90% of worldwide children deaths are attributed to: neonatal causes, pneumonia, diarrhea, malaria, measles, and HIV/AIDS. According to the World Health Statistics 2010, the key to reducing infant mortality rates is the reduction in neonatal mortality, defined as the number of deaths to infants under 28 days of age in a given year. Globally, 40% of deaths in children are attributed to neonatal mortality.

Variations in mortality rates can be attributed to a country's region, but also it is largely related to the level of income of a country, with poorer countries having higher rates. Least developed countries have infant mortality rates 10 times higher and under five mortality is 25 times higher compared to higher income countries. Not only between, but also within a country, infant mortality rates reflect disparities of factors such as race,

socioeconomic status, education, and housing. For example in the USA, the gap between infant mortality rates of white and African American babies is of concern since the rate for African Americans is twice that of the rate for whites.

Infection

Definition

Infectious diseases are illnesses caused by a diverse range of microorganisms. The immune system fights against such infection. 10% of all deaths in the UK, approximately 50,000 people a year, are due to infections, overwhelmingly in the elderly and worldwide the proportion of people dying from infection is 25%. In impoverished tropical environments many children have a 1:8 chance of dying before their 5th birthday.

Description

Microorganisms which cause infection include DNA viruses, RNA viruses, bacteria, fungi, protozoa, and worms. They can also be classified according to whether they replicate inside or outside of cells. Differences between infectious agents and their sites of replication necessitate different immune mechanisms for their control. Table 1 shows the class of microorganism, where it replicates, examples, and the diseases they cause.

Mechanical Barriers to Infection

The skin provides a barrier against infection; when this is intact it provides a relatively effective protection – but it is easily breached by cuts, burns, insect bites and skin diseases. The far larger absorptive surfaces of the intestine and lungs are inevitably more fragile. Moist mucus is effective at trapping small dust particles and droplets containing bacteria or the spores of yeast and fungi. There is a markedly increased susceptibility to infection associated with defects in the mucus, as in cystic fibrosis. Congenital defects in the cilia are also associated with repeated lung infections; cilia waft mucus towards the main bronchi and trachea where it is removed by coughing.

The mouth and pharynx and upper part of the esophagus are protected by stratified squamous epithelium but the epithelium of the rest of the gut is a single layer thick. Mucus again serves to protect the intestinal wall and injury is rapidly repaired.

Infectious Diseases, Table 1 Microorganism types and the diseases they cause

Class and site of replication	Examples	Disease
DNA viruses (intracellular)	Varicella zoster	Chicken pox
	Epstein-Barr virus	Glandular fever
RNA viruses (intracellular)	Rhinoviruses	Common cold
	Rotaviruses	Gastroenteritis
Bacteria (extracellular) (Intracellular)	Staphylococci	Skin infections
	Streptococci	Tonsillitis, pneumonia, impetigo
	Salmonella	Gastroenteritis, enteric fever
	Mycobacteria	Tuberculosis, leprosy
Fungi (extracellular) (Intracellular)	Candida	Thrush
	Pneumocystis	Pneumonia
Protozoa (extracellular) (Intracellular)	Entamoeba	Colitis, liver abscess
	Plasmodium	Malaria
Worms (extracellular) (bowel)	Filarioidea	Filariasis
	Cestodes	Tapeworm

Drainage and Irrigation

Irrigation is an important means by which infection is inhibited. For example, the constant flow of urine from the kidneys helps prevent infection of the urinary tract. Blockage to the outflow of urine impairs renal function and there is a considerable danger that static urine will become infected. Tears, urine, saliva, bile, pancreatic, mucus, and even sebaceous secretions help protect the surfaces they flow over.

It follows that free drainage of secretions is important to avoid infection; blockage of the pharyngo-tympanic tube predisposes to middle ear infection – the clogged opening to a hair follicle may result in a boil.

Chemical Protection

Acid secretions of the stomach help to sterilise the partially-digested food that enters the small intestine. Many secretions contain substances that inhibit the growth or survival of microorganisms; lysozyme in tears is bactericidal and bile acids inhibit the growth of some microorganisms.

Normal Bacterial Flora

There are large numbers of bacteria on the skin, in the mouth and in the large intestine. Normally these are non-invasive commensal microorganisms that do not cause disease. The presence of this normal bacterial flora helps to inhibit the invasion of pathogenic bacteria. Loss of the normal flora associated with the use of antibiotics or excessive use of antiseptic solutions can provide an opportunity for pathogenic bacteria to colonise the vacated tissues. Staphylococcal enteritis is commonly associated with the use of antibiotics. Ingestion of large amounts of non-pathogenic bacteria, such as the lactobacilli found in yogurt, can help protect against this unwanted overgrowth of pathogens during antibiotic therapy.

Sensory Nervous System

This system is vital in protecting the body, for it warns of potential tissue damage. Impaired sensation, for example occurring secondary to lepromatous leprosy or diabetes can result in patients unknowingly damaging their skin and other tissues; the damage is compounded by secondary infections.

Good Public Health and Hygiene

Clean water supply, good nutrition and reasonable standards of hygiene in preparing food have made an immense contribution to the reduced incidence of infection and increased good health and longevity enjoyed by developed countries compared with parts of the world where these, at best, are available only erratically.

Factors Associated with Increased Susceptibility to Infection

Impairment of any of the protective systems listed above increases susceptibility to infection. Certain other factors should be considered.

The immune system cannot gain access to dead, avascular tissue; foreign bodies in the tissues can have the same effect. Examples of sites where infection can gain hold are: infarcts

(tissues that have died because their blood supply has been interrupted, e.g., by a blood clot); accumulations of fluid (e.g., bruises, abscesses, hydronephrosis) – it is important that these are drained; scar tissue such as fibrous adhesions in the peritoneal cavity following abdominal surgery; dead bone caused by lifting of the periosteum or trauma; collapsed lung tissue; other dead tissue produced by burns, trauma and chemical injury; blocked secretions and drainage e.g., middle ear infections, boils, and pyelonephritis.

Innate Immunity

The surfaces of the body (skin, mucous membranes) provide a barrier against infection. These physical barriers are reinforced by secretions. If these barriers are penetrated a wide variety of immune mechanisms utilising proteins and cells act to control and eradicate infection. These immune mechanisms are targeted by molecular recognition of the micro-organism. Micro-organisms are sufficiently different from mammalian tissues that a small range of molecules is sufficient to recognise almost any micro-organism and not interact with normal self. This finite range of molecules that recognise microrganisms is encoded in the mammalian genome and accounts for <100 of the 25,000 or so total genes. The immune mechanisms that are targeted by these molecules are classified as non-adaptive (or innate) immunity.

Adaptive (Specific) Immunity

There is a second category of immune mechanisms that is not effective when a new micro-organism is first encountered but which over a period of a week or two adapts to provide specific defence against that particular micro-organism. This specific defence system employs a variety of effector mechanisms which alone and more usually by enhancing non-adaptive immune mechanisms, efficiently control almost all infections. This is called adaptive (or specific) immunity and relies on cells called T and B, lymphocytes. These lymphocytes recognise micro-organisms by the T cell receptor and the B cell receptor respectively. The molecular part of the micro-organism that these receptors bind to is called antigen and so they are sometimes called antigen specific receptors.

Main Sources of Infectious Disease

Many bacteria have medical importance, and they can cause devastation in countries like Africa, such as *Salmonella*, but have only minor clinical importance in the West. Not all bacteria are bad in fact pure pathogens make up only a tiny number of bacterial species, although many bacteria can act as pathogens if the host becomes immunocompromised. Bacteria are essential for life and of all the cells in the body only 10% belong to the body, the overwhelming majority of the rest are bacteria, residing on surfaces such as skin, gut, mouth etc. In fact the mouth can have a greater concentration of bacteria than the gut or in faeces. This normal flora helps by, amongst other things, occupying sites pathogens would if they got the chance and there is competition between different bacterial species to reside on you as much as there is competition between bacteria and the host.

What is a Bacterium?

Bacteria are living organisms that are called prokaryotes because they lack a cell nucleus. They all contain DNA and RNA but the lack of a distinct nucleus means transcription and translation can occur concomitantly. Medically, it is important to understand the structure of a bacterium, particularly its external structure because this is the part of the organism most in contact with the host so it protects the bacterium (e.g., capsules can prevent some white blood cells called phagocytes from engulfing the bacterium) but it can also warn the host of an "intruder" (e.g., lipopolysaccharide is extremely pro-inflammatory at even tiny concentrations). Lastly, bacterial structure, particularly the cell wall, can reveal a mountain of information on what genus and species the bacterium is. Another key feature is that bacteria generally divide very rapidly, in test-tubes this generation time can be

once every 20 min (somewhat slower in vivo), although there are exceptions such as some mycobacterial species such as *M. tuberculosis* divide once a day. This compares with a division rate of about once every 6 h for a B cell and a generation for humans is 25 years. This means bacteria can evolve much more quickly than the host and it can also acquire resistance against drugs very quickly (sometimes through taking up extra bits of DNA called plasmids). This is why effective, controlled use of antibiotics is so important. To put this in context this means, in theory, 1 bacterium can become 10,000,000,000 after 12 h and every hour of delay means that there could be 10× more bacteria than before. This is why rapid treatment of aggressive infections is essential.

Bacteria come in many shapes and their shape can be used to help identify them. In 1884 a Danish boffin called Hans Christian Gram developed a technique using dyes that could differentiate between certain types of bacteria, this is the Gram's stain and historically has been very important in medicine. This is because it is speedy and economical. Although not infallible, it is very important medically because it can reveal what the bacterial species is, frequently without culturing the bug, by directly staining the biopsy or smear etc. and is able to differentiate at least four different types of bacteria: *Gram positive or Gram negative rods or cocci (round)*. It works by first adding crystal violet as a dye. This is then fixed by iodine. Addition of 95% ethanol or acetone allows the crysal violet-iodine complexes to wash away from Gram-negative bacteria but they get trapped in the thick, dehydrated peptidoglycan of the Gram-positive bacteria. Lastly a counterstain is added to visualise the Gram-negative bacteria. The whole process takes less than 5 min. Some bacteria fail to be detected by Gram staining, this may be because for instance they *lack peptidoglycan (Mycoplasma)* or have a complex cell wall (Mycobacteria). Under these circumstances different staining is required e.g., Ziehls-Neelsen stain for acid-fast mycobacteria.

What Infections are Caused by Bacteria?

Many previously destructive diseases such as syphilis, tuberculosis, tetanus and diphtheria are now well controlled in the West due to improvements in public health, vaccination and antimicrobial treatment. Elsewhere in the world they are a tragic burden that can stifle economic and social development. Some infections likely to be encountered in the West include those caused by: *Staphylococci, Staph. Aureus,* β haemolytic group A streptococci (*Strep. pyogenes* is the beast) cause many of the most severe infections, group B are usually problematic in new-born babies. *Mycobacterium tuberculosis* causes tuberculosis, Clostridia, which include: gram positive spore-forming anaerobic rods. *C. perfringens* – gas gangrene: *C. difficile* – pseudomembranous colitis. *Pseudomonas aeruginosa* – aerobic Gram-negative opportunist particularly in infections in burns. The list goes on and on: *E. coli* (Urinary Tract Infection, gut); *Campylobacter jejuni* (gut); *Salmonella* etc.

What is a Virus?

Viruses are submicroscopic, obligate intracellular parasites. They have no metabolic activity outside the host cell, and thus cannot be considered to be "alive." At the most basic level, a virus particle (virion) consists of a nucleic acid genome surrounded by a protein shell, which may also be surrounded by a membranous envelope. Virions cannot themselves "grow" or undergo division (as bacteria can) but are produced by assembly of preformed components.

Classification of Viruses

Viruses can be classified according to their genomes. These genomes can be more varied than those seen in the entire bacterial, plant or animal kingdom. Viral nucleic acid can be RNA or DNA; single stranded (ss) or double stranded (ds); negative (−), positive (+) or ambisense (+/−); linear circular or segmented. Examples of diseases caused by viruses include: Herpes Simplex Virus, adenovirus, Parvovirus, Reoviruses, Bluetongue, Hepatitis C, Polio, Yellow

Fever, Influenza, Ebola, Measles, Human Immunodeficiency Virus, human T-cell lymphotropic virus type 1, and Hepatitis B.

Virus Structure

The viral genome is wrapped up in a coat made up of multiple copies of a small number of species of protein molecules. Virus particles often form regular geometric shapes, such as helices or icosahedra. There are hundreds of virus structures.

Replication of Viruses

Viruses can replicate only when they infect a susceptible host cell. Following attachment and entry into the cell, the components of the capsid are partially disassembled and the virus begins to direct the cell to synthesise viral components. During this "eclipse" phase, where these new components are being synthesised, infectious virus cannot be recovered. Once the viral genome has been replicated and the viral proteins synthesized, new virus can be assembled. These new viruses may be released from the cell by budding or by cell lysis. The time taken for release of new infectious virus can range from minutes in the case of some viruses (foot and mouth) to several days.

Infertility and Assisted Reproduction: Psychosocial Aspects

Pamela A. Geller[1] and Alexandra Nelson[2]
[1]Department of Psychology, Drexel University Drexel University College of Medicine, Philadelphia, PA, USA
[2]Drexel University Department of Psychology UNC – Chapel Hill Department of Psychiatry, Chapel Hill, NC, USA

Synonyms

ART; Assisted reproductive technology; In vitro fertilization; Infertility-related stress; Intrauterine insemination; Involuntary childlessness; IUI; IVF

Definition

Infertility is defined as the inability to become pregnant with regular intercourse without the use of contraception within 1 year for women up to age 35 and within 6 months for women older than 35. The term infertility is not synonymous with the term sterility (i.e., the physically or medically diagnosed inability to become pregnant). Couples with diagnosed infertility may become pregnant through natural intercourse or through the assistance of fertility treatments. Such treatments range from administration of medication to more advanced techniques such as intrauterine insemination (IUI) or assisted reproductive technologies (ART) involving the handling of both sperm and egg, such as in vitro fertilization (IVF). Fertility treatments also may involve third-party reproductive options including the use of donor gametes or embryos as well as surrogates. The term involuntary childlessness may be used in

reference to individuals or couples with infertility that are unsuccessful in achieving pregnancy or live-birth delivery. Psychosocial aspects refer to the stressors (i.e., psychological, social, and structural) and consequences associated with infertility and assisted reproduction.

Description

Background and Epidemiology

Infertility is a fairly common condition that affects 72.4 million individuals worldwide. In the USA, 7.4% of married couples of reproductive age experience infertility and 12% of couples experience more broadly defined "subfecundity," which includes difficulties becoming pregnant or carrying a pregnancy to term. Risk for infertility increases with age, particularly among women over 35 years. Rates vary with sociodemographic characteristics, with greater risk of infertility among Hispanic and non-Hispanic black women and women who have not completed college (Chandra, Martinez, Mosher, Abma, & Jones, 2005). Couples may experience "primary infertility" during their first attempt to conceive or "secondary infertility" during attempts to conceive subsequent to prior successful conception. Secondary infertility is more common, with 35% of couples unable to have a second child and approximately 70% of women with infertility having been pregnant at least once. Secondary infertility disproportionately affects African American women compared to Caucasian women.

Infertility has numerous causes, which may be attributed to either the female or male partner, as well as a combination of factors, or may be medically unexplained or idiopathic. Common causes of female-factor infertility include polycystic ovary syndrome (PCOS), anovulation, tubal damage, endometriosis, uterine fibroids, pelvic adhesions, and history of cancer or sexually transmitted infection (STI). Male-factor causes of infertility can include low sperm count or motility, varicocele, and history of STI. A number of lifestyle factors can contribute to infertility, including obesity, smoking, and alcohol use. Being underweight can also underlie infertility, as in the case of anovulation secondary to anorexia nervosa in women. Psychological stress has been implicated in infertility, although research attempting to elucidate this hypothesized relationship has produced equivocal results.

Numerous medical interventions have been developed to assist couples with infertility to achieve pregnancy. Worldwide, approximately 40 million individuals receive fertility-related medical care. In the USA, about 12% of women receive at least one type of fertility-related medical services in their lifetimes and about 8% receive medical help to become pregnant in their lifetimes. Available treatments vary by specific cause of infertility and include surgeries to repair tubal damage, hormonal treatments to stimulate ovulation, IUI, and ART procedures such as IVF and intracytoplasmic sperm injection (ICSI). Third-party reproductive treatments, including gamete donation or use of gestational carriers (i.e., surrogates), also are available. These treatments vary considerably in their procedures, costs, time commitments, and many other aspects. Appropriate treatments vary by case, with some initiating fertility treatment with a less intrusive method (e.g., Clomid to simulate ovulation stimulation) before advancing to more invasive techniques (e.g., IVF) if early treatments are not successful. These treatment methods primarily involve the female partner as the patient, regardless of a couple's cause of infertility. Of note, these treatments also may be utilized by women who do not have infertility but who require medical assistance to become pregnant due to absence of a male reproductive partner.

Psychosocial Stressors

The experiences of infertility and fertility treatment are fraught with psychosocial stressors that contribute to distress. Because many women with infertility pursue medical intervention, and because research studies utilize varying sampling and assessment methodologies at widely varying time points during a couple's infertility experience, it is challenging to parse out distress caused

by infertility from that caused by fertility treatment. Below, the psychosocial stressors and consequences of both infertility and its treatment are discussed.

The experience of infertility is often a devastating disappointment to individuals and couples. The vast majority of young adults, when surveyed, report intentions to have at least one child in their lifetime. Receiving a diagnosis of infertility therefore significantly threatens hopes and expectations regarding parenthood and social roles. Reactions may include initial shock and disappointment; anger at oneself, one's partner, or others with children; hopelessness; loss of control; and guilt or self-blame (e.g., over attributions of infertility, such as contraceptive choices, prior elective abortions, or STIs). Further, individuals may confront challenging decisions regarding resolution of their infertility, including whether to pursue (or continue) fertility treatments, consider adoption, or remain childless. Additionally, during the course of fertility treatments, couples may confront difficult decisions such as whether to attempt subsequent treatment cycles in the event of treatment failure, to invest greater funds for more advanced medical procedures in hopes of increasing potential for success, or to undergo a selective reduction to reduce risk in a multiple pregnancy, which has a higher incidence in those receiving fertility treatment. Cultural and religious factors may influence and complicate these decisions.

The medical and procedural aspects of fertility treatments present myriad challenges. Many treatment options are time-consuming and physically invasive. For example, medications often are administered in injectable formats, which can be painful and inconvenient, and many women report unpleasant side effects of hormonal medications such as mood swings. Women receiving ART treatments may need to visit their physician several times per week and routinely undergo blood work and uncomfortable vaginal ultrasounds. ART protocols require surgical procedures to retrieve eggs and implant embryos. Even when pursuing less technologically complex fertility treatments, couples may be required to adhere to carefully timed intercourse, which can be difficult and emotionally taxing for both partners. Awaiting results of pregnancy testing following fertility treatments can be extremely stressful and anxiety-provoking. The rate of treatment failure is high, with only about 35% of ART treatments resulting in pregnancy. Even after achieving pregnancy, individuals may experience stress related to the threat of or actual miscarriage, which occurs in about 17% of ART pregnancies. Miscarriage is more likely to occur in women with a history of prior miscarriage, further compounding grief and distress for a subset of women. Treatment success is impacted by patient factors including patient age, number of follicles, and use of ovarian stimulation medications.

Fertility treatments, particularly ART, are extremely expensive, and low success rates often necessitate multiple treatment cycles to achieve a pregnancy. In general, costs for fertility treatment range from roughly $1,000 for medication treatments to tens of thousands of dollars for more advanced treatments such as IVF (~$40,000) and IVF with donor gametes (~$70,000); costs per successful outcome are much higher due to adjustments for low success rates. Some nations subsidize the cost of fertility treatments, but in the USA, only 15 states currently require possible coverage for fertility-related medical appointments or treatments, and Medicaid insurance does not provide any such coverage.

Although non-Caucasians are most affected by infertility, the majority of individuals receiving fertility treatment in the USA are Caucasian and come from socioeconomically advantaged backgrounds. Factors likely to explain this disparity include prohibitive treatment costs and lack of insurance, as well as culture-specific concerns about using reproductive technologies, spiritual beliefs, and mistrust of or difficulties communicating with health-care providers.

Infertility is considered stigmatizing in cultures across the world, including in the USA. Parenthood often is viewed as a primary adult role, and many women may internalize negative

social appraisals of childless women as selfish, unnatural, unfeminine, and inadequate, even when childlessness is involuntary. Women with infertility may believe that their bodies are abnormal or "handicapped" and may feel alienated and isolated from their fertile peers. Perceived stigma can produce perceptions of low social support, which in turn corresponds to increased anxiety or depression (Slade, O'Neill, Simpson, & Lashen, 2007). Women may encounter unsupportive social interactions marked by insensitive comments by family, friends, or acquaintances, which may be perceived as intrusive, blameful, or critical, impacting self-esteem and causing significant distress (Mindes, Ingram, Kliewer, & James, 2003). Many women choose to keep their infertility private and experience difficulties discussing their infertility experiences with others, including close friends and family.

Among women seeking fertility treatment for reasons other than infertility, other stressors arise. These individuals may include single women, women in same-sex couples, and women who are not yet experiencing infertility but anticipate future threats to their fertility (e.g., due to cancer treatments or older age), who may choose to freeze eggs or embryos. Medical interventions to help these individuals to achieve pregnancy are increasingly common, but stigma continues to surround the choice to raise children in nontraditional family arrangements such as single-parent or same-sex parent households. Additionally, due to the absence of a male reproductive partner, single and lesbian women utilize donated sperm, a reproductive option that introduces decision-making regarding which sperm donor to select, whether to select a known or anonymous donor, and whether and how to disclose the child's paternity to family, friends, acquaintances, and to the child. Less information is available about the psychosocial experiences of these populations, because the majority of studies examine heterosexual samples with infertility. As these populations are likely to encounter uniquely stressful experiences, careful attention from both the research and clinical communities is warranted.

Psychosocial Consequences of Infertility and Fertility Treatment

Individuals with infertility are at increased risk for emotional stress and psychiatric morbidity. Infertility-related stress is pervasive within this population. Such stress may relate to many of the stressors discussed above and is also thought to derive from intimate relationship strain, impact of infertility on sexual functioning, social relationship strain, and the profound conflicts surrounding potential childlessness and need for parenthood. While such stress affects both sexes, research has consistently revealed that women typically experience infertility-related stress to a greater degree than their male counterparts. Women consistently place greater emphasis and importance on having children compared to their male counterparts and are less open to the possibility of remaining childless when confronting infertility. This greater emphasis on having children corresponds to higher infertility-related stress among women. Despite the heightened impact of infertility-related stress on women, infertility-related stress appears to covary between both members of the same couple, suggesting that the burden of infertility-related stress is often shared.

Mood and anxiety symptoms and disorders are elevated among individuals with infertility. Research has consistently demonstrated a link between infertility-related stress and psychological adjustment. Women with infertility have higher anxiety symptomatology as well as higher rates of Generalized Anxiety Disorder (GAD) (King, 2003). Anxiety is thought to stem from uncertainty related to fertility status and treatment outcome, which is supported by the lack of association between GAD and sterility (or diagnosed inability to become pregnant). This uncertainty may persist for quite a long time, as couples may pursue fertility treatment or hold hope for a natural pregnancy for many years. Depressive symptomatology and depressive disorders are also elevated among individuals with infertility, with research revealing higher rates of diagnosable depressive disorders among the infertility population than among the general population. Depression may prevent

some women from seeking treatment and may also impact engagement in activities that might combat the stress of infertility. For some, fertility treatment may be implicated in the genesis or exacerbation of depression, with many studies reporting that women were psychologically well adjusted upon entering treatment but became significantly depressed during and after treatment (Eugster & Vingerhoets, 1999). Unsuccessful treatment can increase women's distress, and while most adjust over time, some women may experience more severe or persistent negative emotions (Verhaak et al., 2007). Grief and complicated bereavement may also occur following unsuccessful treatment. The occasional incidence of psychiatric events in response to fertility treatment has been reported, which may be partly due to interactions with hormonal treatments; uncommonly, these can include severe reactions such as psychotic experiences, with greater risk among women with past psychiatric histories.

Infertility can have a profound impact on partner relationships. Stressors relevant to intimate relationships, such as blaming oneself or one's partner for causing the fertility problem, discordant stress responses to infertility, and sexual dissatisfaction and low sexual self-esteem, can produce significant strain. Intimate relationship problems can contribute significantly to general distress associated with infertility. Research has indicated associations of poorer marital adjustment, disapproval from the spouse, and problems in the marital relationship with infertility-related stress and anxiety. Difficulties communicating about the infertility experience are also associated with infertility-related stress. Both women and men may be deeply affected by marital strain associated with infertility.

Infertility can also strain social relationships. Given the private nature of infertility described above, individuals may have difficulty communicating with others about their experiences. Both disclosure and nondisclosure can be distressing; women who have difficulty communicating about their infertility tend to experience greater stress and distress, but communication may also intensify feelings of distress or may be met with stigmatizing or unsupportive responses. Women may feel distanced from friends or family members with children, as it may be difficult to spend time with others who are experiencing parenthood. This may result in women isolating themselves from friends and family, posing barriers to accessing social support that may otherwise buffer against the deleterious effects of infertility-related stress.

Couples who achieve a successful outcome after fertility treatment generally experience remission of distress experienced during infertility and treatment. However, it is well documented that emotional burden, psychological distress, and difficulty coping are among the most common reasons for couples choosing to drop out of fertility treatment without achieving a successful outcome, even when controlling for the influences of treatment prognosis and financial constraints. Roughly half of fertility patients discontinue treatment under these circumstances without achieving a successful pregnancy. For couples making this choice, reported motivation to relieve emotional burdens presented by fertility treatment implies that discontinuing treatment may relieve some anxiety or distress and may enable pursuit of alternative resolutions to infertility; these individuals may feel released from a painful emotional cycle of anxiety, hope, disappointment, and grief. However, this decision may also mark the painful loss of hope to become a biological parent and may be accompanied by grief, anger, and a sense of failure.

Psychological Interventions for Infertility-Related Distress

A number of psychological interventions have been developed for women and couples with infertility, with fairly strong empirical support for their efficacy. Goals for these interventions often are to help women manage the emotional challenges of fertility treatment, although some have evaluated their utility in bolstering pregnancy rates. Efficacious treatments often utilize

cognitive-behavioral and mind/body approaches, incorporating psychoeducation, stress management, communication skills training, cognitive approaches to address attributions for infertility, and other coping strategies. Sexual functioning and adherence to timed sexual intercourse also may be addressed. Many interventions are conducted in group formats, although individual and couples' counseling are also commonly recommended for those struggling with significant distress. General support groups are commonly utilized, having long been considered a foundational support resource for women experiencing the isolating and stigmatizing effects of infertility. Social support and communication with others about infertility-related experiences is associated with reduced stress and emotional distress as well as reduced perceptions of stigma. Psychological interventions have been most efficacious in treating affective variables like anxiety and depression, and have less support for improving relationship functioning (Boivin, 2003).

Psychosocial Support in the Twenty-First Century

Despite the availability and efficacy of these interventions, they are consistently underutilized. This may be due to the perceptions that these treatments are too time-consuming, expensive, or invasive or that distress does not warrant professional intervention (Boivin, 2003). This indicates a need to explore alternative sources of support that may be more consistent with the preferences of the population.

In the past decade, a well-documented trend has emerged regarding women's increasing reliance on Internet resources for emotional and informational support related to infertility. Within the infertility population, websites and interactive communication forums are popular, particularly among women. They provide opportunities to access support at any hour of the day, from the convenience of one's home, and in an anonymous manner without the stigma or discomfort of speaking to others face to face. Reading web content, including dynamic discussions by others on communication forums, shares qualities with bibliotherapy, while contributing to such discussions by writing messages may share some characteristics with written emotional expression as well as engagement with face-to-face social support.

Emerging research regarding psychosocial impact of web-based support reflects several unique and generally positive features, including reduced isolation, normalization of emotional experiences, improved fertility-related knowledge and decision-making, and improvements in the partner relationship due to decreased burden on the spouse for support. However, researchers raise concerns over the potential for harmful effects. For example, the quality of web-based resources is often questionable, and the vast majority of websites addressing fertility-related information do not adhere to proposed quality standards; furthermore, in websites that enable contributions from the public, there is a very real possibility for exposure to misinformation and unsupported, anecdotal information. Research has revealed a small possibility that individuals may experience negative emotions as a result of using web-based resources and communication, including painful reactions to hearing either happy or sad fertility-related news of others, as well as the potential for disinhibited, harsh communication directed at specific group members. More research is needed to explore the effects of Internet-mediated support to inform patients, medical providers, and administrators and guide the development of such resources to best meet the needs of the population in managing the psychosocial aspects of infertility.

Infertility-Related Stress

▶ Infertility and Assisted Reproduction: Psychosocial Aspects

Inflammation

Nicolas Rohleder and Jutta M. Wolf
Department of Psychology, Brandeis University, Waltham, MA, USA

Definition

The term "inflammation" is derived from the Latin *inflammare* which translates to "to set on fire." Inflammation as a process is a component of the overall immune response against invading pathogens and/or tissue damage. A local inflammatory response at a site of a wound and/or infection is characterized by the classical symptoms *calor* (heat), *rubor* (redness), *dolor* (pain), *tumor* (swelling), and *functio laesa* (loss of function). These symptoms are the result of the inflammatory response system being activated in the affected tissue. More specifically, the inflammatory response is started by local resident cells of the innate immune system, which secrete inflammatory mediators and other effector substances. These substances induce vasodilation (dilation of the blood vessels), which allows increased blood flow to the affected area and also causes rubor and calor. Related to this, an increased permeability of the blood vessel walls allows plasma exudation (transfer of blood plasma) into the affected tissue, which accounts for the swelling. Circulating immune cells are attracted to the affected site through chemotaxis and adhesion molecules (cells are attracted by chemical signals on the surface of cells lining the blood vessels), and leave the blood vessel to enter the affected tissue and help fight infection or contribute to wound healing. Pain is a result of the same

inflammatory cells releasing bradykinin (a substance that lowers pain thresholds), while loss of function is a non-specific consequence of local inflammation.

Description

Different Forms of Inflammation

Depending on the efficiency of the inflammatory machinery in relation to the extent and virulence of the invading pathogen, this response might be contained and resolved, and thus remains local, or it might spread to the rest of the body, thereby initiating a systemic inflammatory response. One form of systemic inflammation is sepsis, which is characterized by hyper amplification of inflammatory processes with deleterious effects on the organism, including organ failure and/or death (Cinel & Opal, 2009).

Another, more recently described form of systemic inflammation is chronic low-grade inflammation (Danesh, 1999). This phenomenon, also described as low-grade systemic inflammation, is characterized by increases in concentrations of the same plasma mediators that signal and contribute to local and other forms of systemic inflammation, that is, mainly interleukin-6 (IL-6) and C-reactive protein (CRP). However, concentrations are markedly lower than those measured, for example, in sepsis, but still increased in comparison to the non-inflamed state of a young and healthy organism.

Age, Lifestyle, and Inflammation

An important characteristic of chronic low-grade inflammation is its association with age. Although it is currently unclear whether increasing concentrations of inflammatory mediators are a consequence of the aging process per se, there is compelling evidence that as organisms age, their plasma concentrations of IL-6 and CRP increase slowly, but steadily (Ershler, 1993). Several lifestyle factors have been found associated with low-grade inflammation, the most important of which appear to be physical inactivity, nutrition, and obesity as a consequence of both. Adipose tissue is an important source of inflammatory cytokines, such as IL-6, and increased presence of adipose tissue is associated with increased plasma concentrations of inflammatory mediators (Yudkin, Kumari, Humphries, & Mohamed-Ali, 2000). Furthermore, certain diets, such as typical high fat, high carbohydrate "western" diets, have been associated with low-grade inflammation, while diets with high contents of omega-3 fatty acids, fruits, vegetables, and nuts, as well as typical "Asian" diets seem to be anti-inflammatory (Giugliano, Ceriello, & Esposito, 2006). Another behavioral or lifestyle factor is tobacco smoking, which is associated with increased plasma concentrations of inflammatory mediators (Bazzano, He, Muntner, Vupputuri, & Whelton, 2003).

Long-Term Consequences of Inflammation

While sepsis is acutely life-threatening, one of the most important and disadvantageous forms of inflammation in terms of long-term consequences is probably chronic low-grade inflammation. There is now strong evidence pointing to a central role of low-grade inflammation in many age-related diseases such as cardiovascular disease, insulin resistance and type 2 diabetes, osteoporosis, and cancer (see Ershler, 1993). Several prospective studies have found that increased concentrations of IL-6 and CRP in older adults are a strong predictor of morbidity and all-cause mortality (Ridker, Cushman, Stampfer, Tracy, & Hennekens, 1997; Ferrucci et al., 1999; Bruunsgaard et al., 2003). Many of the pathways between low-grade inflammation and age-related diseases are becoming better understood now. Atherosclerosis, the pathophysiological process underlying heart disease and strokes, has been shown to be essentially a local inflammatory response in artery walls, and as such can be stimulated more easily and strongly in individuals with higher plasma concentrations of inflammatory mediators. Similarly, the process underlying insulin resistance is becoming more and more understood, and inflammatory mediators seem to play an important role in the ability of target cells to understand insulin signals.

Inflammation in Behavioral Medicine

In summary, chronic low-grade inflammation can be an important process to consider for researchers and practitioners in behavioral medicine, as inflammation is prospectively related with some of the most important diseases of later life, and because inflammation is under the control of the central nervous system. Several pathways link states of the central nervous system with peripheral inflammation. Most notably, recent research has shown that low-grade inflammation is more pronounced in individuals suffering from chronic stress, depression, and posttraumatic stress disorder (e.g., Ford & Erlinger, 2004; Miller & Blackwell, 2006). Similarly, acute stress has been shown to induce short-term increases in plasma inflammatory mediators (Steptoe, Hamer, & Chida, 2007). Recent research indicates that increased inflammatory mediators in depression are in part mediated by negative changes in health behaviors, most notably by reduced physical activity, but the same research also shows that a large proportion of this association must be explained by additional factors (Hamer, Molloy, de Oliveira, & Demakakos, 2009). Typical candidates are the stress systems hypothalamus-pituitary-adrenal (HPA) axis and autonomic nervous system (ANS), which show altered basal activity in many stress-related diseases, including depression and PTSD, and which are important regulators of inflammatory activity. Importantly, the ability of the inflammatory system to understand these stress systems' signaling changes after acute and chronic stress, and alterations in the inflammatory system's sensitivity to these signals, can help explain long-term health effects (for a summary see Raison & Miller, 2003; Rohleder, Wolf, & Wolf, 2010).

In addition to this efferent CNS-to-periphery pathway, inflammatory mediators also send signals to the CNS, leading to a set of symptoms summarized as sickness behavior. These symptoms include affective effects, most notably depressive symptoms and fatigue, but also alterations in sleep and cognition (Dantzer, O'Connor, Freund, Johnson, & Kelley, 2008). Sickness behavior is strongest in the context of acute infection, cytokine therapy, and sepsis, but evidence is accumulating in support of the assumption that low-grade inflammation is sufficient to induce depressive symptoms, cognitive decline, and other components of sickness behavior, albeit less pronounced (see, e.g., Raison, Capuron, & Miller, 2006; Alley, Crimmins, Karlamangla, Hu, & Seeman, 2008).

Inflammatory Bowel Disease

Yukari Tanaka and Shin Fukudo
Department of Behavioral Medicine, School of Medicine, Tohoku University Graduate, Aoba-ku, Sendai, Japan

Synonyms

Colitis

Definition

Inflammatory bowel disease (IBD) is a specific group of chronic inflammatory conditions of the intestine. IBD consists of the two major diseases: ulcerative colitis (UC) and Crohn's disease (CD). UC causes inflammation in the rectum, colon, and infrequently the terminal ileum. CD can involve any part of the gastrointestinal tract from the mouth to the anus and particularly affects the ileum and/or the colon. IBD most commonly begins during adolescence and early adulthood.

Description

Causes

The cause of IBD is not clearly known, but these diseases are thought to be due to an autoimmune process that has been triggered by unknown factors or agents, such as genetic predisposition, infection of microorganisms, and/or environmental factors. As a result of the ulcers and inflammatory reaction of the mucosal layer of the small intestine or the colon, the intestinal wall is damaged leading to bloody diarrhea and abdominal pain. In recent studies, psychosocial stress and/or psychiatric comorbidity unlikely cause(s) IBD. However, IBD itself evokes stress, and evoked stress response induces some psychiatric comorbidities including anxiety disorders, depressive disorders, or somatoform disorders.

Signs and Symptoms

Symptoms may range from mild to severe: abdominal pain and tenesmus, bloody diarrhea, abnormal bowel movement, fever, anemia, and appetite and weight loss. IBD is characterized by recurring episodes of inflammation of the bowel; thus, patients will go through periods in which the disease flares up and causes symptoms. These periods should be followed by remission, in which symptoms disappear or decrease. UC often appears as the most severe inflammation in the rectum, which may cause frequent diarrhea and bleeding. Inflammation and ulceration in UC are primarily limited to the mucosa and the submucosa. By contrast, the inflammation of the Crohn's disease is transmural and sometimes results in intestinal obstruction, deep ulcers, microperforations, and fistulas. Long-standing IBD is also a risk factor of developing colorectal cancer.

Diagnosis

Diagnosis can be made endoscopically or radiologically. UC almost always involves the rectum and the lower left colon. Endoscopic findings reveal ulcers, edema, erythema and friability of the mucosa, and loss of the vascular pattern. Crypt abscess is a more typical histologic finding in the colonic mucosa of active UC. Radiological findings are loss of the normal mucosal pattern and, with more extensive colorectal inflammation, absent haustration. Endoscopic findings in Crohn's disease are deeper ulcers involving the entire wall of the colon. The deep liner ulcers result adjacent to normal tissue results in "cobblestoning." These lesions are typically discontinuous, which results in "skip" lesions. Barium enema in Crohn's disease demonstrates aphthous ulcers, cobblestoning pattern, narrowing of the lumen called "string sign," or fistulas and abscess formation. The notable histopathological feature is the presence of epithelioid granulomas.

Treatment

Standard treatment for IBD depends on extent of involvement and disease severity. Medical management attempts to initiate and lead to a long-term remission, which is the period between flare ups where very little to no symptoms should be experienced. Medications used to treat IBD include: 5-aminosalicylic acid (5-ASA) compounds, steroids, and medications to suppress the immune system. 5-ASA is the main anti-inflammatory drug and the standard first-line treatment for mild-to-moderate IBD. 5-ASA is available in a variety of different formulations and different delivery systems that split the active moiety in various regions of the intestine. Sulfasalazine are poorly absorbed from the intestine and act from inside the intestine. Sulfasalazine can be effective, but sometimes induces some side effects. On the other hand, mesalamine and olsalazine have fewer side effects than sulfasalazine has. Steroids are powerful drugs and commonly used, but they often produce a variety types of side effects, particularly, in long-time uses. Immunosuppressive drugs, the antimetabolite 6-mercaptopurine (6-MP), are also powerful and help patients get off steroids but may prohibit natural immune defenses. Anti-TNF antibody treatment of Crohn's disease is one of the important therapeutic strategies recently developed. It is a monoclonal antibody and blocks TNF-alpha, which is involved in inflammation of the bowel. Surgical treatment is necessary in some severe cases with perforation, toxic megacolon, and severe bleeding.

Informed Consent

Yoshiyuki Takimoto
Department of Stress Science and Psychosomatic Medicine, Graduate School of Medicine, The University of Tokyo, Bunkyo-ku, Tokyo, Japan

Definition

Informed consent is giving consent to receive treatment or to become a subject of research based on adequate disclosure and understanding of relevant facts. The requirement for informed consent is based on the ethical principle *autonomy*. The legal grounding for requirement for informed consent is based on the outcome of litigations of disputes arising in the context of medical practice.

There are at least five necessary elements of informed consent: (1) disclosure of information sufficient to make a reasonably informed decision, (2) understanding by the consenter of information and recommendations disclosed, (3) voluntariness in consenting, (4) competence of the individual to understanding information given and reach a reasoned decision, and (5) assent.

The postulate is that a person gives an informed consent to an intervention if and only if the person receives a thorough disclosure about the procedure, comprehends the disclosed information, acts voluntarily, is competent to act, and consents.

Inheritance, Genetic

J. Rick Turner
Cardiovascular Safety, Quintiles, Durham, NC, USA

Definition

Genetic inheritance addresses how traits are transmitted from one generation to another. While the word "inheritance" alone is typically used and taken to mean genetic inheritance, the term cultural inheritance is also a valid concept and deals with how cultural factors are transmitted.

The laws of inheritance (including dominant inheritance and recessive inheritance) were discovered by Mendel without knowledge of the actual molecular biological mechanism, and his research focused on plants and especially the common pea plant, *Pisum sativum*. Instead of trying to address the appearance of whole plants, and hence all of their characteristics, he focused on the inheritance of single, easily visible, and well-distinguished traits. These included round versus wrinkled seed, yellow

versus green seed, and purple versus white flowers (Britannica, 2009). He also made exact counts of the number of plants bearing each trait. These quantitative data allowed him to formulate the rules governing inheritance, as exemplified by the dominant inheritance and recessive inheritance entries in this encyclopedia.

Insertion/Deletion Polymorphism

Laura Rodriguez-Murillo[1] and Rany M. Salem[2]
[1]Department of Psychiatry, Columbia University Medical Center, New York, NY, USA
[2]Broad Institute, Cambridge, MA, USA

Definition

An insertion/deletion polymorphism, commonly abbreviated "indel," is a type of genetic variation in which a specific nucleotide sequence is present (insertion) or absent (deletion). While not as common as SNPs, indels are widely spread across the genome. Indels comprise a total of 3 million of the 15 million known genetic variants (The 1000 Genomes Project Consortium, 2010). An indel in the coding region of a gene that is not a multiple of 3 nucleotides results in a frameshift mutation. Shifting the reading frame and the DNA transcript sequence may now code for an entirely different set of amino acids or result in a premature stop codon, altering the protein structure and function. Indel variants with multiples of 3 nucleotides result in a protein with extra amino acids (insertion) or loss of amino acids (deletion), but the other amino acids are not affected. The site of the indel in the gene is important since it determines which part of the protein is affected, since not all amino acids are necessary for proper protein function. A 250-base-pair indel in the angiotensin converting enzyme (ACE) gene explains 50% of the variance of serum ACE levels and has been shown to have important clinical consequences (Scharplatz, Puhan, Steurer, & Bachmann, 2004).

Insomnia

Wendy Troxel
Psychiatry and Psychology, University of Pittsburgh, Pittsburgh, PA, USA

Definition

The term "insomnia" is commonly used in the vernacular to refer to symptoms of insomnia including complaints of difficulty falling asleep, frequent or prolonged awakenings, inadequate sleep quality, or short overall sleep duration in an individual who has adequate time available for sleep. In contrast, an *insomnia disorder* is a syndrome consisting of the insomnia complaint combined with significant daytime impairment or distress, and the exclusion of other causes. Commonly reported daytime impairments associated with insomnia include complaints of mood disturbances (e.g., irritability, mild dysphoria, or difficulty tolerating stress), impaired cognitive function, and daytime fatigue (Moul et al., 2002). Importantly, insomnia patients commonly report feeling fatigued or exhausted during the day, but rarely report daytime sleepiness, per se (i.e., the propensity to fall asleep). Another important feature that distinguishes the insomnia disorder from sleep deprivation is that symptoms are present despite adequate opportunity for sleep. That is, in insomnia the opportunity for sleep is adequate, but the ability to sleep is compromised. In contrast, sleep deprivation is characterized by a restricted opportunity to sleep (due to lifestyles, shiftwork, etc.) with adequate ability.

Description

Prevalence and Consequences

Insomnia is the most common sleep disorder, with prevalence estimates ranging from 10% to 15% in the general population (Ohayon, 1996; Ohayon & Guilleminault, 1999; Ohayon, 2002) and up to 20–30% in primary care medical settings (Simon & Von Korff, 1997; Shochat, Umphress, Israel, & Ancoli-Israel, 1999). Substantial evidence demonstrates the significant health and functional consequences of insomnia, including reduced quality of life and increased health-care utilization, health-care costs, disability, and risk for psychiatric disorders and cardiovascular disease (Althuis, Fredman, Langenberg, & Magaziner, 1998; Brassington, King, & Bliwise, 2000; Brostrom, Stromberg, Dahlstrom, & Fridlund, 2004; Caap-Ahlgren & Dehlin, 2001; Daley, Morin, LeBlanc, Gregoire, & Savard, 2009; Foley, Ancoli-Israel, Britz, & Walsh, 2004; Ford & Kamerow, 1989).

Assessment

Polysomnography or other laboratory sleep measures are not recommended in the diagnosis of insomnia, except to rule out other occult sleep disorders. Rather, the diagnosis is based on a comprehensive clinical evaluation, including an assessment of sleep disturbances, habits, and clinical course, as well as a complete medical and psychiatric history, including use of prescribed or un-prescribed medications (including timing and dose), as all of these factors may influence insomnia. In addition to the clinical interview, questionnaires and sleep diaries are frequently used to provide a more in-depth analysis of qualitative aspects of sleep as well as the timing and variability of sleep patterns over successive nights.

Risk Factors

According to the "3-P" model of insomnia, risk factors for insomnia can be categorized into predisposing, precipitating, and perpetuating factors (Spielman, Caruso, & Glovinsky, 1987). Predisposing or vulnerability factors include advancing age, female sex, being divorced or separated, unemployment, and comorbid medical and psychiatric illness (Lichstein, Taylor, McCrae, & Ruiter, 2011; Morgan & Clarke, 1997; Ohayon, 2002; Su, Huang, & Chou, 2004). To date, genetic factors have been inadequately studied, though they may represent another possible risk (Drake, Scofield, & Roth, 2008; Hamet & Tremblay, 2006; Watson,

Goldberg, Arguelles, & Buchwald, 2006). Precipitating events that initiate insomnia may include major life transitions or psychosocial stressors such as moves, relationship difficulties, occupational and financial problems, and caregiving responsibilities (Bastien, Vallieres, & Morin, 2004; Kappler & Hohagen, 2003). Finally, perpetuating factors include counterproductive thoughts and behaviors related to sleep that maintain or exacerbate insomnia. Empirically supported behavioral and cognitive behavioral interventions aim to reduce insomnia by modifying or eliminating these maladaptive sleep-related thoughts and behaviors (Bastien et al., 2004; Morin, 2004).

Institute of Medicine

Martica H. Hall
Department of Psychiatry, University of Pittsburgh, Pittsburgh, PA, USA

Basic Information

The Institute of Medicine is a nonprofit organization whose mission is the advancement of medical and biological sciences in the service of health.

Established in 1970 as a branch the National Academies (National Academy of Sciences, National Academy of Engineering, National Research Council, Institute of Medicine), the IOM is a nonprofit organization committed to the advancement of medical and biological sciences in the service of health. The IOM's underlying principle is that authoritative evidence in the medical and biological sciences expands the capabilities of medicine and health care.

Major Impact on the Field

Members are elected to the IOM based upon their record of scientific achievement. The membership and governing Council interact with other scientists and government officials to identify IOM projects. These projects encompass a variety of formats including establishment of expert committees to facilitate cross-disciplinary discussion and discovery, the conduct of workshops and public forums, the generation and publication of authoritative topical reports and books, and the support of high-impact research studies. These activities are conducted with the express function of advancing medical and biological sciences in the service of health and improved health care.

The IOM recognizes the importance of behavioral and social sciences in the service of health-related medical and biological sciences. This commitment is evidenced in high-profile IOM reports regarding interactions among social, psychological, behavioral, and biological factors that underlie health and functioning. Examples include state-of-science reports on health promotion intervention strategies from social and behavioral research (2000); the influence of early environment on neuronal development (2000); gene-environment interactions in relation to health (2006); the consequences of sleep disorders and sleep deprivation (2006); the physiologic, psychological, and psychosocial consequences of deployment stress in military personnel (2007); and environmental risk factors for breast cancer (2011).

Institutionalization; Long-term care

Definition

Institutional care is provided within a congregate living environment designed to meet the functional, medical, personal, social, and housing needs of individuals who have physical, mental, and/or developmental disabilities. Vulnerable children, and older adults, individuals with developmental disabilities, mental retardation, chronic mental illness, and physical disabilities are more likely to receive care in institutional settings, such as orphanages, nursing homes, residential facilities, and rehabilitation centers. Care and

services in institutional settings often include, but are not limited to, 24-h supervision/monitoring, assistance with activities of daily living, skilled nursing care, rehabilitation, adaptive aids and equipment, psychological services, therapies, social activities, and room and board. The cost of institutional care varies by the facility and the services that are required. Payment for institutional care includes private financial resources, long-term care insurance, Medicaid, and Medicare. In the United States, federal and state governments oversee institutional care facilities which are inspected annually to ensure that they are in compliance with regulatory requirements that address residents' rights, health, and safety.

Institutional Review Board (IRB)

Yoshiyuki Takimoto
Department of Stress Science and Psychosomatic Medicine, Graduate School of Medicine, The University of Tokyo, Bunkyo-ku, Tokyo, Japan

Synonyms

Research ethics committee

Definition

Institutional Review Board (IRB) is a committee containing members of mixed backgrounds and including both scientist and nonscientist members whose task is to review and monitor biomedical and behavioral research involving human subjects. The World Medical Association's Declaration of Helsinki (2010) and Council for International Organizations of Medical Science's International Ethical Guidelines for Biomedical Research Involving Human Subjects establish the international standard for biomedical research and require IRB as scientific review and ethical review committee, which is called the research ethics committee (REC) in the most of the world. IRB is assigned to the authority and responsibility for approving or disapproving proposals to conduct research involving human subjects. The chief purpose of IRB reviews is to assess the scientific and ethical merit and usefulness of the research and its methods and to ensure that research conforms to ethical standards and protects the right and welfare of the research subjects.

Definition

Insulin

Insulin is an essential hormone for maintaining normal blood glucose. It is the principal regulator of glucose utilization in liver, skeletal muscle, and adipose tissue. Abnormalities of insulin synthesis, secretion, or action can result in hypoglycemia or hyperglycemia, including diabetes mellitus.

Synthesis: Insulin is synthesized from the pancreatic beta cells from a single-chain precursor, preproinsulin. Preproinsulin is cleaved to proinsulin which is further cleaved by proconvertases into three polypeptide chains: alpha, beta, and C-peptide chains. Insulin is formed by linkage of the alpha and beta chains by disulfide bonds. The remaining C-peptide is secreted from the beta cell with insulin in equal molar portions. Insulin and C-peptide levels can be used to evaluate pancreatic function and glucose tolerance (Gardner & Shoback, 2007; Kronenber, Melmed, Polonsky, & Larsen, 2008).

Secretion: Insulin secretion is primarily stimulated by glucose. Glucose enters the beta cell through facilitated diffusion mediated by GLUT2 glucose transporter. Glucose is then phosphorylated to glucose-6-phosphate by glucokinase. Glucokinase is the rate-limiting step of glycolysis and primarily determines the rate of insulin secretion in response to blood glucose levels. The metabolism of glucose increases intracellular ATP/ADP ratio resulting in insulin release. Insulin is secreted in a biphasic pattern, an initial peak followed by a sustained plateau after carbohydrate ingestion. Insulin concentrations increase 8–10 min after ingestion of food and peak by 30–45 min. Blood glucose concentrations return to baseline by 90–120 min after ingestion of food. Oral glucose administration increases insulin response greater than intravenous glucose. This is due to stimulation of gut hormones that promote insulin release, called incretins. Incretins like glucagon-like peptides (GLP) increase the sensitivity of the beta cell to glucose. GLP-1 also inhibits glucagon and delays gastric empting. Glucagon is secreted from the pancreatic alpha cells and counters the effects of insulin in the liver by stimulating glycogenolysis.

Insulin secretion is also stimulated by amino acids by increasing the intracellular ATP/ADP ratio. Acutely, free fatty acids and ketones also stimulate insulin secretion. Long-term beta cell exposure to fatty acids inhibits insulin synthesis and secretion. Somatostatin, secreted from pancreatic delta cells, inhibits insulin release (Lifshitz, 2007).

Insulin secretion is also under the control of the autonomic nervous system. The vagus nerve of the parasympathetic nervous systems directly stimulates insulin secretion. In the sympathetic nervous system, activation of β2 receptors increases insulin secretion, while activation of α-adrenergic receptors inhibits insulin secretion. During stress, epinephrine and norepinephrine activate α-adrenergic receptors, blocking insulin release and resulting in hyperglycemia. Other counter regulatory hormones such as cortisol and other glucocorticoids stimulate insulin secretion while inducing peripheral insulin resistance.

Action: Insulin binds to insulin receptors on the cell membrane of target tissues. The insulin receptor is a heterodimeric glycoprotein. Insulin binds to the extracellular α subunits of the insulin receptor which activates intrinsic tyrosine kinase

on the transmembrane β subunits leading to phosphorylation of cytoplasmic substrates inducing signal transduction. In the liver, insulin stimulates glucose uptake, storage of glucose as glycogen, and synthesis of protein, triglycerides, and very-low-density lipoprotein. Also in the liver, insulin inhibits glycogenolysis and gluconeogenesis. In skeletal muscle, insulin stimulates glucose uptake, glycogen synthesis, and protein synthesis by increasing amino acid transport. In adipose tissue, insulin stimulates glucose uptake and storage of triglyceride. Insulin induces production of circulating lipoprotein lipase which hydrolyzes triglycerides from circulating lipoprotein for uptake by adipose cells. Insulin inhibits intracellular lipoprotein lipase to promote the storage of triglycerides. Counter regulator hormones impair insulin action. Epinephrine, cortisol, and growth hormone antagonize insulin action by promoting glycogenolysis, gluconeogenesis, lipolysis, and ketogenesis, and decreasing glucose utilization and clearance (Lifshitz, 2007).

Pathology: Abnormality of insulin production, secretion, or action results in abnormal blood glucose. Uncontrolled secretion of insulin typically presents with hypoglycemia in the neonatal period. Neonatal hyperinsulinism may be transient due to maternal conditions such as uncontrolled gestational diabetes. Congenital hyperinsulinism due to genetic mutations in the islet cell can cause constitutive secretion of insulin and hypoglycemia. Insulin-secreting tumors of the pancreas, insulinomas, are the most common cause of fasting hypoglycemia in otherwise healthy adults.

Genetic mutations that decrease insulin synthesis or secretion can cause neonatal diabetes. Mild defects in insulin synthesis can present later in childhood or early adulthood; this group of mutations is referred to as maturity onset diabetes of the young (MODY). Mutations associated with MODY are transmitted autosomal dominant.

Abnormality of insulin action may be due to genetic mutations of the insulin receptor or due to type 2 diabetes. In type 2 diabetes, target tissues have decreased sensitivity to insulin. The etiology of type 2 diabetes is unclear. It is clear that obesity and consumption of a high-carbohydrate diet may unmask diabetes in a person who is genetically susceptible. The pancreas compensates for insulin resistance by elevated insulin levels. Beta cells begin to lose insulin response to glucose intake, and glucose intolerance develops.

Type 1 diabetes mellitus results from autoimmune destruction of pancreatic beta cells and consequently insulinopenia. Type 1 diabetes typically presents in childhood. Peak age of presentation is bimodal, at 5–7 years of age and at the time of puberty. Symptoms of diabetes usually do not present until greater than 80% of the islet cells have been destroyed (Lifshitz, 2007).

Synthetic Insulin: Recombinant human insulin is necessary for the treatment of type 1 diabetes and neonatal diabetes and may be adjunctive in type 2 diabetes. Insulin analogues are administered subcutaneously several times per day for optimal control. Rapid acting insulin is administered just prior to carbohydrate consumption. Intermediate and long acting insulin can be administered once or twice a day for basal insulin. An insulin pump provides continuous insulin infusion of rapid acting insulin to provide more physiologic insulin therapy. Blood glucose must be monitored closely with any insulin regimen to avoid hypoglycemia (Lifshitz, 2007; Sperling, 2008).

CNS: Insulin and insulin receptors have been found throughout the central nervous system. In the hypothalamus, insulin is associated with regulation of body energy homeostasis. In the hippocampus and cerebral cortex, insulin has been shown to be involved in cognitive function. For example, in animals, changes in insulin signaling in the hippocampus and temporal cortex are associated with memory and learning. In humans, acute increase in insulin is associated with increased memory capacity. However, chronically elevated insulin levels can cause neural damage through microvascular damage by oxidative stress and endothelial damage. Epidemiologic data suggests an association between insulin resistance syndrome and dementia which is also attributed to microvascular damage.

Insulin Pumps

Della Matheson
Diabetes Research Institute, Miller School of Medicine, University of Miami, Miami, FL, USA

Synonyms

Continuous subcutaneous insulin infusion

Definition

Insulin pump therapy, often referred to as continuous subcutaneous insulin infusion (CSII), is an alternate method of insulin administration for persons who require multiple daily injections (MDI) for treatment of diabetes. The concept in insulin pump therapy was first introduced by Arnold Kadish in Beverly Hills, CA, in the 1960s. However, it was not until the early 1980s that the first FDA-approved pump became available for use by people with type 1 diabetes.

The basic design of pumps is that a syringe-driven pump uses a subcutaneously placed catheter to deliver insulin that is controlled by electronics within the pump (Skyler, 2010). The insulin used in pumps is rapid-acting insulin (regular insulin or more recently the insulin analogs: Novolog, Humalog, Apidra). Insulin pumps provide the most physiologic method for delivery of insulin. In nondiabetic people, the pancreas secretes background insulin throughout the day and night that maintains normal blood glucose levels in the non-fed state. The pancreas also secretes insulin in larger quantities in rapid response to blood glucose excursions after food is ingested. Unlike MDI, which employs 1–2 injections of long acting insulin to mimic the background insulin requirement, and 3–4 injections per day of short acting insulin injected before each meal, CSII allows the use of only rapid-acting insulin which is infused continuously throughout the day to provide a background of insulin (basal rate) and allows the wearer to press a button prior to each meal to deliver a larger amount of insulin to accommodate the glucose content of the meal (bolus), thus mimicking the normal insulin secretion patterns. Modern pumps are small, discreet, and fashionable in appearance. They are also often referred to as "smart pumps" because they integrate concepts of intensive insulin therapy and principles of good diabetes self-management into their programs. The features that incorporate these concepts include insulin:carbohydrate ratio calculator for meals, insulin sensitivity factor and target blood glucose to calculate proper correction doses for high blood sugars, insulin-on-board feature which helps to calculate the amount of circulating insulin still active in the blood stream to help prevent overdosage of insulin, and multiple basal rates to customize background insulin to individual variations in need for background insulin. It should be understood that insulin pumps do not automatically provide insulin in response to glucose; the person wearing the pump must program the pump and make decisions about how much insulin should be taken in

collaboration with the health-care team. The future may well usher in more advances in insulin pump therapy that lead us closer to a pump with automatic insulin delivery, aka a "closed loop system." With the advent of continuous glucose monitoring (CGM) and sensor-augmented pumps, research is underway to achieve this goal.

It is well established through the Diabetes Control and Complications Trials (DCCT) that good glycemic control (HbA1c <7.4%) prevents long-term microvascular and macrovascular complications (The Diabetes Control and Complications Trial Research Group, 1993). It is generally accepted that intensive insulin therapy through MDI or CSII is the best method for achieving the targets set forth by the DCCT. However, there appears to be no firm evidence to suggest that CSII is better than MDI to achieve these targets. The main benefits of CSII appear to be enhanced flexibility of lifestyle and quality of life, both of which may impact patient adherence to the strenuous demands of intensive insulin therapy. The risks of insulin pumps have minimized greatly with improved technology over the past 20 years. The greatest risk with use of CSII is diabetic ketoacidosis (DKA); since only rapid-acting insulin is used in the device, if the flow of insulin is disrupted, deterioration to DKA may occur rapidly as there is no long acting insulin to help sustain the individual. With education and proper training, this has been greatly diminished in pump users. Disruption in the flow of insulin most often occurs due to an occlusion in the catheter or bent catheter, pump running out of insulin and user not refilling on a timely basis, a dislodged catheter, and infrequently a mechanical failure of the pump (Ponder, Skyler, Kruger, Matheson, & Brown, 2008).

Currently available on the market in the USA are the following pumps: Animas (Johnson & Johnson), MiniMed (Medtronic), OmniPod (Insulet Corp.), and Amigo (Nipro).

Insulin Sensitivity

Janine Sanchez
Department of Pediatrics, University of Miami, Miami, FL, USA

Synonyms

Insulin effectiveness

Definition

Insulin sensitivity is the ability of insulin to stimulate glucose uptake, promote peripheral glucose disposal, and suppress hepatic glucose production. The primary site of glucose dispose is skeletal muscle. The gold standard method for the determination of insulin sensitivity is the hyperinsulinemic-euglycemic insulin clamp. However, the clamp technique is expensive and complex. Surrogate methods to determine insulin sensitivity include fasting insulin and glucose, oral glucose tolerance test, and intravenous glucose tolerance test. The most common calculations using fasting insulin and glucose are fasting glucose to insulin ratio, homeostasis model assessment of insulin resistance (HOMA), and quantitative insulin sensitivity check index (QUICKI). The HOMA and QUICKI models are mathematical estimates of beta cell function and insulin resistance.

Impaired insulin sensitivity or insulin resistance precedes glucose intolerance in the development of type 2 diabetes. As insulin sensitivity decreases, insulin levels will become elevated in attempt to maintain effectiveness and euglycemia. If insulin sensitivity continues to decline, patients may develop glucose intolerance and then type 2 diabetes. Insulin resistance is associated with a metabolic and cardiovascular cluster of disorders including type 2 diabetes, glucose intolerance, dyslipidemia, fatty liver, hypertension, obesity, polycystic ovarian syndrome, and endothelial dysfunction. Insulin resistance can also occur in patients with poorly controlled type 1 diabetes. This leads to increased insulin requirements to maintain euglycemia.

Insulin resistance can also be associated with rare syndromes due to insulin receptor abnormalities or insulin antibodies. In addition, insulin resistance increases during puberty and decreases when puberty is complete. Clinical signs associated with insulin resistance include acanthosis nigricans (darkening of skin around neck and axilla), obesity, and hypertension.

Exercise, healthy diet, and weight loss can improve insulin sensitivity. The metabolic and cardiovascular diseases associated with insulin resistance also improve as insulin sensitivity improves.

Insulin Shock

► Hypoglycemia

Insulin-Dependent Diabetes Mellitus (IDDM)

Luigi Meneghini
Diabetes Research Institute, University of Miami, Miami, FL, USA

Synonyms

Autoimmune diabetes; Juvenile diabetes; Type 1 diabetes

Definition

Insulin-dependent diabetes mellitus (IDDM) is now referred to as type 1 diabetes (T1DM) and designates an elevation in blood glucose due to insufficient production of insulin thought to result from cell-mediated autoimmune destruction of insulin-producing pancreatic beta cells. Autoimmunity is manifested by mononuclear cell invasion of islets (insulitis) and the production of islet-specific antibodies, such as GAD (glutamic acid decarboxylase), IA-2 autoantibodies, and ICA (islet cell antibodies), detectable in ~85% of newly diagnosed patients. Genetic, environmental, and possibly other unknown factors contribute to disease susceptibility, which is most commonly manifested in the childhood or teenage years (hence the former designation of juvenile diabetes).

If not replaced, absolute insulin deficiency in T1DM results in severe hyperglycemia and diabetic ketoacidosis (DKA), which if left untreated can prove fatal (hence the designation IDDM). Insulin replacement ideally takes the form of basal/bolus insulin therapy, delivered either via multiple daily insulin injections or an insulin pump infusion. Poorly controlled type 1 diabetes can lead to, among other complications, nephropathy (kidney damage manifested by excess protein in the urine) and end-stage kidney damage, retinopathy potentially leading to decreased visual acuity, and neuropathy and the risk of diabetic foot infections or ulcerations. Long-standing diabetes is also associated with increased risk for heart disease, stroke, and peripheral vascular disease. Maintaining good glycemic control, as deflected by an HbA1c of 7% or less, will prevent many of the chronic complications of the disease.

Holistic medicine

Definition

Integrative medicine is a term for an emerging field of study and clinical practice that combines the best of complementary, alternative, and conventional medicine. Complementary and alternative medicine is defined by the National Institutes of Health as a broad range of healing approaches, therapies, and philosophies that conventional Western medicine does not commonly use, study, or make available. Complementary medicine refers to the use of these therapies in addition to conventional medicine; alternative medicine refers to their use in place of conventional medicine. Integrative medicine also incorporates lifestyle interventions that have emerged as important aspects of health promotion and disease prevention within mainstream Western medicine (Institute of Medicine [IOM], 2009a).

Initially driven by consumer demand, integrative medicine is a rapidly growing field that may offer a pathway toward better health care and the potential for significant decreases in national health care costs. It emphasizes the human capacity for healing, the centrality of the relationship between patient and clinician, a focus on the whole person, and use of all appropriate therapeutic approaches, disciplines, and health-care professionals (Consortium of Academic Health Centers in Integrative Medicine (CAHCIM)) (http://www.imconsortium.org). This holistic orientation contrasts with the stereotypical approach of conventional medicine based on specialization and reliance on biotechnology in diagnosis and treatment.

Description

Background

The integrative medicine movement has emerged from dissatisfaction with conventional biomedicine. Some 20 years ago, it was observed that public confidence in the medical establishment was eroding and that the fundamental relationship between patient and physician was disintegrating (Snyderman and Weil, 2002). This state of affairs was attributed to the fact that the historical role of the physician as a comprehensive caregiver had diminished due to increasing reliance on costly and impersonal technologies rather than careful histories and physical examinations. The biomedical approach conceptualized the body as a machine, the doctor's task as that of repairing the machine, and presumed that healing of the whole could be effected via treatment of its component parts. This approach resulted in spectacular successes in some areas of medicine, but a different perspective was seen to be needed for chronic diseases.

By 1993, more than a third of all adults in the United States reported using some form of "unconventional" medicine, such as various relaxation techniques, chiropractic, and massage (Astin, 1998; Eisenberg et al., 1993). In 1995, the National Institutes of Health (NIH) established an Office of Alternative Medicine, which grew by 1998 into the National Center for Complementary and Alternative Medicine (NCCAM). The stated goal of NCCAM is to define, through rigorous scientific investigation, the usefulness and safety of complementary and alternative medicine interventions and their roles in improving health and health care. Alternative and complementary medicine practices fall into broad clusters of approaches including natural products (e.g., special diets, probiotics, dietary supplements, and botanical medicine), mind-body practices (e.g., meditation, deep breathing, cognitive

therapies, yoga, tai chi, and qi gong), and manipulative and body-based practices (manual medicine, chiropractic, massage, special forms of exercise and movement therapies, etc.). NCCAM also supports studies of whole medical systems such as traditional Chinese medicine and Ayurvedic (Indian) medicine. Acupuncture, one of the oldest healing practices in the world, is an important form of complementary medicine.

Academic centers devoted to integrative medicine began to appear that offered programs in research, professional education, and clinical practice. A proliferation of these centers led to the formation of umbrella organizations that provided support for this growing field, such as CAHCIM, founded in 1988, and the Bravewell Collaborative, founded in 2002. The Bravewell group, a philanthropic collaborative, supported the efforts of CAHCIM, which by 2011 included more than 50 academic health centers and associated health-care systems (CAHCIM, http://www.imconsortium.org).

Philosophy of Integrative Medicine

Integrative medicine reflects a systems approach to understanding health and healing. It recognizes that humans are complex entities, and the most important influences on health, for individuals and society, are not the factors at play within any single domain – environmental, behavioral, or genetic – but the dynamics, synergies, and reciprocal interactions among these domains. In other words, the human body functions like an orchestrated network of interconnected systems, whose overall condition is sensitive to environmental context, dietary intake, and other lifestyle factors which can increase susceptibility to other pathogenic variables (IOM, 2009a).

The goal of integrative medicine is to provide patient-centered, evidence-based care that honors an integrated systems approach to health across the life span. Patient-centered care means treating the patient as an integral part of the care team and putting responsibility for important aspects of health monitoring and care in the patient's hands. Evidence-based health care involves increased reliance on a foundational science that takes an empirical approach to treatment efficacy, as well as the investigation of biological mechanisms by which environmental, psychosocial, behavioral, and genetic factors influence health and disease.

Seven of the most common chronic diseases – heart disease, hypertension, stroke, cancer, diabetes, pulmonary conditions, and mental disorders – account for more than half of all health-care costs, and more than 70% of deaths (Centers for Disease Control and Prevention, www.cdc.gov). The traditional view was that these disorders are primarily genetic in origin and largely unpreventable. The integrative medicine community recognizes that factors such as where we live, conditions of our environments, income and education levels, and relationships with friends and family all interact with genetic predispositions to influence health and potentiate the development of acute and chronic diseases. Evidence is accumulating that many disorders can be prevented or their onset delayed via healthy lifestyles characterized by attention to dietary intake, increased physical activity, stress management by various mind-body approaches, adequate sleep, and decreased tobacco and alcohol use. Some integrative medicine centers offer "coaching" in nutrition, physical fitness, stress management, and emotional and spiritual health as parts of a broad-spectrum approach. Such comprehensive interventions have been shown, for example, to slow the progress of atherosclerosis and are now covered in the United States by Medicare (Frieden, 2005). The development of cost-effective programs for maintaining health-promoting behavior over the long term without compromise of individual freedom remains an important goal if the integrative medicine movement is to realize its full potential.

Evidence Base for Integrative Medicine

The Cochrane Library lists thousands of studies of complementary medicine and hundreds of reviews of these studies. Reviews of the literature regarding some approaches, such as meditation, yoga, and therapeutic massage, have often been favorable but typically note that sample sizes tend to be small and the designs contain methodological weaknesses. Many of these studies have been conducted in the form of randomized

clinical trials (RCTs) that are based on well-defined interventions and carefully selected patient populations. As in pharmacological research, however, the results of these RCTs are presented in terms of average treatment effects, compared with a control group, often placebo or "usual care." Thus, the relevance of these findings to decision making in the individual case is limited (Greenfield et al., 2007).

Moreover, integrative medicine interventions sometimes lend themselves poorly to classic RCT methodology because they often involve potentially synergistic, multimodal, and complex interactions that are delivered in the context of a patient-practitioner relationship and influenced by patient preferences, expectations, and motivations. It is known that patients vary in their expectations regarding the perceived efficacy of treatments, and these expectations can influence treatment outcome. For example, the impact of expectations on therapeutic outcomes was analyzed in a series of four RCTs of acupuncture effects on chronic low back pain, osteoarthritis of the knee, migraine headache, and tension headache (Linde et al., 2007). Positive attitudes toward acupuncture and high personal expectations for treatment benefits were consistently associated with better outcomes at the end of treatment and at 4-month follow-up.

Integrative medicine encourages the patient to take an active role in his or her own health, and is sensitive to nuances in the patient-practitioner interaction. The placebo effect is of particular relevance to integrative medicine because of the importance of the patient-practitioner relationship. It has been found, for example, that the therapeutic power of analgesic drugs is markedly greater when administered by a clinician than when administered automatically by an infusion pump (Benedetti et al., 2005).

Progress in understanding mechanism of action of the placebo effect has been slow, however, because of complexities in the definition of the term placebo (Miller and Kaptchuk, 2008). In conventional medicine, where attention to healing by technological intervention has overshadowed healing via practitioner-patient interaction, the role of the placebo effect in treatment effects has often been minimized. Nevertheless, some conventional treatments, including knee surgery (Moseley et al., 2002) and spinal injections (Buchbinder et al., 2009: Kallmes et al., 2009) that are superior to no treatment (wait list) conditions have been matched in efficacy by placebo "controls." Indeed, one focus of research in integrative medicine is on the role of contextual factors in healing, such as the environment of the clinical setting, the cognitive and affective communication of clinicians, and the ritual of administering treatment (Kaptchuk et al., 2008).

Because of such complexities, integrative medicine advocates have called for a broadening of the range of strategies for evaluating the effectiveness of integrative medicine interventions beyond standardized RCTs (Fonnebo et al., 2007). Among these is comparative effectiveness research (CER), which was defined by the IOM (IOM, 2009a) as "the generation and synthesis of evidence that compares the benefits and harms of alternative methods to prevent, diagnose, treat and monitor a clinical condition, or to improve the delivery of care (p. 13)" with the goal of improving health care at the individual as well as the population level. In CER, research designs permit the study of complex interventions as they are applied in clinical practice (FCC, http://www.hhs.gov) and encourage analysis of subgroups within studies to meet the growing interest in personalized or patient-centered medicine (Goodman, 2009; Institute of Medicine [IOM], 2011).

While RCTs, CER, and other strategies examine efficacy, integrative medicine research is also beginning to explore the biological pathways and mechanisms by which interventions exercise their influence. This research is needed to establish biological plausibility and reassure conventional practitioners about the value of integrative medicine.

Relevance to Preventive Medicine

The integrative medicine movement has the potential to reduce health-care costs via attention to strategies for the prevention of chronic disease associated with the maintenance of health and improved quality of life (IOM, 2009a). Evidence for this can be found in corporate programs that focus on prevention and wellness. While not

explicitly conceptualized as integrative medicine programs, these efforts are consistent with the integrative medicine philosophy that advocates a culture of health, including modifications to cafeteria and vending machine options, physical environments that promote exercise, and the use of quiet areas for relaxation and stress reduction. For example, a review of the long-term impact of the health and wellness program at Johnson and Johnson reported significant reductions in medical expenditures over a 4-year period together with decreased outpatient and mental health visits (Ozminkowski et al., 2002). Another program, consisting of work site health education, nutritional counseling, smoking cessation counseling, physical activity promotion, selected physician referral, and health counseling, reported improvements in quality of life and scores on risk factors, together with significant reductions in health care and inpatient expenses (Richard et al., 2009).

In summary, integrative medicine is a rapidly growing field that merges the best of complementary and alternative medicine with conventional medicine. Initially driven by consumer dissatisfaction with aspects of biomedicine, it reasserts the importance of the patient-practitioner relationship and the need to consider health and disease within a holistic orientation. It is developing relevant methodology for systematic investigation of the validity and utility of complex interventions and for investigation of the importance of health and wellness within the context of the interactions of the individual with the environment. Within this framework, the placebo effect is redefined as contextual healing and thereby merits independent investigation. The ultimate success of integrative medicine will depend upon the evidence of relative efficacy of a variety of interventions in a variety of disorders and with an eventual understanding of the mechanisms by which salutary treatment effects are achieved.

Intention

Peter A. Hall
Faculty of Applied Health Sciences, University of Waterloo, Waterloo, ON, Canada

I

Definition

Intention strength can be defined as the quantity of personal resources that an individual is prepared to invest in executing a behavior. Intention strength is closely akin to the concept of "motivation," with high levels of intention strength understood to represent strong motivation to perform a behavior. Intentions play a prominent role in several theories of health behavior, including the *Theory of Reasoned Action* (Fishbein & Ajzen, 1975), the *Theory of Planned Behavior* (Ajzen & Madden, 1986), the *Health Action Process Approach* (Schwarzer, 2001), and *Temporal Self-regulation Theory* (Hall & Fong, 2007). From an empirical perspective, intentions are among the strongest predictors of health behavior performance. However, a number of factors are known to moderate intention-behavior relations, including perceived/actual controllability of the behavior, as well as habit strength (Webb & Sheeran, 2006).

Interleukins

▶ Cytokines

Interleukins, -1 (IL-1), -6 (IL-6), -18 (IL-18)

Nicolas Rohleder
Department of Psychology, Brandeis University, Waltham, MA, USA

Synonyms

B-cell stimulatory factor 2; Cytotoxic T cell differentiation factor; Hepatocyte stimulating factor; Hybridoma growth factor; Hybridoma plasmacytoma growth factor; Lymphocyte-activating factor (LAF)

Definition

Interleukins (IL) are chemical messenger molecules of the immune system, and therefore fall into the category of cytokines. The term "interleukin" denotes their primarily ascribed function, i.e., the communication between (inter) white blood cells (leukocytes). IL-1, IL-6, and IL-18 are pro-inflammatory cytokines due to their predominant function to stimulate inflammatory processes in target cells.

Interleukin-1 is one of the first discovered cytokines, and consists of a family of three different molecules: IL-1alpha and IL-1beta exert their actions through binding to different members of the IL-1 receptor family, while the third molecule IL-1 receptor antagonist (IL-1ra) blocks these effects. The IL-1 family of cytokines was first cloned in 1984 (for a summary, see Dinarello, 1994). IL-1 has a wide range of effects, which include activation of interleukin-6 gene expression and other inflammatory mechanisms, thereby making it a central pro-inflammatory cytokine. In addition to inflammatory stimuli, IL-1 can also be activated by psychosocial factors: For example, IL-1beta gene expression has been shown to be upregulated following an acute laboratory stress paradigm (Brydon et al., 2005), and the same was reported for plasma concentrations of IL-1ra (Rohleder et al., 2006).

Interleukin-6 was first described as a T lymphocyte derived factor that was required for antibody production by B lymphocytes, and was consequently called B-cell stimulatory factor-2 (summarized, e.g., in Kishimoto, 2010). Additional functions were described in parallel, and led to the existence of different names for the same substance (e.g., hybridoma/plasmacytoma growth factor, or hepatocyte stimulating factor, etc.), and only the cloning of the molecule made clear that it was indeed the same protein, which was then named IL-6 (Poupart et al., 1987). IL-6 effects are not limited to the immune system, but include many tissues throughout the body. IL-6 is

therefore frequently referred to as a pleiotropic or endocrine cytokine (Papanicolaou & Vgontzas, 2000). While originally thought to be secreted only from immune cells upon inflammatory stimulation, it is now clear that IL-6 is secreted from a variety of cells, e.g., adipocytes and endothelial cells (e.g., Hoch et al., 2008; Kobayashi et al., 2003). IL-6 acts by interaction with a complex of the IL-6 receptor (IL-6R) and an additional protein gp130 (Heinrich, Behrmann, Muller-Newen, Schaper, & Graeve, 1998) and subsequent activation of the JAK-Stat pathway, ultimately inducing transcription of inflammatory gene products (Kishimoto, 2010).

Interleukin-18 was first cloned in 1995 and referred to as interferon-gamma inducing factor (IGIF) (Okamura et al., 1995). IL-18 shares some similarities in origin, receptors, and signaling pathways with the inflammatory cytokine IL-1, which implies overlaps in function, and underscores the role of IL-18 in inflammatory signaling (Arend, Palmer & Gabay, 2008). In contrast to IL-6, IL-18 seems to be produced mainly by cells of the immune system, such as monocytes/macrophages and dendritic cells. Similar to IL-6, however, IL-18 has the potential to affect more than immune cells, because the IL-18 receptor complex is present on endothelial cells, smooth muscle cells, as well as cells involved in bone and cartilage formation, in addition to immune cells. IL-18 signals through a receptor complex that bears similarity with the IL-1 receptor system, and as such activates the transcription of inflammatory gene products (Arend et al., 2008).

Inflammatory cytokines are interesting molecules in biobehavioral research, because they serve as a link between central nervous system states with pathophysiological factors that are central in a variety of human diseases. Inflammatory cytokine production is modulated by the sympathetic nervous system and the hypothalamus-pituitary-adrenal axis, and pro-inflammatory cytokines in blood are sensitive to acute and chronic stress, and found to be increased in depression and posttraumatic stress disorder (e.g., Steptoe, Hamer, & Chida, 2007; Rohleder, Marin, Ma, & Miller, 2009; Rohleder, Wolf, & Wolf, 2010). Inflammatory cytokines also increase with age, and have been found to predict later life morbidity and mortality (e.g., Bruunsgaard et al., 2003).

International Society of Behavioral Medicine

Neil Schneiderman
Department of Psychology, Behavioral Medicine Research Center, University of Miami, Coral Gables, FL, USA

Basic Information

The International Society of Behavioral Medicine (ISBM) is a federation of 26 national, regional, and more specialized scientific societies, whose goal is to serve the needs of all health-related disciplines concerned with issues relevant to behavioral medicine. Behavioral medicine is an interdisciplinary field concerned with the development and integration of sociocultural, psychosocial, behavioral, and biomedical knowledge relevant to health and illness and the application of this knowledge to disease prevention, health promotion, etiology, diagnosis, treatment, and rehabilitation. Each full member constituent society of the ISBM includes both biomedical and behavioral scientists. Societies with interests relevant to behavioral medicine, but which do not meet all criteria for membership (e.g., having both biomedical and behavioral scientists as individual members), may apply to become affiliate members. The Division of Health Psychology of the American Psychological Association and the Association of Pediatric Psychology are affiliate members. The ISBM was formally founded in June 1990 in conjunction with the First International Congress of Behavioral Medicine, held in Uppsala, Sweden.

One major goal of the ISBM has been to encourage the formation of national and regional societies of behavioral medicine. Beginning with six founding organizations (Academy of Behavioral Medicine Research, USA; Czechoslovakia Medical Association Section on Neurohumoral Integration and Behavioral Medicine and Modification; German Association of Behavioral Medicine and Modification; Dutch Behavioral Medicine Federation; Society of Behavioral Medicine, USA; and the Swedish Society of Behavioral Medicine), by 2010 there were 24 national societies and 2 regional societies (An Australasian Society constituted primarily of members from Australia and New Zealand; and a Central and Eastern European Society with membership from 11 central and eastern European countries). A change in the ISBM bylaws in 2011 now allows specialized scientific societies besides national and regional scientific societies, who otherwise meet ISBM membership criteria, to apply for ISBM membership. It is important to note that societies rather than individual persons belong to the ISBM. Individuals

living in a country that does not have a society belonging to ISBM can derive ISBM benefits (e.g., reduced registration fees for the international congress; journal access) by joining an existing society belonging to ISBM. Listing of the constituent societies of the ISBM as well as the bylaws, charter, membership information, activities of the society, newsletter and members of the Executive Committee, Board and Governing Council can be found at the ISBM website http://www.isbm.info.

A second major goal of the ISBM is to encourage and coordinate communications and interactions among various health professionals including biomedical and behavioral science researchers, educators, clinicians and public health workers without regard to specific discipline loyalties. One major vehicle for promoting interdisciplinary, international scientific communication has been via the International Congresses of Behavioral Medicine, staged by the ISBM in conjunction with host societies every two years since 1990. The Congresses feature keynote addresses master lectures, symposia, oral presentations, posters, and preconference workshops. A unique feature of each symposium is that it usually features representation from more than one country with participation from more than one discipline.

The scientific program features approximately 25 distinct tracks covering a range of biomedical, behavioral, and sociocultural behavioral medicine topics. Symposia and oral presentations are presented in approximately eight simultaneous, parallel sessions. Poster sessions are prominently featured so that they are not in conflict with the oral presentations. About 800 individuals, most formally presenting their research, attend the Congresses. A listing of the ISBM presidents, congresses, and program chairs is presented below.

President	Term	Congress	Date	ISBM Program Chair (s)
		Uppsala	1990	Arne Öhman/ Andrew Steptoe
Stephen Weiss	1990–1992	Hamburg	1992	Kristina Orth-Gomér
Kristina Orth-Gomér	1992–1994	Amsterdam	1994	Neil Schneiderman
Andrew Steptoe	1994–1996	Washington	1996	*Ad Appels/ Craig Ewart* (SBM)
Johannes Siegrist	1996–1998	Copenhagen	1998	Jane Wardle
Neil Schneiderman	1998–2000	Brisbane	2000	Margaret Chesney
Brian Oldenberg	2000–2002	Helsinki	2002	Christina Lee
Gunilla Burell	2002–2004	Mainz	2004	Neil Schneiderman
Antti Uutela	2004–2006	Bangkok	2006	Brian Oldenburg
Redford Williams	2006–2008	Tokyo	2008	Theresa Marteau
Hege Eriksen	2008–2010	Washington	2010	Linda Baumann
Norito Kawakami	2010–2012	Budapest	2012	Frank Penedo
Joost Dekker	2012–2014	Groningen	2014	

Besides the congresses, a second major vehicle for promoting interdisciplinary, international scientific communication by the ISBM has been through the *International Journal of Behavioral Medicine* (IJBM). The IJBM, which is the official publication of the ISBM, presents original research and integrative reviews on interactions among behavioral, psychosocial, environmental, genetic, and biomedical factors relevant to health and illness. The scope of the IJBM extends from research on biobehavioral mechanisms and clinical studies on diagnosis, treatment, and rehabilitation to research on public health, including health promotion and prevention. The IJBM was originally published in 1994 with Lawrence Erlbaum Associates as the publisher and Neil Schneiderman (1994–1998) as founding editor. Ulf Lundberg succeeded Schneiderman as editor from 1999 to 2005 and was himself succeeded by Joost Dekker (2006–2011). Starting with Volume 16 in 2009, under the editorship of Dekker, Springer became the publisher of IJBM. Beginning in 2012, the editorship of the IJBM passed to Christina Lee. Throughout its existence the IJBM has had a strong, scholarly

group of associate editors, balanced in terms of discipline, scientific expertise, geography, and gender. They, in turn, have been supported by an effective editorial board. Within the ISBM the reach of the journal is extensive as all members of ISBM member societies receive free access to the online version of the IJBM. The IJBM offers a free table of contents alert e-mail service that notifies individuals as soon as a new issue of IJBM has been published online.

A third vehicle for promoting interdisciplinary, international scientific communication within the ISBM has been the ISBM Newsletter. Published twice per year, the newsletter provides an outlet for communication to and from the membership of the constituent societies of the ISBM including reports from the ISBM president, newsletter editor, IJBM editor, ISBM committee chairs (e.g., program committee), information of interest from member societies, and interviews with various people who have contributed to the development of the ISBM.

Still a fourth vehicle for promoting interdisciplinary, international scientific communication has been through education and training activities including workshops and teaching seminars that have featured collaborations between prominent members of the ISBM and potential, emerging, or established member societies. These have led to the founding or strengthening of member societies of the ISBM and to published volumes (e.g., Orth-Gomér & Schneiderman, 1996). The Education and Training Committee also has interest in monitoring, developing, and publicizing curricula relevant to behavioral medicine.

The governance of the ISBM occurs through its Governing Council, Executive Committee and Board. Supervising the control and direction of the affairs of the ISBM occurs through the Council. This Council comprises one voting representative from each member society of the ISBM, who is designated by that society. The Board, which conducts the normal deliberative business of the ISBM between Council meetings, reports to the Council. In instances in which the ISBM President finds that there is need for immediate action by a group smaller than the Board, the President will call upon an Executive Committee consisting of the President, Past-President, President-Elect, Secretary, and Treasurer. The Board consists of the members of the Executive Committee, the chairs of the Communications, Education and Training, Finance, International Collaborative Studies, Membership, Nominating, Organizational Liaison, Program, and Strategic Planning committees as well as the editors of the IJBM and newsletter and any elected member(s)-at-large. Although the outcome of elections is based upon the votes of the Governing Council, the ISBM has attempted to consider balance in terms of discipline, scientific stature, gender, and age.

Major Impact on the Field

The International Society of Behavioral Medicine (ISBM) is the largest Behavioral Medicine Organization in the world. Its constituent 26 national and regional societies represent the vast majority of self-identified behavioral medicine researchers in the world. Through its website, Congresses, journals, newsletters, and teaching seminars, the ISBM facilitates communications among behavioral medicine scientists and other professionals throughout the world.

Internet-Based Studies

Ulf-Dietrich Reips
Faculty of Engineering; Faculty of Education and Psychology, Universidad de Deusto, Bilbao, Spain
IKERBASQUE, Basque Foundation for Science, Bilbao, Spain

Synonyms

Internet science; iScience; Internet-mediated studies; Web-based studies

Definition

Internet-based studies are roughly systematized in four categories (Reips, 2006): Internet-based experiments, web surveys and questionnaires, Internet-based assessment, and nonreactive data collection on the Internet. In a wider sense, studies about human activities on the Internet can also be defined as Internet-based studies.

Description

Beginning

The first Internet-based studies were conducted in the mid-1990s, shortly after the World Wide Web had been invented at CERN in Geneva (Musch & Reips, 2000; Reips, 2006). Conducting studies via the Internet is considered a second revolution in behavioral research, after the computer revolution in the late 1960s and early 1970s that brought about many advantages over widely used paper-and-pencil procedures (e.g., automated processes, heightened precision). The Internet revolution in behavioral research added the dimension of interactivity via a worldwide network that resulted in several mostly advantageous characteristics of Internet-based studies (see below).

Examples for studies conducted on the WWW, current and archived, can be viewed at sites like the *Web experiment list* (http://wexlist.net, Reips & Lengler, 2005), see Fig. 1, and the *Psychological Research on the Net* list that is maintained by John Krantz (http://psych.hanover.edu/research/exponnet.html).

Characteristics

Although Internet-based studies have some inherent limitations due to a lack of control and observation of conditions, they also have a number of advantages over lab research (Birnbaum, 2004; Kraut et al., 2004; Reips, 2002; Schmidt, 1997). Some of the chief advantages are that (1) researchers can recruit and study large numbers of participants very quickly; (2) it is possible to collect and access large behavioral data sets, recruit large heterogeneous samples and people with rare characteristics (e.g., people who have had biofeedback training in more than one country or persons suffering from sexsomnia and their peers, Mangan & Reips, 2007) from locations far away; and (3) the method is more cost-effective in time, space, and labor in comparison with lab research. Compared to paper-and-pencil research, most of the advantages of computer-mediated research apply, for example, process variables ("paradata") that can be recorded (Stieger & Reips, 2010).

Types

Internet-based studies are roughly systematized in four categories (Reips, 2006, see Fig. 2): Internet-based experiments (Reips, 2002), web surveys and questionnaires (Dillman & Bowker, 2001; Dillman, Smyth, & Christian, 2009), Internet-based assessments (Buchanan, 2001; Buffardi & Campbell, 2008), and nonreactive data collection on the Internet (Reips & Garaizar, 2011). Within psychology, most Internet-based research is conducted in the fields of social psychology and cognition (Musch & Reips, 2000; Reips & Lengler, 2005). Within behavioral medicine, as judged from an analysis of the articles published in the *Journal of Medical Internet Research*, the most frequented fields seem to be e-health and e-mental health, in particular depression, obesity/weight management, and smoking cessation.

Internet-Based Studies, Fig. 1 The web experiment list and web survey list

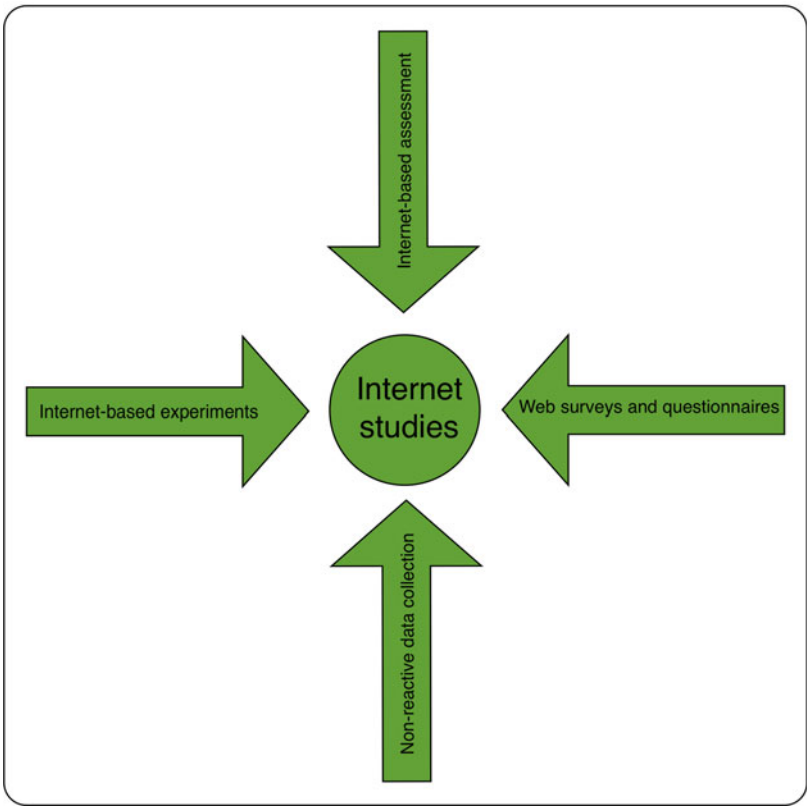
In a wider sense, studies about human activities on the Internet (e.g., accessing Internet support groups, online dating) can also be defined as Internet-based studies (e.g., Eysenbach, Powell, Englesakis, Rizo, & Stern, 2004; Whitty & Buchanan, 2010).

Recently, the advent of social media, that is, highly interactive Internet-based communication platforms, has spurred the interest of researchers. Social networking services like Facebook, Tuenti, Orkut, LinkedIn, Twitter, and Student VZ are seen as vast resources for detailed descriptions of human behavior (Reips & Garaizar, 2011).

Methods

For anyone planning to conduct studies via the Internet, it is important to realize that there is a growing body of literature on theoretical insights, empirical results, and practical guidelines that needs to be taken into account when setting up Internet-based data collection.

Reips (2002) and Reips and Birnbaum (2011) provide guidelines and overviews of techniques, methods, and tools for Internet-based studies. They summarize challenges and solutions in design, security, recruitment, sampling, self-selection, multiple submissions, reactance-free question



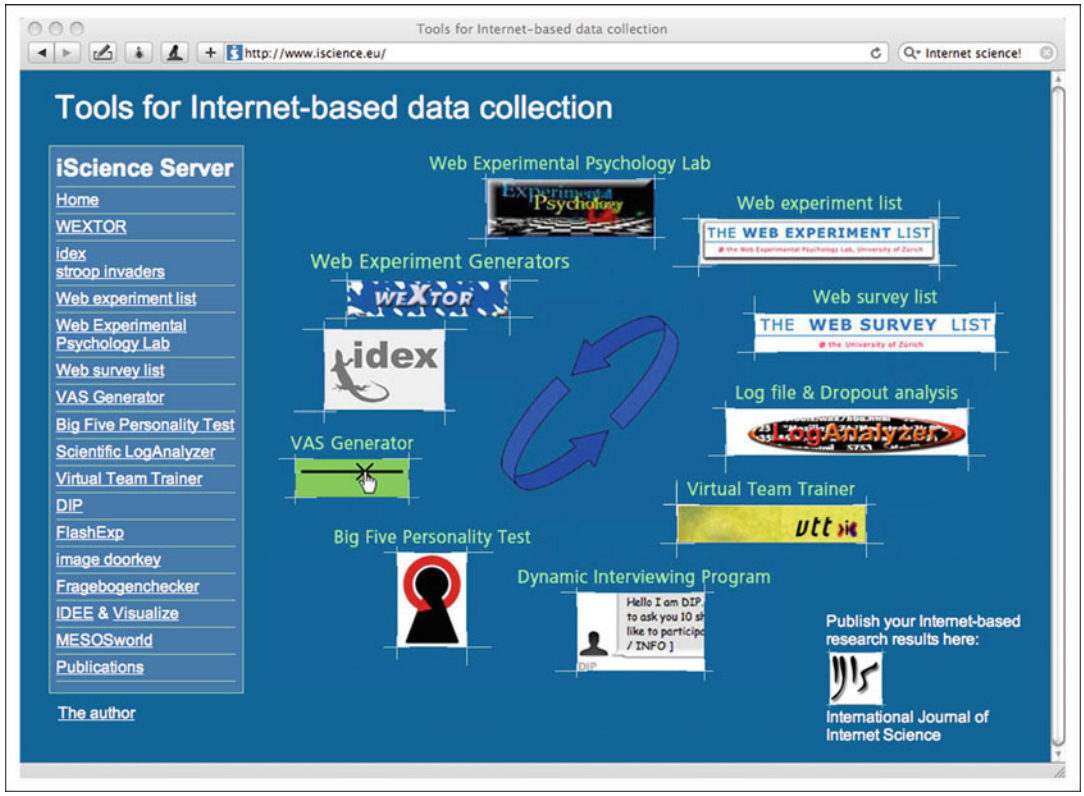
Internet-Based Studies, Fig. 2 Types of Internet-based studies

design, response time measurement, dropout, error estimation, data handling, and data quality. For example, in creating items for a Web questionnaire it is often forgotten to add a neutral option ("please choose") in drop-down menus. Thus, one of the answer options is automatically selected, even if the respondent skips the item. Another pitfall is the higher likelihood for attrition on the web, compared to lab-based studies. Among other methods that have been developed in web methodology and Internet science, Reips (2010) explains the one-item-one-screen (OIOS) design, the seriousness check, subsampling procedures, multiple site entry, and the high hurdle technique and discusses empirical results from investigations into the validity of several of the techniques.

Implications

Most authors agree that the Internet is a viable option for conducting studies in the behavioral and social sciences (Birnbaum, 2004; Joinson, McKenna, Postmes, & Reips, 2007; Kraut et al., 2004; Musch & Reips, 2000; Reips, 2002, 2006). Care should be taken to properly implement an adequate methodology suited for Internet-based studies (Reips, 2002) and consider potentially biasing effects of technology (Schmidt, 2007).

Two important issues for much of human interaction on and with the Internet are: real and perceived privacy as well as trust, for example, in accessing health-related information via the Internet (Buchanan, Joinson, Paine, & Reips, 2007; Eysenbach et al., 2004). Such information can be accessed more easily via the Internet, in part because it can be found more privately. Threats to privacy on the Internet reduce the willingness to look for information online. Furthermore, people are less likely to search for healthcare information through mechanisms or agencies that they do not trust



Internet-Based Studies, Fig. 3 A portal for researchers that links to many tools for Internet-based studies: the iScience Server at http://iscience.eu

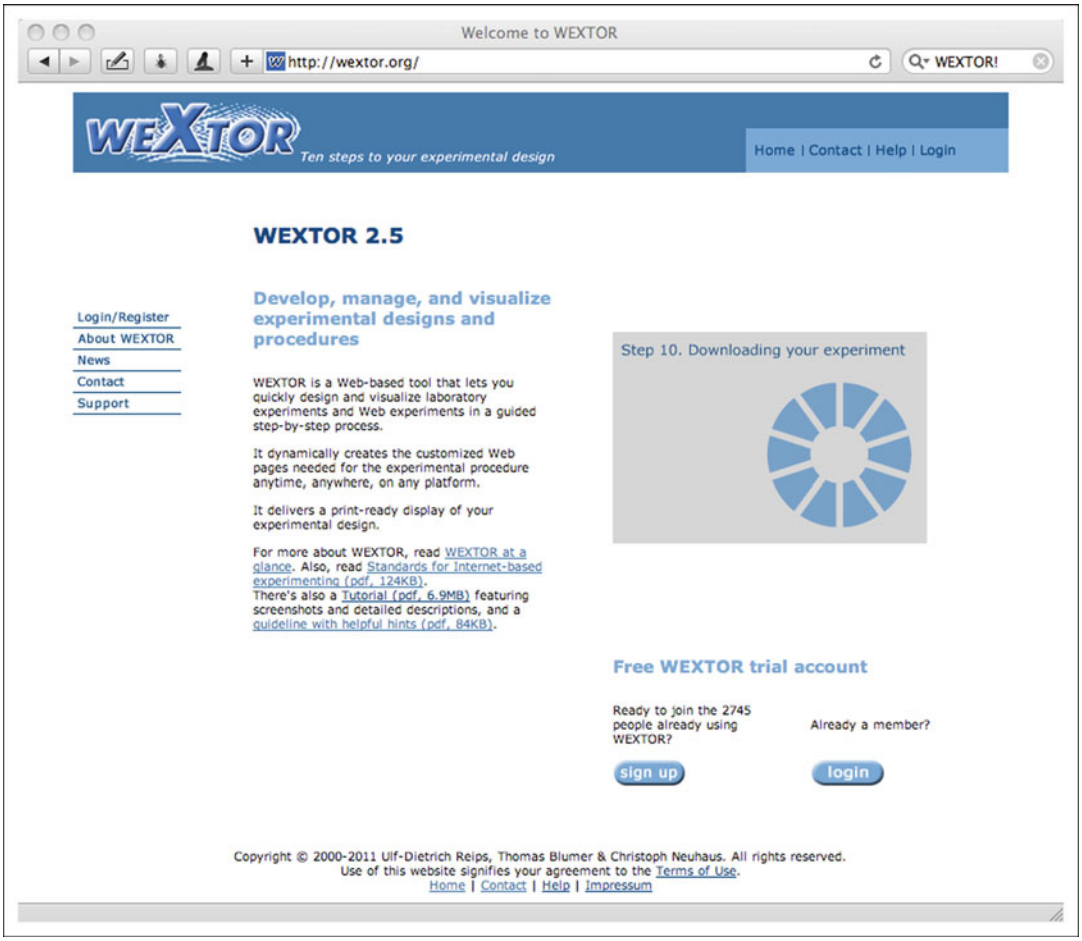
(Buchanan et al., 2007). For the data quality in Internet-based studies that usually involve self-disclosure perceived, privacy and trust are essential as well (Joinson, Reips, Buchanan, & Paine Schofield, 2010).

It seems important that authors, reviewers, and editors of articles reporting results from Internet-based studies follow the guidelines that were developed in this new field. Scientists in behavioral medicine considering to conduct research via the Internet will thus need to prepare for challenges like more heterogeneous samples, higher nonresponse, and the effects of mode and technologies. Benefits like wider reach, better quality of data from truly voluntary respondents, and a reduced tendency for socially desirable responding, reduced costs, and validated tools for Internet-based research will further increase the use of the new methodology.

Resources

The following resources are available for researchers who want to conduct Internet-based studies:

- iScience Server (http://iscience.eu/, Fig. 3): A portal for the methodology of Internet-based research
- iScience Maps (http://tweetminer.eu/, Reips & Garaizar, 2011): A data mining tool for the social media service Twitter
- Questionnaire evaluator (http://iscience.eu/fbchecker/): An interactive web tool to examine questions and questionnaires (in German and English)
- Big 5 (http://webscience.deusto.es/big5/): A self-scoring Big Five personality test ready for use by simply linking it to another online study (in English, German, and Spanish)



Internet-Based Studies, Fig. 4 WEXTOR, a web service to generate and conduct Internet-based experiments

- VAS Generator (http://www.vasgenerator.net/, Reips & Funke, 2008): A tool to create visual analogue scales (VAS) for online studies
- WEXTOR (http://wextor.org, Reips & Neuhaus, 2002, Fig. 4): A system for conducting web-based experiments

Interpersonal Circumplex

Timothy W. Smith
Department of Psychology, University of Utah, Salt Lake City, UT, USA

Synonyms

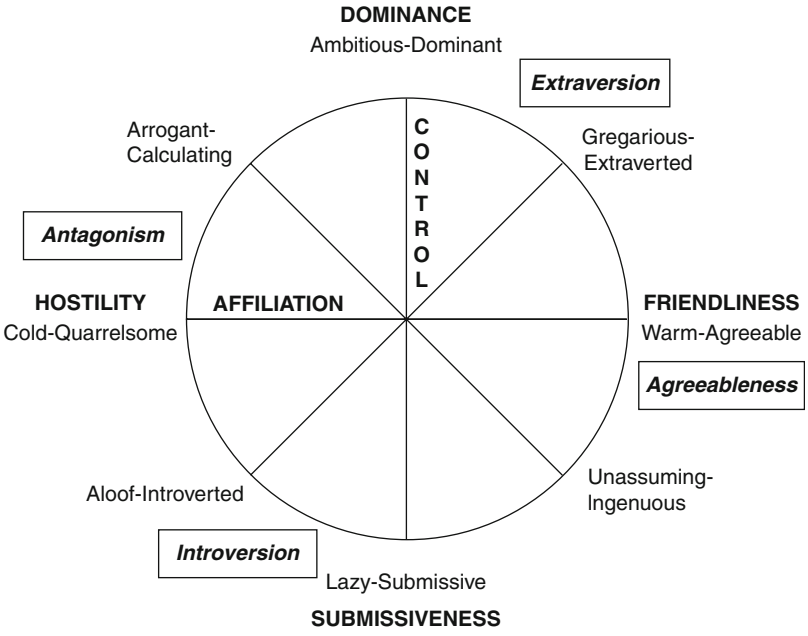
Affiliation; Control; Dominance; Hostility; Social behavior; Submissiveness; Warmth

Definition

The interpersonal circumplex (IPC; see Fig. 1) is a conceptual model of social behavior, comprising two main dimensions: *affiliation* (i.e., warmth, friendliness vs. hostility, quarrelsomeness) and *control* (i.e., dominance, directiveness vs. submissiveness, deference).

Description

The IPC has a long history, dating to the work of Sullivan, Leary, and other mid-twentieth century behavioral scientists (for a review, see Fornier,



Interpersonal Circumplex, Fig. 1 The interpersonal circumplex

Moskowitz, & Zuroff, 2011). This structural model is a cornerstone of the interpersonal tradition in personality, clinical, and social psychology (Horowitz & Strack, 2011) and can be used to describe momentary social behavior, more stable individual differences in social behavior (i.e., personality traits), and characteristics of social relationships and social contexts. The IPC describes specific actions as blends of control and affiliation, and similarly describes personality characteristics and aspects of social relationships as varying in dominance versus submissiveness and warmth versus hostility. In terms of personality traits, as seen in Fig. 1, affiliation and control are rotational equivalents of the Five Factor Model traits of agreeableness versus antagonism and extraversion versus introversion. Agreeableness corresponds to somewhat submissive warmth in the IPC, whereas extraversion corresponds to somewhat warm dominance.

The interpersonal circumplex can also be used to describe social motives. In interpersonal theory, social interactions involve the exchange of two broad and primary social resources: status (i.e., esteem or regard from others) and love (i.e., liking, acceptance, or inclusion by others). These resources are the focus of two similarly broad social motives; *agency* refers to striving for status, achievement, or power, whereas *communion* refers to striving for connection with others and the maintenance of relationships. Hence, agency and communion are the motivational equivalents of the IPC control and affiliation dimensions, respectively. Dominant behavior reflects an attempt to gain or assert status, whereas deference or submissiveness reflects granting status to an interaction partner. Warm behavior reflects seeking affection, acceptance, or inclusion from interaction partners, or granting such connection to them. Hostile behavior, in contrast, reflects withholding or revoking such connection.

The IPC is the conceptual foundation for another major tenet of the interpersonal tradition – the principle of complementarity (for a review, see Sadler, Etheir, & Woody, 2011). In this view, social behavior of one individual tends to invite or evoke responses from an interaction partner that are similar in affiliation (i.e., warmth invites warmth; hostility invites hostility) and opposite in control (i.e., dominance invites deference). Empirical evidence regarding complementarity for the affiliation dimension of the IPC is stronger than for the control dimension (Sadler et al., 2011).

In behavioral medicine, psychosomatic medicine, and health psychology, the IPC has been used primarily in the study of psychosocial risk factors for disease and the psychophysiological mechanisms underlying those associations. Specifically, the IPC and the related concept of complementarity are useful in the development of an integrated understanding of psychosocial influences on disease (Smith & Cundiff, 2011; Smith, Glazer, Ruiz, & Uchino, 2004). A variety of personality characteristics, symptoms of emotional distress, and emotional disorders have been studied as potential risk factors for serious illnesses (e.g., coronary heart disease), all-cause mortality, and reduced longevity. Similarly, a variety of aspects of social relationships (e.g., social isolation, low social support, conflict or strain in personal relationships) and social contexts (low socioeconomic status of individuals and neighborhoods, job stress) have been examined as risk factors for these same outcomes. However, these risk factors are usually studied individually, with little concern about their potentially overlapping associations with disease (Smith, 2010; Suls & Bunde, 2005). Further, risk factors that are conceptualized as aspects of individuals (e.g., personality, emotional distress) are typically seen as a class of influences on disease that is distinct from characteristics of social relationships and contexts also examined as risk factors (e.g., low social support; Lett et al., 2005). This piecemeal approach to risk factors impedes an integrated view of psychosocial risk as it ignores overlapping influences on disease and naturally occurring patterns or aggregations of risk factors (Smith & Cundiff, 2011). To address this problem, measures of multiple psychosocial risk factors can be correlated with independent measures of the two IPC dimensions. Such analyses identify the associated interpersonal style or characteristics associated with multiple risk factors and can thereby identify broader or common dimensions of risk.

For example, anger and hostility predict the development and course of coronary heart disease (CHD), as do depression and anxiety (Chida & Steptoe, 2009; Nicholson, Kuper, & Hemingway, 2006). Each of these individual differences in negative affect is associated with low affiliation in the IPC (Gallo & Smith, 1998; Smith, Traupman, Uchino, & Berg, 2010). The substantial interrelationship among these negative affective characteristics and the fact that they also share a common interpersonal style characterized by low warmth and high quarrelsomeness suggest that they might have overlapping associations with subsequent disease. The complementarity principle suggests that given this specific interpersonal style, these diverse risk factors should also be associated with low warmth and greater conflict in personal relationships, a prediction supported by a growing body of research (for a review, see Smith & Cundiff, 2011). Hence, these diverse risk factors may be linked to adverse health outcomes in part by common interpersonal processes – low levels of social support and high levels of interpersonal conflict.

Risk factors that are conceptualized as aspects of the social environment (e.g., social isolation, low social support, conflict in close relationships) can also be located in the IPC. For example, individuals who report low levels of social support describe their relationships as low in warmth and high in hostility, and reports of conflict and strain in close relationships are associated with seeing one's partner as expressing little warmth and high levels of both hostility and control (Smith et al., 2010; Trobst, 2000). Low socioeconomic status is associated with a variety of negative health outcomes and is also associated with exposure to lower warmth from others and higher levels of both hostility and control (Gallo, Smith & Cox, 2006). That is, low SES individuals often feel both "put off" and "put down" during interactions with others.

The control dimension of the IPC has also been directly related to health outcomes as the personality trait of dominance is associated with greater risk of coronary heart disease (Smith et al., 2008; for a review, see Smith & Cundiff, 2011). Further, high levels of control during marital interactions is associated with increased risk of atherosclerosis among men, whereas low levels of warmth are associated with increased risk among women (Smith et al., 2011).

The IPC also provides a framework for examining the psychophysiological mechanisms linking psychosocial risk factors and disease, such as cardiovascular, neuroendocrine, inflammatory, and immunologic responses to stressors. As noted previously, the IPC can be used to describe individual differences in social behavior (i.e., personality traits), stable aspects of social relationships or contexts, momentary social behavior, and social stimuli. With the IPC, these four classes of influences on physiological stress responses can be examined in a single, integrative framework (Smith, Gallo, & Ruiz, 2003). In general, the IPC framework and related research calls attention to the importance of recurring patterns of interpersonal behavior as a common process underlying many psychosocial influences on health. The related research suggests that recurring interactions involving low affiliation (i.e., low levels of warmth, high levels of hostility), effortful expression of control toward others (i.e., high dominance), or exposure to unwelcome control by others may be common elements of psychosocial risk (Smith et al., 2010).

Definition

Interpersonal processes refer broadly to actual or perceived elements of the social world. These processes can be generally positive (e.g., support) or negative (e.g., conflict) and of more specific types such as emotional support or insensitivity to others. It is also used to refer to the broader social context (e.g., social networks) in which such processes are embedded.

Description

Introduction

Interpersonal processes such as social support and social negativity have long been suspected as contributors to physical health outcomes. However, most biomedical research aimed at understanding disease has focused on biological processes (e.g., physiology, pathogens). There is now strong evidence linking interpersonal processes to biological pathways. This provides a bridge that can connect these perspectives to gain a more integrative understanding of the complex, multiply determined nature of health.

Interpersonal perspectives on health have typically been examined at different levels of analysis. At a broad level, sociologists have examined social networks and how they might influence health-relevant processes. For instance, these studies often examine the number or amount of contact with family or friends and/or the interconnections among them. More recently, sophisticated social network analyses have examined how proximal linkages among social ties might influence health-relevant outcomes such as obesity perhaps via unhealthy social norms. Distinctions are also often made in this literature between different relationship types (e.g., strong, weak ties). One important distinction is the extent to which a social tie is voluntary or obligatory. Voluntary ties, such as a recreational buddy, should be better for health because a person can choose to engage in more rewarding social experiences or sever such ties if they become nonrewarding. On the other hand, obligatory ties, such as relatives, are hard to sever even during difficult circumstances (e.g., familial conflict).

Psychological approaches often focus on the more specific interpersonal functions served by social network members, especially social support. Social support can be differentiated in terms of whether it is perceived or received. Perceived support refers to the belief that support would be available if needed, whereas received support refers to support that is obtained. These dimensions of support are often not highly correlated as individuals may perceive support to be available

but not actually seek it for various reasons (e.g., concerns about how others might react to such needs). As will be covered below, the distinction between perceived and received support is an important one because they often have different links to health outcomes. Perceived and received social support are further differentiated by more specific components including emotional (i.e., esteem enhancing), instrumental/informational (i.e., direct material or informational aid), and belonging (i.e., availability of others to do things with) support. Work in this area has also drawn the distinction between receiving support and being a support provider as the two are often correlated but may also have different links to health. However, the most common distinction in health-related research is related to perceived and received support.

More recently, researchers have also been focusing attention on the negative aspects of interpersonal processes. Although relationships may be sources of joy and support, there is also a "darker side" to interpersonal relationships that includes conflict, hindrance, and undermining. Social negativity is not simply the opposite of support, and research suggests that these are separable dimensions and hence are worthy of study in their own right or in combination. More generally, an examination of social negativity is important because there are theoretical reasons to believe that it may have stronger links to health outcomes compared to positive aspects of relationships. For instance, research on the negativity bias suggests that negative information or experiences have stronger links to psychological and physiological outcomes and hence may be more consequential for health. Similar to the support literature, researchers are also beginning to define more specific components of social negativity. Brooks and Dunkel-Schetter (2011) have recently argued that the main components of social negativity can be defined at the behavioral level and include conflict, insensitivity, and interference.

What is the Evidence Linking Interpersonal Processes to Health?

In a recent meta-analysis of 148 studies, Holt-Lunstad, Smith, and Layton (2010) found strong evidence linking both social networks and perceived social support to lower mortality rates. Overall, there was a 50% reduction in mortality that was attributable to relationships which remained even when considering variables such as age, gender, initial health status, and type of disease. These links were strongest for composite measures of social networks that typically indexed a variety of social ties (e.g., marriage, social activities). However, perceptions of support were also strong predictors of lower mortality rates. These results are consistent with other reviews in which relationships predict lower mortality from more specific causes such as cardiovascular disease and cancer. The one measure in the Holt-Lunstad et al. review that was not significantly related to mortality was received support. These data parallel studies indicating that received support also has inconsistent links with mental health outcomes.

In contrast to receiving support, being a support provider may be associated with beneficial health outcomes. Stephanie Brown and her colleagues have shown that providing support to family and friends is associated with decreased mortality even after considering how much support is received. This literature is sometimes seen as at odds with the caregiver literature which also involves being a support provider but has been consistently linked to negative health outcomes. However, there are important differences between these social contexts as caregiving involves considerable more interpersonal stress (e.g., anxiety over the slow loss of a family member) compared to being an everyday support provider in which there may also be more choice in the matter. Future research will be needed to disentangle the critical interpersonal elements that contribute to when being a support provider confers health costs or benefits.

Finally, a small but growing epidemiological literature also suggests that social negativity is related to higher rates of morbidity and mortality. For instance, a prospective study by De Vogli, Chandola, and Marmot (2007) of over 9,000 individuals found that social negativity predicted greater incident cardiovascular disease. Consistent with a negativity bias, these researchers

found that these effects were stronger than observed for social support. These data highlight the importance of not just considering positive interpersonal processes (i.e., support) but also negative aspects that appear to be powerful contributors to health risks.

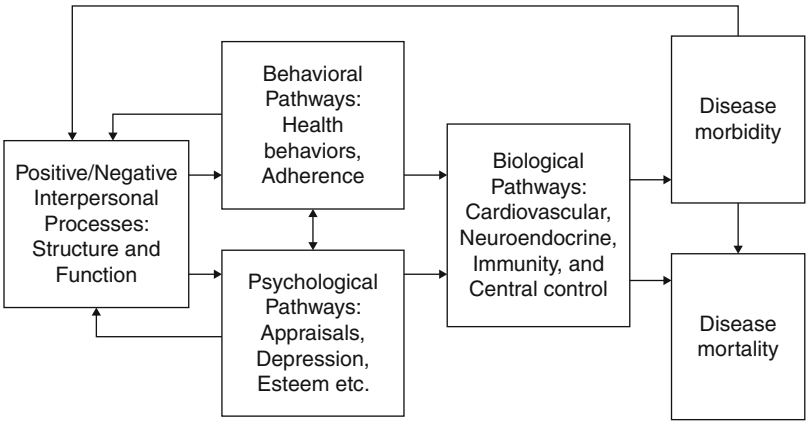
What Are the Pathways Responsible for Such Links?

As shown in Fig. 1, there are several plausible pathways linking positive and negative interpersonal processes to health. One possibility is that interpersonal processes influence health behaviors (for better or worse) which in turn influence health. For instance, social control theorists argue that being socially integrated can influence health in direct and indirect ways. Direct social control refers to active attempts by social network members to influence health (e.g., a parent setting a healthy family diet). Indirect social control refers to the increased motivation to engage in self-care because of meaningful relationships (e.g., wanting to be healthy to see a child grow up). Of course, social networks can also negatively influence health behaviors via unhealthy norms and social influence (e.g., substance abuse, obesity). There is consistent evidence that health behaviors can explain part of the link between interpersonal processes such as social support and health. However, many studies also find that statistically controlling for health behaviors such as exercise and smoking does not eliminate the link between relationships and health. These findings highlight the need to consider additional theoretical pathways.

Contemporary models of relationships and health have postulated psychological processes such as stress, depression, and positive emotional states as important additional pathways (see Fig. 1). For instance, the stress-buffering hypothesis predicts that support may prevent or reduce stress appraisals with corresponding influences on emotion-linked physiological responses. Associations between social support and health that do not involve stress processes have been postulated to be mediated by positive emotions, predictability, and a sense of self-worth. Although there is strong evidence linking interpersonal processes to these psychological processes, currently there is little evidence that these pathways directly explain links between social support and health. Future research will be needed to elucidate the issues that may be responsible for the current state of the literature (e.g., weaker tests of mediation, also see below).

One issue that is important in examining psychological pathways is the need to consider an expanded set of such mechanisms made salient by recent theoretical analyses. As noted earlier, the meta-analysis by Holt-Lunstad, Smith, and Layton (2010) did not find evidence that received support was related to mortality rates. Recent research is elaborating on the key contextual processes that determine whether receiving support has beneficial or harmful influences. For instance, receiving unsolicited support may increase distress because it conveys the message that the recipient is incapable of managing difficulties, thereby threatening a person's sense of esteem or independence. However, receiving support that is viewed as responsive to the recipient is linked to better well-being. This research has not been applied to the health domain but suggests a more specific set of psychological mediators to model in future work.

Finally, it is clear that interpersonal processes have effects on health-relevant physiological pathways. The three most studied biological pathways include those related to cardiovascular, neuroendocrine, and immune function. There is relatively strong evidence linking supportive relationships to lower cardiovascular reactivity during stress, as well as lower ambulatory blood pressure (ABP) during daily life. Likewise, negative relationship processes such as interpersonal conflict can exacerbate cardiovascular reactions and heighten ABP. The literature linking social relationships to immune processes is also strong. Social support has been linked to better immune function as indexed by natural killer cell activity and responses to vaccines. More recently, social support has been related to lower immune-mediated inflammation as indexed by IL-6, although less consistent findings are apparent as a function of other cytokines. Social negativity has also been linked to poorer immune system



Interpersonal Relationships, Fig. 1 Broad model highlighting salient pathways linking interpersonal processes to health

function in laboratory settings, and more recently to greater inflammation.

Neuroendocrine processes are particularly important to model because they may mediate both cardiovascular and immune responses. For instance, immune cells have receptors for many basic neuroendocrine hormones including catecholamines and cortisol. There is evidence linking social support to lower cortisol levels, although this tends to be an area in need of more research. However, researchers interested in social negativity have found consistent links between threats to the social self (e.g., evaluation) and increases in cortisol which might be health relevant.

One promising recent line of research links interpersonal processes to neural activity as indexed by imaging techniques. These studies are important because they are beginning to highlight the brain mechanisms that might coordinate the complex peripheral physiological pathways reviewed above. For instance, Naomi Eisenberger and colleagues have shown that social exclusion or "social pain" activates similar neural pathways involved in physical pain (i.e., dorsal anterior cingulate cortex). Consistent with the ability of supportive ties to buffer physiological reactivity, preliminary work also links positive or supportive interactions to lower activity in brain areas linked to autonomic and neuroendocrine changes (e.g., anterior cingulate cortex).

As shown in Fig. 1, it is also important to consider more complex pathways (e.g., reciprocal links). For instance, disease morbidity is associated with interpersonal processes and highlights the fact that health problems occur within a dyadic (e.g., marital) or broader family context and hence can influence interpersonal functioning in positive or negative ways. The diagnosis of a chronic condition may foster an appreciation for relationships (e.g., an emphasis on what is important in life). In contrast, some chronic conditions can place considerable stress on the family and decrease effective social support as might be the case for a person caring for a family member with Alzheimer's disease. These reciprocal pathways will need increased attention as researchers seek to design optimal interventions that capture the complexity of these interpersonal processes.

Intervention and Policy Implications

As researchers learn more about the links between interpersonal processes and health, it becomes appealing to use this information to inform relevant interventions in clinical populations. There are different types of interventions being implemented, many of which include elements of education and understanding, such as couple-oriented or larger support groups. A recent meta-analysis by Martire, Schulz, Helgeson, Small, and Saghafi (2010) found that couple-oriented interventions (e.g., disease education, role of relationships in illness management) were associated with lower depression and pain, along with better relationship functioning. Support groups also appear to foster psychological adjustment in many cases and can serve

I

unique functions (e.g., personal insight into the disease context). Such support groups are also particularly useful if there are gaps in the support needs of patients or if family members are overburdened. In addition to support groups, some broad interventions such as cognitive behavioral therapy focus on teaching general psychosocial skills and capitalizing on support within existing networks. These interventions appear to be effective in augmenting coping skills, as well as lowering disease-related distress and improving health outcomes.

Of course, the practicality and cost-effectiveness of an intervention are also important to consider. Recent research is examining this issue by focusing on telephone and internet-based support interventions. Preliminary studies have documented some positive influences on mental health outcomes and suggest the potential usefulness of alternative support interventions that may be especially important for individuals with practical (e.g., transportation), physical (e.g., disability), or social (e.g., anxiety) barriers. Future work will be needed to fully evaluate their potential benefits across a wider range of health outcomes.

It is also clear that most interventions focus on individuals who are most at risk or who already have medical problems. An alternative way of thinking about interpersonal interventions is as a form of primary prevention that focuses on healthy individuals. Given that many chronic diseases have a long-term etiology and develop over decades (e.g., coronary artery disease), primary prevention efforts for interpersonal processes may be particularly important to consider. For instance, Repetti, Taylor, and Seeman (2002) have argued that early familial interventions are an important starting point and may pay large dividends in the long term. A focus on primary prevention also raises the interesting possibility that social skills interventions aimed at improving relationship functioning may be useful if applied early on with children and adolescents to place them on healthier trajectories.

Finally, research on interpersonal processes and health may carry important policy implications (Umberson & Montez, 2010). Many of society's most vexing problems have clear interpersonal components (e.g., aggression, abuse, conflict). Given the research evidence to date, public policies can be aimed at increasing funding for understanding the more specific nature of such links or at fostering better interpersonal functioning. For instance, in order to encourage stronger marriages, the Deficit Reduction Act of 2005 devoted significant funds to the Healthy Marriage Initiative (HMI). The HMI focuses on research and demonstration projects regarding relationship education and skill building (e.g., listening, problem-solving). Recent evaluations of these programs have yielded promising effects on relationship quality and communication patterns (Hawkins, Blanchard, Baldwin, & Fawcett, 2008). More recently, the importance of the social determinants of health was acknowledged explicitly in Healthy People 2020, a nationwide health promotion plan. Such policy promises to shine a stronger spotlight on health-relevant interpersonal factors that may elevate funding priorities, public perception, and dialogue on future policy implementation.

Conclusions

Interpersonal processes are clearly related to significant health outcomes. Research is now being evaluated to test more specific models and pathways such as social control, health behaviors, and psychological and biological pathways. Contemporary research is also positioned to better capture the complex nature of interpersonal processes by increasing its focus on dyads, families, and larger social networks. The explicit goal of Healthy People 2020 to understand and harness the social determinants of health confers greater prominence and resources to this area but also signifies higher expectations. Interdisciplinary work that focuses on integrative multilevel analyses using diverse approaches (e.g., laboratory, daily experience, interventions) is likely to facilitate progress toward the long-standing goal of translating basic research into effective interventions and the integration of interpersonal processes into any and all discussions of public health.

Theories of behavior change

Definition

Health-promoting interventions aim to reduce health-risk behaviors and/or to promote behaviors and support environments conducive to health. In this pursuit, use of theory will serve several important purposes in various phases of interventions: In the beginning of intervention planning, theories can be used to *describe the target group* as well as *contribute to understanding of the health-promoting behaviors and environmental conditions*. Theories may also

inform the design of the intervention by helping to *identify possible determinants of both risk and healthful behaviors and environments* and *to select methods to promote change (intervention techniques/behavior change techniques)*. Finally, theories are useful in *evaluating the intervention (e.g., choice of measures)* and *retrieving evidence from interventions for the refinement of existing theories*. (Bartholomew & Mullen, 2011; Bartholomew, Parcel, Kok, Gottlieb, & Fernández, 2011; Michie & Prestwich, 2010; Nutbeam & Harris, 2004). Theories used to these ends may be called intervention theories. More than one theory may be used in an intervention.

Description

Planning of complex interventions should be based on a sound theoretical understanding of how the change is expected to take place (Campbell et al., 2000; Craig et al., 2008). It has been shown that interventions that have a theoretical basis are more successful than those that have not (Peters, Kok, Ten Dam, Buijs, & Paulussen, 2009; Webb, Joseph, Yardley, & Michie, 2010). Theories may focus on determinants that predict or explain outcomes or means of engendering change in the determinants. The first mentioned characterize the problem and are called *conceptual theories*, as they suggest what to change. The latter are *action theories*, as they suggest how the change is achievable.

Given the plethora of theories with potential use in health-promotion interventions, only few can be mentioned below for an overview of theories. A recent systematic review across scientific disciplines (Hobbs et al., 2011) identified several theories – altogether close to 100 – that could be used in interventions to change behavior. Intervention theories can be classified by the ecological level they target.

Frequently used theories are those that focus on the *individual* level, focusing mainly on direct changes in *behaviors* of a person. A well-known example in this category is the theory of planned behavior (Ajzen, 1991) that identifies subjective norms, attitudes toward behavior, and perceived behavioral control as predictors of intention. The latter in turn is considered as the main factor influencing behavior. Behavior change is suggested to occur when salient behavioral, normative, and/or control beliefs are successfully changed. Reflecting growing consensus of central determinants of behavior change, the integrated social cognition model (Fishbein et al., 2001) incorporates eight variables as key determinants of behavior: environment, skills, and intention, and (as predictors of intention), identity, self-efficacy, emotional reaction, perceived advantages and disadvantages of the target behavior, and social influences. Communication-persuasion matrix (McGuire, 2001) outlines seven phases ("RASMICE") of constructing a persuasive health campaign: reviewing the realities, axiological analysis, surveying the sociocultural situation, mapping the mental matrix, teasing out the target themes, constructing the communication, and evaluating the effectiveness. The model includes 12 output persuasion steps that describe the process of being persuaded, e.g., receiver's attention and comprehension, acquiring skills, changes in attitudes, memory storage, and behavior. The matrix includes five input communication factors: message source, message content and style, communication channel, receiver (audience), and destination. Each step requires certain choices related to the communication variables.

Health behaviors are not affected by individual psychological factors only, but also by social and structural factors of environments people live in. Accordingly, some theories focus on changing *environments* for better health. Theories of social networks and social support use concepts of the *interpersonal* level, while there are others that address the *organizational* level. Schein's theory of organizational culture (2004) identifies leaders as key players in changing organizations. According to Schein, organization's design and structure; stories, legends, and myths, as well as formal statements of the organizational philosophy and values are only secondary sources of bringing about change. Schein proposes that these secondary mechanisms are effective only if they are in concordance with primary mechanisms – leaders' behaviors. Organizational

change is influenced by these primary mechanisms, such as what leaders pay attention to, measure and control; how leaders react to critical incidents and organizational crises; what criteria they set for allocating scarce resources and recruiting and promoting personnel; and whether they teach, coach, and model the target behavior.

A renowned example of *community* level theories is the diffusion of innovation theory (Rogers, 2002). It outlines four elements in the diffusion of new ideas in communities: innovation, communication channels, time, and the social system. Innovations are more likely to be successfully adopted when they are, e.g., compatible with existing socioeconomic and cultural values, perceived easy to understand and use, and have observable results in the community.

Theories on the *societal or policy* level may also be used as intervention theories. Milio (1987) has proposed that the development of healthy public policy is not simply the production of policy statements but, instead, is a dynamic process, continuously passing through stages of initiation, adoption, implementation, evaluation, and reformulation. Four major players (public policy makers, interested parties, the public, and the mass media) are important in the policy development. Longest (2010) suggests that the health policy making process is complex, interactive, and cyclical, and the process entails three intertwined phases: policy formulation (agenda setting and development of legislation), policy implementation (rulemaking and operation), and policy modification. Health policies are made within the contest of the political marketplace where demanders of policies and suppliers of policy interact. Preferences and feedback of various interest groups, political circumstances, and formal legislation processes influence the process. Finally, some theories, such as theories related to systems, power, and empowerment can be conceptualized as *multilevel theories* as they are applicable at more than one environmental level.

Frameworks exist to help in selecting appropriate theories for an intervention for a given behavior in a specific population and translating an abstract theory into a practical intervention program. A popular one is intervention mapping (Bartholomew et al., 2011) that outlines six steps during which a theory- and evidence-based program and its implementation and evaluation are systematically planned. The intervention mapping steps include (1) needs assessment, (2) preparing matrices of change objectives, (3) selecting theory-based intervention methods and practical applications, (4) producing the intervention program components and materials, (5) planning program adoption and implementation, and (6) planning for evaluation.

Diagnostic interview

Definition

Interviews are among the most valuable and most frequently used tools in clinical practice. They can be defined as dyadic face-to-face interactions between two people (interviewer and interviewee) that are conducted for specific purposes. Clinical interviews cover a wide range of purposes, for example, rapport building, problem exploration, or establishing a psychiatric diagnosis according to the Diagnostic and Statistical Manual of Mental Disorders (DSM-IV).

Typically, the interaction is asymmetric in the sense that the interviewer poses questions and the interviewee provides answers. Interview questions can be categorized according to their function and/or their form. Interview questions may have the following functions: introductory questions, gathering information, rapport building, transition from one topic of the interview to another, and reassuring that information was understood correctly. Depending on the specific purpose within an interview, the questions may have the following forms: open or closed, direct or indirect, suggestive. Closed interview questions can be answered with a single word or short phrase, whereas open interview questions allow unrestricted answers. Direct questions directly address the topic at hand; indirect questions address broader or related topics to gather information about the topic at hand. Suggestive interview questions imply a certain answer and, thus, should be avoided in an unbiased assessment. The appropriateness of different forms of interview questions depends on the interview phase and information to be assessed.

Interviews may be conducted in a more or less structured way. Structured interviews include a predefined interview schedule. Such a schedule specifies crucial elements of the interview, such as the introduction and the subtopics to be addressed. Furthermore, it defines the interview questions, provides details on sequence of questions, etc. The more elements are specified in advance, the more structured the interview is. The degree of structure should be chosen depending on the interview purpose (e.g., exploration, decision making).

Structured interviews show several advantages, in particular for diagnostic decision making according to DSM-IV. Several established interview schedules are available. For example, the Structured Clinical Interview for DSM-IV (SCID; First, Spitzer, Gibbon, & Williams, 1996) is an established interview system that is frequently used by clinicians. Another frequently used highly structured interview is the Diagnostic Interview Schedule for DSM-IV (DIS-IV; Robins et al., 2000).

Interviews provide multiple advantages in comparison to other assessment tools such as tests and self-reports. First, interviews can be conducted in an interactive way (e.g., the interviewer can rephrase questions if necessary). Second, interviews are often considered the more natural form of an assessment (as compared to test with multiple choice answers). Third, expert judgment can be made throughout the interview (e.g., based on behavior observations), which may provide further information in addition to the answers given by the interviewee. However, interviews also show disadvantages compared to tests and self-reports with regard to psychometric properties and costs of administration time (as interviews are mostly conducted in dyadic face-to-face situations). Hence, the applicability of interviews needs to be considered on a case-by-case basis.

Intima-Media Thickness (IMT)

Jonathan Newman
Columbia University, New York, NY, USA

Definition

Intima-media thickness (IMT) is defined by the measurement of a component of the walls of muscular arteries (intima) by specific modalities of ultrasound, at defined locations in the human body. Intima-media thickness of the carotid artery has been the location most consistently associated with risk of atherosclerotic risk. Because ultrasounds of the carotid artery can be performed safely, at low risk (no ionizing radiation) and with a relatively high degree of reproducibility, IMT has been a common surrogate endpoint in epidemiologic studies and in clinic trials.

Carotid IMT (CIMT) is correlated with other vascular risk factors and is considered an "intermediate phenotype" of early atherosclerosis that independently predicts vascular events. In general, greater CIMT values are associated with greater cardiovascular risk. However, an absolute definition of abnormal CIMT has been problematic due to the effects of age and hypertension on CIMT, independent of their atherosclerotic risk. Despite evidence suggesting intrareader differences in CIMT measurement are quite small (0.04 mm), the clinical utility of serial CIMT measurement (e.g., to assess response to therapy) has not been demonstrated, and the routine use of CIMT has been hindered by the lack of standard assessment techniques in major epidemiologic studies. As a result, there is neither universal consensus on what constitutes an abnormal test result nor guidelines on how CIMT informs risk stratification of individual cardiovascular risk.

Intrinsic Religiousness (Religiosity)

Kevin S. Masters
Department of Psychology, University of Colorado, Denver, CO, USA

Definition

Intrinsic religiousness (initially and still sometimes referred to as intrinsic religiosity) is characterized as religion that is an end in itself, a master motive. Thus, individuals described by intrinsic religiousness view their religion as the framework for their lives, and they try to consistently live the religion they believe. A prototypic intrinsic religiousness test item is "My whole approach to life is based upon my religion."

Description

Intrinsic religiousness was first described by Gordon Allport and colleagues in the 1960s (see Allport & Ross, 1967) when investigating the possible reasons for discrepant findings in the area of religiousness and prejudice. At that time, some studies demonstrated that religiousness was positively associated with prejudice whereas other studies found the opposite. Allport hypothesized that one's religious orientation, or sentiment, may provide guidance in sorting out these findings. The construct of religious orientation was later clarified by Gorsuch (1994) to be a motivational variable.

Intrinsic religiousness has often been measured by the Religious Orientation Scale (Allport & Ross, 1967). More recently, Gorsuch and McPherson (1989) developed the I/E-Revised scale as a more psychometrically sound instrument. Internal consistency measures for intrinsic religiousness scales are excellent, typically in the mid.80s (Donahue, 1985). Scholars in the psychology of religion have debated the relative strengths and weaknesses of the religious orientation construct (e.g., Kirkpatrick & Hood, 1990; Masters, 1991), but it remains the most empirically investigated and heuristic construct in this area of work.

Investigators attempting to determine the relations between religion and health have also turned to religious orientation. Smith, McCullough, and Poll (2003), in a meta-analytic study, found that intrinsic religiousness was the only measure of "positive" religiousness to statistically differentiate itself from other measures of religious attitudes and beliefs in that studies with measures of intrinsic religiousness had stronger negative correlations with symptoms of depression than studies with measures of religious attitudes and beliefs. Similarly, Masters and Bergin (1992) provided a narrative review of the literature and found intrinsic religiousness to be related negatively with depression, anxiety, and obsessive-compulsive symptoms and positively with empathic concern, self-consciousness, internal awareness, flexible approach to life, tolerance, self-control, active coping, self-esteem, efficacy, and ego strength. McCullough and Willoughby (2009) suggest that intrinsic religiousness may be part of a personality core that forms the substrates for conscientiousness, agreeableness, and self-control. They also note that intrinsic religiousness may provide a basis for meaning in life. A recent investigation found intrinsic religiousness related to dampened laboratory-induced cardiovascular reactivity in older adults (Masters, Hill, Kircher, Lensegrav Benson, & Fallon, 2004) wherein the older intrinsically religious adults reacted to stress similarly to individuals 50 years younger and demonstrated significantly less reactivity than their extrinsically religious same-age counterparts. Masters and Knestel (2011) found that among a random sample of community-dwelling adults, those characterized by intrinsic religiousness were

less likely to be divorced, reported overall better health status, lower body mass index, less cigarette use, and fewer number of daily drinks of alcohol than did those characterized as extrinsically religious. There were no differences in the percentages of individuals who were classified as intrinsically religious based on religious denomination. Nevertheless, it is not entirely clear how intrinsic religiousness may interact with religious denomination, and some have suggested that the construct, as currently conceptualized and measured, is more congruent with Protestant notions of religiosity and perhaps most appropriately applied to this religious group (Cohen et al., 2005).

Definition

An intrusive thought has been defined as “any distinct, identifiable cognitive event that is unwanted, unintended and recurrent. It interrupts the flow of thought, interferes in task performance, is associated with negative affect, and is difficult to control” (Clark, 2005, p. 4). Intrusive thoughts are particularly present in psychopathological states such as obsessive compulsive disorders (then often referred to as “obsessions”) and

post-traumatic stress disorder (thoughts or images related to the experienced trauma). Yet, they are also frequently observed in the nonclinical population, where 80–99% has reported experiencing unwanted intrusive thoughts once in a while (Clark & Purdon, 1995). They appear highly similar to worrisome thoughts, but it has been suggested that intrusive thoughts are shorter in duration and are appraised as more ego-dystonic than worries (Clark, 2005).

Intrusive thoughts can be considered a form of so-called perseverative cognition (see ▶ Perseverative Cognition), which is defined as "the repeated or chronic activation of the cognitive representation of one or more psychological stressors (threat)" (Brosschot, Gerin, & Thayer, 2006). Perseverative cognition is believed to be responsible for a large part of the health impact of psychological stressors, because it later prolongs the physiological responses to these stressors.

Inverse Relationship

J. Rick Turner
Cardiovascular Safety, Quintiles, Durham, NC, USA

Synonyms

Negative relationship

Definition

An inverse relationship is one in which the value of one parameter tends to decrease as the value of the other parameter in the relationship increases. It is often described as a negative relationship.

Imagine the age of a car and its value. In general terms, as a car increases in age its value will decrease (the amount of miles driven per unit of time also factors in to this, but we will leave that aside here). This relationship is not perfect since, for two identical cars, the degree to and manner in which they are driven and maintained will impact the value, and the cars may differ considerably in value 10 years after their contemporaneous purchase. Nonetheless, the general association can be described as an inverse one.

In many cases, such a relationship can be captured meaningfully by a correlation coefficient. These coefficients range from −1 to +1 (typically written as just 1, without the + sign). A value of −1 represents a perfect inverse linear association: As one parameter increases, the other decreases in a perfect linear relationship. Values between −1 and zero represent less perfect associations.

In contrast, a positive relationship is one in which both parameters change in the same direction: as one increases so the other increases. Such a relationship would be described by a correlation coefficient between zero and 1, with 1 representing a perfect linear relationship. (The technique of correlation cannot meaningfully describe nonlinear patterns of association between two variables, such as curvilinear and exponential relationships.)

Synonyms

Psychotherapy for IBS

Definition

Psychological treatments are non-pharmacological therapies that mainly modify higher neural function including emotion, cognition, motivation, learning, and memories for IBS patients.

Description

Irritable bowel syndrome (IBS) is a very common gastrointestinal disorder characterized by recurrent abdominal pain and altered bowel habits without major organic diseases as assessed by routine gastroenterological examination (Drossman, 2006). The pathogenesis of IBS is affected or exacerbated by combination of factors including psychosocial states, dysmotility of the gut, and visceral hypersensitivity. The concept of biopsychosocial model best fits to pathophysiology and treatment strategy for IBS. Psychosocial stress likely plays major role in the exacerbation of all of these factors. In fact, IBS patients have symptoms which are more exaggerated by psychosocial stress than healthy controls (Whitehead, Crowell, Robinson, Heller, & Schuster, 1992), show more response in colonic motility to psychosocial stress (Fukudo, Nomura, Muranaka, & Taguchi, 1993), and have the corticotrophin-releasing hormone as a major mediator of stress response (Fukudo, Nomura, & Hongo, 1998).

Brain-gut interaction plays in an important role in the pathogenesis of IBS. Brain-gut interactions mainly consist of reciprocal interactions between the central nervous system (CNS) and the enteric nervous system (ENS) as well as influence of endocrine system, immune system, and gut microbiota. Brain imaging studies have clarified the roles of the anterior cingulate cortex, amygdala, insula, and the brain stem in response to visceral stimulation (Fukudo et al., 2009). These structures produce both visceral pain and negative emotion that are typical symptoms of IBS patients. Psychological stress, anticipatory anxiety, and mental tension in daily life exert a negative influence on CNS, which influences ENS. Gastrointestinal dysmotility and perception lead to symptoms of IBS, i.e., abdominal pain, abdominal discomfort, diarrhea, or constipation. The gut signals which produce these symptoms also influence the CNS. From the psychosocial viewpoint, IBS has a negative impact on subjects' daily activity and quality of life (Drossman et al., 1993). IBS patients frequently show gastrointestinal dysmotility under stress (Fukudo et al., 1993) and have psychiatric comorbidities, especially depressive disorders, anxiety disorders, and somatoform disorders (Drossman, 2006). Note that the present stress alone does not exacerbate symptoms of IBS. Past traumatic life event such as sexual/physical abuse in childhood also exacerbate symptoms of IBS by low stress or environmental changes and can be a factor of intractable IBS. In addition, physician needs to

understand psychosocial risk factors including abuse, economical loss, and social withdrawal behind symptoms of IBS.

A wide range of psychotherapeutic interventions are used for the treatment of IBS, including cognitive behavioral therapy (CBT), hypnotherapy, and relaxation techniques. There are some critical reviews on the effect of the psychotherapy for IBS (Talley, Owen, Boyce, & Paterson, 1996). Therefore, it is still difficult to say that effective psychotherapy for IBS has already been established. However, the evidence level rises in the recent research. Although several pharmacological agents for IBS have been used, some patients do not respond to pharmacotherapy (Levy et al., 2006). Psychotherapy might be useful for these patients. A key issue in effective management of IBS is establishing a doctor-patient relationship. Good psychological and therapeutic effects for IBS patients are produced by clinical practices such as explanation, instruction, and administration accompanying well doctor-patient relationship. Conversely, poor psychological and therapeutic effects such as distrust and negative emotion are produced by clinical practices accompanying negative doctor-patient relationship. Factors that contribute to an effective doctor-patient relationship include empathy toward the patients, patient education, validation of the illness, reassurance, treatment negotiation, and establishment of reasonable limits in time and effort (Grover & Drossman, 2010). A good doctor-patient relationship is associated with a positive prognosis of IBS (Owens, Nelson, & Talley, 1995).

There is evidence from a systematic review and meta-analysis of randomized controlled trials on IBS that psychological treatment in general is effective for IBS (Zijdenbos, de Wit, van der Heijden, Rubin, & Quartero, 2009). The theoretical background of psychotherapies for IBS is as follows. First, IBS patients have deranged lifestyles characterized by more perceived stress, more irregular sleep, and more irregular meals (Shinozaki et al., 2008). Second, there is the close relationship between daily stress or hassles and IBS symptoms (Whitehead et al., 1992). Third, IBS patients have high levels of anxiety, depression, and somatization (Kanazawa et al., 2004). Fourth, intractable IBS patients have often experienced traumatic life events (Drossman et al., 1990). Fifth, the effects of health beliefs and learned behaviors may adversely affect outcome. Sixth, IBS patients are known to respond highly to placebo. Seventh, as described above, doctor-patient relationship plays a role in IBS treatment.

Psychological treatments including a delicate observation and stress management is needed for IBS patients. Treatments compose direct or indirect coping to stress and stress sensitivity. IBS patients often have symptoms characterized by abdominal pains in stressful situation when they cannot secure personal space or relieve symptoms by defecation. Because of these symptoms, IBS patients often avoid transportation, feel insecurity in going to the school or the company, and limit going out. For this situation, behavioral intervention is useful. Behavioral intervention is focused on modifying maladaptive behavior which links to exacerbation or maintenance of IBS symptoms and forming a habit of adaptive behavior. It is composed of setting clear goals on treatment, learning nutrition and lifestyle, brief cognitive restructuring, stimulus control, problem-solving method, and prevention of relapse. IBS patients often have illness behavior which has been formed in the early developmental history. Modification of cognitive error which links to this behavior is needed. The main purpose of CBT is to modify negative automatic thoughts and dysfunctional beliefs and to increase or decrease a particular behavior. Even if individual is in the same environment, how to feel the stress and how to interpret it are greatly variable. Actually, CBT was found to be more effective for IBS than an educational intervention (Drossman et al., 2003). Because IBS is exacerbated by stress, therapeutic modification of the stress sensitivity using stress coping or CBT is effective for IBS symptoms (Kennedy et al., 2005; Moss-Morris, McAlpine, Didsbury, & Spence, 2010).

Relaxation is also useful as direct coping to stress. This coping includes deep breathing, distraction, breaking, slow bathing, and taking holiday. Hypnotherapy is a representative strategy for refractory IBS (Whorwell, Prior, & Faragher, 1984). Autogenic training (AT) is auto-hypnosis

with the goal of being able to self-administer suggestions of relaxation. In brief, traditional AT consists of 6 standard exercises after the formula "I am at peace." The first exercise aims at muscular relaxation by repetition of a verbal formula, "my right arm is heavy" emphasizing heaviness. Subsequent passive concentration is focused on feeling warm, initiated by the instruction "my right arm is warm," followed by cardiac activity using the formula "my heartbeat is calm and regular." Then follows passive concentration on the respiratory mechanism with the formula "it breathes me," then on warmth around the abdominal region with "my solar plexus is warm," and finally on coolness in the cranial region with "my forehead is cool and clear" (Kanji & Ernst, 2000). AT is reported to be effective for intractable IBS patients (Shinozaki et al., 2010).

Ischemic Heart Disease

Siqin Ye
Division of Cardiology, Columbia University Medical Center, New York, NY, USA

Synonyms

Coronary heart disease

Definition

Ischemic heart disease refers to various manifestations of heart disease caused by ischemia, i.e., inadequate blood flow to the myocardium (Morrow & Gersh, 2008).

Description

Ischemic heart disease is typically due to coronary heart disease caused by atherosclerosis (see entry, ▶ Coronary Heart Disease). Patients with ischemic heart disease may have symptoms of angina, or chest pain (see entry, ▶ Angina Pectoris). Sudden rupture of coronary atherosclerotic plaques may cause myocardial infarction, or heart attack (see entry, ▶ Acute Myocardial Infarction). If there is sufficient damage done to the heart, the patient may also develop heart failure or ischemic cardiomyopathy (see entry, ▶ Congestive Heart Failure).

Isometric/Isotonic Exercise

Anthony Remaud
Elisabeth Bruyere Research Institute, University of Ottawa, Ottawa, ON, Canada
Laboratory "Motricité, Interactions, Performance", University of Nantes, Nantes, France

Synonyms

Exercise-general category; Exercise testing; Exercise, benefits of; Graded exercise; Resistance training; Static Exercise

Definition

An *isometric* exercise refers to any physical activity involving static muscle contractions. The term "isometric" is derived from the Greek roots "isos" (equal) and "metron" (measure), which means that during isometric exercise,

muscle length is broadly unchanged and consequently joint angle remains the same. From a biomechanical point of view, this exercise modality means that the net moment generated by the individual at the joint level is equal to the resistant moment applied to the body segment in an opposing direction. Actually, muscles slightly shorten and involve a stretch at the tendon level but the length of the muscle-tendon complex remains constant. Depending on the amount of resistance applied to the body segment, the level of muscle contraction can be maximal or submaximal. Performing the "wall sit/phantom chair" exercise, holding a free weight in a fixed position or pushing against an unmovable object such as a wall can illustrate different types of isometric exercise. Since it does not require any specific equipment, isometric exercise can be performed anywhere, anytime.

An *isotonic* exercise implies dynamic muscle contractions. The term "isotonic" is derived from the Greek roots "isos" (equal) and "tonos" (tension), which means that during isotonic exercise, muscle tension is supposed to remain constant during the movement. From a biomechanical point of view, this exercise modality means that the net moment generated by the individual at the joint level is unchanged throughout the range of motion whereas movement velocity varies. In the literature, isotonic exercises often designate strength training workouts performed with a constant resistance using bodyweight (e.g., push-up exercise) or free weights (e.g., barbell bench press). These types of exercise can be performed in concentric mode if the net moment generated at the joint level is superior to the resistant moment applied to the body segment (muscle shortening) or in eccentric mode if this net moment is inferior to the resistant moment (muscle lengthening). Actually, the isotonic condition is rarely achieved during strength training workouts notably due to the acceleration and deceleration of the load during the movement which modify the resistant moment. Therefore, the terms "isoinertial" or "isoload" have been proposed to better describe this concept.

Different disciplines relevant to health such as physical medicine and rehabilitation, physiotherapy, or athletic training commonly use isometric and isotonic exercises as a means for functional muscle assessment and/or strength training.

Job Classification

Karen Jacobs[1], Miranda Hellman[2], Jacqueline Markowitz[2] and Ellen Wuest[2]
[1]Occupational Therapy, College of Health and Rehabilitation Science, Sargent College, Boston University, Boston, MA, USA
[2]Boston University, Boston, MA, USA

Synonyms

Employment; Job evaluation; National occupational classification; National statistics socio-economic classification; Occupation; Occupational classification; United States Department of Labor

Definition

Job classification is the defining or categorization of types of employment either by function or activity. Job classification is useful to combine jobs for test validation, wage and salary administration, and for the development of performance appraisal instruments (Sackett, Cornelius, & Carron, 1981). Job classification is also critical for structuring personnel selection, training, and career development (Pearlman, 1980). Successful job classification can also be useful for client-oriented applications, allowing people to be matched to job vacancies that fit their skill set (International Labor Organization, 2010). The specificity of the classification is important depending on the type of work. A general level of classification is sufficient for distinctly different jobs, but more specific classifications are necessary to distinguish jobs within occupational groups, such as management jobs or clerical jobs (Schippmann, Prien, & Hughes, 1991). When a job is classified, it should be consistent and should match all other jobs assigned to that class, it should be clear and each job should only fall under one assignment, and the classifications should be interpretable (Hartman, Mumford, & Mueller, 1992).

Description

International Classification of Jobs

Job classification is a process that occurs internationally, with similarities and differences between countries. The United States Department of Labor has classified all workers into one of 840 occupations. These occupations are grouped together based on similar job duties, skills, education, and training (US Department

M.D. Gellman & J.R. Turner (eds.), *Encyclopedia of Behavioral Medicine*,
DOI 10.1007/978-1-4419-1005-9,

of Labor, 2010). Canada utilizes similar ways to classify jobs, and created the National Occupational Classification (NOC) that gives statisticians, labor market analysts, career counselors, employers, and individual job seekers a way to understand the nature of that job and collect appropriate data (Human Resources and Skills Development Canada, 2009). The NOC is organized in such a manner that each occupation is assigned a four digit number that provides information about the job; for example, 3113 is for dentists, and the "31" symbolizes that it is a health field requiring a university-level education (Human Resources and Skills Development Canada, 2009). The United Kingdom uses the Standard Occupational Classification (SOC), which has three volumes. The first volume outlines the background, resources, concepts, and processes of how the jobs are classified, the second codes the index for classification, and the third shows the relationship between the SOC and the National Statistics Socio-economic Classification (Office for National Statistics, 2010). The International Standard Classification of Occupations is a model to classify jobs globally, allows for international reporting, and can be used in countries that have not yet developed their own means to classify jobs (2010).

Job Demand/Control/Strain

Töres Theorell
Stress Research Institute, Stockholm University, Stockholm, Sweden

Synonyms

Decision Authority; Decision Latitude; Mental Work Load

Definition

The job demand/control model is used for studying psychosocial stressors in the work environment.

Description

The *demand/control model* was created for the study of psychosocial working conditions. It was published by Robert Karasek in his Ph.D. thesis in 1976 (Massachusetts Institute of Technology) and as a scientific article (Karasek, 1979). While Karasek had already mentioned social support as a potentially important additional dimension, this part of the model – adding up to the *demand/control/support model* – was first published in 1986 (Johns Hopkins University) by Jeffrey V. Johnson in his Ph.D. thesis (Johnson, 1989). Sociopsychological and biological theory underlying the model was further developed in 1990 by Karasek and Theorell (Karasek & Theorell, 1990).

The basic underlying idea behind the creation of the model was that crucial psychosocial stressors (factors inducing adverse long-lasting stress reactions in employees) in the work environment should be assessed. Reduction of such stressors for the improvement of employee health by means of work redesign should then be the ultimate goal. According to the initial demand/control model theory, high psychological demands are endangering employee health particularly when the employees have little control (low decision latitude; the combination labeled "job strain") over their own conditions. On the other hand, when demands are high and decision latitude is also high ("active work") psychological growth, improved coping, and biological regeneration take place. Still according to the theory, the combination of low demands and low decision latitude ("passive work") is of intermediate importance to employee health. However, employees working for a long time in the "passive" work situation may lose competence and "stop growing" psychologically. The low-demand/high-control situation ("relaxed work") is the ideal situation serving as reference in the model. The "relaxed"/"job strain" diagonal of the model is of more importance to the employee health whereas the "passive"/"active" diagonal is more important to productivity.

The demand/control/support model has been tested in many epidemiological studies. The assessment of demand, control, and support has mostly been made by means of standardized questionnaires. The most widely used Job Content Questionnaire (JCQ) has been translated into many languages (Karasek et al., 1998). A shorter version (Demand Control Questionnaire (DCQ)) has been used primarily in the Nordic countries. JCQ contains scales for the assessment of psychological demand, decision latitude, and its two subcomponents (skill discretion and decision authority), and also social support from superiors and coworkers. JCQ also includes questions about physical demands and job insecurity.

Measures of psychological job demands, decision latitude, and social support can also be derived from job titles. The basis of such assessments is the creation from representative samples in the working population of a "job exposure matrix" (JEM) indicating the average demand, decision latitude, and support scores for each job title. The means can also be specified with regard to age group, length of employment, and gender since these factors could influence the means. In most studies, the three-digit version of the international classification of jobs has been used for the psychosocial JEM. This provides a more "objective" way of assessing the work characteristics. However, in the recording of the demand/control/support model it is mainly the decision latitude dimension that provides sufficiently reliable data since both demands and social support assessments vary more between individuals within occupations than they do for decision latitude. Another more objective or "external" way of measuring is to train experts to do collective assessments of job sites with regard to demand, control, and support.

How does the demand/control/support model relate to people's physiological status? In several epidemiological studies, the model has been examined in relation to biological risk factors for cardiovascular disease. Accordingly in some studies, high or increasing job strain has been significantly related to elevated levels of sleep disturbance, blood pressure (particularly when blood pressure is monitored automatically during 24 h), morning excretion of cortisol in saliva and immunological parameters, such as plasma

fibrinogen, all of which regarded as risk factors for cardiovascular disease. High or rising levels of job strain are also related to lowered plasma testosterone concentration, which has regenerative/restorative functions protecting the body against adverse effects of stress (Theorell, 2009). In addition, low levels of decision latitude have been shown in one study to be related to low parasympathetic activity (another protector against adverse stress effects), as it is reflected in heart rate variability measured by means of 24-h electrocardiogram. All these observations indicate that job strain may affect physiology in adverse ways. Poor social support has been shown to add to the associations. However, there are relatively few studies of physiological correlates of Demand Control Support (DCS) and hence, there is no complete scientific consensus in this area – with the exception of fully automated measures of high blood pressure which are consistently related to high job strain.

Epidemiological studies have also been made of the relationship between job strain and adverse health habits such as smoking, physical activity, and alcohol consumption. The findings in these studies are conflicting. The relationships between health habits and the Demand Control Support (DCS) model depend on contexts, such as social class, age group, country, etc. Social class has been discussed extensively since low socioeconomic status is related to low decision latitude and high socioeconomic status to high psychological demands. Whether or not to adjust for social class remains to be resolved. In many studies, the relationship between the DCS and disease outcome is only marginally affected by adjustment for socioeconomic group, whereas other studies show stronger effects of such adjustments.

Several prospective epidemiological studies have been published regarding the relationship between the DCS model and risk of cardiovascular disease (mainly myocardial infarction). Designs, outcome measures, and DCS exposure measures have varied between studies. Several of the published studies have had too small statistical power or too long follow-up periods (for instance, 20 years). Meta-analytical studies, however, indicate that among working men without initial heart disease job strain (in most studies defined in such a way that 20–30% of the study population is defined as being exposed – the remaining participants are mostly used as reference population) is associated with a 40% elevation of the risk of developing a myocardial infarction during a 5-year follow-up. The job strain–related risk among working men seems to be stronger (in the order of 80% excess risk) in analyses confined to those below age 55 at start of follow-up. The combination of job strain and lack of social support (iso-strain) has been less extensively studied but is also related to risk of cardiovascular disease. There are different opinions regarding the role of smoking, physical activity, and eating/drinking habits in these associations. In several studies, adjustments for such risk factors have not affected the association markedly. For women the epidemiological evidence is not clear.

Early signs of atherosclerosis assessed by means of noninvasive methods (Carotid artery Intima Media Thickness, IMT) have been shown to be correlated with degree of job strain in Finnish men in their younger middle age, even after adjustment for accepted risk factors for cardiovascular disease. This is a developing research field like the study of interaction between genetic stress-related genetic allele combinations and exposure to job strain (Kivimäki et al., 2008).

Mental disease has also been examined in several prospective epidemiological studies including demand/control/support which show that the DCS model can predict risk of depression and "burnout." Depression seems to be particularly strongly related prospectively to high psychological demands and lack of social support at work.

Musculoskeletal disorders (in particular neck-shoulder pain) have also been related to the DCS in many studies. There seems to be an interaction between physical demands (such as heavy lifting or awkward working positions with static load) and high psychological demands/low decision latitude/poor social support in the etiology of neck-shoulder pain. The findings in different studies seem to depend on the type of work (white collar/blue collar), gender, age, and other contextual factors. While there is no full scientific

consensus regarding the role of the DCS model in musculoskeletal disorders, researchers agree that psychosocial job factors represented by the DCS are important in rehabilitation after the onset of such disorders.

The theory underlying the demand/control/support model has been used in several other epidemiological contexts, for instance productivity, international labor markets, pregnancy outcome, and use of protective equipment in industry.

Karasek has recently elaborated the DCS model in his stress disequilibrium theory (Karasek, 2008). This postulates that release and storage of energy are crucial features. In the job strain situation, energy is constantly released with insufficient opportunity for energy storage. During periods of energy storage there is also opportunity for regeneration and anabolism.

Definition

Job demands are aspects of any job that include the costs to the person completing the tasks necessary to the job. While physical demands are often the most obvious job demands, psychological, physiological, social, and organizational costs are also present in the demands of any job (Bakker & Demerouti, 2007). Job demands are dependent on the stress sources present in any environment a job is done and can be measured by the amount of stress caused to the worker participating in the job (Karasek, 1979). The job demands-resources model is a current popular model for exploring job demands by also incorporating job resources and finding a balance between them to reduce job strain (Bakker, Demerouti, Taris, Schaufeli, & Schreurs 2003).

Characteristics Study; Work

Definition

The Job Diagnostic Survey Questionnaire (JDS) intends to (a) diagnose existing jobs to determine if and how these might be redesigned to improve employee's motivation, satisfaction, and productivity and (b) evaluate the effects.

Description

The Job Diagnostic Survey (JDS) was developed by Hackman and Oldham in 1975. JDS is based on theoretical frameworks by Turner and Lawrence (1965), Hackman and Lawler (1971), and further developed by Hackman and Oldham (1975, 1980). JDS is based on the theoretical model the "Job Characteristics Model" (Hackman & Oldham, 1975, 1980) which contains three basic psychological critical states that promote high performance, motivation, and satisfaction at work. The critical states are as follows: (a) a person must experience the work as meaningful, valuable, and worthwhile; (b) a person should assume responsibility for the result of the work; and (c) a person should have knowledge of the results from work.

Experienced meaningfulness of a job is enhanced primarily by three core job dimensions: skill variety (a variety of different activities involving the use of different skills), task identity (doing a job from the beginning to end), and task significance (substantial impact).

Experienced responsibility for work outcomes increases when a job has high autonomy (substantial freedom, independence).

Knowledge of the results is increased when a job gives high feedback (the employee gets direct and clear information about the effectiveness of performance).

Affective responses from the work is investigated using questions regarding (a) general satisfaction (the degree to which the employee is satisfied with the job); (b) internal work motivation (the employee experiences positive internal feelings when performing effectively at work); and (c) specific satisfaction of job security, pay, social, supervisory, and opportunity for personal growth and development.

Job Diagnostic Survey Questionnaire

The original *Job Diagnostic Survey Questionnaire* (JDS) (Hackman & Oldham, 1975) is designed to be completed by workers. It contains questions and statements of Likert type, ranging from one to seven with higher scores indicating the greater extent to which the respondent's own work possesses the characteristics being assessed. JDS includes four major parts. The first part "job dimensions" includes skill variety ($n = 3$), task identity ($n = 3$), task significance

($n = 3$), autonomy ($n = 3$), feedback from job itself ($n = 3$), feedback from agents ($n = 3$), and dealing with others ($n = 3$). The second part "psychological states" includes experienced meaningfulness from work ($n = 4$), experienced responsibility for the work ($n = 6$), and knowledge of the results ($n = 4$). Part three "the affective responses to the job" includes general satisfaction ($n = 5$), internal work motivation ($n = 6$), and specific satisfaction with job security ($n = 2$), pay ($n = 2$), social ($n = 3$), supervisory ($n = 3$), and growth ($n = 4$). Part four "growth needs strength" includes questions in "would like" format ($n = 6$) and "job choice" format ($n = 12$).

The Job Characteristics Model suggests that it is possible to generate a summary score reflecting an overall *motivating potential* (MPS) of a job based on the five core job dimensions:

$$\text{MPS} = \frac{(\text{Skill variety} + \text{Task identify} + \text{Task significance})}{3} \times (\text{Autonomy}) \times (\text{Feedback})$$

Reliability

The instrument is not recommended for use at individual level; however, it shows satisfactory reliability when used on groups of five or more, performing the same type of job. The reliability ranges from a high internal consistency of 0.88 to a low of 0.58 (Hackman & Oldham, 1975). Results from test-retest are not available. JDS norm–referenced data are based on 6,930 persons working in 876 different jobs in 56 organizations (Oldham, Hackman, & Stepina, 1978).

Validity

Early work by Hackman and Oldham (1975) showed good face validity, with items being checked and re-checked during the 2-year development period. Fried and Ferris (1987) describe in their meta-analysis modest support for the model, suggesting that the model does not give a complete picture of the motivational effects of job characteristics. A recent study of the empirical evidence of the Job Characteristic Model was investigated in British establishments (DeVaro, Li, & Brookshire, 2007). The study result generally supports the model's prediction that task variety and worker autonomy are positively associated with labor productivity and product quality.

Oldham and Hackman (2010) describe how they under-recognized in their early work (1975, 1980) the importance for work redesign of the broader context, for example, the organization's formal properties and the culture within which the organization operates. They further suggest important areas for future research and discuss concepts such as social sources of motivation, job crafting, and work design for teams.

In several studies published during the years 2008–2011 using the JDS, only parts of the original questionnaire have been used, most frequently the subscales for job control (Tucker et al., 2009), job autonomy (Grandey, Fisk, & Steiner, 2005), and job satisfaction (Huffman, Youngcourt, Payne, & Castro, 2008; Nelson, Johnson, & Bebbington, 2009).

The JDS is generally applicable across industrial sectors and occupations. Investigations using the JDS have among others previously been published for customer-contact employees (Grandey et al., 2005), university employees (Liu, Spector, Liu, & Shi, 2011), army soldiers (Huffman et al., 2008), mental health professionals (Pedrini et al., 2009), psychiatrists (Kumar, Fisher, Robinson, Hatcher, & Bhagat, 2007), and pediatric nursing (Eaton & Thomas, 1997).

Definition

Job performance relates to the act of doing a job. Job performance is a means to reach a goal or set of goals within a job, role, or organization (Campbell, 1990), but not the actual consequences of the acts performed within a job. Campbell (1990) affirms that job performance is not a single action but rather a "complex activity" (p. 704). Performance in a job is strictly a behavior and a separate entity from the outcomes of a particular job which relate to success and productivity.

Definition

A *job* is "a single position or a group of positions, at one establishment, whose major work activities and objectives are similar in terms of worker actions, methodologies, materials, products, and/or worker characteristics; and whose array of work activities differs significantly from those of other positions" (US Department of Labor, 1982). Employees are reimbursed by working a job, which is how a job differs from a volunteer opportunity. Reimbursement does not have to be monetary but should be something of use and value to the employee.

Occupational health promotes the highest degree of physical, mental, and social well-being of workers in all occupations. It is aimed to prevent workers' ill health caused by working conditions, protect them in their works from risks that include adverse factors to health, and place them in optimum adapted occupational environment.

Related to health, it is therefore important to analyze jobs in order to understand the specific activities and requirements of the people who perform them. According to the US Office of Personnel Management (USOPM), job analysis is a "systematic procedure for gathering, documenting, and analyzing information about the content, context, and requirements of the job. It demonstrates that there is a clear relationship between the tasks performed on the job and the worker's competencies required to perform the tasks" (US Office of Personnel Management [USOPM], 2011). Job analysis requires that certain categories of information be reported in a systematic way (US Department of Labor, 1982). The two major categories of job analysis are Work Performed and Worker Characteristics (US Department of Labor). Together, work performed and worker characteristics define the dimensions of job requirements.

Job related to health thus includes adaption of work to the worker and correspondence between worker's capability and the job requirements.

Description

Some job demands may have an impact on the worker's health and contribute to health problems such as heart disease, depression, and burnout.

Having a defined system to analyze jobs helps people to determine which jobs they are capable of performing that ill health do not occur. For example, if a person acquires an injury that leaves them unable to lift heavy objects, they will have to consult job analyses to determine jobs that they can perform despite their lifting restriction.

Unfortunately, jobs can be a cause of mental, physical, and emotional harm for employees. Because of the health risks sometimes associated with holding a job, there are organizations designed to protect employees. One such organization is the International Labour Organization (ILO). It "is devoted to promoting social justice and internationally recognized human and labor rights, pursuing its founding mission that labor peace is essential to prosperity. Today, the ILO helps advance the creation of decent work and the economic and working conditions that give working people and business people a stake in lasting peace, prosperity and progress. Its main aims are to promote rights at work, encourage decent employment opportunities, enhance social protection and strengthen dialogue on work-related issues" (ILO, 2011).

Job Satisfaction/Dissatisfaction

Karen Jacobs[1], Miranda Hellman[2], Jacqueline Markowitz[2] and Ellen Wuest[2]
[1]Occupational Therapy, College of Health and Rehabilitation Science, Sargent College, Boston University, Boston, MA, USA
[2]Boston University, Boston, MA, USA

Synonyms

Social support at work; Work autonomy; Work fulfillment/non-fulfillment; Work performance feedback; Work satisfaction/dissatisfaction

Definition

Job satisfaction, that is, intrinsic and extrinsic job satisfaction, deals with the contentment with a particular job, done by an employee. Contentment with a job can be due to the internal qualities of an employee, including personality and personal lenses, and also the external features of the workplace including the environment. Some form of management controlling the quality of job outcomes often influences job satisfaction as well as the amount of power the employee is given.

Description

There are two major forms of job satisfaction: *intrinsic and extrinsic job satisfaction*. Intrinsic job satisfaction is the contentment with the type of work the employee is doing, while extrinsic job satisfaction encompasses the environment that the job is being completed in. Intrinsic job satisfaction is most variable between people because of individual preferences for different types of work. Extrinsic job satisfaction includes environmental factors such as salary, coworkers, and management (Jones, 1992).

Job satisfaction may be improved with varying the different types of tasks, the ability to get promoted, changing environmental factors, and higher employment salary. Although commonly thought to be an essential indicator of job satisfaction, salary level only has a marginal correlation of 15% with job satisfaction (Judge, Piccolo, Podsakoff, Shaw, & Rich, 2010). Moreover, job satisfaction has no direct relationship with job performance (Laffaldano & Muchinsky, 1984) but is strictly dependent on the context and outlook of the individual completing the job.

Job satisfaction can be measured by the amount of stress, the work group characteristics, the physical environment, and organizational rewards/punishments (Brief & Weiss, 2002). The most common way to measure job satisfaction in a traditional work environment is to give employees questionnaires, often constructed using a Likert scale. These assessments allow individuals to rate all aspects of the work satisfaction. Items most commonly given low scores may be improved within a workplace resulting in the job satisfaction of all involved to likely increase.

Job dissatisfaction is the discontentment of the conditions involved in measuring job satisfaction. Although these present as opposing concepts, an employee is able to have fluctuating feelings of both of these concepts as the work environment changes. Although an employee may be dissatisfied with the extrinsic aspects of a job, he or she may conversely be satisfied with the intrinsic features of that same job. Extrinsic factors, in particular, are associated with levels of job dissatisfaction high enough to result in a worker quitting a job (Arnett & Polkinghorne, 2010). A lack of achievement, responsibility, and recognition may result in job dissatisfaction (Dunnette, Campbell, & Hakel, 1966). While an employee may enjoy the tasks they are completing, their appreciation at their facility is an important element in maintaining the employee's satisfaction. Working conditions, company policies, and security are most likely to cause job dissatisfaction (Dunnette et al., 1966) as these are least likely to change if offensive.

Conclusion

Work satisfaction/dissatisfaction can be influenced by job characteristics and have an impact on a worker's well-being. For example, work demands such as a high work pressure, emotional demands, and role ambiguity may lead to sleeping problems, exhaustion, etc. Impaired health work resources such as social support, performance feedback, and autonomy might lead to work-related learning, work engagement, and organizational commitment (www.emeraldinsight.com/0268-3946.htm).

Kaposi's Sarcoma

David J. Finitsis
Department of Psychology, University of Connecticut, Storrs, CT, USA

Synonyms

KS

Definition

Kaposi's sarcoma (KS) is a rare disorder typically affecting the skin, mucous membranes, and blood vessels (Kubota, 2000); it was first described by Hungarian physician Moritz Kaposi in 1872 (Safai, 1997). Originally described as a cancer, current research suggests that KS is virally mediated (Hayward, Alcendor, & Arav-Broger, 2010).

Description

KS presents as pink, purple, and/or brownish red maculae or plaques which may hemorrhage (Knipe & Howley, 2007; Kubota, 2000).

Multiple forms of KS have been identified. The classic form is indolent, progressing slowly with localized expression that remains confined to the skin and subcutaneous tissues. This form was originally reported by Kaposi among a circumscribed population of primarily elderly men from Eastern Europe and the Mediterranean. It is rarely life-threatening and may spontaneously remit. A form was subsequently identified in certain regions of sub-Saharan Africa affecting adults and children and may present as either indolent or aggressive. An aggressive form has since been described in immunosuppressed organ transplant recipients (Knipe & Howley, 2007).

The acquired immune deficiency syndrome (AIDS) – related form of KS – is likewise aggressive. Lesions spread rapidly to involve a significant area of the skin and may develop into larger nodules and tumors. Aggressive KS may also extend to the lymphatic and gastrointestinal systems as well as the lungs (Kubota, 2000). With their pervasive involvement of the lymph nodes, mucosal tissue, and solid organs, aggressive forms of KS carry a significant risk of fatal complications (Kubota, 2000; Safai, 1997).

Etiology

Moritz Kaposi originally categorized KS as a small cell sarcoma, but KS presents as multiple lesions with a course that may be indolent in the immunologically intact patient. This differs greatly from cancer which typically manifests as

M.D. Gellman & J.R. Turner (eds.), *Encyclopedia of Behavioral Medicine*,
DOI 10.1007/978-1-4419-1005-9,

a unifocal lesion that spreads by metastasis. The current theory is that an infectious agent causes KS: researchers have identified a unique herpes-like virus from KS lesions, called Kaposi's sarcoma-associated herpesvirus (KSHV) or human herpesvirus 8 (HHV8). Forms of this virus have since been found present in all cases of Kaposi's sarcoma regardless of human immunodeficiency virus (HIV) serostatus (Hayward, Alcendor, & Arav-Broger, 2010).

Treatment

Historically, Kaposi's sarcoma has been treated as a cancer with surgery, radiation, and chemotherapy. Since aggressive KS is linked to immune compromise, treatments that restore the immune system can indirectly treat KS. In its AIDS-related form, the use of highly active antiretroviral therapy (HAART) is associated with the reduction and remission of KS lesions (Hayward, Alcendor, & Arav-Broger, 2010).

Kaufmann, Peter G.

Peter Kaufmann
Division of Prevention & Population Sciences, National Heart, Lung, and Blood Institute
Clinical Applications and Prevention Branch, Bethesda, MD, USA

Biographical Information

Peter Kaufmann was born in a World War II refugee camp near Lauenburg, Germany, on February 5, 1942. He immigrated to the United States with his parents in 1952, settling in Chicago, Illinois. Kaufmann received his BS and MA degrees in Psychology from Loyola University (Chicago) and his Ph.D. from the University of Chicago. He served briefly as Assistant Professor of Psychology at Emory and Henry College in Virginia, then pursued postdoctoral training in neurosciences in the Department of Physiology and Pharmacology at Duke University, in North Carolina, where he conducted research on the cellular organization of the visual system. He continued research in neuroscience at the Duke Center for Hyperbaric Medicine and Environmental Physiology, where he characterized the nature of central nervous system hyperexcitability arising from extreme barometric pressures such as encountered in deep-sea

diving, with support from the National Heart, Lung, and Blood Institute (NHLBI) and the Office of Naval Research.

In 1983, Kaufmann came to the NHLBI to develop a program of research on the neurophysiologic basis of behavioral risk factors of cardiovascular diseases. He rose to Chief of the Behavioral Medicine Branch in 1991, and Leader of the Behavioral Medicine and Prevention Research Group in 1994. In 1996, he organized the NHLBI Task Force on Behavioral Research in Cardiovascular, Lung, and Blood Health and Disease. Upon reorganization of the NHLBI in 2006, he was appointed Deputy Chief of the Clinical Applications and Prevention Branch. In 2000, he served as Acting Director of the National Institutes of Health (NIH) Office of Behavioral and Social Sciences Research (OBSSR). He served on numerous NIH-wide committees, including the NIH Behavioral and Social Sciences Coordinating Committee, the NIH Prevention Research Coordinating Committee, and as member and chair of the Data and Safety Monitoring Board (DSMB) for trials within the National Institute for Drug Abuse Clinical Trials Network. He testified on matters of behavioral and social sciences research in health before the Senate Committee on Appropriations, Subcommittee on Labor, Health and Human Services, and Education in 2000 and in 2002.

In addition to his work at the NIH, Kaufmann served on the Executive Council of the Academy of Behavioral Medicine Research (2003–2009) and the Executive Committee of the Society of Behavioral Medicine (2006–2009), serving as President from 2007 to 2008. He was Secretary of the International Society of Behavioral Medicine in 2009. He has received numerous awards for his work, including the NIH Director's Award (2011), several NIH Merit awards, the Distinguished Service Award of the Society of Behavioral Medicine (2009), Meritorious Research Service Commendation of the American Psychological Association (2003), the National Leadership Award of the Society of Behavioral Medicine (2002), and the Career Service to Health Psychology Award of the American Psychological Association (2002). He was elected Fellow of the Society of Behavioral Medicine in 1991 and Fellow of the Academy of Behavioral Medicine Research in 1992.

Major Accomplishments

Kaufmann's early work in hyperbaric medicine was to examine the reported rostro-caudal progression of high pressure hyperexcitability symptoms, demonstrating simultaneous effects at all levels of the central and peripheral nervous system. Along the way, he gained understanding of gas exchange, cardiac function, and the circulatory system. His initial focus at NHLBI was to develop research initiatives on the neurobiology of cardiovascular diseases, including the role of neuroactive peptides in response to mental stress, genetic influences in hypertension, and cardiovascular reactivity. Extending the work by David Krantz, James Muller, James Blumenthal, David Sheps and their collaborators, he launched the multisite Psychophysiological Investigations of Myocardial Ischemia (PIMI) study, which delineated the effects of mental stress on cardiac function in healthy men and women as well as in patients with obstructive coronary heart disease (CHD). This study demonstrated that vulnerability to mental stress increased mortality of CHD patients.

As identified behavioral risk factors grew in number and importance, Kaufmann recognized the importance of moving beyond descriptive studies and the study of mechanisms of action to develop clinical interventions that could be implemented in clinical practice. Spurred by the NHLBI's leadership in randomized clinical trials methodology, he turned his attention to identifying suitable targets for behavioral interventions and organized several randomized clinical trials to evaluate interventions for behavioral risk factors in cardiovascular diseases. He organized the Hypertension Intervention Pooling Project with Stephen Weiss, a rigorous examination of the methods and design of clinical trials in non-pharmacological management of hypertension.

He designed the stress management arm of the Trials of Hypertension Prevention with David Batey and collaborators and the Raynaud's Treatment Study (RTS), a multi-site clinical trial comparing behavioral and pharmacological treatments for Raynaud's Phenomenon, with Robin Hill. Inspired by Redford Williams' work on the influence of social support in reducing mortality and Robert Carney's research on depression in myocardial infarction patients, he was instrumental in launching the landmark Enhancing Recovery in Coronary Heart Disease Patients (ENRICHD) randomized trial with Susan Czajkowski. The trial evaluated whether cognitive behavioral therapy (CBT), supplemented by pharmacotherapy for treating depression and low perceived social support in patients after myocardial infarction would reduce the incidence of major acute cardiac events. The trial demonstrated the efficacy of CBT for depressed cardiac patients and led to insights about the role of depression in cardiovascular risk.

Kaufmann's work emphasized rigorous research designs and monitoring, contributing to setting the standard for clinical investigation in behavioral medicine. Along the way, he served as steward of numerous individual and group-randomized clinical trials involving stress management, meditation, relaxation therapy, and behavioral risk factor interventions for patients with hypertension, coronary heart disease, obesity, and tobacco addiction. He was successful in promoting collaborative research in behavioral medicine through Program Project Grants, Research Centers in Mind-Body Medicine, Translation Research, Research Centers for the study of health disparities and public health.

During his tenure as Acting Director of OBSSR in 2000, Kaufmann launched a committee to establish methods and a process for evaluating the efficacy of behavioral interventions. The Evidence-Based Behavioral Medicine project emerged and, under the guidance of Karina Davidson, was eventually adopted as a standing committee of the Society of Behavioral Medicine. At that time he also supported the early planning for the National Children's Study and designed and organized the Summer Institute on Randomized Clinical Trials Involving Behavioral Interventions, whose objective was to build a cadre of well-trained clinical trialists. The Summer Institute has continued as an annual event under Kaufmann's leadership with the collaboration and continued support of the OBSSR, particularly through the efforts and dedicated collaboration of Ronald Abeles. The Summer Institute has trained hundreds of junior investigators in the science of clinical trials.

Kaufmann has also provided leadership for numerous NHLBI and trans-NIH research initiatives and conferences, spanning a broad array of topics such as behavioral genetics, basic and applied research on the physiology and pharmacology of mental stress, pain and cardiovascular regulation, the role of mood disorders in somatic illness, translational science, health literacy, socioeconomic status and health, health disparities, and early life influences on health. With Redford Williams, he engaged in scientific exchange with Soviet scientists on behavioral factors in hypertension and in collaborative ventures with behavioral scientists in Lithuania. Kaufmann served on the editorial boards of Psychosomatic Medicine, Psichologija (Lithuania), and as Guest Editor of the Annals of Behavioral Medicine and the Journal of Cardiovascular Electrophysiology. He has held Adjunct teaching appointments at George Mason University in Virginia and Montgomery College, Maryland.

Kawakami, Norito

Akihito Shimazu
Department of Mental Health, Graduate School of Medicine, The University of Tokyo, Bunkyo-ku, Tokyo, Japan

Biographical Information

Prof. Norito Kawakami

Norito Kawakami was born on March 2, 1957, in Okayama, Japan. He graduated from Gifu University School of Medicine and acquired his M.D. degree in 1981. He was awarded his D.M. Sc. in 1985 from The University of Tokyo. After receiving his doctorate, Kawakami began his career as an assistant professor at The University of Tokyo. Then, he worked at the University of Texas School of Public Health, Houston, TX (1990–1991), and The University of Tokyo Faculty of Medicine (1991–1992) as a visiting researcher. He returned to Gifu University School of Medicine as an associate professor in the Department of Public Health (1992–2000). He moved to Okayama University Graduate School of Medicine, Dentistry & Pharmaceutical Science as a professor in the Department of Hygiene & Preventive Medicine (2000–2006). He is currently a professor in the Department of Mental Health, Graduate School of Medicine, University of Tokyo (2006).

Major Accomplishments

Kawakami has published more than 150 research papers in international journals concerning a broad range of topics in occupational health and behavioral medicine, such as the epidemiology of job stress (Kawakami, Kobayashi, Araki, Haratani, & Furui, 1995) and its health effects (Inoue et al., 2010; Kawakami et al., 1997, 2000) and workplace stress management interventions (Kawakami, Kobayashi, Takao, & Tsutsumi, 2005; Tsutsumi, Nagami, Yoshikawa, Kogi, & Kawakami, 2009).

He has also published papers regarding the epidemiology of mental disorders in the workplace and community (Kawakami et al., 1996; Kawakami, Shimizu, Haratani, Iwata, & Kitamura, 2004; WHO World Mental Health Survey Consortium, 2004), social inequality in health, smoking (Honjo, Tsutsumi, Kawachi, & Kawakami, 2006; Kawakami, Takatsuka, Shimizu, & Takai, 1998), and diabetes (Kawakami, Takatsuka, Shimizu, & Ishibashi, 1999).

Kawakami has served as the chair of the International Collaboration Studies Committee

(2004–2008), president of the International Society of Behavioral Medicine (2010–2012), chair of the Scientific Committee of Work Organization and Psychosocial Factors at Work (2006–2011), and as a board member for the International Commission on Occupational Health (2009). He has also served as an associate editor of the International Journal of Behavioral Medicine (2005–2008) and the editor-in-chief of the Journal of Occupational Health (2008–2011).

Kuopio Ischemic Heart Disease Risk Factor Study

Jussi Kauhanen
Institute of Public Health and Clinical Nutrition, University of Eastern Finland, Kuopio, Finland

Definition

The Kuopio Ischemic Heart Disease Risk Factor Study (KIHD) is an extensive epidemiologic research project that was launched in the 1980s. Within 20 years, it has produced over 400 original peer reviewed research papers in health-related international journals. The KIHD is a population-based longitudinal follow-up study, which initially involved nearly 3,000 middle-aged (42–60 years) men from the Kuopio region in Eastern Finland. Ten years later, women of same age ($N > 1,000$) were recruited to the study. A major part of the original cohorts have been reexamined 4, 11, and 20 years after the baseline. Register linkages have been established with national covering registries, i.e., the National Death Registry of Finland, Hospital Discharge Registry, Cancer Registry, and other disease-specific national health registries in Finland, to monitor annual events of early deaths as well as new cases and treatment episodes due to various diseases. Despite its name, the KIHD has not been restricted only to cardiovascular outcomes. Some of the major research lines have been within the domains of chronic disease epidemiology, nutritional epidemiology, alcohol epidemiology, psychosocial epidemiology, as well as molecular and genetic epidemiology. Being a multisdisciplinary project with extensive data collection, the health determinants examined within the KIHD study have involved a wide range of factors from genes to health behavior and environmental risks and from biochemical markers to psychological, psychosocial, and socioeconomic factors. It has been possible to construct some historical cohort designs, to take a lifecourse look at possible early childhood determinants on later health. Some of the key researchers in the project over the years have included authors such as Salonen JT, Kauhanen J, Tuomainen TP, Kurl S, Laukkanen J, Virtanen J (all from Finland), Kaplan G, Krause N (from the USA), and Lynch JW (Australia). The KIHD study is estimated to yield interesting scientific findings well into the 2020s.

Latent Variable

Jamil A. Malik
National Institute of Psychology, Quaid-i-Azam University/VU University Amsterdam, Islamabad, Pakistan

Synonyms

Hidden variable; Hypothetical construct; Hypothetical variable

Definition

Several of the concepts of social sciences extracted from various theories cannot be observed directly, although these concepts might be of interest to social scientists and researchers. For example:

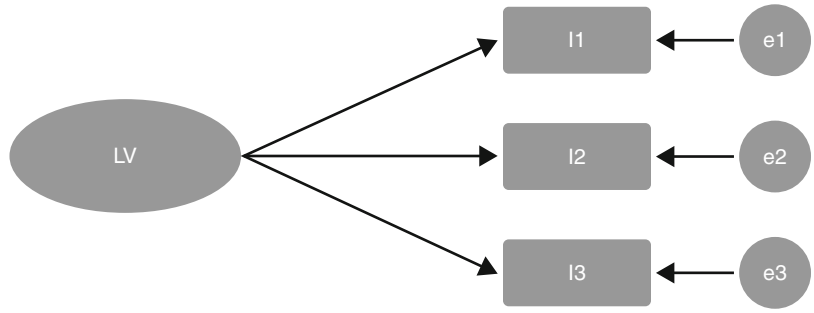
- In health: treatment adherence/compliance and well-being
- In psychology: stress, self-worth, and personality dimensions
- In education: memory, spatial ability, and problem solving
- In sociology: optimism, hostility, socioeconomic status, and attitudes
- In political science: leadership, conservatism, fundamentalism, political competence, etc.

In such cases where a concept is unobservable directly yet researchers are interested in their empirical testing, researchers have to rely on assumptions. In other words, they implicitly or explicitly operationalize these concepts into formal measurement models (constructs). These constructs can then only be measured indirectly via observable indicators/behaviors. Scaling (i.e., collection of relevant information on a questionnaire) is the most common technique to collect data for an unobservable construct. What is relevant is based on the assumptions of the researcher and derived from operational definition of the construct.

Various types of scaling techniques have been developed for deriving information on unobservable constructs of interest from observable indicators. An important family of scaling methods is formed by latent variables. A latent variable model is a possibly nonlinear, path analysis or graphical model. In addition to the manifest variables, the model includes one or more unobserved or latent variables representing the constructs of interest. Latent variable models are developed on two basic assumptions. The first assumption is that the responses on the indicators are the result of an individual's position on the latent variable(s). Secondly, it is assumed that

M.D. Gellman & J.R. Turner (eds.), *Encyclopedia of Behavioral Medicine*,
DOI 10.1007/978-1-4419-1005-9,

Latent Variable,
Fig. 1 Latent variable



the manifest variables have nothing in common after controlling for the latent variable(s), which is often referred to as the axiom of local independence.

Figure 1 shows a latent variable model, i.e., an unobservable variable LV represented by an oval which is assumed to be the result of commonality measured by three manifest indicators I1, I2, and I3. The ovals e1, e2, and e3 are residual also known as error variances. The concept of latent variables is based on the classical test theory, which assumes that any measure is a function of two variables: (1) the true score and (2) the error variation. This assertion can be written as a formula: $(X = T + E)$ where X represents the observed score on the measure, T is the person's true score, and E is the error variation.

Historically, the idea of latent variables arose primarily from psychometrics, beginning with the g factor of Spearman (1904). Spearman developed factor analytic models for continuous variables in the context of intelligence testing. The tradition continued with other psychologists such as Thomson, Thurstone, and Burt, who were investigating the mental ability of children, as suggested by the correlation and covariance matrices from cognitive tests variables. The technique was further developed with the work of Lawley (1943), Thurstone (1947), and Lawley and Maxwell (1963), and finally, it entered into the conceptual framework of confirmatory factor analysis (CFA) with Jöreskog (1971); Wiley, Schmidt, and Bramble (1973); and Sörbom (1974). In subsequent years, CFA became a very popular technique, largely because of the LISREL program by Jöreskog and Sorbom (1993). At present, there are various developments that emphasize this common framework for latent variables analysis, cases in point being the work of Muthén and Muthén (1998), McDonald (1999), and Moustaki and Knott (2000).

Learned Helplessness

Theresa A. Morgan
Alpert Medical School of Brown University, Department of Psychiatry, Brown University, Providence, RI, USA

Synonyms

Locus of control

Definition

Literally, learning to be helpless; a set of motivations, perceptions, and behaviors that conclude that one's behavior does not effect any control over one's surroundings (i.e., that no matter what one does, things will not change). The effect is most notable under aversive conditions where change is easily attained but is not sought due to learned helplessness.

Description

Learned helplessness refers to the condition of an organism (human or animal) wherein behavior is consistent with the perception that actions do not impact outcomes. In humans, this typically manifests as a view of the world as uncontrollable, unpredictable, and insensitive to individual needs or acts. Behaviorally, one might fail to be proactive even when opportunities to effect change exist (Walker, 2001).

The term "learned helplessness" originated with a set of animal studies from the 1960s and 1970s (e.g., Seligman & Maier, 1967; Overmier & Seligman, 1967). In these studies, one group (1) of dogs was given repeated, inescapable shocks while restrained. Later, these same animals appeared to passively accept shocks without seeking escape, even in cases where escape options were readily available (e.g., shock could be escaped by jumping over a small barrier or pushing a button or lever to turn off the shock). The

authors hypothesized that the animals were experiencing "learned helplessness" because previous experience taught them that behavior and the shock were independent; that is, they had learned to behave helplessly in the face of aversive stimuli. Later studies compared animals from this first group to (2) animals that experienced no previous shocks, (3) animals that experienced previous shocks as controllable (yoked to the learned helplessness group), and (4) animals that first received training in escaping shocks but later were given inescapable, uncontrollable shocks. All three later groups (2, 3, 4) learned to avoid shocks, where the first group (1) did not. As such, the critical component to developing learned helplessness is whether an organism first experiences the environment as controllable (see Peterson, Meier, & Seligman, 1995; Walker, 2001).

Since these original studies, learned helplessness has been applied to a wide variety of psychological phenomena, including acceptance of victimization (and abuse), pessimism, psychological well-being, low achievement at work or school, sudden death or illness, and health behaviors such as diet, exercise, and treatment adherence. Much research indicates that learned helplessness becomes a psychological deficit only when it manifests consistently, across multiple situations (Sahoo, 2002). As such, learned helplessness may describe behavior in a discrete situation (e.g., as with the shocks previously described), but it is most linked to problematic life outcomes when it becomes a trait-like, generalized set of perceptions and behaviors.

In humans, learned helplessness is most commonly studied in the context of depression. The "learned helplessness theory" specifically posits that depression occurs after experiencing the world as uncontrollable and then behaving consistent with the perception of helplessness. In this case, it is not actual controllability that is important so much as *perceived* controllability. In depression, learned helplessness theory also includes the perception of future uncontrollability: essentially that bad things happen now and in the future and that nothing one does can have any effect on their occurrence (see Peterson & Seligman, 1985). This hypothesis explains many of the more difficult to treat features of depression, including failure to approach previously enjoyable activities, failure to regulate eating and sleep, and similar self-defeating behaviors. Although research does link learned helplessness and depression, the direction of causality has yet to be firmly established. An alternative hypothesis suggests that a third variable, such as an external locus of control, causes both learned helplessness and depression to manifest (see Walker, 2001).

Leptin

Falk Kiefer[1] and Mustafa al'Absi[2]
[1]Department of Addictive Behavior and Addiction Medicine, Central Institute of Mental Health, Mannheim, Baden-Württemberg, Germany
[2]University of Minnesota Medical School, University of Minnesota, 235 School of Medicine, Duluth, MN, USA

Synonyms

Appetite; Hormones; Peptide

Definition

Leptin (Greek leptos: thin) is a protein hormone released mainly by white adipocytes. It binds at leptin receptors in brain neurons involved in regulating energy intake and expenditure, mainly in the lateral hypothalamus, where the activity of neurons containing neuropeptide Y (NPY) and agouti-related peptide (AgRP) is inhibited, while the activity of neurons expressing α-melanocyte-stimulating hormone (α-MSH) is increased. The effects of leptin were observed by studying mutant obese mice (*ob* mice) that arose at random at the Jackson Laboratory in 1950. The human *ob* gene is located on chromosome 7 encoding a protein of 167 amino acids.

Even though leptin is also synthesized by other tissues including the placenta, ovaries, skeletal muscle, stomach, mammary epithelial cells, bone marrow, pituitary, and liver, circulating leptin concentration is highly associated with the total amount of body fat and positively correlated with BMI. Despite the fact that leptin is reducing appetite in subjects of normal body weight, it was found to occur in obese people with unusually high concentration, thus indicating a possible leptin resistance. The leptin deficiency here may lead to increased food intake and body weight.

Experiments in animals have shown that leptin levels in circulation provide indication of both energy stores and energy balance. Research has also shown that food restriction is associated with suppression of circulating leptin, and that increased food intake increases leptin levels. Administering leptin was also found to reduce food intake resulting in loss of body weight. Leptin crosses the blood brain barrier, and administering it peripherally alters neuronal activity in several hypothalamic and brain stem regions leading to multiple changes that result in reduced appetite.

In addition to its hypothalamic target, recent results suggest that leptin also affects mesolimbic pathways and might provide a link between energy homeostasis and reward-related behavior. Leptin receptors were detected on dopaminergic neurons in the ventral tegmental area (VTA) inhibiting dopamine signaling in the nucleus accumbens (NAc). Based on these findings, there is evidence that elevated leptin is involved in processing of reward-predicting signals such as seeing, smelling, or tasting food. Important insights into the regulatory role of leptin on central processing of food-related stimuli have been gained by studies in patients with rare genetic defects leading to a leptin deficiency syndrome (LDS). In LDS patients, visual food cues were associated with increased striatal activation; moreover, this effect was neutralized by intravenous application of recombinant leptin. A second study reported marked CNS-activation in LDS patients following visual food stimuli.

Recent studies have demonstrated an important role of leptin in addictive behavior. For example, research has found positive correlations of plasma leptin and alcohol craving in alcohol-dependent subjects, as well as showed a positive correlation of plasma leptin and nicotine craving in nicotine-dependent subjects. It is assumed that leptin mediates a reduction of the basal dopaminergic activity in the mesolimbic system, contributing to a hypodopaminergic functioning associated with reward deficiency. These results suggest that addictive substances as well as food

may hold a greater reward value for subjects showing higher leptin plasma levels.

Life Events

Anna C. Phillips
Sport & Exercise Sciences, University of Birmingham, Edgbaston, Birmingham, UK

Synonyms

Stressful events

Definition

Life events are specific occurrences experienced by an individual that are perceived as stressful, e.g., bereavement, divorce, and moving house. Life events are not always negative events but can be something positive which is perceived as stressful due to the amount of change it brings into the individual's life, e.g., getting married and changing job.

Life event measures are often used to identify relationships between stress and health within behavioral medicine research. Life events are usually assessed by standardized interview or questionnaire. Such questionnaires ask the individual to indicate which events have happened to them over a specific time period such as 1 year or one month. Life events are usually limited to several key domains such as health, marriage, relationships, bereavement, work, housing, and finance. Some life event measures are specific to certain populations or age groups such as the Life Events Scale for Students (Linden, 1984). These measures often ask individuals to rate how stressful each event that occurred was on a rating scale. This method is based on the well-established Life Events and Difficulties Schedule (Brown & Harris, 1989). Other questionnaires use pre-identified weightings of the severity of events to determine an overall life events burden score, such as the Undergraduate Stress Questionnaire (Crandall, Preisler, & Aussprung, 1992) in which more severe events such as bereavement are given higher weightings.

Synonyms

Life course; Life cycle; Life time

Definition

In its most general sense, life span refers to the length of time between birth and death. Importantly, life span is distinct from life expectancy, which reflects the average number of years that an individual might be expected to live (often reflective of a biological limit on life). Developmental behavioral theories posit that certain factors impact behavior and that these factors, and thus individual behavior, change as the individual ages. Such theories of behavior specify that what happens earlier in life affects what happens later. As such, incorporating a life span approach in behavioral medicine implies the implementation of longitudinal studies that begin early on in the developmental stages (i.e., childhood) and continue into late adulthood. As the cost and feasibility of such life span studies can be prohibitive, many behavioral researchers opt instead to conduct cross-sectional studies of various age cohorts representative of the full age spectrum. Although informative, such study designs do not examine the *process* of aging, and as such, they cannot provide a causal explanation of how the processes of aging impact behavioral outcomes and vice versa. Finally, life span differs from health span (Rowe & Kahn, 1987, 1998), which reflects the length of time prior to the onset of disease or disability. Health span has been adopted in the behavioral medicine literature as an indicator of healthy aging.

Life Time

► Life Span

Life Years Lost

Anthony J. Wheeler and Scott DeBerard
Department of Psychology, Utah State University, Logan, UT, USA

Synonyms

Potential years of life lost (PYLL); Years of potential life lost (YPLL)

Definition

Life years lost (LYL) represents the number of years not lived to full potential due to disease or other fatal events. The metric LYL is calculated by subtracting the actual number of years lived from an expected duration, usually drawn from a standard life table. For example, if an individual died from breast cancer at age 49, and was expected to live to age 75, they would have lost 26 life years. The specific definition and calculation of LYL vary, with some researchers weighting quantities of LYL differently to adjust for social and economic losses.

Lifestyle

Jordan Carlson
Public Health, San Diego State University, University of California San Diego, San Diego, CA, USA

Synonyms

Health behaviors

Definition

The term lifestyle does not have a well-accepted definition but can be understood to be the health behaviors in which a person engages on a daily basis.

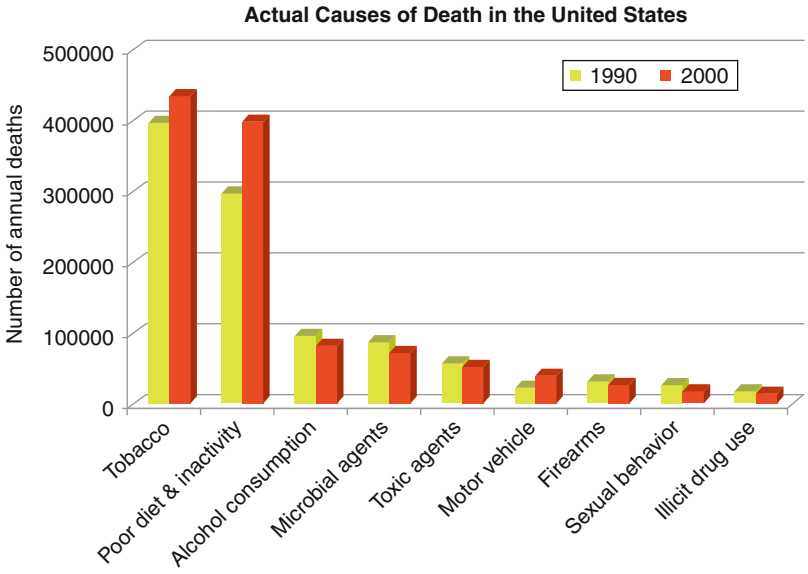
Description

Lifestyle Versus Nonlifestyle Health Behaviors

Health behaviors are actions taken by a person to maintain, attain, or regain good health and to prevent illness. Lifestyle health behaviors are different from other health behaviors in that they are engaged on a daily basis. For example, smoking is a lifestyle health behavior because it typically occurs on a daily basis. Medical care, such as medical appointments or cancer screenings, do not occur on a daily basis and thus can be considered nonlifestyle health behaviors.

Commonly Studied Lifestyle Behaviors

There are many lifestyle behaviors that are related to health outcomes and commonly studied in behavioral medicine (Glanz, Rimer,



Lifestyle, Fig. 1 Actual causes of death in the United States (Data from Mokdad et al., 2004)

Viswanath, & Orleans, 2010). Following are some examples:

- Dental hygiene
- Diet/nutrition
- Driving safety/seat belt use
- Drug use
- Medication adherence
- Physical activity
- Safe sex practices
- Sedentary behavior
- Smoking
- Social behaviors
- Stress management/relaxation
- Sun exposure/protection

Lifestyle Behaviors and Chronic Diseases

The leading causes of death in the USA drastically shifted in the twentieth century. At the beginning of the century, the leading causes of death were pneumonia, influenza, and tuberculosis (Armstrong, Conn, & Pinner, 1999). By 2000, the leading cause of death was heart disease (710, 760 deaths), followed by cancer (553, 091 deaths) and stroke (167, 661 deaths). The "actual causes of death" were estimated based on the behavioral causes of these diseases (Mokdad, Marks, Stroup, & Gerberding, 2004). The leading actual causes of death in 2000 were tobacco use (435,000 deaths; 18.1% of all deaths) and poor diet and physical inactivity (400,000 deaths; 16.6% of all deaths) (Fig. 1). These death rates were drastically higher than those from all other actual causes of death and were much higher in 2000 than in 1990. These actual causes of death are considered preventable and are often the focus of lifestyle behavior interventions.

Lifestyle Changes

Spencer M. Richard and Scott DeBerard
Department of Psychology, Utah State University, Logan, UT, USA

Synonyms

Alcohol abuse; Management; Obesity treatment; Smoking; Smoking cessation; Substance abuse; Weight; Weight loss

Definition

Lifestyle changes are defined as changes that alter various lifestyle-related behaviors such as diet, physical activity, sexual behavior, smoking, alcohol consumption, substance use, and other behaviors not otherwise defined as psychopathology. Lifestyle changes may often relate to other comorbid mental and/or physical health conditions such as substance abuse disorders, obesity, asthma, sexually transmitted diseases, depression, and anxiety.

Description

Diet/Physical Activity

Obesity and overweight account for a substantial portion of medical care costs in the United States. Current research suggests that approximately two thirds of the population in the United States qualifies as overweight (body mass index between 25.1 and 29.9) or obese (body mass index > 30; World Health Organization, 2010).These rates are often attributed to lifestyle factors including unbalanced diet and lack of physical exercise/activity. Little research has been done to effectively measure the direct health-care cost benefits of modifying these lifestyle factors. However, one recent projection estimated that by altering diet alone (i.e., decreasing caloric intake by 100 kcal/day, saturated fat by 5 g/day, and sodium by 400 mg/day), national health-care costs could potentially be cut by $60 billion to $120 billion per year (Dall et al., 2010).

Interventions on diet and physical activity have traditionally focused on cognitive behavioral approaches intended to produce weight loss and increased physical activity. Overweight and obese individuals experience increased risk of several mental and physical health problems including cardiovascular disease, depression symptoms, sleep problems, diabetes, and others (Centers for Disease Control & Prevention, 2010). In general, empirical research has shown a trend for 5–10% weight loss during the course of treatment, followed by subsequent relapse and weight gain by at least half of participants at or beyond preintervention weight (Wadden & Butryn, 2003). Altering diet and exercise has been shown to significantly reduce weight and lower risk for weight-related illnesses and cardiometabolic disease (Goodpaster, et al., 2010). Recent trials indicate increased efficacy of behaviorally based interventions with values and acceptance components (Forman, Butryn, Hoffman, & Herbert, 2009; Lillis, Hayes, Buntin, & Masuda, 2009). These approaches have been shown to lead to better maintained weight loss and physical activity measurements as well as increased mental health outcomes. Additional evidence suggests that use of internal and externally based incentives may increase adherence to lifestyle changes in diet and exercise.

Smoking

Cigarette smoking has been shown as a significant risk factor for myriad physical health problems including coronary heart disease, stroke, cancers, chronic obstructive lung disease (COPD), and death (Centers for Disease Control & Prevention, 2011). Smoking directly or indirectly causes approximately 440,000 deaths annually in the United States, including 80% of lung cancer deaths in women and 90% of lung cancer deaths in men. In addition, smoking has been implicated in reproductive health problems including infertility, preterm birth, low birth weight, and increased risk of sudden infant death syndrome. Smoking cessation has been linked with a number of positive health outcomes. Individuals that quit smoking before middle age may

significantly reduce risk of developing lung cancer (Peto et al., 2000).

In general, smoking cessation at younger ages increases health benefits exponentially. Smoking cessation treatment is often brief (as little as one targeted session) and can be delivered in many environments including primary care, outpatient counseling, and in home by a number of professional and paraprofessional primary care and/or mental health workers including nurses, doctors, counselors, and psychologists. Treatment methods focusing on motivation enhancement, behavioral commitment, acceptance, and mindfulness have been indicated as recommended treatment modalities by the National Registry of Evidence-based Programs and Practices (NREPP). In addition, smoking cessation may lead to other related lifestyle improvements including decreased long-term substance use and may moderately increase quality of life (Sarna, Bialous, Cooley, Jun, & Feskanich, 2008).

Alcohol/Substance Use

Alcohol and other substance use represent a considerable health risk and account for a substantial health-care and legal system resources. The National Institute on Drug Abuse (NIDA) estimates annual costs of nearly $600 billion in the United States alone including costs of prevention, treatment, legal costs, and lost worker productivity (National Institute on Drug Abuse, 2009). The abuse of alcohol and other drugs are widely varying depending on the nature and frequency of use and type of substance being used. In general, substance use has been linked to several physical and mental health problems including cardiovascular disease, COPD, birth defects, paranoia, psychotic symptoms, depression, and anxiety, among many more.

Alcohol and other drug use are treated in both inpatient and outpatient medical and mental health settings. Similar to smoking cessation treatment, significant health benefits are observed by reducing or eliminating alcohol or other substance use. Depending on the extent of use and type of substance being used, treatment may include any combination of the following aspects recommended by NIDA and NREPP: medications (including antagonists or substitutes for the substance of abuse), individual counseling, group counseling, detoxification, supervision, ongoing case management, and treatment of other comorbid medical and mental health conditions. Effective psychological treatments tend to include multidimensional approaches including cognitive-behavioral intervention, family therapy, motivation enhancement, acceptance, mindfulness, behavior commitments, and contingency management.

Summary

Lifestyle changes can have significant and long-lasting physical and mental health effects. Treating problematic lifestyle behaviors can be a brief, cost-effective, and meaningful strategy by a variety of health-care service providers to improve physical and mental health of their patients and clients.

Lifestyle, Active

Victoria Anne Sublette
School of Public Health, University of Sydney, Sydney, NSW, Australia

Synonyms

Active way of life; Healthy lifestyle

Definition

An active lifestyle is one in which individuals incorporate regular and substantial physical movement into their daily routines to benefit their cardiovascular, muscular, and psychological health.

Description

Engagement in an active lifestyle includes regular physical activity which protects physical and mental

health by reducing individuals' risk of developing diseases and depression and is associated with a significant reduction in premature mortality rates from all causes for men and women (Keim, Blanton, & Kretsch, 2004; Morrison, Bennett, Butow, Mullan, & White, 2008).

Low-impact exercise and weight-bearing exercise such as walking and dancing promotes bone development in the young and preserves bone density during adulthood. Achieving peak bone mass protects individuals against the development of osteoporosis, a disease characterized by a reduction in bone density due to calcium loss, leading to brittle bones and an increased risk of fractures (Department of Health and Ageing, 2010).

Physical Benefits of an Active Lifestyle

- Helps build and maintain healthy bones, muscles and joints
- Builds endurance and muscular strength
- Protects against brain damage caused by stroke
- Lowers risk factors for cardiovascular disease, colon cancer, and type 2 diabetes
- Improves balance, strength, suppleness and mobility
- Instrumental in reaching and maintaining a healthy weight
- Helps control blood pressure
- Increases energy
- Reduces muscle tension
- Improves sleep
- Improves body shape

Psychological Benefits of an Active Lifestyle

- Reduces stress
- Improves mood and self-esteem
- Reduces symptoms of depression and anxiety
- Improves cognitive function
- Improves quality of life

(Centers for Disease Control and Prevention, 2010; Keim et al., 2004; Van Praag, 2009).

An active lifestyle also has profound benefits for brain function. Physical activity improves learning, memory, and cognitive processes such as planning, scheduling, and coordination. An active lifestyle also stimulates the adult and aging brain to generate new neurons preventing cognitive decline in older age and protects the brain against damage caused by stroke, promotes recovery after injury, and is an antidepressant (Van Praag, 2009).

Moderate and vigorous-intensity aerobic or resistance training exercise can reduce symptoms of depression. Research has found inactive persons are approximately twice as likely to have symptoms of mild to moderate depression than individuals who are more active. The antidepressant effect of physical exercise has been shown to be similar in magnitude to antidepressant medications in some studies (Van Praag, 2009).

Guidelines for an Active Lifestyle

For those 5–18 years old, 60 min a day of moderate to vigorous physical activity combined is recommended. Children and adolescents should include muscle-strengthening and bone-strengthening exercises as part of their 60 min a day at least 3 days a week. Examples of moderate activities are a brisk walk, a bike ride, or active play. Examples of vigorous exercise are running, swimming laps, organized sports, and ballet (Centers for Disease Control and Prevention, 2010; Department of Health and Ageing, 2010; U.S. Department of Health & Human Services, 2008).

Recommendations for adults age 18 years and over are at least 150 min (2 h and 30 min) a week of moderate-intensity, or 75 min (1 h and 15 min) a week of vigorous-intensity aerobic physical activity. Vigorous-intensity aerobic exercise moves large muscles in a rhythmic manner for a sustained period of time and includes brisk walking, jogging, biking, dancing, and swimming. Aerobic exercise should be performed in increments of at least 10 min each. Adults should also perform muscle-strengthening activities that involve all major muscle groups at moderate to high intensity two or more days a week.

For optimum health, an active lifestyle that incorporates greater physical health benefits and weight control can be obtained by engaging in physical activity of more vigorous intensity or of longer duration (Centers for Disease Control and Prevention, 2010; Department of Health and Ageing, 2010; U.S. Department of Health & Human Services, 2008).

Lifestyle, Healthy

Emily Kothe
School of Psychology, University of Sydney, Sydney, NSW, Australia

Definition

The term healthy lifestyle does not have a single widely accepted definition. According to the World Health Organization, lifestyle is a way of living which is based on identifiable patterns of behavior. These patterns of behavior are determined by the interplay between individual, social, and environmental factors.

In this context, healthy lifestyle can be defined as a pattern of behavior which maximizes health protective behaviors while minimizing health risk behaviors.

Description

Lifestyle health behaviors are typically defined as behaviors which are performed on a daily (or almost daily) basis. This is distinct from other health behaviors such as medical screening which is performed less regularly.

While it is important to recognize that healthy lifestyle is not a unitary concept which can be prescribed to all people, a number of key patterns of behavior are included in most descriptions of healthy lifestyle (see Table 1).

These include:

- Active lifestyle
- Healthy diet

Together, poor diet and physical inactivity are among the leading causes of major noncommunicable diseases. These two lifestyle patterns contribute substantially to the global burden of disease. Following a healthy lifestyle pattern, characterized by an active lifestyle and healthy diet, can lead to large reduction in individual risk of disease.

Active Lifestyle

An active lifestyle can be defined as a pattern of behavior which includes regular physical activity and limited sedentary behaviors. Regular engagement in physical activity is known to be health protective and is known to be associated with is associated with improved mental and physical health.

Research shows that regular physical activity is associated with reduction in all-cause mortality and with decreased risk of osteoporosis, cardiovascular disease, diabetes mellitus, and some forms of cancer (Morrison, Bennett, Butow, Mullan, & White, 2008). For more information, see "active lifestyle."

In addition to including physical behavior, an active lifestyle is characterized by limited engagement in sedentary behaviors. Sedentary

Lifestyle, Healthy, Table 1 Physical activity guidelines by age group

Age range	Physical activity guidelines	
5–18 years	60 min (1 h) a day of moderate to vigorous physical activity	Children and adolescents should include muscle-strengthening and bone-strengthening exercises as part of their 60 min a day at least 3 days a week
18–64 years	150 min (2 h and 30 min) a week of moderate-intensity	Adults should also perform muscle-strengthening activities that involve all major muscle groups at moderate to high intensity two or more days a week
	or	
	75 min (1 h and 15 min) a week of vigorous-intensity aerobic physical activity	
65+ years	At least 30 min (half an hour) of moderate intensity physical activity on most, preferably all, days	Older people should be active every day in as many ways as possible, doing a range of physical activities that incorporate fitness, strength, balance, and flexibility

Source: Centers for Disease Control and Prevention (2010), Department of Health and Ageing (2010), U.S. Department of Health & Human Services (2008)

behaviors are those which involve very limited energy expenditure (e.g., computer use, TV viewing).

As a pattern of behavior, sedentary behavior often co-occurs with limited physical activity since it often displaces more physically active behaviors. This pattern of behavior is particularly unhealthy since the influence of sedentary behavior on health appears to be independent of the influence of physical inactivity. Research suggests that combining sedentary behavior and physical inactivity has approximately twice the negative health impact as either behavior alone (Owen, Healy, Matthews, & Dunstan, 2010). For more information, see "► Lifestyle, Sedentary."

Healthy Diet

An individual's diet plays an important part in long-term health. Diet is known to directly influence the risk of a number of life-limiting diseases (e.g., some forms of cancer, heart disease). Diet may also influence risk of disease through its influence on weight and obesity.

As a pattern of behavior, healthy diet is a pattern of eating behavior which maintains a state of well-being while reducing risk of chronic disease.

The World Health Organization recommends that dietary guidelines for populations and individuals should include the following recommendations:

- Achieve energy balance and a healthy weight
- Limit energy intake from total fats and shift fat consumption away from saturated fats to unsaturated fats and towards the elimination of trans-fatty acids
- Increase consumption of fruits and vegetables, and legumes, whole grains, and nuts
- Limit the intake of free sugars
- Limit salt (sodium) consumption from all sources and ensure that salt is iodized

Many countries have dietary guidelines that give more specific guidance in relation to these broad concepts. For example, the Dietary Guidelines for Americans recommend that salt intake be limited to a maximum of sodium intake of 2,300 mg for healthy adults and 1,500 mg for individuals with hypertension.

It is important to recognize that a healthy diet can be accomplished with a range of different dietary patterns. The suitability of each dietary pattern for a given individual will depend on that person's culture, income, family structure, age, health status, and home/work environment.

Lifestyle, Modification

Jordan Carlson
Public Health, San Diego State University, University of California San Diego, San Diego, CA, USA

Synonyms

Behavior change; Behavior modification; Behavioral intervention; Lifestyle changes

Definition

The term lifestyle modification can be used to refer to behavioral interventions that attempt to create change in multiple lifestyle health behaviors.

Description

Lifestyle Versus Nonlifestyle Health Behaviors

Health behaviors are actions taken by a person to maintain, attain, or regain good health and to prevent illness. Lifestyle health behaviors are different from other health behaviors in that they are engaged in on a daily basis (e.g., smoking, dietary behaviors, physical activity). Medical care behaviors (e.g., attendance of medical visits or cancer screenings) are not engaged in on a daily basis and thus can be considered nonlifestyle health behaviors. For more information and examples of commonly studied lifestyle behaviors, see "▶ lifestyle."

Although the term lifestyle can be used to refer to single behaviors in which people engage on a daily basis, this entry will focus on lifestyle modification of multiple health behaviors. For information on single behavior modification, see "▶ behavior change," "▶ behavior modification," and "▶ behavioral intervention."

Rationale for Multiple Versus Single Behavior Modification

The leading causes of death in the USA are heart disease, cancer, and stroke. Each of these diseases has the same underlying cause: poor diet, physical inactivity, and smoking (among others). One rationale for multiple vs. single health behavior modification is that changing multiple behaviors will affect health more than single behavior modification. Another rationale is that lifestyle health behaviors tend to cluster or co-occur. For example, a smoker or drug user is also likely to engage in poor dietary habits and be physically inactive. Thus, targeting multiple vs. single lifestyle behaviors should have the greatest potential to improve physical health outcomes of

primary interest in behavioral medicine, such as heart disease, cancer, and stroke (Prochaska, Spring, & Nigg, 2008; Prochaska, 2008).

Individual Versus Population-Based Approach

There are two main approaches to lifestyle modification: individual and population-based (Prochaska et al., 2008). The individual approach is person-centered and often includes tailored modification strategies for each person. For example, a person who consumes no fruits and vegetables but is physically active may be targeted to improve his/her fruit and vegetable consumption, while a person who consumes no fruits and vegetables and is physically inactive may be targeted to make improvements in both areas. In the individual approach, change/success is measured at the person level. An advantage to this approach is that it increases the potential overall impact on a person's health, while a disadvantage is that it likely increases the behavior change demands and program complexity.

The population-based approach to lifestyle modification typically includes a modification program across an entire population. These programs often create change to community policies and/or environments. Advantages of population-based approaches include the ability to reach large numbers of people and create sustainable changes. Disadvantages are that some people may not be reached by the modification program and environmental and policy changes can be costly and time intensive.

Theories of Lifestyle Modification/Behavior Change

Detailed information on behavior change interventions and theories can be found under the terms "▶ behavioral intervention" and "▶ theory." In brief, individual level theories such as the Transtheoretical Model of Behavior Change, Social Cognitive Theory, and Learning Theory have been useful in designing lifestyle modification interventions. More recently, ecological models (Sallis, Owen, & Fisher, 2010) have been used to inform population-based intervention approaches. Ecological models take into account multiple levels of influence on health behaviors, such as the individual, interpersonal, environment, and policy levels.

Success of Lifestyle Modification Programs

Success of multiple behavior lifestyle interventions has been documented, although this is a new area of research. A recent review found that multiple health behavior interventions resulted in greater weight loss than single behavior interventions (Sweet & Fortier, 2010). However, it is unknown how lifestyle behaviors change together and if intervention efforts should focus on grouping certain behaviors together (e.g., target diet and physical activity together but drug use separately).

Lifestyle, Sedentary

Jordan Carlson
Public Health, San Diego State University, University of California San Diego, San Diego, CA, USA

Synonyms

Inactivity; Sedentary activity; Sedentary behaviors

Definition

A sedentary lifestyle consists of a daily routine of high amounts of sitting and/or very low energy expenditure activities paired with very low levels of physical activity.

Description

Sedentary Behavior

Sedentary behaviors are those that involve very little or no muscle movement and/or energy expenditure and usually involve sitting. Examples of sedentary activities include TV viewing, computer use, sitting in an automobile, or most other activities that involve sitting. For more information, see "► sedentary behaviors."

Physical Inactivity

A person who engages in little to no physical activity (specifically moderate-to-vigorous intensity physical activity) is said to be physically inactive. For more information, see "► exercise" and "► physical inactivity."

Sedentary Lifestyle Consists of Sedentary Behavior and Physical Inactivity

High amounts of sedentary activity often co-occur with low amounts of physical activity. Sedentary activity competes with physical activity and displaces physical activity when a person chooses sedentary behaviors over physical activity. This type of person typically avoids most or all types of physical activity and spends most of the day engaged in sitting behaviors such as TV watching or other screen time behaviors (e.g., computer use). He or she may be inactive in their occupation and leisure time, travel by automobile rather than active forms of transport, and engage in relatively little household work. This type of person is often referred to as a "precontemplator" as termed in the Transtheoretical Model of Behavior Change (see "► Transtheoretical Model of Behavior Change"), meaning that they have not considered becoming more active and would be difficult to reach with behavioral intervention.

Prevalence of Sedentary Activity and Physical Inactivity

Sedentary prevalence rates were measured objectively in 2004 using electronic activity monitors on a nationally representative sample of US youth and adults (Matthews et al., 2008). Adults were sedentary for an average of 7.5 h per day, with older age being related to more sedentary time. Children spend 6 h per day in sedentary activities, while youth spent 7.5–8 h per day sedentary. Women/girls spent only slightly more time in sedentary activity than men/boys, on average.

According to self-reports, 35.5% of US adults were classified as physically inactive based on the US Department of Health and Human Services physical activity guidelines. Inactivity is more prevalent in women, older adults, people of race/ethnic minority, less educated people, and those who are obese (Carlson et al., 2008). Objective data suggests much higher rates of physical inactivity: 58% of children, 92% of adolescents, and 96% of adults have been classified as inactive (Troiano et al., 2008).

Sedentary Lifestyle and Health

Sedentary behavior has recently been linked with multiple negative health outcomes, independent of the amount of physical activity in which a person engages. Specifically, the amount of time a person spends viewing TV, number of breaks from sitting (i.e., how many times a person stands up), and total time spent sitting were found to be associated with biomarkers (i.e., risk factors and symptoms) of cardiovascular disease, such as obesity, waist

circumference, systolic blood pressure, plasma glucose, triglycerides, HDL cholesterol, and mortality (Owen, Healy, Matthews, & Dunstan, 2010).

Physical inactivity is also related to a myriad of health problems, such as cardiovascular disease, type 2 diabetes, some cancers, and mortality (Blair et al., 1996; Haskell, Blair, & Hill, 2009).

Because the biology underlying the link between sedentary behavior and health is thought to be unique from the biology of inactivity and health, a person who lives a sedentary lifestyle is likely affected negatively by both processes. Thus, a sedentary lifestyle is thought to have around twice the negative health impact as being either sedentary or physically inactive (Owen et al., 2010).

Lipid

Jonathan Newman
Columbia University, New York, NY, USA

Synonyms

Plasma lipid; Total cholesterol

Definition

Lipid is a general term of broad importance in human health and disease. There are both endogenous (produced by the body for physiologic processes) and exogenous (dietary intake) sources of lipid. Lipids are produced by the human body for many physiologic functions, including the synthesis of cell walls (made from cholesterol, a lipid). Dietary lipid is found most commonly as fatty acids, cholesterol, and cholesterol esters which are

absorbed by the body and used to sustain physiologic processes or stored for future energy use.

In cardiology and cardiovascular disease, lipid is generally considered to be the cholesterol content in the blood. The subcategories of lipid are low-density lipoprotein (LDL), high-density lipoprotein (HDL), very-low-density lipoprotein (VLDL), and triglycerides (TGs). The function of each lipid is outlined in other sections (see ▶ Lipid, Plasma; ▶ Lipoprotein).

Lipid Abnormalities

Leah Rosenberg
Department of Medicine, School of Medicine, Duke University, Durham, NC, USA

Synonyms

Dyslipidemia

Definition

Lipid abnormalities encompass a variety of pathophysiological states of dysregulated cholesterol metabolism.

Description

Lipid abnormalities are extremely common in industrialized societies and are well known to be linked to adverse cardiovascular events, such as myocardial infarction and stroke. Dyslipidemias such as increased low-density lipoprotein (LDL), decreased high-density lipoprotein (HDL), and/or increased triglycerides have been identified as strongly associated with the risk of incident cardiovascular events. Lipid abnormalities are an excellent target for both primary and secondary prevention efforts, as there are a variety of lifestyle and pharmacologic approaches to correct these levels.

Cholesterol is a type of lipid that is hydrophobic and thus insoluble in human plasma. Lipids are carried with proteins into tissues for their varied cellular functions. Cholesterol and other lipids have enzymatic roles that are integral to human metabolism. When lipids are connected to a protein, they are referred to as lipoproteins. There are five biologically important lipoproteins, two of which will be discussed here: LDL and HDL. Both LDL and HDL ferry cholesterol esters and have distinct receptor types based on their function. LDL in the liver can be converted in secretable bile acids and excreted into the feces. Alternatively, LDL can be brought into extrahepatic cells, causing excessive cholesterol in the intracellular space. HDL cholesterol differs from LDL as it scavenges excess cholesterol from cells for excretion and thus has protective cardiovascular events. In common clinical parlance, LDL is known as "bad cholesterol," whereas HDL is called "good cholesterol."

Triglycerides are another important class of lipids. They are storage molecules that, when hydrolyzed, release free fatty acids into the circulation. They are created from the breakdown of fats and carbohydrates and are stored in adipose tissue. When excess calories are ingested, they are ferried to fat stores by triglycerides in the bloodstream.

When the levels of LDL, HDL, and triglycerides are abnormal, it is referred to as dyslipidemia. One definition of lipid imbalance or dyslipidemia that uses data from a large-scale observational study called NHANES III states that dyslipidemia is defined by being below the 10th percentile for HDL levels or above the 90th percentile for LDL and triglyceride levels nationally. Essentially, dyslipidemia implies high LDL and triglycerides and/or low HDL.

The Adult Treatment Panel (ATP III) guidelines, authored by the National Cholesterol Education Program (NCEP), are guidelines published in

Lipid Abnormalities, Table 1 The Adult Treatment Panel (ATP III) Treatment Guidelines

Risk category	LDL target	LDL threshold to start TLC	LDL threshold to start drug therapy
CHD/CHD risk equivalent	<100 mg/dL	≥100 mg/dL	≥130 mg/dL
			100–129 mg/dL on TLC (optional)
Moderately high	<130 mg/dL	≥130 mg/dL	≥130 mg/dL
Moderate	<130 mg/dL	≥130 mg/dL	≥160 mg/dL
Low	<160 mg/dL	≥160 mg/dL	≥190 mg/dL
			160–189 mg/dL on TLC (optional)

CHD = coronary heart disease, LDL = low-density lipoprotein, TLC = therapeutic lifestyle changes.

Lipid Abnormalities, Table 2 2004 Update to The Adult Treatment Panel (ATP III) Treatment Guidelines

Risk category	LDL target	LDL threshold to start TLC	LDL threshold to start drug therapy
CHD/CHD risk equivalent	<100 mg/dL	≥100 mg/dL	≥100 mg/dL
	<70 mg/dL (optional)		<100 mg/dL (optional)
Moderately high	<130 mg/dL or <100 mg/dL (optional)	≥130 mg/dL	≥130 mg/dL
	<100 mg/dL (optional)		100–129 mg/dL (optional)
Moderate	<130 mg/dL	≥130 mg/dL	≥160 mg/dL
Low	<160 mg/dL	≥160 mg/dL	≥190 mg/dL
			160–189 mg/dL on TLC (optional)

CHD = coronary heart disease, LDL = low-density lipoprotein, TLC = therapeutic lifestyle changes.

2001 for the diagnosis and treatment of dyslipidemia in adult patients. These guidelines provide an evidence-based approach for identifying and treating patients with lipid abnormalities, with a particular focus on reducing LDL by lifestyle modification and lipid-lowering therapy (primarily HMG-CoA reductase inhibitors or statins). The major feature of the ATP III guidelines was a focus on multiple risk factors to determine baseline cardiovascular risk in order to identify risk-based LDL goals (see Table 1) for non-pharmacological therapy (i.e., therapeutic lifestyle changes, TLC) or lipid-lowering drug therapy (i.e., statins). Four groups of baseline cardiovascular risk are defined as follows: high risk (coronary heart disease or coronary heart disease risk equivalents including peripheral artery disease, abdominal aortic aneurysm, symptomatic carotid artery disease, diabetes, or the presence of two or more risk factors with a 10-year Framingham risk score >20%), moderately high risk (two or more risk factors with a 10-year Framingham risk score 10–20%), moderate risk (two or more risk factors with a 10-year Framingham risk score less than or equal to 10%), and low risk (0 or 1 risk factor). The ATP III guidelines also discussed optimal goals for triglycerides (less than 150 mg/dL) and LDL (greater than or equal to 40 mg/dL) and also identified metabolic syndrome as an important at-risk phenotype.

In 2004, another NCEP report was published as an update to the ATP III guidelines. This report was endorsed by the National Heart, Lung, and Blood Institute, American College of Cardiology Foundation, and American Heart Association. Based on several randomized trials that were completed after the ATP III guidelines were published, the LDL cut points for initiating statin therapy (as well as on-treatment goals), especially for patients in the high-risk and moderately high-risk categories, were lowered (Table 2).

In 2008, the JUPITER trial, or Justification for the Use of Statins in Primary Prevention: An Intervention Trial Evaluating Rosuvastatin was published. JUPITER was a landmark randomized double-blinded, controlled trial comparing rosuvastatin (a statin) or placebo in patients,

mostly in the low- to moderate-risk category who had an LDL less than 130 mg/dL, who otherwise would not typically be a candidate for initiating statin therapy. An additional and important inclusion criterion was a C-reactive protein (a cardiovascular biomarker) of 2 mg/dL or higher. Compared with placebo, there was a significant reduction in cardiovascular events associated with rosuvastatin treatment. Despite the importance and clinical implications of the study findings, critics of JUPITER have stated concerns that the study was stopped prematurely (thus overestimating the reduction in cardiovascular events), questioned the magnitude of the absolute risk reduction observed in the trial (i.e., the rates of the primary end point were 0.77 and 1.36 per 100 person-years of follow-up in the rosuvastatin and placebo groups, respectively), and/or questioned the utility of C-reactive protein. It is unclear as of this writing whether CRP will be incorporated in the next NCEP report to select patients for statin therapy who have an LDL less than 130 mg/dL who are not at high risk.

Fat metabolism

Definition

Lipid metabolism is a complex process which involves multiple steps from production within the body or dietary intake to degradation or transformation into several lipid-containing structures in the body.

Description

Lipid metabolism is a complex process that involves multiple steps involving the dietary intake of lipids (exogenous) or the production of lipids within the body (endogenous) to degradation or transformation (catabolism) into several

lipid-containing structures in the body. A brief description of metabolism related to fatty acids and cholesterol is provided below.

The dietary fat in the form of triacylglycerol (TAG), cholesterol, cholesteryl esters, and free fatty acids is absorbed by the intestine after going through various steps during digestion from mouth to intestine.

Fatty acids, once absorbed from intestine, are activated in the intestinal wall and eventually resynthesize the TAG. Some of the shorter-chain fatty acids go to the liver after binding to albumin in the blood. TAG, long-chain fatty acids, and cholesterol, after activation, are packaged in the chylomicron particles and moved to the blood stream via the lymphatic system to reach the entire body. The TAG is mainly broken down in the capillaries of skeletal muscles and adipose tissues. Other organs like heart, lung, liver, and kidneys are also involved. TAG in the chylomicrons is degraded to free fatty acids and glycerol by lipoprotein lipase. This enzyme is primarily produced in the adipose tissues and muscle cells. Thus formed free fatty acids may be either used for energy or may be stored as TAG after reesterification. However, glycerol that is released from TAG is used almost exclusively by the liver to produce glycerol 3-phosphate and this can be used either in the glycolytic pathway to produce energy or in the production of new molecules of glucose(gluconeogenesis).Fatty acids can also be produced by the body and this process occurs mainly in the liver and adipose tissues.

Fatty acids that are stored in the adipose tissue in the form of TAG serves as a major energy storage. The complete oxidation of fatty acids produces 9 kcal/g of fat as compared to proteins and carbohydrates which produce about 4 kcal.

The major degradation (catabolism) of saturated fatty acids occurs in mitochondria and this process is called beta oxidation. During beta oxidation, two-carbon fragments are removed successively generating high-energy-rich substances (like NADH and FADH2 molecules). After the oxidation of fatty acids, acetyl Co-A is produced and eventually it is used in the formation of ketone bodies. Thus formed ketone bodies can be used as energy source or for production of other important biochemical substrates. However, the oxidation of unsaturated fatty acids results in lesser calories and this process requires additional enzymes in the metabolic pathway.

Lipid metabolism also includes the formation and degradation of several other important lipid particles like phospolipids which plays a very important role in the structure of cellular membranes, prostaglandins, and several hormonal activities in the body.

Cholesterol is not only provided to the body by the dietary intake but also synthesized by virtually all the tissues in the body, although liver, intestine, adrenal cortex, reproductive tissues including ovaries, testes, and placenta produce most of the cholesterol in the body. These sites also utilize cholesterol in the process of production of multiple hormones in the body.

Degradation of the cholesterol happens mainly in the liver, where the sterol nucleus is eliminated from the body after conversion into bile acids and bile salts, which are excreted in the feces or it may undergo enterohepatic circulation.

The lipoproteins (chylomicrons, high-density lipoproteins, and low-, intermediate-, very-low-density lipoproteins) are involved with transporting these various lipid particles in the body with the apolipoproteins on their surface.

Total cholesterol in the blood

Definition

Plasma lipid is the cholesterol content in the blood. Plasma lipid profile includes total cholesterol, triglycerides (TG), high-density lipoproteins (HDL), intermediate-density lipoproteins (IDL), low-density lipoproteins (LDL), and very low-density lipoproteins (VLDL). The fasting lipid profile is generally recommended due to significant variations in the TG levels due to food contents.

Elevated LDL cholesterol levels and lower levels of HDL are associated with increased risk for incident cardiovascular disease. Non-HDL cholesterol is calculated as the difference between total cholesterol and HDL levels. Non-HDL cholesterol includes all the cholesterol present in the lipoproteins attributed to atherogenicity. Non-HDL cholesterol is considered as better tool for risk assessment than the assessing LDL cholesterol alone.

Definition

Lipoproteins are complex substances containing lipids and specific proteins called apolipoproteins or apoproteins.

Description

Lipoprotein particles include chylomicrons, high-density lipoproteins (HDL), very low-density lipoproteins (VLDL), intermediate low-density lipoproteins (IDL), and low-density lipoproteins (LDL).

Each of these particles differs in their lipid and protein composition, density and size, and site of origin. Lipoproteins act as transporter of lipids

and render the lipids as water-soluble. Each lipoprotein is described in terms of their origin and metabolism in the following sections.

Chylomicrons are assembled in the intestinal cells, and they carry the dietary triacylglycerol, cholesterol, fat-soluble vitamins, and cholesterol esters to the peripheral tissues of the body. Chylomicrons are highest in their lipid content and lowest in density as compared to other lipoproteins. The characteristic apolipoprotein associated with chylomicron is B-48. The molecule of the chylomicron is modified after the attachment of apolipoprotein E and apolipoprotein C, mainly apolipoprotein C-II. Once the chylomicrons are released into blood circulation, the lipid component of chylomicrons is extracted from the adipose tissue, cardiac and skeletal muscle with the help of enzyme called lipoprotein lipase. This enzyme is activated by apolipoprotein C-II on the surface of chylomicron molecule. Thus, extracted lipid is further used for the energy supply and the storage. After extraction of lipids, chylomicrons are called chylomicron remnants, and these particles are metabolized and degraded in the cells of liver. This process generates amino acids, free cholesterol, and fatty acids.

VLDL are produced by the liver and composed of triacylglycerol. The function of VLDL is to transport the lipid from the liver to peripheral tissue. Apolipoprotein B-100 is located on surface of VLDL. After secreted into blood circulation, VLDL obtains apolipoprotein C-II and apolipoprotein E from HDL. During this exchange, some of the triacylglycerols are transferred from VLDL to HDL and some of the cholesteryl esters from HDL to VLDL. This exchange is mediated by cholesteryl ester transfer protein. With this modification, VLDL is converted in to LDL. During this transition, intermediate dense lipoproteins (IDL) and VLDL remnants are produced. Furthermore, IDL may be further taken up by the cells with the help of apo E. There are three isoforms of apolipoprotein E (E2, E3, and E4). Type III hyperlipoproteinemia (familial dysbetalipoproteinemia or broad beta disease) is manifested when apolipoprotein E2 is deficient and the patients usually present with premature atherosclerosis.

LDL contains lesser amount of triacylglycerol than VLDL and higher concentration of cholesterol and cholesteryl esters. The role of the LDL is to provide the cholesterol to the peripheral tissues. Apolipoprotein B-100 is located on the surface of LDL and binds to the LDL receptors on the cell surface. If there is deficiency of functional LDL receptor, this condition produces significant elevation in the LDL as seen in type II hyperlipidemia (familial hypercholesterolemia) causing premature atherosclerosis.

HDL are formed in the blood, and they have apolipoprotein A-1 on their surface and serve several important functions. HDL selectively transfer the cholesterol from the peripheral tissue and transport it back into liver for the bile acid synthesis and to steroidogenic cells for hormone synthesis. Thus, HDL help in the homeostasis of cholesterol. HDL also pick up the unesterified cholesterol in the circulation, and they also act as circulating reservoirs of apolipoprotein C-II. With all these functions, HDL are sometimes referred to as good cholesterol.

Locus (Genetics)

J. Rick Turner
Cardiovascular Safety, Quintiles, Durham, NC, USA

Synonyms

Gene

Definition

A locus is a spot or "address" on a chromosome at which a gene for a particular trait is located in all members of a species. It can also refer to the location of a mutation or other genetic marker. A given locus can be found on any pair of homologous chromosomes (Brown, 2009).

In 1909, the botanist Wilhelm Johannsen coined the term "gene" to describe the heritable characters discussed by Mendel. Between 1907 and 1919, the geneticist Thomas Hunt Morgan (a Nobel Laureate in Medicine) and his colleagues conducted an elegant series of experiments using the fruit fly *Drosophila melanogaster*. Fruit flies have marked advantages for use in transmission genetics research: they are abundant in nature, and they are very easily fed and accommodated. In addition, they are prodigious reproducers. They have a generation time of 10 days, and females produce around 300 eggs (of which half are female). This mathematics means that in the space of a single month, i.e., just three generation times, one fruit fly couple can lead to over three million flies (Watson, 2006).

In 1907, there was no current knowledge of established genetic differences, making it difficult for Morgan to know precisely where to start his research, as reflected by a comment by Watson (2006): "You cannot do genetics until you have isolated some characteristics to track through the generations." A search for mutant genes was started since mutant genes (variations from the normally occurring genes, sometimes called abnormal variants) lead to distinct characteristics. This led to the identification of some flies with white eyes (the normal color is red). The trait for white eye color was found to be located on the X chromosome and was inherited with a factor that determines the fly's sex. Morgan and others subsequently showed that each gene for a particular trait was located at a specific spot, i.e., a locus, on a chromosome in all individuals of a species.

Locus of Control

Julia R. Van Liew
Department of Psychology, University of Iowa, Iowa City, IA, USA

Synonyms

Attributional style; Hardiness; Self-efficacy

Definition

Locus of control refers to one's general predisposition to perceive control, or lack thereof, across various situations. The extent to which one attributes valued outcomes or reinforcement to either internal or external circumstances reflects their dimension of locus of control. Individuals with an internal locus of control believe in the power of their own decisions and behaviors to impact life events and determine their own future. Those with an external locus of control, on the other hand, view life events as dictated by environmental factors outside of one's control, such as luck, fate, or powerful others.

As originally defined by Rotter (1966), locus of control is a broad concept that is present across dimensions of functioning. The field of behavioral medicine has specifically applied it to the control individuals feel in regard to their physical health, termed health locus of control. The Health Locus of Control scale (HLC; Wallston, Wallston, Kaplan, & Maides, 1976) and Multidimensional Health Locus of Control scale (MHLC; Wallston, Wallston, & DeVellis, 1978) assess this specific construct. Researchers are interested in the relationship between health locus of control and a variety of health behaviors and outcomes, such as engagement in health-promoting and preventive behaviors, adherence to medical regimens, health care utilization, and coping with chronic illness.

Loneliness

Elizabeth A. Majka and John T. Cacioppo
Department of Psychology, The University of Chicago, Chicago, IL, USA

Synonyms

Social isolation; Social pain

Definition

A subjective sense of social isolation produces feelings of *loneliness* or social pain (Cacioppo & Patrick, 2008). This distressing constellation of feelings and emotions results from a discrepancy between one's actual and desired social relationships. Thus, lonely individuals are not satisfied with the quality of their actual social relationships, leaving them lacking a sense of social inclusion and belonging. Not to be confused with objective social isolation or a low quantity of social relationships, individuals can feel lonely when alone just as much as they can feel lonely when surrounded by a sea of people. Identifying individuals who suffer from loneliness is important, since over time loneliness can seriously impair physical, cognitive, and psychological health.

Loneliness is typically assessed using self-report items assessing the degree to which individuals endorse statements describing thoughts and

feelings commonly associated with loneliness such as "I lack companionship" or "I feel alone" (Russell, Peplau, & Cutrona, 1980). Scores on these sorts of measures fall on a continuum, ranging from very low in loneliness (i.e., feeling highly socially connected) to very high. Therefore, although labeling individuals as lonely or non-lonely may be convenient shorthand, people may fall anywhere on the loneliness continuum. Feelings of loneliness can be experienced transiently in response to an experience of social rejection or to a shift in circumstances (e.g., beginning college, divorce, widowhood, relocating to a new city), or loneliness can be experienced more chronically, functioning as a trait-like characteristic.

Three theoretical perspectives dominate the loneliness literature (Cacioppo & Patrick, 2008). One theory of loneliness posits that dissatisfaction with specific types of relationships (e.g., social network members vs. romantic partner) leads to different types of loneliness (e.g., social vs. emotional). Another perspective suggests that social skill deficits and personality traits (e.g., shyness) can hinder relationship development and maintenance, thereby leading to feelings of loneliness. Finally, a third theory of loneliness takes an evolutionary approach, positing that feelings of loneliness – although aversive – are adaptive in that they motivate humans to pursue and maintain social connections, thereby enhancing survival of oneself and one's offspring. Adoption and twin studies indicate loneliness has a heritability coefficient of approximately 0.50 (Boomsma, Willemsen, Dolan, Hawkley, & Cacioppo, 2005).

Loneliness also predicts various cognitive impairments, including poorer executive functioning, depressive symptomatology, and sleep fragmentation (Cacioppo & Hawkley, 2009). When people feel lonely, they are more likely to cope with stressors by withdrawal rather than by active coping and seeking emotional and instrumental support from others. Loneliness is also associated with an implicit hypervigilance for social threats, which has a cascading effect on social cognition. Briefly, although people who feel lonely want to connect with others, they tend to anticipate rejection and engage in self-protective behavior that paradoxically can be self-defeating. Accordingly, a meta-analysis of loneliness interventions indicated that the most effective interventions addressed these maladaptive social cognitions (Masi, Chen, Hawkley, & Cacioppo, 2011).

Loneliness and Health

Louise C. Hawkley and John T. Cacioppo
Department of Psychology, The University of Chicago, Chicago, IL, USA

Definition

Loneliness is the distress that accompanies feelings of social isolation and lack of connectedness

and belonging. Although people who are married and have close friends tend to be less lonely than those who do not, people can live relatively solitary lives and not feel lonely, and conversely, they can live an ostensibly rich social life and feel lonely nevertheless. As many as 80% of those under 18 years of age and 40% of adults over 65 years of age report being lonely at least sometimes. For as many as 15–30% of the general population, loneliness is a chronic state. Left untended, loneliness has serious consequences for physical and cognitive health and well-being.

Description

Loneliness and Physical Health and Mortality

Loneliness has been shown to predict increased morbidity and mortality (reviewed in Hawkley & Cacioppo, 2010). The effects of loneliness seem to accrue over time to accelerate physiological aging and mortality. For instance, loneliness exhibited a dose-response relationship with cardiovascular health risk in young adulthood such that the greater the number of measurement occasions at which participants were lonely (i.e., childhood, adolescence, and at 26 years of age), the greater their number of cardiovascular health risks (i.e., BMI, systolic blood pressure (SBP), total and HDL cholesterol levels, glycated hemoglobin concentration, and maximum oxygen consumption). Loneliness has been associated with increased systolic blood pressure in middle-aged adults, and a persistent trait-like aspect of loneliness accelerated the rate of systolic blood pressure increase over a 4-year follow-up period. Notably, the loneliness effect was unique and independent of the effects of depressive symptoms, perceived stress, social support, and hostility, variables that are correlated and sometimes mistakenly assumed to be synonymous with loneliness. Similarly, in a study of women, chronic high-frequency loneliness was prospectively associated with incident coronary heart disease over a 19-year follow-up in analyses that adjusted for depressive symptoms and a range of demographic and cardiovascular risk factors. Finally, a number of large epidemiologic studies have shown that all-cause or cardiovascular mortality risk is greater in chronically than situationally or rarely lonely adults.

Loneliness and Mental Health and Cognitive Functioning

Loneliness has been associated with personality disorders and psychoses, suicide, impaired cognitive performance and cognitive decline over time, increased risk of Alzheimer's disease, diminished executive control, and increases in depressive symptoms (Cacioppo & Hawkley, 2009). Loneliness and depressive symptoms are correlated, and recent analyses have demonstrated a causal role for loneliness; loneliness predicted increases in depressive symptoms over 1-year intervals, but depressive symptoms did not predict loneliness (Cacioppo, Hawkley, & Thisted, 2010). This is consistent with experimental evidence which has shown that hypnotically induced feelings of loneliness increase depressive symptoms while also increasing perceived stress, fear of negative evaluation, anxiety, and anger, and diminishing optimism and self-esteem (Cacioppo et al., 2006).

Feelings of social isolation have been associated with cognitive decline and dementia. A causal role for loneliness is supported by evidence that cognitive functioning in 75–85-year-olds did not differ as a function of loneliness at baseline but diminished to a greater extent among those high than low in loneliness over a 10-year follow-up, an effect that persisted after adjusting for objective measures of social activity and social network size. In another prospective study, loneliness was inversely associated with performance on a battery of cognitive measures in initially dementia-free older adults and predicted a faster decline in cognitive performance on most of these measures over a 4-year follow-up. In addition, incidence of Alzheimer's disease was predicted by degree of baseline loneliness adjusting for relevant covariates, including depressive symptoms.

Mechanisms for Health Effects of Loneliness

Health behaviors and sleep. Physical activity is a well-known protective factor for physical health,

mental health, and cognitive functioning. Loneliness has been associated with a lower likelihood of engaging in physical activity and a greater likelihood of discontinuing physical activity over time in middle-aged adults. This effect is not attributable to frequency of social contact or social network size, ruling out social control as a mechanism for the effects of felt isolation on physical activity. Loneliness is also a risk factor for obesity and a propensity to abuse alcohol. A compromised ability to exercise self-discipline and regulate emotions has been implicated in the poorer health behaviors exhibited in lonelier individuals.

Sleep affords physiological restoration, and sleep quality is important in accomplishing sleep's restorative effects. Non-restorative sleep (i.e., sleep that is non-refreshing despite normal sleep duration) results in daytime impairments such as physical and intellectual fatigue, role impairments, and cognitive and memory problems. Loneliness heightens feelings of vulnerability and unconscious vigilance for social threat, implicit cognitions that are antithetical to relaxation and sound sleep (Cacioppo & Hawkley, 2009). Cross-sectional and longitudinal studies have shown that loneliness predicts poor self-reported sleep quality, greater daytime dysfunction (i.e., low energy, fatigue), and more nightly micro-awakenings, effects that are largely independent of sleep duration and depressive symptoms (Hawkley, Preacher, & Cacioppo, 2010).

Physiological functioning. In young adults, loneliness has been associated with elevated levels of total peripheral resistance (Cacioppo et al., 2002; Hawkley, Burleson, Berntson, & Cacioppo, 2003), the primary determinant of systolic blood pressure (SBP) until at least 50 years of age. In older adults, loneliness has been associated with elevated SBP and predicted an accelerated increase in SBP over a 4-year follow-up, an effect that was adjusted for and independent of age, gender, race/ethnicity, cardiovascular risk factors, medications, health conditions, and the effects of depressive symptoms, social support, perceived stress, and hostility (Hawkley, Thisted, Masi & Cacioppo, 2010).

Changes in TPR levels are themselves influenced by a variety of physiological processes, including activity of the autonomic nervous system and the hypothalamic-pituitary adrenal (HPA) axis. To date, loneliness has not been shown to correlate with sympathetic nervous system activity at the heart, but was associated with a greater concentration of epinephrine in overnight urine samples in a middle-aged and an older adult sample (Hawkley et al., 2010). At high concentrations, circulating epinephrine binds α-1 receptors on vascular smooth muscle cells to elicit vasoconstriction and could thereby serve as a mechanism for increased SBP in lonely individuals.

Dysregulation of the hypothalamic-pituitary-adrenal axis contributes to inflammatory processes that play a role in hypertension, atherosclerosis, and coronary heart disease. Loneliness has been associated with urinary excretion of significantly higher concentrations of cortisol and with higher levels of salivary or plasma cortisol (reviewed in Hawkley & Cacioppo, 2010). A 3-day diary study clarified the causal direction; prior-day feelings of loneliness were associated with a higher cortisol awakening response the next day, but morning cortisol awakening response did not predict feelings of loneliness later the same day (Adam, Hawkley, Kudielka, & Cacioppo, 2006).

Gene Effects. Cortisol exerts broad anti-inflammatory effects, but although loneliness is associated with elevated cortisol levels, it increases risk for inflammatory disease. This apparent contradiction may be explained by glucocorticoid insensitivity. Evidence consistent with glucocorticoid insensitivity has been demonstrated in chronically lonely versus socially connected older adults and has further been shown to vary across the loneliness continuum (Cole et al., 2007; Cole, Hawkley, Arevalo, & Cacioppo, 2011). Genome-wide microarray analyses showed that markers of immune activation and inflammation (e.g., pro-inflammatory cytokines and inflammatory mediators) were over-expressed and markers of inhibitors of the pro-inflammatory NF-κB (nuclear factor-kappa B) transcript were under-expressed in genes of the lonely relative to the socially connected group. Analyses also indicated a possible

decrease in glucocorticoid receptor–mediated transcription in the lonely group, despite the fact that there were no group differences in circulating glucocorticoid levels. These results are consistent with a functional desensitization of the glucocorticoid receptor, which permits increased NF-κB activity and thereby induces a pro-inflammatory bias in gene expression. Loneliness differences in NF-κB/glucocorticoid receptor–mediated transcription activity were not attributable to objective indices of social isolation, nor were they explained by demographic, psychosocial (i.e., perceived stress, depression, hostility), or medical risk factors.

In an extension of this work, a recent study showed that feelings of social isolation were associated with a proxy measure of functional glucocorticoid insensitivity, namely, an attenuation in lonelier individuals of the typically positive correlation between cortisol levels and the ratio of neutrophil percentages relative to lymphocyte or monocyte percentages. This result signifies a diminished sensitivity of leukoctyes and leukocyte trafficking to the influence of cortisol in lonelier individuals (Cole, 2008).

Immune Functioning. Loneliness has been associated with impaired cellular immunity as reflected in lower natural killer (NK) cell activity and higher antibody titers to the Epstein-Barr virus and human herpes viruses. In addition, loneliness has been associated with poorer antibody response to a component of the flu vaccine, suggesting that the humoral immune response may also be impaired in lonely individuals (reviewed in Hawkley & Cacioppo, 2010).

Summary

Social integration was once thought to have effects on health via health behaviors, but we now know that the effects of perceived social isolation include biological consequences, therefore implicating central nervous system control. Evidence consistent with central influences includes implicit hypervigilance for social threat and diminished self-regulatory capacity. Loneliness is itself a product of central processes, i.e., maladaptive social cognitions that bias lonely individuals relative to socially connected individuals to perceive, expect, and remember more negative social information. Interventions that address maladaptive social cognitions have been shown to be more successful in reducing felt loneliness than interventions that work to increase number of social contacts. A role for central processes in the health effects of loneliness suggests that interventions that address maladaptive social cognitions may also influence biological, behavioral, and health outcomes.

Longevity

Denis Gerstorf[1] and Christiane A. Hoppmann[2]
[1]Institute of Psychology, Humboldt University, Berlin, Germany
[2]Department of Psychology, University of British Columbia, Vancouver, BC, Canada

Synonyms

Life expectancy

Definition

The population-level concept of life expectancy refers to the average number of years of life remaining at a given age under the assumption that everyone will experience (for the rest of their lives) the same risk of death as evinced by current life tables. At the individual level, there is tremendous heterogeneity in the length of individual life spans within any society.

Description

The last century has witnessed unprecedented increases in longevity. This chapter provides an overview of population-level trends of longevity and describes important individual-level factors that contribute to between-person differences in longevity. In a first step, the terminology is clarified and population trends regarding past, present, and future developments in life expectancy are considered. In a second step, the chapter illustrates the importance of taking into account psychosocial predictors of between-person differences in longevity and discusses how and why sociodemographic characteristics, levels of functioning, as well as trajectories of change in behavioral and experiential characteristics are uniquely associated with mortality risks. The chapter concludes by pointing to key societal challenges for the future.

Population Trends in Longevity

The oldest reliably documented human being was a French woman by the name of Jeanne Calment who died in 1997 at the age of 122 years. This historically unparalleled life span demonstrates that, under optimal circumstances, humans can live up to 125 years. Such an age, however, is only reached by very few exceptional cases. A more realistic estimate of how long people can expect to live is provided by the population concept of life expectancy. Life expectancy at birth, for example, is the average number of years of life remaining for newborns under the assumption that everyone will experience (for the rest of their lives) the same risk of death as

evinced by current life tables (Olshansky, Hayflick, & Carnes, 2002). Over the past century, the world has witnessed a remarkable rise in life expectancy. For example, the average US American could expect to live for 49 years in 1900. In 2000, this number was 77 years, an increase of 64%. Another impressive illustration is that over the past 170 years, increases in life expectancy, in nations with the highest life expectancies, progressed at a rate of about 2.5 years per decade or 6 h per day (Vaupel, 2010). This remarkable increase in life expectancy was primarily due to a reduction in infant mortality (in the US, approximately 10% of infants born alive died before 1 year of age in 1900 vs. less than 1% in 2000). This trend originated in substantial advances in public health, hygiene, and nutrition (e.g., sewage, refuse disposal, safe drinking water) as well as medical care and technology. For example, key medical milestones in the early twentieth century were the discovery of antibiotics in 1928 and penicillin entering mass production in the 1940s, which substantially reduced mortality due to bacterial infections, diarrhea, and pneumonia.

Currently, life expectancy at birth is over 80 years in many industrialized nations such as Japan, Australia, or Canada (Organisation for Economic Co-operation and Development, OECD Factbook, 2010). Whereas rising life expectancy was historically driven by reductions in infant mortality, the fastest growing segment of the population today are the oldest old. For example, the number of individuals aged 85+ in the US has increased by 300% between 1960 and 2000, and the number of individuals aged 100+ is expected to grow from 37,000 in 1990 to 850,000 in 2050 (U.S. Bureau of the Census, 2004). Notwithstanding such general increases, there are tremendous geographical disparities in life expectancies. For example, the US only ranks 49 worldwide with a current life expectancy of 78 years (Central Intelligence Agency, CIA World Factbook, 2011), probably due to limitations in health-care coverage, unhealthy lifestyles (e.g., obesity), and public health problems (e.g., sanitation, pollution). In addition, some nations are currently experiencing dreadfully low or even declining life expectancies. According to the World Health Organization, for example, life expectancy in several African regions such as Angola is below the age 45 because of the AIDS pandemic. Similarly dramatic, Russia experienced a drop in average life expectancy by 6% in the 1990s that is only slowly coming back up. Alcohol abuse (as proxy for self-destructive behaviors and external causes of death due to homicide, suicide, and accidents) and stress (related to economic uncertainty and a poor outlook for the future) each accounted for about 25% of the documented increase in mortality rates (Brainerd & Cutler, 2005).

For the future of life expectancy, some demographers expect that every other girl born today in the developed world can expect to live up to the age 100 years (Vaupel, 2010). Such an optimistic prospect, however, rests heavily upon the assumption that progress in reducing mortality rates continues at the same pace as over the past two centuries. This assumption is not shared by other more conservative demographers (Olshansky et al., 2005) who instead predict that increases in life expectancy may slow down (e.g., because of little room for further reducing infant mortality) or even come to an end (e.g., due to unhealthy lifestyles resulting in sharp increases in obesity-related illnesses). The verdict for which of these estimates is going to be correct is out, but the aging population will put considerable strain on the health-care, welfare, and pensions systems.

Individual Differences in Survival

Besides such demographic trends, there is tremendous heterogeneity in the length of individual life spans within any society. Some individuals die relatively young (e.g., in their 40s or 50s), whereas others reach very advanced ages (e.g., age 90). This observation raises the pivotal question of key individual-level factors that are associated with heterogeneity in length of life. One such factor is sociodemographic characteristics. More specifically, individuals with low education and low income who belong to an ethnic minority have a lower life expectancy than highly educated, affluent Caucasians (Kaplan, Pamuk,

Lynch, Cohen, & Balfour, 1996). Another example is gender, with a considerable female survival advantage (e.g., up to six female centenarians per one male centenarian; Vaupel, 2010). This pervasive gender differential in life expectancy is thought to reflect a combination of genetic (e.g., with the second X chromosome, women have genetic information stored in duplicate, thereby reducing the risk for genetic defects), physiological (e.g., sturdier body makeup to sustain childbirth), and behavioral factors (e.g., better health behaviors; Owens, 2002).

In recent years, behavioral and experiential factors have also been identified as key predictors of heterogeneity in mortality hazards. Among the most obvious candidates are health behaviors and lifestyle factors, including lack of regular physical activity, unhealthy diets, stress, smoking, and heavy drinking. It has further been documented that impaired cognitive functioning (Deary, Weiss, & Batty, 2011), personality characteristics such as neuroticism (Wilson et al., 2005), lack of social integration (Seeman, 2001), diminished well-being (Danner, Snowdon, & Friesen, 2001), and perceptions of poor health (Idler & Benyamini, 1997) each uniquely predict mortality over and above established mortality correlates. What are the pathways and underlying mechanisms that link psychosocial factors with differences in mortality? It is an open conceptual question if psychosocial factors constitute mortality risks on their own or if they reflect the effects of pathologic processes. For example, poor well-being may have detrimental physiological effects on cardiovascular and immune functioning (Pressman & Cohen, 2005), resulting in further loss of functioning and ultimately death. Alternatively, well-being may reflect quite accurate perceptions of levels and particularly changes in functioning across a variety of other domains that are more directly linked to mortality such as physical health (Maier & Smith, 1999). Examining such questions will shed light on crucial, potentially modifiable risk factors.

Importantly, evidence is accumulating that the direction and size of changes in psychosocial characteristics evince unique and additional associations to mortality that go beyond those reported for levels of functioning. The probably most prominent example of such processes is the terminal decline concept. The general notion is that at some point shortly before death, individual functioning declines rapidly. Empirical evidence for precipitous mortality-related deteriorations has accumulated in the cognitive (Bäckman & MacDonald, 2006), personality (Mroczek & Spiro, 2007), and well-being domains (Gerstorf et al., 2010). It is possible that such declines represent a pervasive phenomenon and are indicative of general processes of brain atrophy and system breakdown. As more and more individuals live longer and longer lives, further understanding how terminal decline progresses and what factors may mitigate these processes will become one of the top priorities on the research agenda of the social and behavioral sciences.

Synopsis

The chapter concludes by raising three major questions for scientific inquiry and social policy regarding longevity-related insights at the population and individual level. First, the prospect of living a longer life will profoundly shape the way individuals allocate their time and resources during different life phases. More flexible and individualized ways of living are required to integrate different spheres of life, including education, employment, child rearing, retirement, and leisure (Carstensen, 2009). The second question revolves around whether the years gained are also characterized by the quality of life. Here, issues of vitality and time free of chronic and debilitating diseases in the face of increasing life expectancy come into focus (Hoppmann & Gerstorf, this volume, ▶ Vitality). A third issue concerns the modifiability of psychosocial risk factors and proximal steps to translate research findings into prevention and intervention strategies. The overarching aim is to strengthen individual resources, capabilities, and behaviors that are linked to living longer, thereby addressing the needs of a growing population of elderly, worldwide.

Glycemic index

Definition

The glycemic index (GI) measures how much a 50-g portion of carbohydrate raises a person's blood-sugar level when compared to glucose with a GI of 100. Carbohydrates that are rapidly broken down during digestion and release glucose rapidly into the blood stream have a high GI. Carbohydrates that break down and release glucose more slowly have a low GI. A diet of low GI foods can help control diabetes, improve the body's sensitivity to insulin, assist with weight loss by minimizing hunger, and lower blood lipid levels. Whole fruits, vegetables, beans, and foods without added sugar and refined grains usually have a lower glycemic index.

Dr. David Jenkins and Dr. Thomas Wolever of the University of Toronto developed the GI in 1981. They classified foods according to the following guide:

- Low GI ranging 55 and below
- Medium GI ranging between 56 and 69
- High GI ranging 70 and above

Glycemic index is one aspect of looking at a food. Since foods are usually not eaten in isolation, the other foods eaten at a meal will influence the glycemic load of a meal.

Lung Function

Akihisa Mitani
Department of Respiratory Medicine, Mitsui Memorial Hospital, Chiyoda-ku, Tokyo, Japan

Pulmonary function

Definition

Lung function is measured by various tests, including the pulmonary function test (PFT),

arterial blood gases (ABG) analysis, and oxygen desaturation during exercise. These tests can evaluate symptoms and signs of lung disease, reveal the cause of breath shortness, and may help confirm lung diseases, such as asthma and chronic obstructive lung disease (COPD). They are also useful for monitoring the progression of lung disease or evaluating the risk of surgery in the preoperative patients (ATS Committee on Proficiency Standards for Clinical Pulmonary Function Laboratories, 2002; American Thoracic Society, 1995; Crapo, 1994; Hughes & Pride, 1999; Hyatt, Scanlon, & Nakamura, 1997).

Pulmonary function tests include spirometry and the quantitation of lung volume and diffusing capacity. Spirometry is in widespread use, because it takes 10–15 min without any risk. It measures mainly forced expiratory volume in 1 s (FEV1.0) and forced vital capacity (FVC), which classify pulmonary disorder into a restrictive disorder and an obstructive one (American Thoracic Society, 1995). The patients with a restrictive disorder have reduced FVC, which means that the expansion of the lung is restricted and the effort of breathing is increased. This type of disorder is caused not only by diseases of the lung parenchyma (such as lung fibrosis) but also pleural or extrapulmonary diseases (such as pleural effusion, pneumonectomy, vertebral deformity, and myasthenia gravis). On the other hand, obstructive lung disorder, in which airway obstruction limits airflow, is defined by reduced FEV1.0/FVC. Obstructive disorder is the first attribute of asthma and COPD, and spirometry is essential to diagnose these diseases (especially in the case of COPD). The crucial difference between them is the reversibility of the obstructive disorder. Reduced FEV1.0/FEV of the patient with asthma could recover 10 min after administration of a short-acting bronchodilator, unlike in the case of COPD.

Lung volume measurement is important when FVC is decreased and useful for interpreting the result of diffusing capacity test. The diffusing capacity is a capacity of lung to transfer gas across alveoli. Carbon monoxide is widely used, and the amount of carbon monoxide disappeared from the lung is measured. The diffusing capacity for carbon monoxide (DLCO) is useful both in restrictive and obstructive disorders. In the patients with pulmonary fibrosis, DLCO is reduced because of increased alveolar membrane thickness. These two tests are so useful, but tend to be performed in specialized centers.

Arterial blood gas (ABG) analysis is used to measure the partial pressures of oxygen (PaO_2) and carbon dioxide ($PaCO_2$) and the pH of an arterial sample. The decreased level of PaO_2 (hypoxia) means insufficient oxygen supply to the body, principally indicating the existence of respiratory dysfunction. The high level of $PaCO_2$ (hypercapnia) may result from conditions that impair pulmonary ventilation, not infrequently occurring in the patients with severe COPD.

Oxygen desaturation during exercise is also indicative especially in patients with chronic lung disease, such as COPD and pulmonary fibrosis. It can assess lung function as part of physical function. The 6-min walk test is in widespread use. A decrease in SpO_2 of more than 4% reflects significant desaturation.

Lupus: Psychosocial Impact

Yori Gidron
Faculty of Medicine and Pharmacy, Free University of Brussels (VUB), Jette, Belgium

Definition

Lupus is a brief name of the formal medical term systemic lupus erythematosus (SLE). This is an autoimmune disease, affecting different organs in the body including the heart, lungs, skin, joints, and nervous system. It can be life threatening, though the advancement in medical treatment has made this outcome rare. Sadly, SLE mimics other illnesses in that its symptoms overlap with many other diseases; hence, patients may be misdiagnosed for long periods of time. It is prevalent mainly in women, between 15 and 35 years old. In SLE, the immune system produces antibodies against proteins in cell nuclei. Furthermore, various immune cells show excessive apoptosis, whose level correlates with disease activity. About 30% have skin symptoms (e.g., red rashes); many patients have joint pain, particularly in the hands and wrist, muscle pain, and anemia. Finally, cardiac inflammation and atherosclerosis are common. Some of the symptoms such as weight gain and retinal damage also result from treatment side effects.

Among the risk factors of SLE are environmental exposure to cigarette smoke, Epstein-Barr virus, and silica, which may interact with genetic predisposition (Simard & Costenbader, 2007). Common psychosocial sequels of SLE include worry about one's appearance due to skin problems on the face, uncertainty about the future, anxiety, and depression (Beckerman et al., 2011). Additional psychosocial consequences of SLE also include various phobias including agoraphobia and social phobia, possibly due to facial disfigurement as a result of the disease (Líndal, Thorlacius, Steinsson, & Stefánsson, 1995). One unique prospective study found that daily hassles concerning interpersonal issues and mood changes, assessed over a period of time electronically, predicted future flares in SLE patients (Pawlak et al., 2003). Thus, SLE is a complex poorly understood disease, which involves multiple systems and is affected by and affects patients' psychosocial well-being. The role of behavior medicine in SLE is essential given that psychosocial factors predict its course possibly since they could be related to the immunological changes in SLE due to neuroimmune interactions, and as they are outcomes of this disease as well.

Macrophages

Riyad Khanfer
School of Sport and Exercise Sciences,
The University of Birmingham, Edgbaston,
Birmingham, UK

Definition

Macrophages are white blood cells which form an important part of the innate immunity (non-specific). They are widely distributed in the body's tissues. Macrophages have irregular shape with granules in their cytoplasm. They are phagocytes and play a crucial role in the initiation of the adaptive (specific) immune response. They engulf, remove, and digest necrotic cell debris, bacteria, and other foreign bodies and also play important roles in the early phases of infection and inflammation (Levinson 2006; Waugh and Grant 2001).

Known as antigen-presenting cells, macrophages migrate between tissues, and when they encounter pathogen/antigen, they engulf it, more importantly, they digest the antigen via specific intracellular processes and transport the most antigenic fragment to their own cell membrane and display it on their surface, where they carry it until they come into contact with the adaptive immune cells (T lymphocytes) in the lymphoid tissues. These lymphocytes become activated and sensitized as a result and eventually proliferate and differentiate into three main types of memory T cells which generate a specific memory against this particular original antigen (Janway et al. 2005).

In the inflammatory response, macrophages produce many cytokines (cell messengers); among them are two important proinflammatory cytokines: interferon-γ and tumor necrosis factor (TNF). Macrophages have also been found to play a role in tumor immunology; they can infiltrate tumor mass and destroy tumor cells in tissue culture by producing reactive oxygen intermediates (ROIs) and tumor necrosis factor (TNF) (Janway et al. 2005; Weinberg 2007).

MRI

Definition

Magnetic resonance imaging is a noninvasive imaging method used for visualizing structures in the body. The participant is placed in a strong static magnetic field that aligns all atomic nuclei in the body. A radiofrequency pulse is applied at a resonant frequency to selectively energize one type of atom (typically hydrogen). When the pulse is discontinued, the energy is emitted and detected by a detector coil. Due to the differences in concentrations of atoms in different structures, this energy can be used to reconstruct an image of the tissue in the detector coil.

Description

Magnetic resonance imaging (MRI) uses several separate components to collect an image. First, a superconducting electromagnet (created by passing electrical current through super-cooled wires) provides a static electromagnetic field. The strength of the magnet is denoted by "Tesla" strength. Most research scanners have a strength of 3.0 T – approximately 600 times more powerful than a kitchen magnet. As such, it is extremely important that participants remove any metal prior to entering the scanner room. Anyone with metal implants cannot have an MRI scan. Second, radiofrequency coils send energy to, and receive energy from, the sample being analyzed. Finally, gradient coils create a small alteration in the static magnetic field to create a spatial distribution in the signal to allow for image reconstruction in 3D space.

MRI data is collected in "slices" which are a certain thickness. Within each slice, space is divided into small squares known as "voxels." A voxel is the smallest sampling unit and is typically a few millimeters on each side. The size of a voxel determines the spatial resolution of the image. Smaller voxels will result in a clearer image. Most MRI paradigms take at least two separate scans: a high-resolution anatomical image with voxels approximately 1 mm^3 and a lower-resolution functional image (see below) with voxels approximately 9 mm^3. The lower-resolution functional image is then placed over the higher-resolution image to determine the anatomy that corresponds to the functional activity.

When tissue is placed into a strong magnetic field, the nuclei of atoms align in parallel with the magnetic field. Most nuclei align in a parallel (low energy) state, but some nuclei align with the magnetic field in an antiparallel (high-energy) state. An electromagnetic pulse is then applied to the sample, which flips some of the nuclei from low-energy to high-energy states. When the pulse is discontinued, the nuclei revert to the low-energy state and release the energy as photons, which are then detected with receiver coils. This is the basis of the MR signal. The return to the low-energy state and release of energy at the end of a pulse is termed "relaxation" and produces two parameters. "Transverse relaxation" (or T2 decay) is a measurement of how quickly the spins of the nuclei lose coherence after the pulse is discontinued. "Longitudinal relaxation" is a measurement of how long it takes the spins to return to the low-energy (parallel) state and is quantified using a time constant denoted as T1.

Numerous parameters can be manipulated to record certain properties of the MRI signal that make MRI a very versatile method for collecting images. First, the time between successive excitation pulses is the "repetition time" (TR). If the TR is too short, full recovery of the T1 parameter will not occur before the subsequent pulse occurs. Second, it is important to consider how long of a delay to include between the discontinuation of

the pulse and the recording of the MR signal. This parameter is termed the "echo time" (TE). By selecting optimal TR and TE values, the MR image can be tuned to either T1 or T2 contrast. T1 images are most commonly recorded for anatomical images and include a short TE and a medium TR. A final parameter that can be manipulated is the flip angle, which indicates the degree to which the net magnetization changes following the excitation pulse.

The selection of certain parameters to maximize the image of a particular feature of the image is referred to as a pulse sequence. Common pulse sequences include echo planar imaging (EPI) in BOLD fMRI (discussed below), fluid-attenuated inversion-recovery imaging (FLAIR), diffusion tensor imaging, and magnetization transfer imaging.

Structural MRI

Structural MRI is most commonly utilized to quantify certain types of tissue and identify patterns of change in structure that co-occur with disease or time. It can be used to measure the volume in grey mater, white matter, and cerebrospinal fluid using high-resolution T1 images discussed above. FLAIR images can be used to identify white matter hyperintensities that co-occur with aging, as well as certain psychiatric disorders. Diffusion tensor imaging measures the directions of water diffusion along multiple vector directions to assess the white matter tracts that connect disparate regions of the brain. Finally, magnetization transfer imaging can be used to assess the integrity of myelin in regions of interest.

Functional MRI

The methods described above are primarily used for visualizing structures in the body. In the 1990s, it was discovered that with appropriate tuning of the pulse sequence, brain activity could be detected. The key to this discovery is the magnetic properties of blood. Red blood cells contain hemoglobin that binds to oxygen to be carried to the tissues. Oxygenated hemoglobin has very little sensitivity to magnetic fields, whereas deoxygenated hemoglobin is paramagnetic and will distort a magnetic field. This distortion will alter the decay of the transverse magnetic component following the termination of the excitation pulse – termed T2* ("T2 star"). When neurons in the brain increase activity, they require more oxygen. The body responds by increasing blood flow to that region of the brain, which flushes out deoxygenated blood. This reduction in deoxygenated blood creates a stronger MR signal intensity. This change in signal is known as the blood-oxygenation-level-dependent (BOLD) contrast. This discovery has led to an explosion of research on human brain function as researchers can now noninvasively monitor brain activity. By comparing BOLD activity while performing a task with activity during a control condition, researchers can identify regions of the brain whose activity increases or decreases in response to performing the task.

One limitation of BOLD contrast is that it is a relative measure – signal is compared to a control condition – and therefore an absolute measure of blood flow to an area is unreliable. An alternative method for quantifying blood flow is arterial spin labeling (ASL). As arterial blood flows through the carotid artery toward the brain, a 180° excitation pulse is applied. This has the effect of magnetizing the water in the blood, which then travels to the brain. When this paramagnetic water arrives in the brain, it alters the magnetization of the area and causes an increase in the MR signal intensity. This signal intensity is compared to a control image to quantify the blood that was flowing to the region during the transit time.

Recent Developments

High-Field MRI

Early MRI scanners had strengths of 1.5 T, and research scanners in hospitals now are commonly 3.0 T. As the strength of the magnet increases, there is a nearly linear increase in signal-to-noise ratio. Some research centers now have 7.0 T magnets, and stronger magnets are currently under development. These stronger magnetic fields may allow better information about tissue composition, including iron deposition in the basal ganglia.

Functional and Effective Connectivity

As computing power and software have increased in the past decade, new methods for measuring

networks and interactions of brain regions have been developed. Seed-voxel correlation maps extract the signal from a small group of voxels and then correlate the activity over time with the signal from all other voxels in the brain. The result is a "functional connectivity" map of regions whose activity correlates with the seed region. Such a method cannot infer causal influence between regions, but it has been useful in understanding so-called Resting State Networks – networks of brain activity that are active in the absence of an experimental task. More sophisticated techniques have been developed for inferring causality between regions, including Granger Causality Analysis, Dynamic Causal Modeling, and Structural Equation Modeling.

Maintenance Phase of the Transtheoretical Model of Change

Seema Mutti
School of Public Health & Health Systems, University of Waterloo, Waterloo, ON, Canada

Definition

The Transtheoretical Model of Change (TTM) is characterized by six 'stages of change' (precontemplation, contemplation, preparation, action, maintenance, and termination) that individuals move through when attempting to change problematic health behavior, such as smoking (Shumaker, Ockene, & Riekert, 2009).

Individuals reach the 'maintenance' phase of the TTM when the positive health behavior, for example, complete abstinence from smoking, is sustained for a period of 6 months or longer (Glanz, Rimer, & Viswanath, 2008). Self-efficacy (or situation-specific confidence) plays an integral role in this stage. As an individual's ability to abstain from the risky health behavior increases, so too does their ability to avoid relapse. The risk of relapse is eliminated once an individual reaches the final 'termination' stage of the TTM, in which the positive health behavior has become automatic (Shumaker et al., 2009).

Maladaptive/Maladjustment

David Busse and Ilona S. Yim
Department of Psychology and Social Behaviour, University of California, Irvine, Irvine, CA, USA

Synonyms

Dysfunctional/dysfunction; Maladaptation; Maladjustive

Definition

Maladjustment is the result of insufficient responses to demands that may occur throughout the life span and result in impaired functioning, distress, and/or poor health. The term *maladaptive* refers to processes (e.g., specific behaviors, patterns of thought or emotion that yield negative outcomes) whereas maladjustment is the result or outcome of this process.

Description

The terms maladjustment and maladaptive are used in a wide range of contexts, which may broadly be categorized as social, psychological, and biological. Social maladjustment refers to how a person develops and maintains interpersonal relationships, especially with peers. Maladaptive behaviors in this realm often emerge during childhood when individuals learn how to navigate their social world and solve interpersonal problems. During this period, children face changing school settings and social networks. Children who are not able to successfully adjust to these new environments may exhibit a range of maladaptive behaviors, such as aggression or rough play, which may lead to peer rejection (Ladd & Price, 1987).

The terms maladjustment and maladaptive, when applied to the psychological domain, may also refer to how well somebody is able to regulate their emotions. Emotions typically serve adaptive purposes in how individuals interact with the environment. Thus, psychological maladjustment may be characterized by high levels of "emotional inertia" (Kuppens, Allen, & Sheeber, 2010), or the inability to respond appropriately to the dynamically changing demands of a given situation.

Finally, maladjustment and maladaptie processes can also pertain to how individuals physiologically respond and adapt to environmental demands. The human body attempts to respond optimally to the continually changing environment, a concept that has been termed *allostasis* (McEwen & Stellar, 1993). Key systems involved in this

process are the autonomic nervous system, the hypothalamic pituitary-adrenal axis, and the immune and cardiovascular systems. Repeated activation of these systems exerts wear and tear on the body, termed *allostatic load*. High levels of allostatic load, when quantified using objective health parameters, have been associated with increased risk of cardiovascular disease and lower physical and cognitive functioning (Seeman, Singer, Rowe, Horwitz, & McEwen, 1997).

Maladjustment and maladaptive processes have been studied throughout the life span, ranging from the prenatal period to old age. These studies provide important insight into the immediate and long-term health consequences of maladjustment at different times in life. Researchers study maladjustment in the context of how certain prenatal events during critical periods can have lasting implications on development throughout the life span. For example, the Dutch Famine Studies are a series of studies that examine the mechanisms linking disease outcomes to deprivation in utero. A blockade of food supplies in the Netherlands between November 1944 and April 1945 created a natural experiment from which to study the effects of maternal malnutrition. It was later found that children who were in gestation during the famine had higher rates of adult diseases, including coronary heart disease (Roseboom et al., 2001) and schizophrenia (Hoek, Brown, & Susser, 1998). Similarly, a study of 141 Canadian families who endured a severe and prolonged ice storm during the winter of 1998 demonstrates how severe stressors can result in postnatal maladjustment. Children whose mothers were exposed to more severe stress had poorer cognitive and language development at age two than children whose mothers who experienced less stress during the ice storm (King & Laplante, 2005).

Typically, the effect of maladaptive behavior is studied during later periods of life. A classic example for how maladaptive behavior can lead to adverse health outcomes is the link between certain components of Type A behavior patterns (i.e., hostility) and coronary heart disease (CHD). Type A behavior is characterized by aggressiveness, impatience, and competitiveness. Although these behaviors often lead to high status in the workplace, they may also be maladaptive in the context of maintaining health. By itself, maladaptive behavior does not have an effect on disease pathogenesis. Rather, this process occurs through the repeated and exaggerated activation of biological regulatory systems (e.g., high blood pressure), conflictual and unsupportive social relationships, and health-compromising behaviors (e.g., smoking). A link between maladaptive personality traits and development of disease has been demonstrated in past research. A longitudinal study with over 4,700 college students showed that greater hostility at age 19 predicted more risk factors for CHD, including higher caffeine consumption, larger body mass index (BMI), higher cholesterol, and more tobacco use (Seigler, Peterson, Barefoot, & Williams, 1992).

Marker (Genetics)

J. Rick Turner
Cardiovascular Safety, Quintiles, Durham, NC, USA

Definition

A genetic marker is a DNA sequence with a known physical location on a chromosome. Genetic markers can help link an inherited disease with the responsible gene. DNA segments close to each other on a chromosome tend to be inherited together. Genetic markers are used to track the inheritance of a nearby gene that has not yet been identified but whose approximate location is known. The genetic marker itself may be a part of a gene or may have no known function (Genome.gov, 2011).

Marriage and Health

Wendy Troxel[1] and Julianne Holt-Lunstad[2]
[1]Psychiatry and Psychology, University of Pittsburgh, Pittsburgh, PA, USA
[2]Department of Psychology, Brigham Young University, Provo, UT, USA

Definition

Socially connected people live longer, healthier, and happier lives than their socially isolated counterparts (Holt-Lunstad, Smith, & Layton, 2010). Given the central role that marriage plays for most adults, a great deal of research has focused on this particular social relationship in association with physical and mental health. For instance, prior research suggests that married adults have lower rates of morbidity and mortality compared to unmarried adults (Jaffe, Manor, Eisenbach, & Neumark, 2007; Johnson, Backlund, Sorlie, & Loveless, 2000). Likewise, married individuals have greater life satisfaction, happiness, and are at lower risk for depression (Gove, Hughes, & Style, 1983; Inaba et al., 2005). The conclusion often drawn from this literature is that being married is beneficial for health, but perhaps less so for women than for men. Ironically, several lines of evidence suggest that marriage *should* be associated with better health, perhaps, particularly so in women. Specifically, marriage may protect against social isolation, may promote health-enhancing behaviors and deter health-damaging behaviors, and may affect health indirectly, by increasing socioeconomic resources, particularly for women. In contrast, given the health costs of conflictual social relationships and the fact that marriage is the primary social relationship for most adults, being in an unhappy marriage may serve as a potent psychosocial stressor, thereby elevating disease risk. In aggregate, these divergent perspectives on the advantages of having a spouse on the one hand, and the disadvantages of marital discord, on the other hand, suggest the utility of examining marital status and marital quality simultaneously. However, few studies to date have adopted this approach of simultaneously examining marital status and marital quality (for exceptions see Gallo et al., 2003a; Holt-Lunstad, Birmingham, & Jones, 2008; Troxel, Matthews, Gallo, & Kuller, 2005). Theoretically, individuals in a high-quality marriage should be at a health advantage relative to unmarried individuals and to individuals in low-quality marriages because they reap the material benefits of marriage *and* the social support benefits of being in a harmonious union.

Description

Marital Quality Matters

Indeed, mounting evidence suggests that various indicators of marital quality, including satisfaction or strain, are associated with increased risk of the development of CVD risk factors or prognosis in cardiac patients (as reviewed in Kiecolt-Glaser & Newton, 2001). For instance, Orth-Gomer and colleagues (2000) found that marital strain was associated with a 2.9-fold increased risk of recurrent cardiac events in female cardiac patients. Similarly, Coyne and colleagues (2001) reported that among male and female coronary heart disease (CHD) patients, poor marital quality was a more robust predictor of mortality in women than in men. Our laboratory has shown in an initially healthy sample of women that those who are satisfied in their marriage show less atherogenic risk trajectories over time (Gallo, Troxel, Matthews & Kuller, 2003b), have lower levels of subclinical measures of carotid atherosclerosis (Gallo et al., 2003a), and are at lesser risk of developing the metabolic syndrome over an 11-year follow-up, as compared to their dissatisfied or unmarried counterparts (Gallo et al., 2003a; Troxel et al., 2005). In aggregate, findings suggest that the quality of the marital relationship is implicated in the development and progression of CVD; however, the effects may be stronger in women. Moreover, how marriages "get under the skin" to influence cardiovascular risk and outcomes remains a question of critical importance.

Pathways Linking Marriage with Health

Both the presence of a spouse as well as the quality of the marital relationship may influence health directly and indirectly through behavioral, psychological, and physiological mechanisms. For instance, social relationships may influence the extent to which individuals engage in health-relevant behaviors (e.g., smoking, sedentary lifestyle, fatty diet intake, and excessive alcohol consumption). More recent data suggests that being stably married or being in a happy marriage is associated with better sleep (Troxel, Buysse, Hall, & Matthews, 2009; Troxel et al., 2010), another critical health behavior. Marriage has also been linked to psychological factors such as lowered stress and depression, which have demonstrated influences on cardiovascular health themselves (Rozanski, Blumenthal, & Kaplan, 1999; Smith & Ruiz, 2002). Notably, social relationships may also exert direct physiological effects on autonomic, inflammatory, or neuroendocrine pathways (Robles & Kiecolt-Glaser, 2003).

Sex Differences in the Effects of Marriage on Health

Based on their review of the marriage and health literature, Kiecolt-Glaser and Newton (2001) concluded that women may be more vulnerable to the health consequences associated with marital distress than men. For example, Coyne and colleagues (2001) reported that among male and female coronary heart disease (CHD) patients, poor marital quality was a more robust predictor of mortality in women than in men. Research further suggests that this gender disparity may be attributable to gender differences in physiological responding to marital interactions. Indeed, compared with men, women display more pronounced physiological responses (i.e., cardiovascular, endocrine, and immunologic) to marital interactions, particularly when negative interactions are assessed (e.g., Kiecolt-Glaser, Glaser, Cacioppo, & Malarkey, 1998; Smith, Gallo, Goble, Ngu, & Stark, 1998). However, more recent data suggests that these sex differences may be less pronounced than formerly demonstrated (Manzoli, Villari, Pirone, & Boccia, 2007), perhaps suggestive of a cohort effect.

Summary

Social isolation is a significant risk factor for morbidity and mortality. The marital relationship is arguably the single-most important adult social relationship and can protect against social isolation. Consistent evidence shows that married individuals have greater life satisfaction, happiness, mental health, and lower rates of morbidity and mortality compared to unmarried adults (Johnson et al., 2000; Manzoli et al., 2007). However, not all marriages are created equal. More recent data points to the importance of assessing qualitative aspects of marriage as well marital status. Indeed, evidence suggests that marriage is health-protective, particularly if it is a high-quality marriage. Understanding the mechanisms underlying the health effects of marital status and quality remains a critical next step in order to understand how relationships "get under the skin" to impact health and well-being.

Synonyms

Massage; Touch

Definition

Massage therapy (MT) has been defined as the manual manipulation of soft tissue intended to promote health and well-being (Moyer, Rounds, & Hannum, 2004). This definition includes therapeutic treatments of different duration and types of touch administered. Additionally, the sites of the body where the treatment is applied can vary depending on the treatment method and the desired effects.

Types of Massage Therapy

Today, several different massage methods are in use. The most popular forms include the following.

Swedish massage (or "classic massage"), the most common form of massage in Western countries, is based on five techniques termed "effleurage" (sliding or gliding), "petrissage" (kneading), "tapotement" (rhythmic tapping), friction, and vibration/shaking, which are applied to different parts of the body (e.g., back, shoulders, neck, legs, arms).

Reflexology massage is based on the theory that specific zones in the hands and the feet represent an image of the body. Manipulation techniques, such as pressure, applied to these areas are thought to improve functioning in related parts of the body (stomach, back, head, etc.).

Shiatsu, by origin a Japanese technique, uses pressure of fingers and palms but also rolling, brushing, vibrating, and grasping of the hands centered on the energy meridians of the whole body.

The Trager method, named after its founder, involves a gentle, rhythmic movement and touch of different body parts with the aim to relax the body, reduce pain, and increase mobility.

Effects of Massage Therapy

Efficacy varies considerably between different forms of MT and with regard to specific desired outcomes. Moreover, short-term effects of MT (e.g., immediate reduction in anxiety and stress) may differ from long-term benefits (e.g., reduced trait anxiety or depression). However, overall beneficial effects of MT have been documented for several psychiatric and medical conditions, including depression, posttraumatic stress disorder, eating disorders, attention-deficit disorder, chronic fatigue, fibromyalgia, back pain, migraine headache, postoperative pain, labor, rheumatoid arthritis, multiple sclerosis, spinal cord injury, autism, diabetes, asthma, HIV, and breast cancer, as well as in preterm neonates (Field, 2002; Field, Diego, & Hernandez-Reif, 2007; Moyer et al., 2004).

Underlying Mechanisms

Despite the beneficial overall effects of MT, the underlying mechanisms are only partly understood to date. General and specific effects of MT have been reported, and accordingly, the underlying biological mechanisms might vary. The stimulation of pressure receptors was suggested to promote vagal activity, and thereby to improve parasympathetic activity (Diego, Field, Sanders, & Hernandez-Reif, 2004). Beyond this, increases in serotonin, endorphins, and oxytocin might generally link MT to reduced anxiety, arousal, and depressiveness. Specific analgesic effects of MT have been interpreted in line with the gate control theory (Melzack & Wall, 1965) and with increased circulation and waste elimination in the affected/treated muscles.

Overall Evaluation

MT has proven effectiveness in a variety of psychiatric and medical conditions. The underlying mechanisms and long-lasting effects of MT remain to be identified.

Maternal Stress

Kristin A. Long[1] and Melissa A. Alderfer[2]
[1]Department of Psychology, University of Pittsburgh, Pittsburgh, PA, USA
[2]Division of Oncology, The Children's Hospital of Philadelphia, Philadelphia, PA, USA

Definition

For the purpose of this entry, maternal stress is defined as the objective stressors and subjective feelings of distress or strain experienced by mothers related to having a child with a chronic illness.

Description

One out of every ten children in the USA experiences a chronic illness such as asthma, diabetes, or cancer. These illnesses may impair the child's functioning, decrease health-related quality of life, and/or contribute to emotional distress. However, because children are typically embedded within families, the impact of chronic illnesses extends beyond the individual child and includes parents and siblings. Despite changing gender roles over the past 50 years, mothers remain at the forefront of child rearing in many American families. Therefore, the reciprocal relationships between a child's illness or treatment and mothers' emotional health are particularly important.

Many aspects of childhood chronic illnesses may be stressful for mothers. Initially, the mother may be the first person to notice the child's symptoms and suspect a medical problem. She also may be responsible for seeking medical care for her child. Although a medical problem may have been suspected, the confirmation of a diagnosis may be shocking and devastating. Chronic illnesses may be life threatening or life limiting for the child and are typically unpredictable and incurable, requiring long-term management of symptoms and side effects of treatment. Complex treatment regimens may involve frequent and/or extended hospitalizations, invasive procedures, and daily medication management and adjunct treatments, such as physical therapy. Mothers often assume the burdens of managing the child's medical treatment at the hospital and at home. These responsibilities can alter the typical mother role – nurturing her child(ren)'s development may take a backseat to ensuring adherence to a treatment regimen. Furthermore, daily demands of treatment may constrain mothers' employment and career options, potentially limiting professional goals and altering self-perceptions. These employment restrictions, coupled with medical costs stemming from the child's diagnosis and treatment, may impact the family's financial stability. In sum, mothers of children with chronic illnesses experience a range of emotional, personal,

professional, and practical stressors related to their child's illness and well-being.

Evidence of Maternal Stress

Maternal stress in the face of a child's medical illness is ubiquitous and well documented. Feelings of distress and symptoms of depression and anxiety have been reported in mothers of children with cancer (Vrijmoet-Wiersma et al., 2008), cystic fibrosis (Berge & Patterson, 2004), irritable bowel disease (Mackner, Sisson, & Crandall, 2004), epilepsy (Rodenberg, Meijer, Dekovic, & Aldenkamp, 2005), congenital heart disease (Lawoko, 2007), and spina bifida (Vermaes, Janssens, Bosman, & Gerris, 2005). Across diagnoses, shock, fear, uncertainty, and helplessness are common experiences. For example, parents of children with kidney disease report unremitting feelings of uncertainty about prognosis; fatigue and distress arising from vigilant monitoring of symptoms and management of complex medical regimens; and feelings of anger, depression, stress, and frustration (Tong, Lowe, Sainsbury, & Craig, 2008). Parents of children with cancer report higher levels of anxiety, depression, and traumatic stress symptoms and lower quality of life than normative or comparison samples (Alderfer & Kazak, 2006). In addition to distress, mothers of children with cerebral palsy, for example, report more stressful life events than mothers of typically developing children (Rentinck, Ketelaar, Jongsmans, & Gorter, 2006), and higher levels of parenting stress have been reported by mothers of children with spina bifida (Vermaes, Gerris, & Janssens, 2007) and cancer (Alderfer & Kazak, 2006). The literature suggests that distress is generally greatest at the time of diagnosis, and for most mothers, improves with time.

Risk and Protective Factors

Although stress is common among mothers of children with chronic illnesses, there is considerable variability in the intensity and duration of distress experienced by mothers. Perceived amount of and satisfaction with social support has been found to be a powerful protective factor against distress for mothers of children with chronic illnesses including cerebral palsy (Rentinck et al., 2006), congenital heart disease (Lawoko, 2007), cancer (Vrijmoet-Wiersma et al., 2008), and spina bifida (Vermaes et al., 2005). Similarly, a positive family environment buffers against maternal distress in the context childhood chronic illnesses such as spina bifida (Vermaes et al., 2005) and cancer (Vrijmoet-Wiersma et al., 2008). In addition to social and family factors, mothers' positive beliefs about the illness, the medical team, and one's ability to manage the illness seem to be important for adjustment. For example, in the context of childhood cancer, more positive adjustment is reported when parents conceptualize the illness as a manageable, meaningful experience; report higher self-efficacy; and endorse greater trust in the healthcare team. Personal characteristics, such as trait anxiety and reliance upon disengaged or emotion-focused coping strategies, have been found to be associated with greater levels of distress (Alderfer & Kazak, 2006). Across illnesses, sociodemographic factors predicting greater maternal stress include minority status, unemployment, financial strain, lower levels of education, and higher levels of concurrent, non-illness-related stressors. Surprisingly, objective indices of illness severity generally do not influence maternal stress. In general, parents who endorse greater emotional strain at the time of their child's diagnosis continue to experience elevated distress even after the treatment ends.

Effects of Maternal Stress on the Family

Systems theories suggest that both the child's illness and maternal adjustment to illness-related stressors impact the family. For example, the literature shows that children with cancer report more anxiety, hopelessness, depression, internalizing problems, and externalizing problems when their mothers report more depression and anxiety, or poorer global mental health (Alderfer & Kazak, 2006). Healthy siblings of children with various medical diagnoses are also at elevated risk for psychological distress (Sharpe & Rossiter, 2002), and a small literature suggests that siblings of children with medical illnesses exhibit more behavioral problems and poorer overall adaptation when their mothers report higher levels of distress (Alderfer & Kazak, 2006).

The literature remains inconclusive about how maternal and paternal stress are related, with some work suggesting that congruence in coping style may be important for understanding the relationship between levels of parents' distress. Higher levels of anxiety and depression and discrepancies in perceptions of appropriate levels of emotional expression in mothers and fathers have been linked to greater marital distress in the context of childhood cancer (Alderfer & Kazak, 2006). At the family level, there are likely to be bidirectional relationships between maternal stress and aspects of family functioning (e.g., cohesion and communication), but more research is needed.

Effects of Maternal Stress on the Medical Condition

Pediatric illnesses are increasingly conceptualized using transactional models considering biological, psychological, and social influences. Accordingly, maternal stress is one psychosocial influence on the child's disease course. For example, the pediatric asthma literature shows that family characteristics, including caregiver mental health and perceived stress, impact outcomes such as asthma symptoms, healthcare utilization, and quality of life (Kaugars, Klinnert, & Bender, 2004). One possible mechanism is that maternal stress interferes with asthma management by reducing adherence to treatment protocols, increasing exposure to allergens or irritants (e.g., tobacco smoke) that exacerbate asthma symptoms, or limiting the degree to which treatment protocols are incorporated into daily routines.

In illnesses known to be exacerbated by stress (e.g., asthma, cardiovascular disease, diabetes), the relationship between maternal stress and child health outcomes may be mediated by stress-induced physiological changes to the child's immune and neuroendocrine systems. In pediatric asthma, the patient's reactivity to maternal stress can lead to alterations in the immune response resulting in increased inflammation or susceptibility to upper respiratory infections, leading to asthma exacerbations (Wright, Rodriguez, & Cohen, 1998).

Interventions Addressing Maternal Stress

Given increased stress in mothers of children with chronic illnesses, along with the impact of this stress on the family's psychosocial functioning and the child's medical status, interventions have been designed to alleviate mothers' distress and/or improve their adaptive functioning. Also, family interventions have been designed to provide education, promote adherence, improve family functioning, or reduce family members' distress.

A relatively small number of psychosocial interventions have been empirically evaluated. Results consistently show that educational interventions are not effective in reducing maternal distress across illnesses, while social support and cognitive-behavioral therapy interventions show more promise (Drotar, 2006). For example, mothers of children with cystic fibrosis, asthma, and diabetes enrolled in a social support intervention that paired mothers of children with the same diagnosis reported reduced distress. In childhood cancer, a meta-analysis evaluating behavioral, cognitive-behavioral, family systems, or psychoeducational interventions reported small but significant mean effect sizes for decreased parent distress and improved parent adjustment (Pai, Drotar, Zebracki, Moore, & Youngstrom, 2006).

Summary

As primary caretakers, mothers of children with chronic illnesses experience a range of practical and emotional stressors related to their child's medical diagnosis and treatment, on top of normative childrearing, employment, and/or household management tasks. These sustained responsibilities can take an emotional toll. Mothers of children with chronic illnesses endorse strong negative emotions including shock, fear, and helplessness, along with elevated levels of depression, anxiety, and traumatic stress symptoms. Positive family environments and greater perceived social support may buffer against maternal distress, and at the same time, maternal stress may influence the psychosocial functioning of other family members. Maternal stress also can impact the child's illness course via less effective illness management behaviors

and/or changes to the immune or endocrine systems. Interventions targeting maternal distress have modest empirical support, but more research is needed.

Biographical Information

Karen Matthews was born in Los Angeles, CA. She received her undergraduate degree in psychology from the University of California, Berkeley, and her Ph.D. in psychology from the

University of Texas at Austin, where she worked with David C. Glass, studying the Type A behavior pattern. Her first faculty position was at Kansas State University, where she joined in 1976 as an Assistant Professor. She later joined the faculty of the University of Pittsburgh's Psychiatry Department in 1979, jointly appointed to the Departments of Psychology and Epidemiology. She was promoted to Professor in 1989 and named as Distinguished Professor in 2009.

Matthews investigates the psychosocial characteristics of individuals and their early life experiences that ultimately lead to coronary atherosclerosis and hypertension later in life. Her work has focused on two stages of the life span when change in cardiovascular risk reliably occurs: adolescence and midlife. Change can provide an optimal setting for observing how hormonal and other biologic processes, social roles, and psychological characteristics interact to accelerate an individual's cardiovascular risk. Her approach has integrated knowledge and methods derived from psychology, psychiatry, epidemiology, and cardiology.

Major Accomplishments

Matthews has made influential contributions to several areas of health psychology. Her early work was in the Type A behavior pattern, and her detailed analysis of psychological perspectives of Type A later became a *Citation Classic*. She has since been a major contributor to the understanding of how stress impacts the cardiovascular system. She has made key contributions to understanding how psychological stress serves as a potential link between personality characteristics, such as hostility and Type A; social and environmental factors, such as low socioeconomic status; and the development of cardiovascular disease. In work that has been ongoing for over three decades, she has proven herself to be one of the earliest health psychologists to incorporate a lifespan perspective in health psychology, tracing the early origins of stress reactivity and stressful environments to the development of cardiovascular risk later in life.

Matthews has also conducted seminal work in understanding cardiovascular risk in women. Her work, supported by a MERIT award by the National Heart, Lung, and Blood Institute (NHLBI), has included elucidating gender differences in cardiovascular and neuroendocrine stress reactivity, including the role of the hypothalamic-pituitary-gonadal axis in stress reactivity in women. She has also made major contributions to the understanding of the epidemiology of cardiovascular risk in women. With epidemiologist Lewis Kuller, she has played a central role in elucidating the symptomatic and cardiovascular changes occurring with the menopausal transition. This work has helped form the basis of one of the largest and currently ongoing multiethnic studies of women transitioning through menopause, for which she is a principal investigator. Reflective of the multidisciplinary nature of this work, Matthews' approach represents a unique blend of concepts and methods from psychophysiology, developmental psychobiology, and epidemiology.

Matthews has had a major role in establishing health psychology as a formal subdiscipline of psychology. With Steve Manuck and Al Shapiro (deceased), she designed one of the first cardiovascular behavioral medicine research training programs, which began in 1983 (HL07560 through 2013). This program was one of the earliest formal high-quality training programs in health psychology. Matthews also served as Editor-in-Chief of *Health Psychology* from 1990 to 1995, with the goal of making the journal the most important health psychology journal in the field and negotiating with the American Psychological Association (APA) to make it the primary APA health psychology journal. Further, she provided the perspectives of a health psychologist on several NIH advisory panels, including the National Heart, Lung, Blood Advisory Council and the Center for Scientific Review Advisory Committee (Chair). She also was President of the American Psychosomatic Society (1990–1991), the second female President of the Society and one of few Presidents with a Ph.D. by that time. As the field matured, she continued to be instrumental in providing an infrastructure for advanced training and

resources for health psychology research as Director of the Pittsburgh Mind-Body Center. In this role, she directed scientists at Carnegie Mellon University and the University of Pittsburgh to identify the important common pathways of risk across multiple diseases.

Reflective of her distinguished work, Matthews has received awards from diverse organizations, including American Heart Association Established Investigator; Cardiovascular Research Award from the North American Menopause Society and Pfizer; American Psychosomatic Society President's Award; Award for Distinguished Contributions to Health Psychology, Division 38 of APA; Award for Significant Research Contribution from the Society of Pediatric Psychology; Distinguished Scientist Award from the Society of Behavioral Medicine; and APA Award for Distinguished Scientific Applications of Psychology. She became a member of the Institute of Medicine in 2002 and was awarded the Philosophiae Doctor Honoris Causa from the University of Helsinki in 2007.

Maximal Aerobic Capacity Test

► Maximal Exercise Stress Test

Maximal Aerobic Power Test

► Maximal Exercise Stress Test

Maximal Exercise Heart Rate

James Turner
School of Cancer Sciences, The University of Birmingham, Edgbaston, Birmingham, UK

Synonyms

HR_{max}; Tachycardia

Definition

Maximum exercise heart rate refers to the highest or fastest rate at which the heart can beat during exercise and is expressed as the number of heartbeats per unit of time, usually beats per minute (bpm).

Heart rate increases linearly with oxygen consumption and therefore exercise intensity. Maximal exercise heart rate is most accurately recorded upon volitional exhaustion and termination of a maximal exercise stress test. Maximal exercise heart rate declines with aging; therefore, several formulae are also available to estimate maximal heart rate on the basis of age. The most widely used formula, $HR_{max} = 220 - \text{age (in years)}$, provides a rough approximation. However, due to lower maximal heart rates among well-trained individuals, several population-specific formulas also exist. In behavioral research, estimated or measured maximal exercise heart rate can be used to prescribe exercise (e.g., walking speed) based upon the relationship between oxygen consumption, heart rate, and exercise intensity.

Maximal Exercise Stress Test

James Turner
School of Cancer Sciences, The University of Birmingham, Edgbaston, Birmingham, UK

Synonyms

Cardiac stress test; Exercise tolerance test; Fitness test; Graded exercise test; Maximal aerobic capacity test; Maximal aerobic power test; Maximal oxygen uptake test; Symptom-limited exercise test; VO_2max test

Definition

An exercise stress test is a general term used to describe the assessment of cardiorespiratory

functional capacity for either health and fitness reasons, or for clinical and diagnostic purposes. Such tests, primarily conducted on a motorized treadmill or stationary cycle ergometer, involve exercising at several workloads or exercise intensities/difficulties, during which cardiovascular and respiratory measurements are recorded. Depending on the rationale for testing, the type of test employed, and the health and fitness status of the individual taking part, exercise stress tests might terminate at volitional exhaustion, upon observation of a particular clinical symptom, or at some other predetermined outcome measure.

Description

Maximal oxygen uptake (VO_2max) is the accepted measure of cardiorespiratory fitness and is the product of cardiac output and arterial-venous oxygen difference (i.e., the ability to extract and utilize oxygen from the blood). During exercise, cardiac output is markedly increased above resting levels and shows further elevations when the intensity or difficulty of exercise is increased. Using a treadmill-based exercise test, for example, increases in exercise intensity are achieved by increasing the speed and gradient of the treadmill belt. VO_2max is measured using closed-circuit spirometry: analyzing the fractions of expired oxygen and carbon dioxide. VO_2max is reached when, despite subsequent increases in exercise intensity, oxygen consumption plateaus. VO_2max is expressed as milliliters or liters of oxygen consumed per minute ($ml/l \cdot min^{-1}$) and is often adjusted for body mass or fat-free mass (i.e., dividing oxygen consumption by kilograms). This value is dependent on the health and fitness status of individuals, age, gender, body size and composition, as well as genetic factors.

Exercise stress tests can be maximal or submaximal. Maximal tests, in which individuals exercise with verbal encouragement until they are unable to continue (i.e., perceived volitional exhaustion), offer the most accurate assessments of VO_2max. Submaximal tests are terminated at an endpoint, for example, when heart rate reaches a predetermined percentage of an estimated age-predicted maximum (see ▶ Maximal Exercise Heart Rate). The oxygen consumption upon termination of submaximal tests is extrapolated to predict the value at the predicted maximum heart rate (i.e., VO_2max). The decision to employ submaximal exercise testing is usually based upon the availability of equipment and possibly medical supervision. In clinical and diagnostic exercise testing, maximal or submaximal exercise tests can be used to assess the severity of disease and prognosis of patients with known or suspected coronary artery disease. Tests in this scenario often include more detailed physiological measurements in addition to expired gas fractions and heart rate measurement, such as blood pressure assessments, electrocardiogram recordings, and use of pharmacological agents and radioactive tracers. In the health and fitness industry, or in behavioral research, exercise stress tests can be used to characterize individuals in terms of cardiorespiratory fitness, or used to accurately prescribe exercise training interventions.

McGill Pain Questionnaire

Tavis S. Campbell, Jillian A. Johnson and Kristin A. Zernicke
Department of Psychology, University of Calgary, Calgary, AB, Canada

Synonyms

McGill pain index

Definition

The McGill Pain Questionnaire (MPQ) was developed in 1971 by pain researcher Ronald Melzack. It was devised as a system for subjectively assessing pain experiences along three dimensions. Scoring of this inventory provides a quantitative index of pain (Melzack, 1975).

- The first dimension, *sensory quality*, focuses on the variations that occur in the sensation of pain, such as temporal, spatial, pressure, and thermal properties.
- The second dimension, *affective quality*, highlights the fear, tension, and autonomic properties that are part of the pain experience.
- The third dimension, *evaluative quality*, refers to the words that describe the subjective overall intensity of the pain experience.

In addition to these three dimensions of pain, the MPQ is subdivided into four parts (Melzack, 1975).

- Part 1 consists of front and back drawings of the human body. Individuals indicate the location of pain by marking the drawing with an "I" or "E" to indicate if the pain experienced is internal or external.
- Part 2 consists of 20 sets of descriptive words to describe the pain experience. The individual circles the word in each set that best describes their experience of pain. The words are ordered from least to most painful.
- Part 3 asks how the patient's pain changes with time (continuous, intermittent, etc.).
- Part 4 measures the strength or intensity of the pain on a five-point scale from "mild" to "excruciating". The Present Pain Index (PPI) score is derived from this section of the scale.

The McGill Pain Questionnaire is among the most widely used brief assessment tools for pain.

Mean (Average)

J. Rick Turner
Cardiovascular Safety, Quintiles, Durham, NC, USA

Synonyms

Arithmetic mean; Average

Definition

The mean of a set of data points is defined as their sum divided by the total number of data points. The actual name for this parameter is the "arithmetic mean," a term that distinguishes it unambiguously from the geometric mean, which is defined quite differently. Having said this, the geometric mean is seldom used in behavioral medicine, and it is a reasonable assumption that the "default" value of the term "mean" in the literature is the arithmetic mean.

The mean is a measure of central tendency that is most appropriately used for continuous data, i.e., variables that are measured on a continuous, uninterrupted scale and can take any value on that scale. Relevant examples are height, weight, blood pressure, and heart rate. Other common measures of central tendency are the median and the mode. Each of these can provide a more meaningful summary of a data set depending on the characteristics of the data, and care should be taken when deciding which measure to present when reporting the data. If there is any doubt in this choice, a good practice is to present more than one of them.

Meaning (Purpose)

Login S. George and Crystal L. Park
Department of Psychology, University of Connecticut, Storrs, CT, USA

Synonyms

Beliefs; Goals; Purpose; Worldview

Definition

Most definitions of meaning encompass a sense of understanding, significance, and purpose in life. Meaning refers to how an individual perceives and conceptualizes life, one's self, and relationships between the two. Meaning consists of global and situational aspects. Global meaning refers to individuals' general orienting systems and consists of beliefs, goals, and subjective feelings of purpose or meaning in life. Situational meaning refers to the meaning associated with specific events or contexts. Situational meaning is the result of the interaction between specific contexts and individuals' global meaning systems (e.g., the degree to which a specific event violates or fits an individual's general beliefs regarding the world).

Description

Research has established links between each of the components of global meaning (beliefs, goals, and a subjective sense of meaning) with general levels of physical and psychological health (see Park, 2011, for a review). Global beliefs regarding the amount of control individuals have over the circumstances in their lives have been shown to be positively related to health and well-being (see Lachman & Firth, 2004, for a review). Other global beliefs, such as beliefs in a just world, appear to buffer stressors in both lab-based and workplace settings. The effects of global beliefs on health appear to be the result of both physiological and behavioral pathways. For example, a high sense of control appears to moderate physical and psychological reactivity to daily stressors and has also been found to be inversely related to aortic calcification. Many studies have found that performance of health behaviors mediated the relationship between control beliefs and health benefits, suggesting that behavioral pathways are involved in the relationship between global beliefs and health.

Research on the relationship between global goals and health suggests that various dimensions of goals have different relations with health.

Goals have multiple dimensions such as structure, process, content, pursuit, attainment, maintenance, and disengagement, and relationships with health may vary across them (Maes & Karoly, 2005). Preliminary research suggests that being committed to goals that are perceived as attainable, feeling that one is making progress toward his/her goals, and experiencing less goal ambivalence and goal conflict are related to better health.

The subjective experience of meaning in life seems to be related to better physical and psychological health as well. Studies have found an inverse relationship between meaning and mortality rates, and a positive relationship with meaning and self-rated health and psychological well-being. A sense of meaning in life appears to affect well-being in both direct and indirect pathways. A higher level of meaning in life has been related to better autonomous functioning, lower heart rate, and decreased heart rate reactivity. It has also been related to the performance of health-promoting activities in various samples such as Anglo women, Japanese adults, and cardiac outpatients.

The impact of meaning on health seems to be particularly salient during crises or highly stressful experiences perceived to entail a high probability of damage or loss (e.g., receiving a diagnosis of serious illness). Crises may disrupt global meaning, which can diminish one's sense of meaning or purpose in life. Global beliefs affect how individuals deal with and recover from stressful situations. For example, beliefs regarding control have been found to moderate the impact of economic hardship on health and to predict lower levels of pain, stress, fatigue, and blood pressure in individuals suffering from rheumatoid arthritis. A high sense of control may help individuals make more adaptive appraisals of stressful situations (e.g., "this is a situation I can handle") and enable persistence in coping efforts.

Crises may also disrupt individuals' global goals. Studies suggest that the extent to which individuals perceive an event to disrupt or hinder their goals affect physical and psychological well-being. The higher the perceived disruption of goals, the more negative the impact. The subjective sense of meaning in life seems to play a role in the impact of crises as well. A high sense of meaning can serve as a resource that allows individuals to maintain and achieve higher health-related quality of life amidst stressful situations.

Current literature on meaning and its impact on emotional and physical health are largely correlational, which renders it impossible to draw conclusions about causal links between meaning and health. It is possible that there is a bidirectional relationship between the two or that the direction of causality is the reverse of what has been commonly presumed (i.e., that the better one's physical and psychological health, the more likely one is to perceive meaning in life). It is also possible that unidentified third variables (confounds) are influencing the relationship between the two.

Measures of Perceived Control of Health

▶ Multidimensional Health Locus of Control Scales

Measures of Quality of Life

Natalie E. Bustillo
Department of Psychology, University of Miami, Coral Gables, FL, USA

Synonyms

Measures of well-being; Quality of life assessments; Quality of life instruments

Definition

General quality of life (QOL) refers to how individuals function in the various life domains (The WHOQOL Group, 1998). General QOL encompasses how well individuals are able to carry their daily responsibilities (e.g., work and family). Factors that contribute to general QOL include physical well-being, emotional well-being, social well-being, and functional well-being. Health-related QOL refers to physical and mental well-being as it relates to specific diseases (Centers for Disease Control and Prevention [CDC], 2000). Health-related QOL includes how well individuals are able to cope with the physical limitations that result from specific diseases as treatments may be accompanied by decrements in QOL. Health-related QOL is also referred to as disease-specific QOL.

Description

General QOL

The following are examples of commonly used measures that have been developed to assess general QOL.

The Medical Outcomes Study 36-Item Short-Form Health Survey (SF-36; Ware & Sherbourne, 1992) consists of eight QOL domains. The eight domains are: (1) limitations in physical activities because of health problems, (2) limitations in social activities because of physical or emotional problems, (3) limitations in usual role activities because of physical health problems, (4) bodily pain, (5) general mental health (psychological stress and well-being), (6) limitations in usual role activities because of emotional problems, (7) vitality (energy and fatigue), and (8) general health perceptions. The measure is a subjective, self-report measure that is easy to administer. The questions have Likert scale response options.

The Medical Outcomes Study SF-36 was used to develop the Medical Outcomes Study 12-Item Short-Form Health Survey SF-12 (SF-12; Ware, Kosinski, & Keller, 1996). The SF-12 consists of two subscales that each contains 12 items. The first subscale is Physical Component Summary and the second subscale is the Mental Component Summary. The advantage of using the SF-12 instead of the SF-36 is that it takes less time to administer due to having fewer items and may be more beneficial for research studies characterized by long assessment batteries. The reliability of the Physical Component Summary ranged between 0.864 and 0.890, while the reliability of the Mental Component Summary ranged between 0.760 and 0.774 among populations in the United States and United Kingdom.

The World Health Organization Quality of Life (WHOQOL) instrument was designed to assess cross-cultural QOL (World Health Organization [WHO], 1993). The WHOQOL-BREF was later developed as a brief version of the original measure in order to make its use more convenient (The WHOQOL Group, 1998). The WHOQOL-BREF consists of 26 items that tap into the domains of physical health (e.g., sleep, pain, and energy), psychological health (e.g., happiness, concentration, and feeling positive about self), social relationships (e.g., social support and sexual life), and environment (e.g., safety, financial resources, and home

environment). The measure also contains one overall health question and one overall QOL question. The WHOQOL-BREF has been developed in several countries across the world, including United States, China, Czech Republic, Indonesia, Poland, Russia, and Thailand. The development of the WHOQOL-BREF allows for the comparability of general QOL across various cultures.

Health-Related QOL

Disease-specific QOL can also be assessed for various illnesses. The following are examples of measures that have been used to evaluate the health-related QOL of cancer, heart disease, and diabetes.

The Memorial Symptom Assessment Scale Short Form (MSAS-SF) is a shortened version of the Memorial Symptom Assessment Scale (Chang, Hwang, Feuerman, Kasimis, & Thaler, 2000). The MSAS-SF consists of 32 items that tap into physiological and psychological symptoms. Each item contains two parts. The first part of the item assesses whether or not the symptom was present in the past 7 days. The second part of the item assesses the distress caused by the symptom (if the symptom was indeed present). The MSAS-SF yields a physical symptom subscale score, psychological symptom subscale score, and global distress index. Although the measure does not assess QOL specific to any one specific illness, psychological and physical symptom severity is an important component of health-related QOL. The MSAS-SF was validated among a sample of cancer survivors and demonstrated adequate reliability. The Cronbach's alpha coefficients for the composite scores were 0.82, 0.76, and 0.80 for the physical symptom subscale score, psychological symptom subscale score, and global distress index, respectively.

The Functional Assessment of Cancer Therapy (FACT) scale was developed to assess general cancer-related QOL for survivors receiving cancer treatment (FACT-G; Cella et al., 1993). The FACT-G was validated using a sample of breast, lung, and colorectal cancer and consisted of 29 items. The FACT-G yields five composite scores: physical well-being, social/family well-being, relationship with doctor, emotional well-being, and functional well-being. A total score may derived by calculating the sum of the five subscales. Although the FACT-G was originally designed to assess general cancer QOL, new scales have been developed in order to assess cancer-specific QOL. Specifically, the FACT instrument is available for survivors of breast cancer, bladder cancer, bone marrow transplant, primary brain tumors, colorectal cancer, cervical cancer, head and neck cancer, lung cancer, ovarian cancer, prostate cancer, and HIV infection. The FACT is commonly used to assess cancer-specific QOL and has been translated to seven languages (Cella & Bonomi, 1996).

The MacNew Heart Disease Health-related Quality of Life (MacNew) Questionnaire was developed to evaluate health-related QOL in patients with coronary heart disease (Höfer, Lim, Guyatt, & Oldridge, 2004). The MacNew is comprised of 27 items and yields three domains: physical limitations, emotional function, and social function. The internal consistency of the MacNew reflects adequate reliability (Cronbach's alpha ranges from 0.93 to 0.95 for the three domains). The MacNew is available in various languages, including English, Dutch, Farsi, German, and Spanish.

The Diabetes-39 is a measure designed to assess the disease-specific QOL of individuals diagnosed with diabetes (Boyer & Earp, 1997). The scale is comprised of 39 items and 5 subscales: (1) energy and mobility, (2) diabetes control, (3) anxiety and worry, (4) social burden, and (5) sexual functioning. The scale has been found to correlate with the well-established Sf-36 instrument, suggesting the measure is a valid tool for assessing diabetes-specific QOL.

Overall, several measures have been developed in order to assess general and health-related QOL. Assessing QOL may aid in further understanding how individuals are impacted by diseases, both physically and psychologically. Advances in the field of QOL measurement may play a role in the development of effective interventions to treat individuals who have experienced decrements in QOL due to illness.

Median

J. Rick Turner
Cardiovascular Safety, Quintiles, Durham, NC, USA

Definition

The median is a measure of central tendency. It a value such that, when the data are arranged

in order of magnitude, an equal number of data points lie above and below it. For any odd number of data points (e.g., 9), obtaining the median is straightforward (here, it is the fifth value). For an even number of data points (e.g., 10), it is the mean of the middle two observations (here, the mean of the fifth and sixth).

In comparison to the mean of a data set, the median has the advantage that it is less influenced by outliers. Consider the following data set: 3, 3, 4, 4, 5, 5, 100. The median is 4, a value which provides a good indication of the central tendency of the data set. The mean of the data set is 17.71, a value that is intuitively much less indicative of the data set's central tendency.

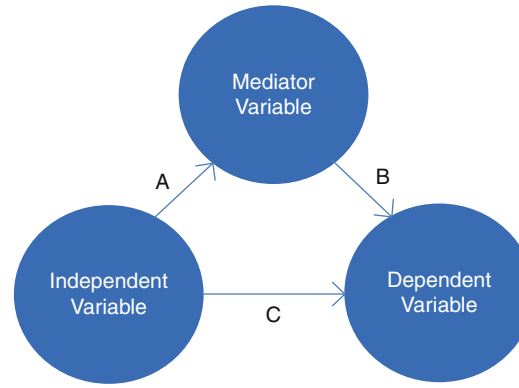
Synonyms

Intermediate variable

Definition

A mediator is a variable that serves to explain the nature of the relationship between an independent variable and a dependent variable or between a predictor and criterion variable (Baron and Kenny, 1986; MacKinnon, Krull, & Lockwood, 2000). It provides an indirect means by which the independent variable may affect the dependent variable. Specifically, a mediator influences the dependent variable while being influenced by the independent variable itself (MacKinnon et al., 2000). In experimental research, researchers manipulate a mediator to more clearly understand the means through which a causal effect is operating.



Mediators, Fig. 1 A meditational model as depicted in Baron and Kenny (1986)

A simple meditational model is depicted in Fig. 1 as shown in Baron and Kenny (1986). As illustrated, path (C) represents a direct effect of the independent variable on the dependent variable when no mediator is accounted for. In contrast, the causal path linking the independent variable to the mediator (A) and the mediator to the dependent variable (B) represents an indirect effect of the independent variable on the dependent variable via the mediator (Kraemer, Stice, Kazdin, Offord, & Kupfer, 2001). In this case, the independent variable influences the dependent variable through the mediator. If controlling for the mediator reduces the direct effect that the independent variable has on the dependent variable to zero, it can be said that complete mediation is present. However, if after controlling for the mediator, the effect of the independent variable on the dependent variable is significantly reduced but remains statistically different from zero, it can be said that partial mediation has occurred (Judd & Kenny, 1981). In behavioral medicine, as in any science, researchers use mediation analyses to test causal

pathways. For example, one could examine whether levels of various biomarkers such as C-reactive protein mediate the relation between hostility and acute coronary syndrome, by measuring hostility, the biomarkers and the disease endpoint, and implementing the Baron and Kenny test.

Medical Decision-Making

William Whang
Division of Cardiology, Columbia University Medical Center, New York, NY, USA

Definition

Medical decision-making is the process by which a diagnosis or treatment plan is formulated from the available test information, often with incorporation of known patient preferences.

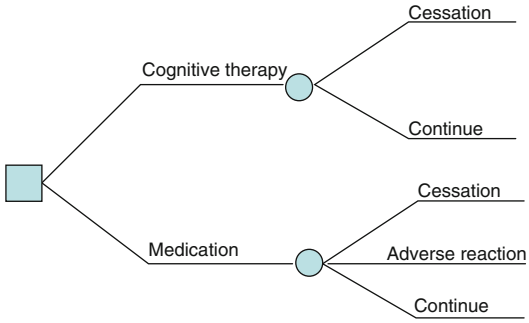
Description

Diagnoses and treatment choices by health-care providers and their patients are made under uncertainty. Medical decision-making can describe the process by which a diagnosis is derived from the retrieved facts at hand (Mark, 2008). It can also define the choices that are available for treatment or prevention of illness and attempt to maximize the expected health benefits given the probable outcomes of each choice.

Most clinicians use cognitive shortcuts, or heuristics, in order to guide them in their decision-making (Mark, 2008). For instance, the representativeness heuristic involves assessing whether a patient's clinical features match the representative features of different diagnostic hypotheses. Medical decision-making often involves the generation of initial hypotheses and testing of these hypotheses against data obtained through diagnostic tests.

The accuracy of diagnostic tests is defined in relation to a reference standard that is meant to reflect the true condition of a patient (Weinstein & Fineberg, 1980). For a test with binary results, it is useful to employ a 2 by 2 table to illustrate the concepts related to test assessment. The *sensitivity* of a test represents the extent to which a test identifies patients with disease and is defined as the proportion of patients with true disease who test positive (in the table, sensitivity equals [true positive]/[true positive + false negative]). *Specificity* represents the extent to which a test identified patients without disease and is defined as the proportion of patients without disease who test negative ([true negative]/[true negative + false positive]). The sensitivity and specificity of a diagnostic test can be incorporated in calculation of the *positive predictive value* of a test or the proportion of patients with a positive test result who actually have disease ([true positive]/[true positive + false positive]).

		Disease	
		Present	Absent
Test result	Positive	True positive	False positive
	Negative	False negative	True negative



Medical Decision-Making, Fig. 1 Hypothetical decision tree of treatment for smoking cessation

Decision analysis is a formal method that illustrates and estimates the likely outcomes associated with different medical choices and has been used frequently in cost-effectiveness research (Weinstein & Fineberg, 1980). In Fig. 1, a hypothetical choice between medication and behavior therapy for smoking cessation is outlined in a decision tree. The probability of each outcome, and the health "units" associated with each (e.g., quality-adjusted life years), can be estimated in order to assess the choice that is more likely to result in improved health.

Medical Outcomes Study

William Whang
Division of Cardiology, Columbia University Medical Center, New York, NY, USA

Definition

The Medical Outcomes Study (MOS) was a 2-year observational study of patients with chronic conditions, conducted in a cross-sectional phase among 22,462 patients and in a longitudinal phase among 2,349 patients (Tarlov et al., 1989). One of its two main purposes was to analyze how outcomes vary depending on factors such as the type of delivery system in which a patient receives care, clinician specialty training, and intensity of resource use. Another main purpose was to develop practical tools for monitoring patient outcomes and their determinants. For instance, the MOS core survey includes 116 items that measure quality of life in terms of physical, mental, and general health. In addition, the MOS Short-Form General Health Survey has been used in 12-item, 20-item, and 36-item versions for quality of life assessment in numerous conditions (Stewart et al., 1989). One of the initial publications from the MOS defined the impact of depression on patient functioning and well-being (Wells et al., 1989).

Clinical health psychology

Definition

Medical psychology has historically been defined as the branch of psychology concerned with the application of psychological principles to the practice of medicine. Medical psychology shares with the fields of health psychology and behavioral medicine an interest in the ways in which biological, psychological, and social factors interact to influence health. Medical psychologists use psychological theories and principles in order to improve the health and well-being of patients with physical illness. They are clinical psychologists who work in hospitals, medical centers, and health care facilities. Medical psychologists use techniques of psychotherapy, behavior modification, and cognitive, interpersonal, and family therapy to help patients manage chronic illness, reduce physical symptoms of disease or treatment, and manage emotional aspects of their illness.

Recently, the term "medical psychologist" has also been used to describe psychologists who prescribe medication. In the United States, psychologists in New Mexico, Louisiana, and all branches of the armed forces can prescribe medication after passing an examination and receiving board certification (e.g., American Board of Medical Psychology, Louisiana State Board of Medical Examiners). In order to receive board certification, these professional psychologists must have a doctoral degree in clinical psychology from an accredited institution, and must pursue postdoctoral training in medical psychology (including specialized training in psychopharmacology). The use of the term "medical psychologist" to describe psychologists with prescription privileges has been controversial. Division 38 of the American Psychological Association has stated that "the term 'medical psychologist' should not be equated with having prescription authority," citing the historical usage of the term "medical psychologist" (which had not previously been associated with medication prescription by psychologists) and the potential for confusion among psychologists, healthcare professionals, and the general public.

Medical Sociology

Richard Peter
Institute of Epidemiology and Medical Biometry, University of Ulm, Ulm, Germany

Definition

Medical sociology is a theory-based discipline which applies theory and methods from social sciences and epidemiology to analyze the impact of micro (individual)- and macro (societal)-social environments on disease onset and on the course of disease. Core aspects of interest concerning the micro-social level are social relationships in different areas of life, i.e., the workplace, the family, and their associations with health. One special aspect of a micro-social environment is the doctor-patient relationship. The focus on the macro level is on social inequalities in health, i.e., the distribution of morbidity and mortality along social classes, and on social inequalities in health care and health-care systems. More recent developments in medical sociology attempt to explain the macro-social associations with the help of micro-social factors, e.g., social inequality in health by higher levels of work-related stress in lower social class subjects.

Medical Utilization

Karl-Heinz Ladwig
Institut für Epidemiologie, Neuherberg, Germany

Synonyms

Adherence; Compliance

Definition

Medical utilization describes the degree to which a population or a given group uses medical and dental services, procedures, facilities, and practitioners in a specified time period. The utilization rates of health services are often based on exposure variables like the number of outpatient visits, number of physicians consulted, use of emergency services, hospitalization, and total health care costs that are quantitatively assessed as the number of services used per year or per 1,000 patients eligible for a medical service.

Description

Medical utilization research assesses not only the extent of medical service use, but also analyzes the necessity, appropriateness, and efficiency of medical services. In a hospital setting, this analysis may include the appropriateness or possible delay of decisions regarding admissions, duration of stay, and discharge practices. The concept is tied to the concepts of ▶ adherence and ▶ compliance which describe the degree to which a patient correctly follows medical advice.

Medical utilization is largely dependent on societal and personal determinants (Andersen & Newman, 1973). The societal determinants ("supply-side") encompass mainly resources and the particular organization that a national health care system offers to its consumers. In highly developed western countries, the total volume of resources relative to the population may be similar. Nevertheless, there may also be particular substantial differences which may not be addressed sufficiently enough in utilization research so far.

The progress in health research may alter patterns of medical utilization by itself. For example, a progress in diagnostic tools may decrease the number of patients with manifest acute myocardial infarction when referred to a chest pain unit but may increase the admission of sub-acute cases (McManus et al., 2011). Progress in antipsychotic medication may result in a shift from custodial care to treatment on an outpatient basis thus decreasing hospital admission of mental health conditions (Andersen & Newman, 1973).

Medical utilization can also be viewed as a type of individual behavior ("demand-side"). Psycho-pathological health conditions strongly impact medical over- and underutilization:

Medical *overutilization* is often seen in patients who suffer from medically unexplained symptoms, and the concept has received attention as part of the diagnosis of somatization disorder. These patients consult multiple physicians for the same problem ("doctor shopping") but remain dissatisfied and distressed with their medical care. Characteristically, they deny any psychological influence on the symptoms, resist psychiatric referral, and remain unreassured after receiving somatic evaluation results (Barsky, Orav, & Bates, 2005).

Medical *underutilization* is highly prevalent in mental health patients. Only 50% of bipolar patients may be adherent to their prescribed medication. Side effects and dissatisfaction with treatment are strong predictors of underutilization in these patients (DiMatteo, Lepper, & Croghan, 2000). Underutilization of basic treatment requirements are also often seen in patients with severe somatic disease conditions (e.g., coronary heart disease) and co-morbid depressed mood. Here, successful anti-depressive treatment may improve adherence to all therapeutic options (e.g., cardiac medications) required for the patient (Rieckmann et al., 2006).

Individual characteristics of patients beyond clinical features of psychopathology may also impact medical utilization patterns. It has been sufficiently demonstrated in population-based studies that females (less-convincing education level and older age) are independent unspecific contributors to medical utilization (Ladwig, Marten-Mittag, Formanek, & Dammann, 2000). Furthermore, inadequate health information, attitudes, health beliefs, and the quality of the physician-patient relationship are strong determinants of medical utilization (O'Donohue & Cucciare, 2005).

Medically Unexplained Physical Symptoms

▶ Somatoform Disorders

Medically Unexplained Symptoms

Benjamin H. Natelson
Department of Pain Medicine & Palliative Care, Beth Israel Medical Center and Albert Einstein College of Medicine, Bronx, NY, USA

Synonyms

Unexplained symptoms; Unexplained patient complaints

Definition

A set of patient complaints that with careful history, physical examination, and lab testing has no apparent medical cause is thus unexplained. When this happens, some physicians jump to a psychiatric explanation in lieu of no other – often leaving the patient stigmatized. Instead, a group of experts has arrived at operational definitions of symptom-based syndromes to allow for diagnosis and research. When the symptom is predominantly fatigue, severe enough to reduce activity substantially, and lasting at least 6 months, the diagnosis is idiopathic chronic fatigue. When the symptom is predominantly body-wide pain, also lasting many months, and the patient is tender on palpation, the diagnosis is fibromyalgia. When the pain is limited to face and jaw, the diagnosis is temporomandibular joint syndrome, and when the pain is in the abdomen and associated with constipation and/or diarrhea, the diagnosis is irritable bowel syndrome. The fact that patients with one of these syndromes often have at least one other has supported the psychiatric interpretation of these being variants of somatization disorder (Barsky & Borus, 1999). However, data are accumulating that differences do exist among these syndromes (Evengård et al., 1998; Weaver, Janal, Aktan, Ottenweller, & Natelson, 2010), and focus on pathogenesis has gradually shifted from the focal areas in the body affected to the brain with the notion that nociceptive systems are dysregulated (Schweinhardt, Sauro, & Bushnell, 2008). Functional brain imaging studies show patients with widespread pain and chronic fatigue, respectively, to have much larger responses to painful or fatigue-producing stimuli than control subjects (Cook et al., 2004; Lange et al., 2005) – suggesting a sensitized response to these stimuli. Another major factor influencing thinking about these syndromes in the physician community is the emergence of nationally approved drugs that effectively treat the symptoms of some of these disorders. All of this work suggests that, at least for some patients, the pathophysiological process underlying these syndromes is not the same. In addition to these newly available drugs, patients report substantial symptomatic improvement with a program of gentle physical conditioning (Hauser et al., 2010); similarly, providing patients behavioral ways to cope with chronic symptoms via cognitive behavioral therapy (Price, Mitchell, Tidy, & Hunot, 2008) also can help with symptom reduction and improve health-related quality of life.

Medication Event Monitoring Systems

Jessica Haberer
Medicine and Center for Global Health, Massachusetts General Hospital, Harvard University, Boston, MA, USA

Definition

Medication event monitoring systems are devices and reporting mechanisms for keeping track of pill-taking behavior.

Description

Introduction

Estimates from the World Health Organization indicate that patients in developed countries only take about 50% of prescribed medicine for chronic diseases like hypertension and diabetes. Many factors contribute to incomplete adherence, including side effects, stigma, forgetfulness, depression, and poverty. Behavioral science plays a critical role in understanding and improving adherence.

A variety of approaches to measuring adherence are discussed in the topic Adherence. This topic focuses on medication event monitoring systems, which are devices and reporting mechanisms for keeping track of pill-taking behavior.

The First-Generation Monitor

The first well-known device is the Medication Event Monitoring System (MEMS^{TM}), which was introduced in 1986. With MEMS, a specialized bottle cap contains a microelectronic switch, a clock, and a memory chip; the cap fits on multiple standard and large sized medication bottles. Every opening and closing of the MEMS cap records a time and date stamp that is stored and later downloaded to a computer via a USB cable. The data can be displayed graphically or in spreadsheet format for analysis. MEMS data has been used primarily in research projects, as well as some clinical scenarios.

There are several advantages to this type of electronic medication adherence monitoring. First, the time and date stamp provides a dose-by-dose estimate of adherence, thus enabling an understanding of patterns of pill-taking behavior. Most other adherence measures, such as self-report and pill counts, provide average estimates that do not distinguish between contiguous and intermittent lapses in adherence, which may have significantly different effects on the effectiveness of therapy.

MEMS caps, however, also have significant limitations. First, a pill bottle opening does not necessarily equate to pill ingestion. Second, the cap can only be used with a single bottle, which makes the use of pill boxes and other adherence aids impossible and prevents monitoring of multiple medications with a single device. Third, patients may take out multiple pills at a time for later dosing (i.e., a "pocket dose"). Similarly, patients may open the bottle without taking a pill (i.e., a "curiosity event"). Subjective reports may be used to correct for these shortcomings; however, the accuracy of these self-reports is unknown and dilutes the objectivity of MEMS.

Another significant limitation of MEMS is the fact that the data must be periodically downloaded onto a computer for analysis. Researchers and clinicians are typically unaware of adherence problems until regularly scheduled visits, which may occur weeks to months after the lapse(s) occurred. For some conditions, like HIV/AIDS, lapses as short as a few doses may have irreversible clinical consequences, and real-time data transmission could allow for interventions prior to these clinical consequences.

Second-Generation Monitors

In the past few years, many new devices have been introduced for medication event monitoring, which add a variety of features to build on the first-generation monitor. See Table 1 for a summary description of which features are associated with each of these devices.

Several second generation monitors offer multiple compartments, each with a microelectronic sensor, to allow for monitoring of multiple medications. Another approach to multiple medications is to store all medications in the device and dispense one or more pills at predefined time periods. These devices serve as monitors by recording when the dispensing compartment is opened to retrieve the pill(s). An alternate system for dose monitoring is to equip blister packs with microelectronics, such that a wire is broken when the pill is removed from its compartment. Dosing can then be recorded through a radio-frequency identification (RFID) signal. A similar yet less sophisticated RFID system monitors the removal and insertion of entire blister packs into a device.

Many second-generation monitors offer reminder features and have liquid crystal displays indicating which pills to take, as well as other clinically relevant information, such as potential side effects or health education messages. A newer version of the MEMS cap displays the number of openings to help track if a dose was taken. Other devices have auditory alarms and/or visual cues to remind patients when to take their medications.

Another common feature of second-generation monitors is the capacity for data transmission via the phone or internet. While some devices require cable connections, others are wireless, using Bluetooth to transmit to cell phone networks. These devices, thus, allow for real-time monitoring and the potential for real-time adherence interventions. Some systems have options to send phone calls, emails, and/or text messages to the patient, as well as friends, family members, health-care providers, and/or researchers to facilitate adherence support.

Despite these new features, this second generation of medication event monitors still has limitations. First, some devices have more pill capacity than others, and those with larger capacity have less portability. Second, few devices have options for liquid medications or medication applicators. Additionally, pocket doses and curiosity events remain a limitation for most devices, although some have compartment covers that limit each opening to one dose of medicine.

Third Generation

A third generation of monitors seeks to document actual ingestion of a medication. The ability to detect actual drug ingestion is highly

appealing; however, such an approach may seem invasive and inappropriate. Ultimately, acceptability remains to be seen. These third-generation monitors use two approaches: metabolite detection and documentation of taggant ingestion (a taggant is chemical or physical marker added to materials to allow various forms of testing). See Table 2 for a summary description of which features are associated with each of several third-generation devices.

In a monitoring system using metabolic detection, the patient urinates on a filter paper after medication ingestion. If a specific metabolite is present, a code is revealed on the filter paper. The patient then sends a text message with that code to document medication ingestion and in return automatically receives mobile phone airtime credit as an incentive. The Taggant ingestion systems involve a variety of materials and technologies, including a biocompatible antenna, magnet, and digestible microchip. A taggant is attached to each pill and detected by a small, wearable patch, wristwatch, or handheld reader as it travels through the digestive tract. Data is then transmitted in real time via cell phone networks. Another approach combines both metabolite detection and taggant ingestion. In this system, a taggant is released as the medication reaches the stomach and intestines. Following absorption, the taggant is metabolized to a volatile breath marker, and a breath sample is analyzed and data stored in the monitoring device for later assessment.

While these technologies are intriguing, the sensitivity and specificity of the ingestion detection mechanisms needs to be established. Results, for instance, may vary with pharmacokinetics. Additional complications include the requirement of collaboration with drug manufacturers and the need to adhere to the adherence monitoring strategy (e.g., patients must wear the taggant detection device or urinate on a filter paper) over time.

Summary and Conclusions

All of the above described medication event monitoring devices provide objective information for understanding pill-taking behavior, which is critical for both interpretation of clinical trials and evaluation of treatment effectiveness. Emerging methods and strategies offer improvements in objective discrimination of adherence, especially those with the capacity for real-time data transmission. This approach allows for proactive prevention of the consequences of nonadherence, which has previously not be possible. Any detection strategy, however, is only as good at the accompanying intervention.

A final, important consideration for all medication event monitors, regardless of their generation, is cost. In the United States alone, medication nonadherence is estimated to cost hundreds of billions of dollars annually. Moreover, studies in both developed and developing settings indicate the cost-effective nature of adherence interventions (e.g., for HIV/AIDS

treatment). Further research is needed into the effectiveness of medication event monitors as adherence interventions, and policies must be established for public and private insurance coverage.

Meditation

Alan M. Delamater
Department of Pediatrics, University of Miami Miller School of Medicine, Miami, FL, USA

Synonyms

Attention training; Concentration; Contemplation; Mental training

Definition

Meditation refers to a variety of mental techniques designed to focus the mind, improve well-being, and facilitate spiritual development. Most of the world's religions include some type of meditation technique. In recent years, mediation techniques have also become increasingly recognized as helpful in the treatment of many physiological and emotional disorders, as well as promoting wellness in healthy individuals.

There are two major types of meditation techniques: concentration and insight. Concentrative meditations involve the development of single-pointed attention, i.e., concentration on a single object. In insight meditation, the object is to focus the attention on changing objects as they occur in the mind on a moment to moment basis. A good example of concentrative meditation is transcendental meditation in which an individual focuses on a mantra, paying attention to the silent repetition of the mantra in the mind while screening out other stimuli. As concentration deepens, feelings of calm or tranquillity are experienced. Research has shown that when individuals practice this type of meditation, they experience a restful hypometabolic state in which their respiration, heart rate, blood pressure, muscle tension, and other indicators of sympathetic nervous system activation all decrease. This state of hypometabolic alertness has been termed the relaxation response by Herbert Benson. The relaxation response can be reliably elicited by the repetition of a mental stimulus (e.g., a mantra) while the individual adopts a relaxed mental attitude in a quiet environment.

Concentration is also an important component of insight meditation, but is used in insight meditation to focus on changing objects rather than a single object of attention. A key factor in insight meditation is the development of bare attention and mindfulness. Bare attention is observing phenomenon as they are, without comment, evaluation, or judgment. Mindfulness is the application of bare attention to changing objects as they occur in each moment, with an attitude of acceptance so that there is no clinging to objects that

are desirable and there is no aversion to objects that are not desirable. In mindfulness practice, one does not identify with objects of attention. The goal is to increase the frequency of noticing objects as they arise and pass away in consciousness. As mindfulness becomes stronger and more sustained, insights about the nature of the mind and reality develop, including three fundamental characteristics of existence: impermanence, suffering, and the concept that the self is a creation. Insight or vipassana meditation has its origins in Buddhism and was developed over 2,500 years ago; vipassana is the Pali word meaning to clearly see the nature of. In recent years, mindfulness has been incorporated into psychotherapeutic techniques. In addition to promoting spiritual development, research has shown that mindfulness can be helpful for stress reduction in healthy people as well as people with chronic health conditions and be an important aid in the treatment of a variety of psychological disorders.

Menopause

Suzana Drobnjak
Department of Psychology, University of Zurich, Binzmuehlestrasse, Switzerland

Definition

Menopause is a natural event in a woman's life. It describes the end of menstruation or, more precisely, a permanent cessation of the primary functions of the human ovaries. Menopause can only be determined retrospectively, once 12 months have lapsed with no menstrual cycle. At this point a woman is considered to be infertile. Women usually enter menopause at the age of 50–52 years.

Menopause is distinguished from other related terms. Premenopause describes the years before the Perimenopause and it begins around the age of 40. At this time, the levels of reproductive hormones are becoming lower. Perimenopause, on the other hand, describes the beginning of irregular menstrual cycles until the final menstruation cycle, which then leads to Menopause. And finally, the Postmenopause is the time after 12 months of Menopause.

Menopause is associated with many biological and psychological changes. It begins when follicular maturation stops due to lack of follicles in the ovaries. At this time, the concentration of estrogen falls to low levels. Ovulation and the production of progesterone stop. The absence of estrogen disturbs the homeostasis of the

hypothalamus-pituitary-gonadal axis. The low estrogen levels lead to a lack of negative feedback to the hypothalamus and pituitary. Consequently, the hypothalamus raises production of gonadotropin-releasing hormones, which leads to an increased release of follicle-stimulating hormone and luteinizing hormone. The body adjusts to the new hormonal balance and this leads to the appearance of several menopause symptoms, such as vasomotoric symptoms (hot flashes, headache, sweating, etc.), neuro-vegetative symptoms (insomnia, anxiety, depressive mood, etc.), organic symptoms (vaginal dryness, itchiness, etc.), metabolic symptoms (reduction of bone density, fat redistribution, etc.), and sexual symptoms (loss of libido function, etc.).

Aside from biological factors, Menopause transition can also lead to psychological changes. On the one hand, the risk of depression, anxiety, problems with concentration, and fatigue increases. On the other hand, the aforementioned symptoms of Menopause could affect well-being and life quality. It seems that psychological distress can also be influenced by social changes in this phase of life, such as the moving out of adult children. Confrontation with the process of aging can also negatively affect general well-being. These symptoms, however, generally depend on individual predispositions and manifest differently in every women.

Mental Health Surveillance

William Reeves
Office of Surveillance,
Epidemiology and Laboratory Services Centers for Disease Control and Prevention,
Atlanta, GA, USA

Synonyms

Mental illness monitoring or tracking; Mental illness surveillance; Mental illness (mental health surveys); Population health monitoring or tracking

Definition

According to the World Health Organization, "mental health represents a state of well-being in which the individual realizes his/her own abilities, can cope with the normal stresses of life, can work productively and fruitfully, and is able to make a contribution to the community." Mental health is not merely the absence of mental illness; mental health and mental illness represent distinct constructs. However, reflecting perceived stigmatization, *mental health* is commonly used rather than *mental illness*.

Mental illness comprises conditions affecting cognition, mood, or behavior associated with distress or impaired functioning. The American Psychiatric Association (APA) classification system separates mental illnesses into categories based on symptoms observed by a health professional or reported by the patient; these are currently defined in the Diagnostic and Statistical Manual of Mental Disorders 4th edition (DSM-IV-TR). The World Health Organization's International Classification of Disease, 10th Revision, Clinical Modification (ICD-10-CM) defines mental illness categories similar, but not identical, to those in DSM-IV-TR. The APA is developing the DSM-V and working to achieve greater coordination with future editions of the ICD.

According to the US Centers for Disease Control and Prevention, "public health surveillance is the ongoing systematic collection, analysis, interpretation, and dissemination of data about a health-related event for use in public health action to reduce morbidity and mortality and to improve health." In practice, mental health surveillance systems collect information concerning occurrence of mental illness.

Description

Mental illness surveillance serves several public health functions as follows: (1) informing public health interventions; (2) estimating the impact of mental illness; (3) portraying the natural history of various conditions and impact of treatments on outcomes; (4) determining the distribution and occurrence of mental illness; (5) generating hypotheses and stimulating research; (6) evaluating prevention and control measures; and (7) facilitating program planning. Individual surveillance systems cannot serve all these functions, and multiple approaches must be used in combination to provide a complete mosaic.

As with infectious and chronic medical diseases, public health strategies for mental illness aim to reduce its incidence, prevalence, clinical course, impairment, and economic impact. Surveillance provides the evidence base to develop prevention and control strategies. Fundamentally, surveillance must quantify the burden imposed by mental illness and identify the high risk, often underserved, populations in need of intervention services. In addition to representing an important public health problem in its own right, mental illness is significantly associated with chronic medical diseases (e.g., obesity, diabetes, and cardiovascular disease), which adds additional morbidity and mortality. Mental illness surveillance must consider these associations.

Surveillance also serves to monitor trends, and detect and characterize changes. The greatest public health successes related to infectious disease (e.g., small pox, polio, influenza) have utilized this aspect of surveillance. More recently, chronic disease (e.g., cancer, cardiovascular disease) prevention and control strategies have successfully used surveillance trend-data. Recognition is increasing as to the importance of tracking trends in mental illnesses associated with exposure to military combat or large-scale disasters (e.g., 9/11, Katrina, Deep Water Horizon).

Three categories of surveillance systems collect mental illness data. Optimally, their measures should be combined to plan, implement, and evaluate mental illness control strategies.

Population surveys measure occurrence of mental illness at national, state, and local levels. The US Department of Health and Human Services conducts national mental illness surveillance as part of ongoing surveys (e.g., National Survey on Drug Use and Health and National Health Interview Survey). More detailed national mental illness surveys occur sporadically (e.g., 1990/1992 and 2001/2003

National Comorbidity Surveys and 2001/2002 National Epidemiologic Survey on Alcohol and Related Conditions). National-level mental illness surveillance provides the evidence base for formulating policy and tracking progress on goals such as *Healthy People 2010 and 2020*. However, national-level surveillance has limited utility for state and local authorities responsible for designing, managing, and evaluating mental illness control programs. Currently, the Behavioral Risk Factor Surveillance System (BRFSS) represents the only ongoing US state/county-specific surveillance system. BRFSS measures mental illness, in selected states, through optional modules. Some population surveys define mental illness by stringent APA criteria from clinical evaluation using the Structured Clinical Interview for DSM (SCID) and Composite International Diagnostic Interview (CIDI). More often, large-scale mental illness surveys use standardized and validated screening instruments (e.g., Patient Health Questionnaire-9), which have varying degrees of diagnostic sensitivity and specificity. Currently, US population surveys of mental illness measure only depression and nonspecific psychological distress and so data is not available concerning anxiety disorders which are at least as common, equally severe and also associated with chronic medical conditions.

Health care surveys gather information from providers and insurers concerning patients' diagnoses and health care use. They provide data on occurrence of mental illness in people who have access to and utilize medical care. Evaluation of health care surveys in conjunction with population surveys provides information on health disparities. Examples of US health care surveys include the National Ambulatory Medical Care Survey (NAMCS), National Hospital Discharge Survey (NHDS), and the National Nursing Home Survey (NNHS). The manner by which health care surveys identify mental illness varies. In the USA, coding systems used by hospitals and medical providers typically involve the ICD-9 coding system, which is not fully congruent with the DSM. Mental health professionals generally use the DSM nomenclature while primary care providers may use other terminology. In practice, regardless of which diagnostic system is used, diagnosis varies based on training, local practice, availability of treatment resources, and available payment codes.

Vital statistics records represent the fundamental source of demographic, geographic, and cause-of-death information. Over 99% of deaths in developed countries, such as the USA, are registered. Suicide is the most serious potential outcome of mental illness. In 2006, suicide was the 11th leading cause of death in the USA and most people who commit suicide have a psychiatric diagnosis at the time of their death. Suicide rates provide one of the few indicators of mental illness impact that can be compared cross-nationally.

As discussed above, most current public health efforts aim to provide mental illness services with the goal of reducing the impact of mental illness on the population. Public health research efforts have also been initiated to explore protection and promotion of mental, emotional, and behavioral health, and primary prevention of mental illness.

Mental Illness

Andrew Fox
Recovery and Wellbeing Inpatient Services, Birmingham and Solihull Mental Health NHS Trust, Birmingham, West Midlands, UK

Synonyms

Psychiatric illness; Psychological disorder

Definition

Mental illnesses are particular ways of thinking, feeling, or behaving that are typically associated with distress or impairment and that are not accepted as normal by the dominant local culture. The concept remains controversial, and there is ongoing debate about how best to describe and understand the experiences often subsumed under this term.

Description

Classification of Mental Illnesses

Mental illnesses are made up of clusters of symptoms (abnormal or statistically infrequent

behavior, emotion, or thoughts) and are typically classified according to different categories, or diagnoses, so that a particular mental illness is considered as either present or not. There are many different forms of mental illnesses, and people may be classed as displaying several at any one time (known as comorbidity). The key manuals used to diagnose mental illnesses are the International Statistical Classification of Diseases and Related Health Problems (currently on its tenth revision; ICD-10) published by the World Health Organization and the Diagnostic and Statistical Manual of Mental Disorders (currently on its fourth edition), published by the American Psychiatric Association. According to these established manuals, individuals must demonstrate a certain number of symptoms in order to be considered as displaying evidence of the presence of a mental illness. Some example diagnoses from the ICD-10 include moderate depressive episode, bipolar affective disorder, panic disorder, posttraumatic stress disorder, generalized anxiety disorder, paranoid schizophrenia, and anorexia nervosa. More recent "dimensional" attempts to classify mental illnesses (e.g., "salience syndrome"; Van Os, 2009) have incorporated the notion that symptoms of mental illness lie at one end of a continuum of human experiences, with less debilitating but similar experiences within the range of what may be considered present within the general population.

An alternative to diagnosis of mental illness is psychological formulation (Johnstone & Dallos, 2006). This approach attempts to integrate hypothesized etiological factors into an explanatory framework for the individuals' current difficulties (e.g., low mood, anxiety). There are many different possible frameworks used for formulation, often – but not always – structured around the perspective of a school of psychotherapy.

Causes of Mental Illnesses

The precise cause of different mental illnesses remains unclear, with many hypothesized mechanisms for each of the many different categories of mental illness. The popular diathesis-stress model proposes that individuals are vulnerable to experiencing symptoms of mental illness through their genetic predisposition, and environmental stress triggers the onset of symptoms. Another popular and somewhat related general approach is the "biopsychosocial" perspective that suggests that multiple biological, psychological, and social factors are all implicated in the onset of mental illness. Psychological formulations often attempt to integrate hypothesized etiological factors with those that maintain the difficulties.

Treatment of Mental Illness

Given the multiple etiological and maintenance factors that can be considered in mental illness, there are many possible treatment options; however, the most popular remain medication and psychotherapy ("talking therapy"). Individuals may be offered a combination of treatment options including medication and psychotherapy.

Specialist practitioners, often psychiatrists, but sometimes nurses and psychologists, prescribe medication that is licensed for particular mental illnesses when there is evidence that it may reduce some or all of the unwanted symptoms that a person may be experiencing. Individuals may be encouraged to try several different forms of medication until they find one that they and their mental health practitioner feel helps them.

There are also numerous psychotherapies that are offered for different mental illnesses, often by psychiatrists, psychologists, nurses, social workers, and other individuals trained in specific forms of psychological therapy. Popular forms of psychotherapy include psychoanalysis, cognitive behavioral therapy, systemic (or family) therapy, and humanistic therapy. All forms of psychotherapy involve meeting for discussion with a trained mental health practitioner; however, the focus and content of these discussions will vary according to the type of psychotherapy.

Controversies Regarding the Concept of Mental Illness

The concept of "mental illness" is highly controversial; the psychiatrist Thomas Szasz (1961) has been an influential opponent of the term, and the concept continues to attract criticism.

The varieties of human experience and behavior that comprise what is viewed as a mental illness are often fluid, and what is termed mental illness in one time or context may not be termed mental illness in another (e.g., homosexuality was classified as a mental illness by the original Diagnostic and Statistical Manual of Mental Disorders). As there are often legal powers available to control the freedom of individuals labeled as mentally ill, there has been criticism of how diagnostic labels of mental illness have been used to control and oppress minority groups. Some of the symptoms linked to particular categories of mental illness – schizophrenia in particular – are so heterogeneous that they have been widely criticized as lacking validity and reliability (Bentall, 2003). Furthermore, the term itself ("illness") may lend itself to the false assumption that experiences subsumed under the category of a mental illness are primarily the result of a physiological disease process and should be treated in a medical way. Indeed, there is often a social stigma associated with the label of a mental illness, especially if understood as resulting from some underlying physiological cause, and this can have negative consequences for those labeled as mentally ill (e.g., reduced employment opportunities).

Given the criticisms of the concept of "mental illness," alternative terms have been suggested, such as mental, psychological, or emotional distress.

Mental Stress

Kristen Salomon
Department of Psychology, University of South Florida College of Arts & Sciences, Tampa, FL, USA

Synonyms

Anxiety; Distress; Psychological stress

Definition

A form of stress that occurs because of how events in one's external or internal environment are perceived, resulting in the psychological experience of distress and anxiety (Lazarus & Folkman, 1984). Mental stress is often accompanied by physiological responses (Cacioppo, 1994). Mental stress is most often induced in the laboratory by demanding and/or noxious stimuli, involving motivation to meet a performance criterion (Blascovich, Mendes, Tomaka, Salomon, & Seery, 2003) and/or social-evaluative threat (Dickerson & Kemeny, 2004), or interpersonal interactions, particularly those involving conflict (Glass & Singer, 1972). Common mental stress tasks include preparing and giving a speech, performing arithmetic, tracing around star with only a mirror image as a guide, performing a reaction time task (Steptoe & Vögele, 1991), and discussing a disagreed upon topic with another person (Gottman & Levenson, 1992).

Meta-Analysis

J. Rick Turner
Cardiovascular Safety, Quintiles, Durham, NC, USA

Definition

A meta-analysis is a quantitative evaluation of the evidence provided by two or more individual research studies that have addressed the same question. It commonly involves the statistical combination of summary statistics from various trials, but it also refers to analyses performed on the combination of raw data.

Description

Purposes of meta-analyses include:

- Providing a more precise estimate of the overall treatment effect of interest.
- Evaluating whether overall positive results are also seen in prespecified subgroups of participants.
- Evaluating apparently conflicting study results.

The conceptual basis of meta-analysis is straightforward: More data will provide a better opportunity to get a meaningful answer to a research question. However, appropriate implementation of the required statistical techniques and the appropriate interpretation of the results obtained are not so straightforward. Synthesizing the results from many individual studies can be difficult and confusing. Inconsistency between published studies addressing the same research question is not uncommon, particularly when different study designs have been employed.

Even though a meta-analysis does not require a new study to be conducted, it is still a research method in its own right. Therefore, "to ensure that a meta-analysis is scientifically valid, it is necessary to plan and conduct the analysis in an appropriate way. It is not sufficient to retrospectively go to a bunch of studies that you like the look of and stick them together!" (Kay, 2007).

One way to combat inconsistencies is to employ the pooled data approach, i.e., to combine the data from all of the studies and to conduct a new analysis on these data. The size of the new data set will be (much) larger than the size of any of the individual data sets, and the analysis of a larger data set lends itself more readily to the identification of a relatively small but still clinically important treatment effect. Such treatment effects can have considerable public health benefits if they are seen in a very large number of patients with a common disease.

At the outset, the purpose for a meta-analysis must be stated, and the treatment effect of interest determined. Subsequently, the basic steps required for the conduct of a meta-analysis are as follows:

- Establishing rules for which of the identified studies will be allowed into the meta-analysis. This includes determining and detailing approaches to ensure consistent quality of the studies and how to handle poor quality studies.
- Identification of all relevant studies.
- Data abstraction and acquisition.
- Data analysis.
- Evaluating robustness.
- Dissemination of results and conclusions.

One straightforward approach to meta-analysis is to include every study identified and obtained. A counterargument is that, almost certainly, some studies will be "better" than others, and that "less good" studies perhaps should not be included if the "best" information is to be provided to the clinicians who will read

the meta-analysis and therefore may base treatment decisions on its results. In the latter case, a priori inclusion and exclusion criteria must be created in advance of searching for studies. These effectively define "better" and "less good," and hence determine which of the studies about to be identified will be included in the meta-analysis.

The results of a completed meta-analysis would typically include the following:

- The estimated treatment effect (a point estimate) for each individual study included in the analysis, and a 95% confidence interval about each study's estimate.
- The overall estimated treatment effect and its 95% confidence interval.

This information can be displayed in tabular form or in a graphical form called a confidence interval plot.

Having calculated the result of a meta-analysis, it can be informative to assess the robustness of the analysis. In any meta-analysis some of the studies included will be larger than others, and sometimes a small percentage of included studies can be considerably larger than the majority of others. The nature of the calculations performed in meta-analysis mean that the larger trials tend to influence the result more, since they tend to have greater precision. It can therefore be helpful to assess the robustness of the overall conclusion by performing the analysis without the data from the largest study or studies to see if the result remains qualitatively the same. If it does, then the result is deemed robust. If it does not, confidence in the overall result can be undermined. Additionally, if the results are considerably different, and the studies are considerably different from each other (heterogeneous), it may not be appropriate to conduct any form of meta-analysis using them.

While an analysis is certainly conducted when performing a meta-analysis, the term *meta-methodology* may better reflect the methodology used to collect the data before conducting the actual analysis (Turner, 2011). This term emphasizes the methodological rigor that is needed in getting ready to conduct the analysis.

Metabolic Syndrome

Anna Maria Patino-Fernandez
Department of Pediatrics, University of Miami, Miami, FL, USA

Synonyms

Insulin resistance (IR) syndrome; Syndrome X

Definition

The metabolic syndrome (MS) in adults has been defined in the literature by various organizations, including the National Cholesterol Education Program Expert Panel (2001), although a standard definition does not exist in either the adult or child literature. In adults, the clustering of four health risk factors, obesity, hyperinsulinemia, high blood pressure, and dyslipidemia, has been referred to as syndrome X, insulin resistance syndrome, and/or metabolic syndrome (Reaven, 1988). The dominant underlying risk factors for this syndrome appear to be abdominal obesity and

insulin resistance. Insulin resistance is a generalized metabolic disorder in which the body can no longer use insulin efficiently. This is why the metabolic syndrome has also been called the insulin resistance syndrome. The MS risk factors manifest in childhood and have a major impact on the development of medical problems throughout the life course. Although the clustering of these risk factors is not well understood in children, children who are overweight are more likely to have hyperlipidemia, elevated blood pressures, and elevated insulin levels (Cook, Weitzman, Auinger, Nguyen, & Dietz, 2003). A decrease in insulin sensitivity is one of the first manifestations of MS in youth (Arslanian & Suprasongsin, 1996), and insulin levels in children are positively associated with levels of triglycerides, blood pressure, and body mass index, and negatively associated with high-density lipoprotein cholesterol (Batey et al., 1997). The MS definition has been modified for the examination of MS in children and includes the presence of at least three of the following abnormalities: overweight, hypertension, hypertriglyceridemia, low HDL cholesterol, and impaired glucose tolerance (Cruz Weigensberg, Huang, Ball, Shaibi, & Goran, 2004).

The American Heart Association and the National Heart, Lung, and Blood Institute recommend that MS in adults be identified as the presence of three or more of the following:

- Elevated waist circumference:
  - Men – equal to or greater than 40 in. (102 cm)
  - Women – equal to or greater than 35 in. (88 cm)
- Elevated triglycerides:
  - Equal to or greater than 150 mg/dL
- Reduced HDL ("good") cholesterol:
  - Men – less than 40 mg/dL
  - Women – less than 50 mg/dL
- Elevated blood pressure:
  - Equal to or greater than 130/85 mmHg
- Elevated fasting glucose:
  - Equal to or greater than 100 mg/dL

Individuals with MS are at increased risk for coronary heart disease and other diseases related to plaque buildups in artery walls (e.g., stroke and peripheral vascular disease) and type 2 diabetes. The metabolic syndrome has become increasingly common in the United States, with over 50 million Americans having it. Some people are genetically predisposed to insulin resistance. Acquired factors, such as excess body fat and physical inactivity, can elicit insulin resistance and the metabolic syndrome in these people.

For managing both long- and short-term risk, lifestyle interventions are the first-line treatments to reduce the MS risk factors. These lifestyle interventions include:

- Weight loss to achieve a desirable weight (in adults, a BMI less than 25 kg/m^2)
- Increased physical activity, with a goal of at least 30 min of moderate-intensity activity on most days of the week
- Healthy eating habits that include fruits and vegetables; reduced intake of saturated fat, trans fat, and cholesterol; and appropriate portions

Metabolic processes

Definition

The word metabolism is derived from Greek and means "change." It involves all chemical reactions or changes in a living organism. In simple terms, "metabolism is the chemistry of life (Bing, 1971)." Due to the importance of metabolic processes to life, the processes have been highly conserved throughout evolution.

Description

Metabolism consists of multiple processes resulting in the breakdown and formation of molecules that sustain life. Metabolic processes are complex and can be influenced by internal and external factors. These processes are highly regulated and aim to maintain physiological balance or homeostasis in the face of a constantly changing environment. There are two types of metabolic reactions: anabolic and catabolic. These processes work hand in hand, although one may predominate depending on physiological or pathological state. Anabolic reactions predominate at times of high substrate availability and involve transformations of smaller molecules into larger complex storage compounds. Catabolic reactions predominate at times of low substrate availability and are involved in the breakdown of molecules for energy utilization (Berg, Tymoczko, & Stryer, 2012).

Catabolism involves energy production by breaking down complex molecules to simpler ones for energy usage or cell repair. For example, break down of glycogen, a carbohydrate, to glucose, a monosaccharide, produces cellular energy. This energy in turn can be used to create other complex products through anabolic reactions. Anabolic reactions are important as they produce important compounds essential for basic function of life including the synthesis of deoxyribonucleic acid (DNA) for genetic coding or peptide and steroid hormones from amino acids and cholesterol, respectively (Dominiczak, 2007).

In metabolic processes, one molecule is transformed to another or to energy via cellular respiration. The steps of metabolic pathways are regulated by various enzymes that act as catalysts to speed up the chemical reactions. These enzymes are regulated at several levels from production to function by several factors including the cell's environmental milieu. Abnormalities in several metabolic pathways are associated with various disease conditions, both genetic and acquired. Manipulation of metabolic pathways is also important in treatment of several medical conditions.

Important Biochemical Compounds in Metabolism

Living organisms need food to grow and survive. Food can be divided into essential biochemical

compounds called macro- and micronutrients: proteins, carbohydrates, lipids, vitamins, and minerals. Other important biochemical compounds include nucleotides, which are important in the transfer of genetic information for growth, maintenance, and repair.

Protein

Protein is made from amino acids joined together via peptide bonds. Degraded amino acids are converted to nitrogen which in humans is transformed to urea (Brody & ScienceDirect, 1999). Urea is excreted in urine by the kidneys. Protein is vital in life as it is involved in many metabolic pathways either as catalytic enzymes or as peptide hormones (e.g., insulin) (Brownie & Kernohan, 2005) regulating metabolic enzymes and processes. Proteins also function as the cellular cytoskeleton, part of immune system as antibodies and help in transport of substrates into cells as transporters of part of cell membrane channels.

Carbohydrate

Carbohydrate is formed by simple sugars or monosaccharides. These monosaccharides are fructose, galactose, and glucose. Monosaccharides are stored as complex carbohydrates (polysaccharides) such as glycogen in animal or starch in plants for energy utilization and help in structural formation of cells alongside with proteins (Dominiczak, 2007).

Lipids

Lipids consist of a broad group of hydrophobic molecules (Brownie & Kernohan, 2005), which are soluble in organic solvents. Lipids function as structural components in building of cell membranes (Berg et al., 2012). Although they are less accessible as substrates, lipids are also important source of energy storage (Dominiczak, 2007). Cholesterol is an example of a lipid, which can subsequently be converted into bile acids or steroids to function as hormones in the endocrine system (Molina, 2004).

Vitamins

Vitamins are organic compounds derived from the diet. They can be divided into water-soluble (vitamin B and C) or fat-soluble vitamins (vitamin A, D, E, and K). For most metabolic pathways, coenzymes or metabolic intermediates are essential to carry functional groups to be used in specific enzyme activity. Without these coenzymes, the chemical reaction will not be successful. Many vitamins act as coenzymes, for example, vitamin B1 (or thiamine) is a coenzyme in carbohydrate metabolism. Thiamine deficiency is common in chronic excessive alcohol consumption, and this can lead to disease of the nervous system known as Wernicke's encephalopathy or beriberi causing problems to the cardiovascular, muscular, and nervous systems. Other functions of vitamins include maintenance in life and support for growth (King, 2011).

Minerals

Minerals or inorganic compounds are needed for many different metabolic pathways. Some common examples of minerals are sodium, potassium, chloride, magnesium, iron, calcium, and phosphate. They all have different functions. Some examples are as follows: the electrolytes sodium, potassium, chloride, and water are important for blood pressure regulation; iodine is essential for the production of thyroid hormone; and iron is a key component of hemoglobin which carries oxygen. Calcium and phosphorus are important minerals for bone metabolism. Calcium is also the key to several cellular functions including muscle contraction, neurotransmission, hormone release, and metabolic enzyme regulation (Brody & ScienceDirect, 1999).

Nucleotides

Within cells, there are heterocylic compounds called purines and pyrimidines. These serve as bases for nucleotides and are formed from amino acids. Purine bases include adenine and guanine, while pyrimidines are thymine, cytosine, and uracil. When purine or pyrimidine bases are linked to carbohydrate, they are called nucleosides. Nucleotides are phosphorylated nucleosides (King, 2011). Functions of nucleotides include acting as coenzymes, (e.g., nicotinamide adenine dinucleotide, NAD+), cell mediators (e.g., cyclic adenosine monophosphate, cyclic-AMP), and as

energy storage in the form of adenosine triphosphate (ATP) for future energy transfer. Importantly, nucleotides are involved in gene coding in the form of deoxyribonucleic acid (DNA) and ribonucleic acid (RNA) (Berg et al., 2012; King, 2011).

Energy Metabolism

Unit of Measurement

Energy is measured in joules or calories. Joule, named after English physicist James Prescott Joules, is the unit of measurement for energy in the international system of unit. One joule is equal to 0.2390 calorie, and one calorie is equal to 4.184 J (Brody & ScienceDirect, 1999). Calories printed on food labels provide the measured energy gained within the body when the food is eaten and absorbed.

Krebs Cycle

After food is absorbed from the digestive system, they can be converted into energy. Fatty acids are used as a major energy source in most organs except the brain. The brain gets energy through breaking down glucose into carbon dioxide. It also uses ketone bodies during starvation or fasting states (Brody & ScienceDirect, 1999). The liver on the other hand, uses mainly fatty acid for energy so it can function to produce, store, and release glucose. The glucose stored within the liver can be used by other organs when in need. Both the breakdown of glucose and fatty acids are metabolized through a pathway called the Krebs cycle (Brownie & Kernohan, 2005).

The Krebs cycle is also known as the tricarboxylic acid cycle. It is a pathway which uses oxygen and nutrients to produce adenotriphosphates (ATP), the energy currency of cells (Krebs & Roberts, 1973). Proteins, carbohydrates, and fatty acids can be metabolized to acetyl-CoA which then produces energy. These processes involved energy transfer or release for maintenance of life (Brownie & Kernohan, 2005).

Energy Transfer

A main aim of metabolism is to transfer energy or release energy for usage. There are two basic laws of thermodynamics for energy, they are:

1. Energy can neither be created nor destroyed. It can only change forms. Therefore, the total amount of energy in an organism is the same.
2. Entropy always increases. This means energy can be produced by converting high-energy compounds to low-energy end product.

In life, energy changes can be expressed using the term free energy, which is the difference in the energy content from the initial compound and the end product. For example, the energy content from glucose (initial compound) will be different when it is converted to carbon dioxide and water (end product). If there is a negative change in free energy, meaning there is release of energy from the initial high-energy compound when converted to a low-energy end product. One common example is the conversion of adenosine triphosphate (ATP) to adenosine diphosphate (ADP). The process which releases energy is called exergonic reaction (Brownie & Kernohan, 2005).

A positive change in free energy means extra energy is needed for the process to convert the initial compound to the end product(s). This process is called endergonic reaction. The energy released is used to maintain the metabolic rate (Brownie & Kernohan, 2005).

Metabolic Rate

The minimum body energy requirement within a body is called basal metabolic rate (BMR). It is the body's energy usage at rest in the postabsorptive state (no processes of digestion). The metabolic rate varies during different activities. During sleeping state, for example, metabolic rate may fall by 10% from the BMR, while BMR may increase by 10% postmeals. It also changes with different physical activities, aging, temperature, environment, and stress (Brody & ScienceDirect, 1999).

A useful way to measure metabolic rate is by measuring respiratory quotient (RQ). As mentioned above, one of the end products of Krebs cycle is carbon dioxide and, during metabolic pathways, oxygen is an essential compound. So by measuring the ratio between carbon dioxide released from respiration and the oxygen consumed, the result will be the total energy usage. The consumption of different substrates has

different respiratory quotients and is regulated closely by different mechanisms (Brody & ScienceDirect, 1999).

Regulatory Mechanisms

Metabolic processes are very complex and can be influenced by many factors to ensure responsiveness to alterations in the environment. This regulation occurs through several mechanisms: the nervous system, the endocrine system, and at cellular level, the activation of enzymes and feedback inhibition.

Nervous System

The nervous system controls metabolism through the sympathetic and parasympathetic nervous systems. These systems can stimulate a metabolic pathway directly or indirectly through the endocrine system via release of hormones. For example, release of catecholamines stimulates energy production by breaking down fat and glycogen stores within the body. Epinephrine released can also act indirectly by activation of different receptors causing release of hormones, which in turn trigger a cascade of reactions. An example of this will be epinephrine causing the release of insulin or glucagon via α and β receptors within the endocrine organ, pancreas (Molina, 2004).

Endocrine System

The endocrine system regulates metabolism through release of hormones into the circulation. Hormones act via their receptors to regulate different metabolic pathways. For example, growth hormone released from the pituitary gland will act on receptors in the liver to stimulate released of peptides called insulin-like growth factors (IGF), and this will lead to different metabolism thus stimulating growth (Molina, 2004).

Activation of Enzymes

Many proteins are inactive and need addition of specific molecule to be converted to the active form. These activated proteins will then be able to function in metabolic pathways as active enzymes. The availability of the specific activating enzymes will thus determine balance of metabolic pathways.

Adenosine triphosphate or ATP is one of the commonest compounds which will donate a phosphate to attach to another protein, such as tyrosine resulting in active form of tyrosine ready for metabolism. The process to break and free phosphate from ATP needs specific enzymes, namely, protein kinases, to be available. Therefore, the availability of protein kinases acts as a regulatory factor. This process of attaching phosphate to proteins is called phosphorylation. There are many different protein kinases available (Berg et al., 2012).

On the other hand, dephosphorylation can stop or slow down some metabolic pathways. It will remove the phosphate from the active protein by hydrolyzing phosphate to become orthophosphate. Without the additional phosphate molecule, the active protein will become dormant. The key enzymes on dephosphorylation are called protein phosphatases (Berg et al., 2012).

Feedback Inhibition

The availability of the final products of the metabolic pathway can act as part of a feedback regulation causing preceding steps in the pathway to slow or stop. This prevents overproduction of certain compounds, for example, the end product of pyrimidine base nucleotide cytidine triphosphate will inhibit aspartate transcarbamoylase, the enzyme required for the first step of metabolism of cytidine triphosphate (Dominiczak, 2007).

In summary, metabolism is the chemistry of life. There are many essential biochemical compounds needed to maintain life, and these compounds are used for storage, maintenance, or conversion into energy. Metabolic pathways are regulated by different mechanisms to maintain homeostasis. Any problems in any steps of metabolic pathway can lead to different diseases. Through manipulation of metabolic pathways, it is also possible to treat several medical conditions.

Methylation

Jana Strahler
Clinical Biopsychology, Department of Psychology, University of Marburg, Marburg, Germany

Synonyms

DNA-methylation; Gene methylation; Methylation of bases; Protein methylation; Transmethylation

Definition

Addition of a methyl group ($-CH_3$), simple four-atom molecule, to a chemical compound.

Description

In biological systems, methylation is involved in multiple biochemical processes such as the regulation of gene expression, protein function, and RNA metabolism. Enzymes are the main catalyzers constantly working to methylate or demethylate in a dynamic process.

DNA methylation refers to the modification of DNA caused by enzyme-induced addition of methyl groups to nucleobases, which alters the amount of messenger RNA. In general, methylated genes are ineffective, while unmethylated genes are active. The pattern of methylation differs between gene regions with the coding region being highly methylated while the promotor region is mostly free of methylation. DNA methylation typically occurs at sites where cytosine is directly followed by guanine. While there is no change in DNA sequence, DNA methylation prevents translation and therefore, alters gene expression. Thus, the addition of methyl groups to DNA can affect whether the gene's signal to produce a protein is triggered. The absence of the protein product alters the development and function of the cell.

Protein methylation refers to the posttranslational addition of methyl groups to basic amino acid residues in DNA- and RNA-binding proteins which regulates protein function.

Transmethylation denotes the transfer of a methyl group of methyl group donators to C-, O-, or N-atoms of a biomolecule under the catalytic influence of transmethylase. Example: Synthesis of creatine, a nitrogenous organic acid that increases the formation of adenosine triphosphate.

Failures in DNA methylation cause reduced or heightened gene activity. Gene methylation is likely to be a major mechanism in different disease states such as atherosclerosis or lung cancer development and progression. In this context, methylation state is discussed as a potential marker for the early detection of cancer, that is, a biomarker for tumorigenesis. Furthermore, methylation plays a role in gene-environment interaction. Previous studies have shown that early life experiences may alter

gene expression mediated via differential methylation patterns. Subjects suffering from Posttraumatic Stress Disorder show more unmethylated, active genes than unaffected subjects, and most of those genes are involved in immune system regulation. Thus, there is evidence for an association between stress-related disorders and epigenetic changes in immune system genes. Furthermore, there is also evidence for an association between diet and dietary supplements and gene methylation status implicating a possible mechanism for the effects of nutrients on human health.

Importantly, the *pattern of gene methylation is heritable*. Modifications made to DNA are maintained every time the cell divides. As already noted, lifetime experiences, dietary habits, or environmental factors can change gene activity, that is, the amount of DNA methylation. There is evidence for genetic transmission of methylation patterns to the offspring (called transgenerational epigenetic inheritance). This suggests that epigenetic mechanisms may impact health for several subsequent generations but are also attractive targets for interventions in complex diseases. Future research will provide new advances in treatments and new tools for the identification of the function of genes. The identification, cataloging, and interpretation of DNA methylation is subject of the Human Epigenome Project.

Migraine Headache

Jeanetta Rains[1] and Donald Penzien[2]
[1]Center for Sleep Evaluation, Elliot Hospital, Manchester, NH, USA
[2]Head Pain Center, University of Mississippi Medical Center, Jackson, MS, USA

Synonyms

Classic migraine; Common migraine; Headache with aura; Menstrual headache; Migraine with aura; Premenstrual headache; Sick headache; Vascular headache

Definition

Migraine is the most prevalent neurological disorder, and is ranked by the World Health

Organization as 19th worldwide of all diseases causing disability. Migraine is recurrent headache characterized by moderate to severe pain, pulsating pain, unilateral location, and pain that is aggravated by routine physical activity (e.g., walking, climbing stairs). Associated features include nausea and/or vomiting, and photophobia(heightened sensitivity to light and sound). Headaches generally last 4–72 h (untreated or unsuccessfully treated) although migraine in children are often less than 4 h in duration and chronic migraine – considered a complication or migraine – may exceed 72 h and in some cases may present as unremitting. The majority of migraineurs receive treatment in the primary care setting with a wide variety of acute and preventative medications. But even the best pharmacologic options have their limits. Headache is recognized as not merely a physiological problem but rather a *psycho*physiological disorder (i.e., a physical disorder subject to psychosocial influences and environmental stressors). Thus, identification of modifiable headache risk factors and management of headache triggers are common goals of headache care. Specific behavioral headache treatments may be utilized to augment, facilitate, or in certain cases offered in lieu of pharmacologic treatment. Behavioral treatments target the patient's headache-related physiological responses (relaxation training, biofeedback) or behaviors, emotions, and cognitions (cognitive-behavioral therapy, stress management). A very substantial quantity of empirical research evaluating these treatments has been produced within the past three decades.

Description

Migraine Diagnoses

The widely used nosology for headache is *The International* diagnosis *Classification of Headache Disorders-II* (IHS, 2004) which provides detailed DSM-style hierarchical diagnostic criteria for primary and secondary headache disorders; a revised edition, the ICHD-II-R, is forthcoming. The majority of migraines can be subclassified according to IDHD-II as: 1.1 Migraine without aura (previously termed common migraine) or 1.2 Migraine with aura (classic migraine). About one in five migraine sufferers experiences an aura prior to onset of a migraine headache. The migraine aura is a phenomenon in which one or more visual or sensory disturbances develop over a few minutes and disappear within 60 min. Migraine headache usually follows within 1 h, but may occur before or during the aura or may be entirely absent. There are many different types of visual and sensory auras which may differ between attacks. Visual disturbance may be positive features (e.g., flickering, blurred, curved, or luminescent area in the visual field) and/or negative features (e.g., loss of vision). Aura may involve one such symptom or a succession of visual disturbances. Unilateral sensory disturbances are also common, such as pins-and-needles, arm or leg numbness or tingling, or one-sided weakness. Disturbances of speech may also occur, though they are a much less common aura symptom. Such neurological symptoms are fully reversible.

Chronic migraine is the most common headache diagnosis seen in neurology practice and multidisciplinary clinic. Most cases of chronic migraine evolve over time from less frequent migraine without aura. As chronicity develops, the headaches tend to lose their episodic character. Chronic migraine is characterized by having daily or almost daily head pain more than 15 days per month and the average headache duration greater than 72 h (aka, transformed migraine, chronic daily headache). The pattern of progression of migraine from episodic to chronic over time has been well documented in headache literature, sometimes referred to as *chronification* or *transformation* of migraine. Medication overuse is the variable that has received the greatest attention as a potential cause for progression. Medication-overuse headache (MOH) has been associated with over-the-counter and prescriptions medications commonly used in the treatment of migraine. Though these medications are effective for intermittent use, frequent use over an extended period of time may complicate headache itself. ICHD-II defines minimum patterns of medication use considered to be associated with 8.2

Medication-overuse headache: ergotamines or triptans $\geq$10 days/month on a regular basis $\geq$3 months; opioids or combination analgesics $\geq$10 days/month on a regular basis for $>$3 months; and simple analgesics $\geq$15 days/month $>$3 months. MOH is generally recognized to be relatively resistant to traditional pharmacological as well as behavioral treatments. However, following withdrawal of the overused medications MOH generally reverts to an episodic pattern which is responsive to behavioral and prophylactic treatments.

Epidemiology

Migraine afflicts an estimated 28 million people in the United States. Surveys from the United States and elsewhere find 8% of children, 6% of men, and up to 18% of all women (about 12% of the population as a whole) experience migraine. Roughly, three out of four migraine sufferers are female. Migraine prevalence peaks in the third and fourth decades of life. At this time period, for example, migraine is 3.3 times more common in women than men. The female preponderance and variance with age is presumed to be related to hormonal milestones in women. Females with migraine often notice a change in their migraine pattern with hormonal fluctuation. Migraine increases at menarche and with the menstrual period. Improvement or worsening occurs during pregnancy and menopause. The headaches improve in the 1950s and 1960s in some patients, and are replaced with isolated aura symptoms.

Genetic Predisposition

There is a genetic predisposition to migraine. Approximately, 80% of migraine sufferers have a family history of migraine affecting a first-degree relative. Twin studies have demonstrated a familial influence. The concordance for migraine in monozygotic twins is greater than it is for dizygotic twins. However, it is also clear that the genetic background of the disorder is complex.

Disability and Impact

Migraine is associated with significant disability, lost work, and productivity. Headache is among the most prevalent medical problems and migraine is ranked by the World Health Organization as 19th worldwide of all diseases causing disability. Although only about one fourth of headache sufferers seek professional attention, over 40 million Americans consult a physician each year because of headache. Estimated aggregate indirect costs to employers in the United States for reduced productivity due to migraine range from 6.5 to 17 billion dollars annually. The problem can range from sporadic, infrequent headache with only minimal impact, to chronic, persistent headache that can severely disrupt the patient's life.

Risk Factors in the Transformation from Episodic to Chronic Migraine

Transformed migraine refers to the condition in which episodic migraine headache progresses to or "transforms" to chronic migraine – occurring at least 180 days per year. That is, high frequency chronic headache emerges, or escalates in frequency over time, from an earlier pattern of lower frequency episodic headache. Epidemiological studies suggest that there are specific variables or risk factors that might lead to progression from episodic to chronic migraine in selected patients: medication overuse, psychiatric comorbidity, stress, obesity, snoring, sleep disturbance, and others. Such modifiable risk factors may become potential targets for headache prevention.

Medication overuse: One of the most important and common causes of transformation is headache medication itself. When taken often, the very medications used to treat tension-type and migraine headache attacks can transform episodic headache into chronic headache. The medications known to play a role in this process include many over-the-counter and prescribed analgesics, analgesics combined with caffeine, opiates, ergotamines, and triptans. All these medications can be effective in treating episodic headache when used on an occasional basis. However, when used frequently, they may transform and aggravate headache. This process is called medication-overuse headache. MOH usually improves when the overuse ceases. Within 2 months (and frequently sooner), the

chronic headache pattern will revert back to the earlier episodic headache pattern or will remit. When episodic headache persists, it is often much more responsive to conventional treatment after the medication overuse has been eliminated.

Stress: Stress is the most commonly identified trigger for a headache in the average headache sufferer. Therefore, it is not surprising that frequent life changes and chronic daily stressors or "hassles" are also implicated in the development of chronic headaches.

Sleep Disturbance: Headache may be aggravated by frequent sleep disturbance. The most common sleep problem for headache sufferers is insomnia, including difficulty falling asleep, difficulty staying asleep, or poor quality "non-restful" sleep. Voluntarily limiting sleep or "burning the candle at both ends" can also increase risk of headache. Snoring during sleep is a specific risk factor for chronic headache in some patients. Though the cause is not known, it could be because snoring disturbs sleep quality or compromises breathing at night.

Obesity: Obesity is an independent risk factor for chronic migraine after adjusting for comorbidities and demographic variables. Interestingly, obesity is not a risk factor for migraine in general. The prevalence of episodic migraine in general does not vary significantly with the body mass index (BMI). However, studies have shown among migraineurs, high BMI was associated with more frequent headache attacks.

Caffeine: Finally, although caffeine can be beneficial in moderate amounts, and is used in some medications, it can also be a risk factor. Caffeine is the most widely used mood-altering substance in the United States. It is present in many beverages, dietary supplements, and in some foods such as chocolate. Many Americans consume caffeine daily with very little awareness that they are ingesting a drug with potent effects. For some headache sufferers, caffeine can aggravate headache in much the same way that medication overuse can.

Others: Female gender, presence of comorbid pain conditions, and psychiatric comorbidity have also been linked to transformation.

Psychiatric Comorbidity

Epidemiological studies have determined migraine and several psychiatric disorders to be comorbid. Psychiatric comorbidity portends a poorer prognosis for both pharmacologic and behavioral treatments. Migraine is comorbid with depression (OR 2.2–4.0), generalized anxiety (OR 3.5–5.3), panic disorder (OR 3.7), and bipolar disorder (OR 2.9–7.3). Patients with chronic migraine are at increased risk for major depression (OR 6.4 vs. 2.7) as well as for anxiety disorders (ORs 6.9 vs. 3.2 for all migraineurs).

Pharmacologic Treatment

A wide range of acute and prophylactic medications are available for treatment of migraine. Acute medications fall into general classes of medicines including analgesics, ergotamines, and triptans. Analgesics are considered nonspecific migraine medications as they work on pain systems in general, not just activated pain pathways involved in migraine. In contrast, triptans and ergotamines are migraine-specific medications. Analgesic and abortive medications are recommended for intermittent use. The American Migraine Prevalence and Prevention workgroup recommends a preventive medication for 4–5 non-disabling attacks or two or more disabling attacks per month. In addition, the use of behavioral headache medicine techniques combined with a daily medication will reduce the frequency of headaches further. A headache preventive therapy goal is to reduce attacks by 50% or more. Prophylactic or preventive medications are taken daily to prevent migraine attacks from occurring and commonly include a variety of antiepileptic, antidepressant, and antihypertensive medications. OnabotulinumtoxinA (BOTOX) is an injectable neurotoxin that has recently been FDA approved for migraine treatment. The mechanisms of action for migraine prevention remains unknown, but inhibition of nociceptive signaling has been suggested. Other medications (e.g., antiemetics, steroids) may also be utilized.

Behavioral Treatments for Migraine

Over the past three decades, several behavioral treatments for migraine prevention have been

used widely as independent therapies or in combination with medications. Most behavioral treatments are classified into three broad categories: cognitive-behavioral therapy (i.e., stress-management training), relaxation training, and biofeedback (often administered in conjunction with relaxation). In most instances, behavior therapies are used for preventing migraine episodes rather than for alleviating symptoms, once an attack has begun. Although these modalities may be effective as monotherapy, they are more often used in conjunction with medications. Goals for behavioral treatments include: reducing the frequency and severity of headache episodes; reducing headache-related disability; reducing reliance on medications; enhancing personal control over headache; and reducing distress and psychological symptoms.

Over 300 studies evaluating behavioral treatments for migraine have been published since the earliest empirical report evaluating a behavioral intervention for recurrent headache was published in 1969. The overwhelming majority of published clinical trials yielded positive outcomes, leading many professional practice organizations to recommend use of behavioral headache treatments alongside the preferred pharmacologic treatments for primary headache. An exhaustive meta-analysis of behavioral treatments for migraine funded by the Agency for Healthcare Research and Quality found these behavioral interventions yielded 35–55% reduction in migraine versus 5% reduction for no-treatment controls. The meta-analysis was the basis for an evidence-based guideline for migraine management produced by the *U. S. Headache Consortium* whose membership included the American Academy of Family Physicians, American Academy of Neurology, American Headache Society, American College of Emergency Physicians, American College of Physicians, American Osteopathic Association, and the National Headache Foundation. The Consortium's recommendations pertaining to behavioral interventions for migraine are as follows:

(a) Relaxation training, thermal biofeedback combined with relaxation training, electromyographic biofeedback, and cognitive-behavioral therapy may be considered as treatment options for prevention of migraine (Grade A Evidence).
(b) Behavioral therapy may be combined with preventive drug therapy to achieve added clinical improvement for migraine (Grade B Evidence).

Behavioral treatment typically entails 6–12 individual clinic sessions with a professional. Cost and availability of behavioral medicine specialists that provide services severely limit access of the average patient to behavioral treatments. In recent years, alternative delivery formats have been developed to increase availability and cost-effectiveness, such as group administration and minimal therapist-contact treatments. Minimal-contact or "home-based" formats have been the most extensively developed in this arena and provide similar treatment components to their clinic-based counterparts. Skills are introduced in the clinic but training occurs primarily at home guided by written materials and audio recordings. Consequently, only three or four clinic sessions may be necessary when behavioral techniques are delivered via this format. Meta-analyses have demonstrated the utility of the minimal-contact treatment approach, indicating that for many patients such treatments can be as effective as those delivered in a clinic setting.

Self-management

Headache Diary: Daily quantitative recordings of headache yield measures of headache frequency, duration, and intensity and may be employed to identify medication overuse, chronobiological patterns, menstrual and other headache triggers (see below), and to assess treatment outcomes. Diaries should be recorded daily, since memory for pain is prone to distortion. Diaries encourage patients to be systematic in their assessment of headache patterns and enable health-care providers to observe efficacy of treatments and dosages over time.

Headache Triggers: Identification and management of individual headache triggers is a common component of behavioral headache therapies. A trigger is an event that provokes

headache within 24 h at least 50% of the time. The level of vulnerability to any specific headache trigger factor varies from person to person. An individual's vulnerability to any given trigger factor also can rise and fall over time. Just the same, a person's overall tendency to experience a headache in response to trigger factors is likely to be an inherited trait. Prospective headache diaries are used to correlate headache onset or exacerbation with potential stimuli. The more common headache triggers reported by patients across studies is stress, menstruation, sleep disturbance, fasting or skipping meals, and weather. Additional triggers include alcohol, smoking, exercise, sexual activity, bright lights, odors, specific dietary additives, and others. There may be a threshold effect, in which multiple triggers or a combination of triggers tend to provoke headache. Headache trigger management includes: education about common headache precipitants, training patients to identify their unique triggers through prospective self-monitoring in a headache diary, applying behavior change principles to limit exposure to avoidable triggers (e.g., sleep deprivation) or apply self-management skills in responses to unavoidable triggers (e.g., stress).

Miller, Neal

J. Rick Turner
Cardiovascular Safety, Quintiles, Durham, NC, USA

Biographical Information

Neal Elgar Miller was born on August 3, 1909, in Milwaukee, Wisconsin. He earned a Bachelor's degree from the University of Washington in

1931, a Master's from Stanford the following year, and his doctorate from Yale in 1935. He was then a social science research fellow at the Institute of Psychoanalysis, Vienna, for a year before returning to Yale as a faculty member in 1936.

During the Second World War, he served as an officer in charge of research in the Army Air Corps' Psychological Research Unit #1 in Nashville, Tennessee, and later directed the Psychological Research Project at the headquarters of the Flying Training Command in Randolph Field, Texas. Miller returned to Yale as Professor of Psychology and in 1952, he was appointed the first James Rowland Angell Professor of Psychology.

In 1966, Miller transferred to Rockefeller University, where he spent an additional 15 years of service. He became professor emeritus at Rockefeller in 1981 and research affiliate at Yale in 1985.

Major Accomplishments

Miller is often credited as being the founder of behavioral medicine. He made significant contributions to our understanding of the relationship between reinforcement mechanisms and the control of autonomic behavior, and pioneered the field of biofeedback, which is used successfully today to treat a variety of medical conditions. He was also active in many other fields of scientific investigation.

His early research focused on the investigation of Freudian theory and clinical phenomena using experimental analysis of behavior techniques. He concluded that fear is a learnable drive, and began to investigate other autonomic behaviors to determine if they could be modified through instrumental conditioning. He used behavioral methodologies and neurophysiological techniques to investigate hunger and thirst. This integration of ideas and practices laid the foundation for modern neuroscience, and also fundamentally changed understanding of behavior and motivation. Interdisciplinary collaboration was a hallmark of his work.

Following animal model work on anxiety, Miller began to investigate other autonomic behaviors, trying to find out if they could also be modified through instrumental conditioning. He investigated hunger and thirst, using behavioral methodologies and neurophysiological techniques. He concluded that the autonomic nervous system could be as susceptible to classical conditioning as the voluntary nervous system. This led to his work on biofeedback. Initial reaction in the scientific community to his claim that people could learn to control autonomic functions was not positive. However, his sustained investigation revealed that this is indeed the case, and biofeedback became gradually accepted in scientific circles as a method to help treat various medical conditions, including high blood pressure, epilepsy, attention deficit and hyperactivity disorder (ADHD), and migraines.

During his career, Miller was president of many learned societies, including the American Psychological Association (APA), the Society for Neurosciences, the Biofeedback Society of America, and the Academy of Behavioral Medicine Research.

Miller received the APA Distinguished Scientific Contribution Award in 1959 and the APA Citation for Outstanding Lifetime Contribution to Psychology in 1991. In 1993, APA's Board of Scientific Affairs voted to honor him by establishing the Annual Neal Miller Distinguished Lecture, to be dedicated to neuroscience and animal research and presented at each APA convention. Miller himself presented the first lecture in 1994. The Academy of Behavioral Medicine Research established the Neal E. Miller New Investigator Award in his honor, and he received the National Medal of Science in 1964.

Editor's note: Dr Miller passed away in 2002.

Millon Behavioral Medicine Diagnostic (MBMD)

Mike Antoni
Department of Psychology, University of Miami, Sylvester Cancer Center, Miller School of Medicine, Miami, FL, USA

Synonyms

MBMD

Definition

Short Definition

The Millon Behavioral Medicine Diagnostic (MBMD) is a broadband self-report psychosocial instrument designed to assess physically ill and behavioral medicine patients to help develop effective treatment and management plans.

Description

The Millon Behavioral Medicine Diagnostic (MBMD) is a broadband self-report psychosocial instrument designed to assess physically ill and behavioral medicine patients aged 18–85 years to develop effective treatment and management plans. It provides information on test response patterns, health behaviors, psychiatric features, personality-based interpersonal coping styles, stress-moderating variables, and predicted responses to medical treatments.

The test was developed using a 3-step validation process wherein theory-generated items were used to form the 29 clinical scales representing the domains tapped by the test (Millon, Antoni, Millon, Minor, & Grossman, 2006). The initial validation sample comprised 720 patients (cancer, cardiac, diabetes, HIV, neurological, pain) drawn from medical settings across 22 states in the USA and Canada. Item content was refined to optimize scale internal consistency and test-retest reliability. Concurrent validity was determined through correlations with scales widely used in behavioral medicine research and with medical staff ratings. The MBMD is a 165-item true-false test in English and Spanish versions appropriate for a sixth grade education reading level. The test requires 20–25 min to complete and can be scored through a computer program, a fax-in service to the test publisher, or using hand-scoring templates.

The MBMD reports result in a profile depicting the raw scores and norm- and gender-adjusted prevalence scores for each scale representing the major test domains (Psychiatric Indicators [5 scales], Coping Styles [11 scales], Stress Moderators [6 scales], and Treatment Prognostics [5 scales] and Management Guides [2 scales]). Scores on other test domains,

Negative Heath Behaviors and Response Patterns, are expressed as categories. The test also yields a multipage report that highlights patient assets and liabilities in each domain, and uses "cross-domain" synthesis to modulate the interpretation of individual scores based on other domains in the profile (e.g., response pattern, psychiatric indicators, and coping style). At the end of the report there is a one-page Health Provider Summary that includes the most salient aspects of the patient's test results expressed in bulleted short phrases, and a list of noteworthy item endorsements that may require immediate attention and follow-up.

Subsequent validation studies based on 711 patients undergoing bariatric surgery procedures and 1,200 patients undergoing treatment for chronic pain in a variety of treatment settings across the USA have produced specialized test reports designed for use in these settings. Designed to accompany the general MBMD report, each of these "specialized" reports contains additional report sections germane to pretreatment considerations and longer-term patient management. The bariatric report contains information across 24 variables describing hypothesized benefits of additional presurgical assessments and interventions, and the benefits of postsurgical adjunctive behavioral interventions. The pain report comes in two versions – a presurgical report and a nonsurgical report. The pain reports include general medical prevalence scores, and chronic pain-specific percentile scores. The pain reports contain probabilistic statements relevant to pretreatment and posttreatment patient management. The MBMD is associated with health behaviors and medical outcomes in diverse clinical populations (Cruess, Meagher, Antoni, & Millon, 2007, Cruess, Localio, Platt, & Kimmel, 2010; Farrell, Shen, Mallon, Penedo, & Antoni, 2011; Harper, Wager, & Chacko, 2010; Lavoie et al., 2010; Pereira et al., 2010).

Mindfulness

Alan M. Delamater
Department of Pediatrics, University of Miami Miller School of Medicine, Miami, FL, USA

Synonyms

Insight meditation; Meditation

Definition

A key factor in insight meditation is the development of bare attention and mindfulness. Bare attention is observing phenomenon as they are, without comment, evaluation, or judgment.

Mindfulness is the application of bare attention to changing objects as they occur in each moment, with an attitude of acceptance so that there is no clinging to objects that are desirable and there is no aversion to objects that are not desirable. In mindfulness practice, one does not identify with objects of attention. The goal is to increase the frequency of noticing objects as they arise and pass away in consciousness. Concentration is also an important component of insight meditation, but is used in insight meditation to focus on changing objects rather than a single object of attention (Goldstein, 1976; Goleman, 1988).

As mindfulness becomes stronger and more sustained, insights about the nature of the mind and reality are experienced, including three fundamental characteristics of existence: impermanence, suffering, and not self, i.e., the concept that the self is a creation. Insight or vipassana meditation has its origins in Buddhism and was developed over 2,500 years ago; vipassana is the Pali word meaning to clearly see the nature of phenomenon.

In recent years, mindfulness has been incorporated into psychotherapeutic techniques and health-care interventions. There is a growing evidence base for its efficacy in treating pain, anxiety, stress, depression, and chronic health conditions, as well as for stress reduction and improved well-being in healthy people (Baer, 2006; Bohlmeijer, Prenger, Taal, & Cuijpers, 2010; Hofmann, Sawyer, Witt, & Oh, 2010; Shapiro & Carlson, 2009). Mindfulness has been adapted to several treatment programs, including mindfulness-based stress reduction (Kabat-Zinn, 2003), mindfulness-based cognitive therapy (Segal, Wiliams, & Teasdale, 2002), dialectical behavior therapy (Linehan, 1993), and acceptance and commitment therapy (Hayes, Strosahl, & Wilson, 1999).

Mini-Finland Health Survey

Arpo Aromaa
Health and Functional Capacity,
National Institute for Health and Welfare,
Helsinki, Finland

Definition

The Mini-Finland health survey (MFhes) is the first comprehensive nationwide study combining interview, questionnaire, and examination methods. Its baseline field work was carried out by the Social Insurance Institution's (SII) Mobile Clinic Unit (*Autoklinikka*) during 1978–1980 in a representative sample of adults aged 30 years,

and 96% of the sample was interviewed and 90% examined. The register-based follow-up of the sample of 8,000 is complete until 2010.

Description

In Europe in the twentieth century, the SII Mini-Finland health examination survey (MFhes; *in Finnish: Mini-Suomi terveystutkimus*) carried out in 1978–1980 was the first comprehensive nationally representative study of health, chronic diseases, functional limitations, their determinants (social environmental, behavioral and biological risk, and protective factors), use of health services comprising rehabilitation, and need and unmet need for care and help. It combined the sociomedical, epidemiological, and social science research traditions of the SII, i.e., the paradigms and methodological skills of the Mobile Clinic Unit's health examinations and the Social Security Health Interview surveys, both initiated in 1964, soon after the introduction of the sickness insurance scheme covering the whole population of Finland. In addition to the general goals of a health survey, a special aim was to compare data on chronic diseases and need for care independently obtained by a health interview and a health examination.

The Sample

A two-stage cluster sample of 8,000 people aged 30 years and over in 40 study areas (clusters) was designed, and a list of eligible individuals with contact information was drawn from the national population register. The sampling frame comprised the whole population, i.e., also institutionalized people.

The Concept of Health

Health was conceptualized as a perceived, biological, and social phenomenon. Special emphasis was placed to the measurement of functional capacity, its limitations, handicaps, and disabilities. Work ability and functioning were concepts used to measure the state of "health" independently of the presence or absence of diseases.

The Phases of the Field Work

The main phases of the field survey were the health interview; the health examination, comprising a two phase field work; and a third phase, the in-depth examination in the SII rehabilitation research center.

The Health Interview and the Examination

First, nurses (626 nurses over the whole country) carried out a structured health interview in the persons' home (or institution), and 7,703 persons (96% of the sample) participated. Within 1–6 weeks of the interview, all individuals in the sample were invited by letter to the Mobile Clinic Unit's health examination. The unit was situated centrally in the study area. In the initial screening phase, 7,217 individuals (90% of the sample) were interviewed and examined. A few months later, on the basis of findings in the screening phase and health-related data drawn from the SII's registers, those that might suffer from one of the core chronic diseases were asked to come to the clinical phase, 5,819 individuals (73%) attended the clinical phase and 4,840 (61%) were subjected to a doctor's structured history and examination, which as indicated by the screening phase findings concentrated on the cardiovascular and respiratory system, on the musculoskeletal system, or on all of them.

Non-attendants were approached by a mail questionnaire after the field study proper. Therefore, some health data are available on 98% of the whole sample.

Health-Related Content of the Health Interview

Perceived health, chronic disease or defect, care received, illness-induced change of occupation or duties, handicap caused by illness or defect in the present work, functional limitations (ADL and IADL), sickness days, psychological symptoms, perceived need of care or help for psychological symptoms and visits to a psychiatrist or a psychologist, use of medical care, prescription medicines (name and classification according to the main indication) currently used, dental care, preventive health examinations, smoking, and dietary habits.

Methods of the Health Examination

The health data were obtained by questionnaires, symptom interviews, tests of functioning, and clinical measurements. In the screening phase, the order of the measurements was the following: (1) height, weight, and BMI; (2) interviews on symptoms; (3) a urine sample; (4) blood pressure (mercury sphygmomanometer) and heart rate; and (5) ECG and respiratory tests by a Vitalograph spirometer. Other tests and measurements were carried out in varying order. They comprised supplementary interviews, a joint function test, a dental examination, a chest X-ray, and a blood sample. Finally, psychometric group tests were carried out and reaction time was measured. The screening phase comprised, i.e., questions on psychological symptoms and the general health questionnaire (GHQ-36). The clinical examination for mental health problems consisted of a present state examination interview (short version) carried out by one trained psychiatric nurse. Half of these interviews were carried out during the screening phase and half during the clinical phase. In the clinical phase proper, to assess reliability/repeatability, all screening measurements were repeated on a 20% randomly drawn subsample of the subjects, and a clinical doctor's examination directed according to the earlier findings was carried out. The examining doctor recorded also any other concurrent diagnoses and assessed each examinee's work and functional ability, disabling diseases and need for care. Current good diagnostic and therapeutic practice was used as a yardstick when assessing the need for care and unmet need for care.

Finally, 991 persons were examined in depth for workability and rehabilitation needs in the SII Rehabilitation Research Centre.

Information Obtained by Questionnaires and Interviews During the Health Examination

Perceived health, chronic disease, diseases diagnosed by a doctor (a disease list of 32 diseases) and follow-up questions for each disease mentioned (hospital care ever, medicine use ever, current care by a medical doctor, current use of medicines), hospital care, surgical operations, care by a medical doctor, prescription medicines (name and classification according to indication), nonprescription medicines, work ability and work disability, ability to participate and perform tasks and duties outside gainful employment, as well as in leisure time activities. There were also a set of questions on the ability to perform IADL and ADL activities. The final part comprised questions on physical activity such as physical strenuousness of work, leisure time physical activity comprising also details of regular exercise, and physical activity on the way to and from work. The last part of the main questionnaire of the health examination inquired about work and working conditions. A set of questions were specially constructed to describe leisure time activities and hobbies, and the final questions inquired about alcohol use in a way to allow quantification of the amount of absolute alcohol consumed on average during a week over the past month.

Record Linkage at the Time of the Field Work and Follow-up of the Cohort

By record linkage, after the field survey, further data were obtained from national registers on use of services, diseases, and disabilities. Final diagnostic assessments were made by combining all available information. As a result, diagnostic and other clinical data are available on 5,292 people invited to come to the doctor's examination. These are all of the individuals meeting the criteria screening positivity for the clinical phase and equal 66% of the sample.

Record linkage was used also for a follow-up of the sample, which today is complete until year 2009.

Biobank and Data Set

Frozen serum and plasma are stored by the National Institute for Health and Welfare (THL), and samples are being used for prospective studies to assess the impact of many biochemically determined risk and protective factors on mortality and risk of chronic diseases.

The large data set has been fully characterized and described, and upon proper agreement, the data can be and have been used extensively for collaborative research by THL and outside scientists.

Social Circumstances, Living Conditions, and Behavior

The readership may be especially interested in some of the available data on social circumstances and living conditions as well as methods used for measuring health-related behavior.

The usual information on family/household is available such as data on the number of family members, their age distribution, the subject's marital status, the family head's occupation (current or latest previous) and his/her receipt of any pension benefit, the subject's educational attainment, the community (municipality) in which the subject has lived longest, the subject's receipt of a pension, and total family income.

The subject's main occupation and employer, working hours, possible unemployment or layoff, the salary basis (e.g., hourly or monthly payment, paid by the piece), and comparable information related to job and employment.

Furthermore, information such as the distance to the nearest public health center doctor, to the nearest private doctor, and to the nearest dentist was gathered.

Current Context of the Mini-Finland Health Survey

The Mini-Finland health survey was originally designed as a single-handed cross-sectional and epidemiological follow-up study. However, it is now part of a unique set of nationally representative cross-sectional and individual level follow-up studies based on the same concept and with the same or similar health interview and health examination data. I refer to the Health 2000 national survey (Aromaa & Koskinen, 2004) and the ongoing Health 2011 national survey. The data gathered on these studies are even richer, and in addition to serum and plasma samples, the biobank now also contains DNA and RNA samples. After complete sequencing of the genome has become possible, the genetic information on the Health 2000 subjects has been extensively used to identify genes increasing the risk of the major public health problems, and corresponding effects on and interactions with social determinants, living conditions, and biological risk and protective factors of chronic diseases.

Mini-Mental State Examination

Jane Upton
School of Sport and Exercise Sciences, University of Birmingham, Edgbaston, Birmingham, UK

Definition

This is a practical method for grading the cognitive state of patients for the clinician (Folstein & McHugh, 1975).

Description

The mini-mental state examination was developed in 1975 (Folstein & McHugh, 1975) and has since been widely used in clinical and research settings. It is most commonly used by clinicians in a medical setting to assess for dementia, where it is administered serially to assess the effect of time on the progression of dementia. It is a 30-item screening tool which takes approximately 10 min to complete by a trained administrator. Severe cognitive impairment is indicated by a score of ($\leq$9 points) moderate (10–20 points) and mild (21–24 points). A score of 25 and over indicates normal cognition.

It includes the following tasks of cognition:

- Orientation to time and place
- Registration: The ability to learn the names of three objects

- Attention and calculation: The performance of serial 7's, or spelling "world" backward
- Recall: Remembering the three objects that they had learned in the registration task
- Language: Naming a pencil and watch, repeating a sentence, following a three-stage commend, reading and obeying a command, and writing a sentence
- Basic motor skills: Copying a design of two intersecting pentagons

Psychometric Properties

Reliability was investigated by Molley and colleagues, who reported an intraclass correlation for the mini-mental state examination of 0.69 (Molloy, Alemayehu, & Roberts, 1991). The inter-rater agreement, particularly for the attention and calculation task, has been reported as being poor (Davey & Jamieson, 2004). This examination has been found to be responsive to change (Uhlmann, Larson, & Buchner, 1987).

Synonyms

Health disparities; Multicultural health

Definition

Minority health refers to the special medical, psychosocial, and/or health needs of minority groups, including addressing the amelioration and prevention of health disparities. Health disparities refer to inequalities in the overall rate of disease prevalence, incidence, morbidity, mortality, or survival rates among certain groups of people when compared to the general population, as well as differences in the quality, outcomes, cost, or use of and access to health-care services (Minority Health and Health Disparities Research and Education

Act, 2000). Although primarily associated with health issues among ethnic and racial minorities, minority health also addresses the medical, psychosocial, and/or health needs of people with disabilities and minorities on the basis of age, socioeconomic inequality, and sexual orientation. Thus, any sociodemographic variable could lead to a minority health concern.

Description

Historical Background of Minority Health in the United States

As early as the beginning of the 1900s, intellectual leaders and activists such as W.E.B. Du Bois and Booker T. Washington documented the effect of contextual factors (i.e., economic poverty, inferior education, segregation and racism) on the health and quality of life of minority groups, particularly African Americans (Thomas, Benjamin, Almario, & Lathan, 2006). In 1915, Washington launched a comprehensive public health education campaign, the Negro Health Improvement Week, to promote health education among segregated Blacks and to increase awareness of existing health disparities. Later, the campaign evolved into the National Negro Health Movement, one of the most effective movements to promote direct and indirect cooperation between government organizations and members of a minority group for the betterment of minority health. An important legacy of the National Negro Health Movement was that the Black community became among the most active American groups in the national and worldwide movement for minority health improvement.

During the 1960s and inspired by the civil rights movement, other ethnic minority groups also became increasingly involved in advocacy efforts aimed at community health improvement. A notable example was that of Latinos and the development of organizations such as the National Organization for Mexican American Services (NOMAS) and the Southwest Council of La Raza (SWCLR), which later became the National Council of La Raza (National Council of La Raza [NCLR], 2011). These organizations aimed to increase representation of the Latino perspective at the local and national level on issues of health, education, immigration, housing, employment, training, and civil rights enforcement. Nevertheless, despite these early efforts, it was not until two decades later that minority health issues made it onto the national agenda.

In 1985, Margaret Heckler, Secretary of the US Department of Health and Human Services, released the Federal Report of the Secretary's Task Force on Black and Minority Health (Department of Health & Human Services [DHHS], 1985) to introduce minority health onto the national agenda. This report provided the first comprehensive national minority health study published by a government department to document widespread and persistent disparities in health status between various ethnic/racial minorities (i.e., African Americans, Hispanics, Native Americans, Asians and/or Alaskan Natives) and Whites. Additionally, Heckler's report provided several primary recommendations to address for the improvement of minority health. These recommendations were to (1) implement the dissemination of health education through community outreach; (2) develop culture- and context-sensitive health education programs and interventions; (3) improve access, delivery, and financing of health services to minority populations; (4) promote communication, coordination, and collaboration among federal and local agencies in administering programs addressing minority health issues; (5) improve the quality, availability, and use of health data pertaining to minority populations; and (6) increase and support research to inform the improvement of minority health. Given their relevance, the aforementioned recommendations continue to be at the forefront of the research and practice of minority health issues even to this date.

To manage the implementation of recommendations set forth by Heckler's report, the DHHS created the federal Office of Minority Health (OMH) in 1986 (OMH, 2011). Two years later, and also in response to the same report, the Centers for Disease Control and Prevention (CDC) established its own Office of the Associate Director for Minority Health (ADMH), which later became the CDC's Office of Minority Health

(OMH) in 2002 and most recently the Office of Minority Health and Health Disparities (OMHD) (CDC, 2011). Unique to the OMHD is its expanded focus on addressing minority health issues for populations defined not only by race/ethnicity but also by socioeconomic, age, disability, and risk status related to sex and gender. Also, acknowledging the importance of research as essential to the advancement of minority health, the National Institutes of Health (NIH) established the Office of Research on Minority Health in 1990. In 2000, the Minority Health and Health Disparities Research and Education Act signed by President Bill Clinton elevated the NIH Office of Research on Minority Health to become the National Institute on Minority Health and Health Disparities (NIMHD, 2011). Since its establishment, the NIMHD has focused on emphasizing the need for and improvement of the visibility of basic, clinical, social, and behavioral research focusing on minority health issues and health disparities, as well as promoting research infrastructure and training of highly qualified minority scientists.

Important national and state initiatives exist that aim at health promotion and disease prevention and management among minority groups. For three decades, Healthy People, the nation's health agenda, has set a target for reaching health objectives for minority populations. In Healthy People 2000, the focus was on reducing health disparities, while Healthy People 2010 aimed to eliminate health inequality. Expanding on the goals of these two previous agendas, Healthy People 2020 aims at improving the health of all groups, thus extending its focus to address minority health beyond racial/ethnic groups to the inclusion of people with disabilities and minorities on the basis of age, socio-economic inequality, and sexual orientation. Expanding minority health to focus on vulnerable populations at risk beyond ethnic/racial groups is a more appropriate way to represent the needs and changing demographic profile of the US population.

Behavioral Medicine and Minority Health

The United States is undergoing fundamental changes in its minority populations that will challenge the current health-care system and the field of behavioral medicine (Institute for the Future, 2003; Yali & Revenson, 2004). Continuing with current trends, there will be an increase in older populations, as well as growth in the number of people varying in sexual orientation. Likewise, the prevalence of certain ethnic/racial minorities will also increase. It is estimated that by 2050, non-Hispanic Whites will make up less than half of the US population (46.3%), with minority and immigrant groups becoming a majority. Of all ethnic/racial minorities, Hispanics or Latinos are expected to experience the largest population growth, from 16% today to 30% by 2050 (US Census Bureau, 2010). As these population changes take place, the need for culture-sensitive and contextual approaches to the research and practice of minority health will be increasingly necessary. Given its interdisciplinary approach and biopsychosocial perspective, behavioral medicine provides an appropriate platform for the conceptualization, assessment, treatment, research, and policy development of minority health issues as defined by changing demographics in the USA. In developing an understanding of the effect of cultural and contextual determinants of health and illness to the prevention, promotion, etiology, diagnosis, treatment, and rehabilitation of minority health, behavioral medicine can efficiently and effectively address even the most complex issues pertaining to minority health.

Minority Subgroups

Orit Birnbaum-Weitzman
Department of Psychology, University of Miami, Miami, FL, USA

Synonyms

Ethnicity subgroups; Subethnic groups; Subgroup heterogeneity

Definition

Minority subgroups refer to the within-group variation that is notably manifested among individuals from the same ethnic and racial group according to one or more sociodemographic factors including but not limited to nationality, language, religion, gender, social/immigration histories, educational level, and socioeconomic status.

Description

All racial/ethnic minority populations, including persons of Hispanic/Latino, African/Black, and Asian descent in the United States, are characterized by considerable diversity and can be further classified into minority subgroups. However, data on health aspects among minority groups have usually been combined in behavioral health analysis (For example see Whitfield, Weidner, Clark, and Anderson, 2002). To a large extent, the health-care system still fails to understand the complexity and diversity of immigrant and ethnic populations (Srinivasan and Guillermo, 2000). There is a need for greater specificity of racial and ethnic subgroups in behavioral medicine research (Feinleib, 1993). Studies that fail to disaggregate minority subgroups may be inaccurately reporting health research and overlooking health risks experienced by some immigrant groups (Srinivasan and Guillermo, 2000). Methodological difficulties typically arise in assessing the variables that are important in further classifying ethnic minorities into subgroups. However, by subsuming them under larger racial categories aggregating their data into one undifferentiated group, the health and health-care needs of specific minority subgroups are overlooked. Although scant, recent epidemiological studies are making an effort to collect additional data to characterize the heterogeneity of the standard racial/ethnic categories and provide data on subgroup differences. This trend will improve development of effective treatment interventions to address public health needs of ethnic minorities.

American ethnic subgroups vary substantially with respect to demographic and socioeconomic characteristics (see McCracken et al., 2007 for example in Asian Americans). There are extreme variations in income and rates of poverty among ethnic subgroups (Stone and MCQuillan, 2007; Srinivasan and Guillermo, 2000), and these variations can affect health. Minority subgroups also vary markedly in terms of religion, culture, and language. The social and political histories of minority subgroups and the variability within these subgroups have implications for the general health and mental health of this population (see

for example Williams, Nazroo, Kooner, and Steptoe, 2010). Time since immigration is directly related to language spoken at home and English-language fluency and is also a source of variability within minorities (McCracken et al., 2007). Ethnic subgroups that have lived longer in the United States are more likely to speak English better or speak only English at home. This suggests that certain minority subgroups face different barriers to medical care as a result of linguistic and cultural differences (McCracken, et al., 2007). Generational factors and the process of adjustment to living in the United States also have an impact on health and mental health.

Acculturation and adoption of westernized diets and behaviors can also contribute to explanations of health differences in minority subgroups. Within ethnic populations, minority subgroups show mixed profiles of health behaviors such as smoking, alcohol consumption, and levels of physical activity (Alegria et al., 2008; Williams et al., 2010). Additionally, samples from minorities living in the same geographical catchment areas suggest that despite little variation in environmental context, subgroup variations arise as a consequence of individual differences in religious and psychosocial experiences (Williams et al., 2010). Interreligious variation observed in some studies highlights the relevance of studying subgroup heterogeneity and indicates that a clear understanding and assessment of these concepts will increase the understanding of health differences between ethnic/racial groups (Williams et al., 2010). Furthermore, differential exposure to stressful experiences in particular discrimination stress can further explain inequalities in physical and mental health among minority subgroups and has been an important topic in minority research (Perez, Fortuna, and Alegria, 2008; Gee, Ro, Shariff-Marco, and Chae, 2009). Variations in perceived discrimination are related to sociodemographic and cultural differences across ethnic subgroups.

Hispanics/Latinos are the largest minority group in the United States, but they are not a homogeneous group. Hispanics are a diverse group in terms of nativity status, country of origin, racesocioeconomic status, and exposure to U.S. culture (Borrell and Crawford, 2009; Amaro and Zambrana, 2000). Recent findings suggests that nativity status, racial identification, and country of origin may have implications for Hispanics' mortality and morbidity outcomes (Borrell and Crawford, 2009). In contrast to the paradox of lower mortality rates for Hispanics as compared with non-Hispanics, disaggregated data suggest that the mortality advantage does not apply to all Hispanics (Borrell and Crawfors, 2009). Younger Hispanics, Puerto Rican men and women, Mexican American women, and those Hipanics who identify themselves as White exhibit higher death rates than non-Hispanic Whites (Borrell and Crawford, 2009). Health status varies within Hispanics according to nationality and can differ between Puerto Ricans, Mexicans, and Cubans living in the USA (Borrell and Crawford, 2008). The prevalence of hypertension among Hispanic Americans falls between that of Blacks and non-Hispanic Whites but appears to increase with the process of acculturation within Hispanics (Borrell and Crawford, 2008). In addition, the prevalence of hypertension and other cardiovascular risk factors increases with decreasing socioeconomic status within Hispanic/Latino subgroups. (Borrell and Crawford, 2008). Similarly, in contrast to the more commonly established belief that Latino populations are at lower risk of psychiatric disorders, when Latinos are disaggregated into ethnic subgroups and by nativity, a different picture of Latino mental health emerges, exhibiting a more limited application of the immigrant paradox (Alegria et al., 2008). Research shows that some Latino subgroups suffer from psychiatric disorders at rates comparable to non-Latino White individuals (Alegria et al., 2008).

Although there is a great quantity of detailed data available about the health of minorities, the need for greater specificity of minority subgroups is also evident in studies of African Americans and other Black populations in the United States. While an African American born and raised in the South, a Jamaican, a Haitian, a Kenyan, and an African American born and raised in the Northeast can all "Black", they are likely to differ in

terms of beliefs, behavior, and mental and physical functioning (Williams and Jackson, 2000). Such diversity within the Black population may predict important differences in terms of health status (Williams and Jackson, 2000). There have been few empirical studies of ethnic differences in health within the American Black population. One recent study used data from a national survey of the US Black population to examine the relationships among ethnicity, nativity, depressive symptoms, and physical health in the two largest ethnic groups of American Blacks, African Americans, and Caribbean Blacks (Griffith, Johnson, Zhang, Neighbors, and Jackson, 2011). Results showed that African Americans, US-born Caribbean Blacks, and Caribbean-born Blacks had significantly different self-ratings of their health and self-reports of being diagnosed with a chronic physical health condition: Caribbean-born Blacks had the best health outcomes, and US-born Caribbean Blacks had the worst (Griffith, et al., 2011). This data highlights the importance of considering the ethnic diversity, within the American Black population.

Asian Americans and Pacific Islanders are another major US racial/ethnic group, defined by the US Census Bureau as individuals with origins in the Far East, Southeast Asia, or the Indian subcontinent (see McCracken et al., 2007). Asian groups are not limited to nationalities and include ethnic terms as well, such as the "Hmong". Most incidence data and national level mortality data are available only for all Asian/Pacific Islander groups combined (McCracken et al., 2007). However, these populations are extraordinarily different with respect to country of origin, time since immigration, socioeconomic status, and other characteristics that affect health (McCracken et al., 2007). Chinese Americans are the largest Asian ethnic group in the United States and have one of the oldest immigration histories. The differences in cancer incidence and mortality among the Asian American ethnic subgroups illustrate the heterogeneity of this population (McCracken et al., 2007). In a recent review McCracken and colleagues (2007) showed that subgroups of Asian Americans have different type of cancers according to their immigration histories. For example, subgroups of Asian Americans with more recent immigration histories, such as Vietnamese and Koreans, have a higher burden of cancers not typically observed at high rates in westernized countries, such as stomach and liver cancer. In contrast, other groups with older immigration histories, such as Japanese and Filipinos, have a higher rate of cancers commonly observed in the United States such as colorectal and breast cancers (McCracken et al., 2007).

Missing Data

J. Rick Turner
Cardiovascular Safety, Quintiles, Durham, NC, USA

Synonyms

Missing values

Definition

The term "missing data" refers to data that are not present in a final data set. While the term can apply to one or more subjects' entire set of data that should be present, the more usual situation is where only part of one or more subjects' entire set of data is missing.

Various methodologies have been developed to address this issue. One common and straightforward approach is to delete such records from any analyses that involve variables for which the records have missing values. This is called the complete-subject analysis approach (Greenland & Rothman, 2008). It is a viable option whenever subjects with complete data have effectively been randomly sampled from all the subjects in the study, in which case the missing data are regarded as "missing completely at random."

However, this approach does have drawbacks. It can be very inefficient if many subjects have missing values, and particularly if many subjects have just a few missing data values each, since so many data points are effectively discarded (it discards all the data present in a subject's record, even if only one study variable in the record has a missing value). Therefore, many alternative approaches have been developed (Greenland & Rothman, 2008).

As Donders et al. (2006) observed, "Missing data are a common problem in all types of medical research." Simple methods of handling missing data include complete or available case analysis, the missing-indicator method, and overall mean imputation. Unfortunately, however, these approached lead to inefficient analyses and, more seriously, they often produce severely biased estimates of the association(s) being investigated (Donders et al. 2006). More sophisticated imputation techniques, such as multiple imputation, yield better results.

Missing data are also a problem for researchers employing structural equation modeling (SEM) techniques. Different approaches include full information maximum likelihood (FIML), listwise deletion, pairwise deletion, and similar response pattern imputation (Enders & Bandalos, 2001). These authors performed a Monte Carlo simulation examining the performance of these missing data methods and found that FIML estimation was superior across all conditions of the design.

Mode

J. Rick Turner
Cardiovascular Safety, Quintiles, Durham, NC, USA

Definition

The mode is a measure of central tendency. It is the most frequently occurring value in a data set.

Unlike the mean, which is extremely well suited as a measure of central tendency for continuous data, the mode is better suited to numeric data for which there are only a few unique values.

There may be more than one value of the mode for a data set, which happens when two or more values occur equally often. It is also possible for there to be no mode for a data set, which happens when each value is unique. These properties of the mode, i.e., that it may have multiple values in some instances and be undefined in others, are considerable drawbacks to its use.

Moderators/Moderating Factors

Pamela S. King
Pediatric Prevention Research Center, Department of Pediatrics, Wayne State University School of Medicine, Detroit, MI, USA

Definition

A moderator variable is a qualitative (e.g., gender, SES) or quantitative (e.g., amount of social

support) variable that affects the direction and/or strength of the relationship between an independent or predictor variable and a dependent or criterion variable. In research, in order to infer that a variable is a moderating variable, there must be a significant statistical interaction between the predictor and the moderator (i.e. $p < .05$).

Description

Conceptual Meaning

A moderator variable affects the relationship between a predictor variable (X) and an outcome variable (Y). Moderator variables commonly affect the strength of the relationship between X and Y. For example, social support is thought to function as a moderator of the relationship between stress and negative health outcomes: in the presence of low social support, there is a strong relationship between stress and negative health outcomes; in the presence of high social support, however, the association between stress and health is weak to nonexistent. In some cases, a moderator can affect the direction of association between X and Y (e.g., a positive association between X and Y at high levels of the moderator, and a negative association between X and Y at low levels of the moderator).

Statistical Approach

Researchers typically use regression analyses to detect a moderator effect. In this type of analysis, the moderator variable and the predictor variable (X) are both entered as predictors in the regression model (i.e., "main effects"). The interaction between the predictor and moderator (i.e., the product of the moderator and predictor variables) is also entered as a predictor in the regression model. Because of the way the interaction term is computed (moderator × predictor), the main effects for the predictor and moderator will be highly correlated with the interaction term, which could result in problems with the regression model due to multicollinearity. To prevent problems due to multicollinearity, it is recommended that the predictor and moderator variables be "centered" before calculating their interaction. Centering simply means that these variables are transformed by subtracting each variable by its sample mean (e.g., X−mean of X). If a moderator effect is present, the interaction term in the regression model will be significant ($p < .05$). In the presence of a significant interaction, main effects for the predictor and moderator are usually not interpreted.

In order to interpret statistically significant interactions, researchers usually plot regression lines (representing the association between X and Y) for high and low values of the moderator. This allows researchers to see how the association between X and Y is different for different levels of the moderator. After plotting the simple regression lines for high and low values of the moderator, researchers can test the significance of the slopes of the regression lines. In some cases, one slope might be significant, but the other might not, indicating a significant association between X and Y for one level of the moderator, but not for the other level of the moderator.

Distinction Between Moderator and Mediator Variables

It is important to note the distinction between the term moderator and the term mediator, as these two terms are often confused in the literature. Both moderators and mediators are "third variables" discussed in the context of the relationship between a predictor and an outcome. As discussed above, moderator variables are those that can affect the strength and/or direction of the relationship between X and Y (i.e., X × Moderator → Y). A mediator variable, on the other hand, is a mechanism; it explains how a predictor and an outcome are related. The relationship between the predictor, the mediator, and the outcome can be written as X → Mediator → Y. In other words, the predictor causes the mediator, which then causes Y (i.e., the mediator is in the middle of a causal chain linking the predictor to the outcome).

Monozygotic Twins

Jennifer Wessel
Public Health, School of Medicine, Indiana University, Indianapolis, IN, USA

Synonyms

Identical twins

Definition

Monozygotic (MZ) twins are pairs of individuals resulting from the fertilization of one egg (monozygote literally means one egg, or zygote). The zygote goes through several cell divisions, and the cells then separate into two groups, resulting in two separate embryos.

MZ twins have identical copies of all of their genes. Therefore, unlike dizygotic (DZ) twins who can be same-sex or opposite-sex pairs, all MZ twins are same-sex pairs. At young ages their epigenetic material is nearly identical, but as they age the different environmental influences they experience can change their epigenetic material. Phenotypes, e.g., physical and mental traits and disease states, can therefore differ between pairs of twins.

Mood

Maria Kleinstäuber
Department of Clinical Psychology and Psychotherapy, Johannes Gutenberg-University of Mainz, Mainz, Germany

Synonyms

Affective state; Feeling; Feeling state

Definition

In contrast to *emotion* mood is defined as a transient, low-intensity, nonspecific, and subtle affective state that often has no definite cause. Along with all the transient affective states of everyday life, mood also includes low-activation, low-energy states such as fatigue or serenity. Although the terms *mood* and *affect* are often used synonymously, affect is more of an umbrella term that includes both emotions and moods. Short-term and transient feelings are called mood states or affect states, whereas stable, long-term individual differences in the tendency to experience a certain mood state are defined as affective traits. Affective traits can be differentiated from *temperaments* in that they are broader, more general, dispositional constructs, which combine several affective traits and cognitive or behavioral characteristics. Furthermore, the concept of affective traits, in contrast to the concept of temperaments, does not include any implications regarding the origin of the trait.

Description

Affective experiences of everyday life are characterized by mixed mood states, rather than the experience of pure emotion. Mood states inform us continuously about our general state of being and, therefore, play an important role in human self-regulatory processes. Potentially important factors that are involved in intraindividual fluctuations in mood, or differences across individuals can be divided into four broad categories: affective traits and temperaments, exogenous factors (e.g., events, activities, ingestion of substances, physical aspects of environment), endogenous rhythmic patterns and sociocultural rhythms (e.g., circadian rhythms, mood changes across menstrual cycle or the seasons), as well as individual differences in characteristic variability of moods.

Moods and Biobehavioral System

Mood states should not be assumed to be isolated subjective experiences, but instead should be seen as an important component of a complex biobehavioral system that includes affective, cognitive, biological, and behavioral components. Theories focusing on the issue of causal primacy touch on the question of whether cognitions arise first and produce affective states, or whether affective states appear independently and can induce cognitive changes. These theories have so far turned out to be unproductive. Instead it has been proposed that the various components of the biobehavioral system are connected by complex feedback loops and work synchronously. Changes in one component, therefore, produce changes in all of the others. This assumption supports the behavioral medical conceptualization of health and illness, which integrates biological, behavioral as well as psychological issues in an interactive way. It also emphasizes the role of the affective component (including states of mood) on health status.

Measuring Mood

In affective research, mood is mostly assessed using self-ratings. Some rather contradictory assumptions exist about the dimensional structure of self-reported mood. Current evidence strongly supports the existence of two orthogonal dimensions: Positive Affect and Negative Affect.

This implies that knowledge of an individual's current level of negative mood says very little about their level of positive mood. Therefore, in appraising mood it is very important to assess both dimensions separately. Although most research on mood is based on self-ratings, a variety of concerns regarding this method exist, such as biases due to social desirability, expectancy effects, or the idiosyncratic interpretation of anchoring points of rating scales. Behavioral measures of mood are an alternative approach to self-ratings. A typical behavioral technique employs a consensually accepted manipulation of mood (e.g., autosuggestion techniques such as reading positive, negative or neutral self-referent statements) followed by a battery of behavioral measures (e.g., measures of psychomotor speed or activation). This method also has serious limitations, such as biases due to the motivation of participants to comply with the perceived expectations of the experimenter, or the problem of time-limited effects.

Impact of Mood

Moods can have an impact on a variety of cognitive and behavioral processes. Most of the past research has been on associations between mood and memory, judgmental and evaluative processes, and overt behavior. These associations also play an important role in conceptualizations of illness and health in behavioral medicine. Research on associations between mood and memory has identified various phenomena. *Mood-congruent encoding* implies that material is learned more thoroughly if the affective tone of that material is consistent with an individual's mood state. This is considered a robust phenomenon occurring with most mood states. *Mood-congruent retrieval* is defined as an increased recall of material that is of the same affective tone as the mood experienced during retrieval. This effect has been shown less frequently. *Mood-dependent memory* implies that an individual remembers material learned in a particular mood state better on occasions when the individual is in that same mood state. One of the most popular theories attempting to explain these phenomena is the *Associative Network Theory*. It postulates that memory is an associative network of nodes representing units such as concepts, schemata, events, and also affective states. Due to associative links that can form between these units, activation of a memory unit spreads to neighboring associated nodes. The effects mentioned are also relevant to behavioral medical approaches. A typical example is that of mood-congruent effects of depressive mood being associated with poorer memory for positive experiences and/or better memory for negative experiences, which in turn can maintain the vicious cycle of depressive syndrome. An enduring depressive mood can in turn be associated with complications in the healing processes of various diseases.

For explaining the impact of mood on judgments, the *Affect Infusion Model* (AIM; Forgas, 1995) can be applied. *Affect infusion* describes the process whereby affectively loaded information becomes involved in the judgmental process and biases the judgmental outcome. According to the AIM, the occurrence of affect infusion on judgment appears in dependence upon the use of different judgmental strategies, which in turn depend upon features of the target, the judge, and the situation. The model implies that more extensive processing strategies increase the impact of mood on judgment, as such strategies offer a greater scope for the incorporation of affectively loaded information. This association between mood and judgments has extremely important consequences for behavioral medical approaches, for the reason that mood has a major impact on people's perceptions of symptoms of illness, their health efficacy judgments, and their expectations of potential diseases they might have in the future. Individuals in a positive mood seem to judge their health more favorably than individuals in a negative mood. Furthermore, it has been demonstrated that negative mood is associated with negative judgments about symptoms, symptom severity, or health status across

different illnesses (e.g., asthma, Parkinson's disease, rheumatoid arthritis). In addition, negative mood seems to be associated with a lower detection threshold and a higher selective attention for physical symptoms.

Finally, research on the association between mood and behavior has demonstrated relatively consistent results for the mood-congruent effects of positive mood, with the exception that positive mood promotes positive behaviors – only if the behavior is not a threat to continuation of the positive mood. For negative moods the findings are much more contradictory. In behavioral medicine in particular, mood-effects on behavior play an important role concerning disease-preventive as well as disease-management behaviors. Typical examples are that individuals in a negative mood show insufficient asthma control behavior or that negatively tempered individuals with chronic heart failure fail to seek advice for relevant cardiac symptoms.

Mood and Health Status

In general, mood seems to be associated not only with the subjective perception of health status but also with objective aspects of health. For example, individuals with a chronic tendency to experience negative mood report higher levels of health problems, especially more psychophysiological disorders. Similar findings have been demonstrated for highly reactive persons (e.g., persons who quickly change the intensity of their moods). For cardiovascular disease in particular, enduring tendencies toward negative mood seem to be linked to the duration, development, and course of the disease. Enduring negative mood seems to contribute to pathophysiological processes in the complex network of bidirectional signals linking the nervous, endocrine, and immune systems. Thus, negative mood can have an impact on immune function and can indirectly produce a higher risk for infectious diseases. Affective research shows that not only negative mood, but also positive mood has an impact on health status and is associated with favorable health outcomes. It has been demonstrated that positive affect activates the neuroendocrine, autonomic, and immune systems. For example, cortisol level has been shown to be consistently lower in individuals with higher levels of positive mood, and beneficial effects of positive mood on cardiovascular function including blood pressure and heart rate have also been found. The impact of positive mood seems to be independent of the impact of negative mood; therefore, it is speculated that positive mood has its own specific biological correlates.

In conclusion, it is not surprising that mood can impact the healing processes of different diseases. Behavioral interventions focusing on improving mood in patients with chronic diseases, therefore, seem to play an important role in the treatment of medical problems. In patients with different chronic medical conditions (e.g., heart disease, diabetes mellitus, asthma, cancer, arthritis), behavioral therapeutic interventions (e.g., relaxation, biofeedback, graded exercise) have been found to have a positive effect on anxiety and depressive mood.

Mortality

G. David Batty
Department of Epidemiology and Public Health, University College London, London, UK

Synonyms

Case fatality; Death; Fatality; Vital status

Definition

Mortality is a measure of human longevity and, by proxy, health that is widely utilized by demographers, epidemiologists, actuaries, and economists. Mortality data typically describe the number of deaths by place and time. Many nations, particularly high-income countries, have a civil registration system of deaths, often accompanied by the underlying cause of death as coded on a death certificate by an attending physician. In accordance with the rules of the International Classification of Diseases (WHO), the underlying cause of death is defined as "the disease or injury which initiated the train of morbid events leading directly to death, or the circumstances of the accident or violence which produced the fatal injury."

Mortality Rates

G. David Batty
Department of Epidemiology and Public Health, University College London, London, UK

Synonyms

Death rate

Definition

A mortality rate is an estimate of the proportion of a population group dying during a specific period of time. Mortality rates can be based on how many people die of any cause ("total mortality"), or can be used to describe the death rate of a certain illness or condition, such as dementia or avian influenza.

Mortality rate is calculated as the number of people dying (numerator) derived by the number of people at risk of dying (denominator). The latter estimate is typically based on midyear population data.

In order to produce readily understandable results, the mortality rate – which is typically calculated as a small fraction – is often multiplied up by expressing it as deaths per 100 or 1,000 individuals. For instance, in a town of 10,000 residents, if 10 people die of a heart attack over a given period of time, the mortality rate due to this condition would be said to be 1 in 1,000 persons.

Motivational Interviewing

Demetria Cain
Center for Health Intervention and Prevention, University of Connecticut, Storrs, CT, USA

Definition

Motivational interviewing is a guided, client-centered style of counseling used to help clients explore and resolve ambivalence toward health behavior change. Based on the principles of motivational psychology, it is designed to produce rapid, internally motivated change by mobilizing the client's own change resources. Motivational interviewing is not defined by a technique, but by its spirit as an interpersonal style for facilitating change (Miller & Rollnick, 1991; Rollnick & Miller, 1995).

Description

Motivational interviewing developed from William R. Miller's research on studying behavioral self-control training as a treatment for alcohol addiction. In his early research, Miller noted that a non-confrontational treatment approach lowered drinking levels among alcoholics compared to a therapist outpatient treatment approach (Miller, 1978). Motivational interviewing formed from the notion that counseling can have a huge effect on behavior change when it emphasizes personal responsibility and supports cognitive dissonance in clients who experience ongoing health behavior problems but exhibit awareness for the behavior's negative consequences.

Stemming from these initial concepts, Miller and Rollnick (1991) further elaborated on the fundamental concepts and approaches for this style of counseling in a clinical procedure description. The five basic principles of motivational interviewing are *expressing empathy*, *developing discrepancy*, *avoiding argumentation*, *rolling with resistance*, and *supporting self-efficacy*. In expressing empathy, the therapist seeks to communicate great respect for the client. The therapist's role is a blend of supportive confidant and knowledgeable consultant. The client's freedom of choice and self-direction is supported and respected. Persuasion is given in gentle, subtle ways with the assumption that behavior change is up to the client. In developing discrepancies, motivational interviewing seeks to focus the client's awareness toward discrepancies in their behavior. When people perceive a discrepancy between where they are and where they want to be, they become motivated to change. When the therapist avoids argumentation, they employ strategies to assist the client in accurately seeing the consequences of their behavior. Direct confrontation of behavior can produce resistance. Instead, the therapist passively guides the client to voice their own arguments for change. In rolling with resistance, the therapist views ambivalence toward change as normal, and resistance is explored openly. Instead of challenging a client's resistance, the therapist moves with it, but with the goal of shifting the client's perceptions in the process. Self-efficacy is the belief that one can perform a particular behavior or accomplish a particular task and is a critical determinant of behavior change (Bandura, 1982). Through the therapist's support, the client must be confident that behavior change is possible.

Motivation interviewing was used as the style of counseling in Motivational Enhancement Therapy and tested in the National Institute on Alcohol Abuse and Alcoholism's (NIAAA) multisite cooperative agreement called Project Match. In this clinical trial, patients with alcohol abuse and dependence were matched to different treatment options based on their personal characteristics. Motivational Enhancement Therapy was shown as effective as a 12 Step Facilitation therapy and a Cognitive Behavioral Coping Skills Therapy for alcohol dependency treatment (Miller, Zweben, DiClemente, & Rychtarik, 1992).

Motivational interviewing's efficacy comes from its ability to help guide clients through a natural process of recovery. The Transtheoretical Model of Behavior Change (Prochaska & DiClemente, 1984) describes the stages of change clients move through as they progress in

modifying problem behaviors. The stages of change are precontemplation, contemplation, determination, action, maintenance, and relapse. In motivational interviewing, the therapist assists the client in moving from one stage to the next by addressing where they are and where they want to be.

Motivational interviewing has been synonymous with brief interventions because of terms like "brief motivational counseling," but they are distinctly different concepts (Holder, Longabaugh, Miller, & Rubonis, 1991). The six elements believed to be active ingredients to induce change in brief interventions are summarized in the acronym FRAMES and consist of giving FEEDBACK of personal risk or impairment, placing emphasis on personal RESPONSIBILITY for change, giving clear ADVICE to change, providing a MENU of alternative change options, expression of therapist EMPATHY, and facilitating client SELF-EFFICACY(Miller & Sanchez, 1994). Although the elements of FRAMES are analogous with motivational interviewing, it is important to distinguish the differences between the mechanisms that make brief interventions effective and the methods designed to encourage behavior change in motivational interviewing (Rollnick & Miller, 1995).

Techniques used by therapist in motivational interviewing are structured into the two phases: building motivation for change and strengthening commitment to change (Miller et al., 1993). While building motivation for change, the therapist helps the client make the decision to change by using open-ended questions to elicit self-motivational statements of problem perception, using reflective listening to demonstrate empathy, summarizing themes that need further emphasis, and affirming the client's challenges. While strengthening commitment to change, the therapist helps the client move from contemplation to action by recognizing the client's readiness for change, discussing a potential plan of action, communicating free choice, and discussing consequences of action or inaction.

Although motivational interviewing was formed out of alcohol treatment research, it has moved into other realms of health behavior change research. Motivational interviewing has shown promise in behavior change related to HIV risk behavior, substance abuse, smoking cessation, physical activity, diabetes self-care, and many others.

Those interested in learning more about motivational interviewing can seek information on this style of counseling from resources developed for clinicians, researchers, and trainers. Through the Motivational Interviewing Network of Trainers (MINT), there are opportunities to learn motivational interviewing through one of many training courses.

Pedro C. Castellon
Epidemiology and Public Health, Miller School of Medicine, University of Miami, Miami, FL, USA

Synonyms

Masters of public health; MPH; Public health education

Definition

The need for dedicated health professionals to focus on the health of the population led to the creation of a new career and formal training and education in public health. By the end of the nineteenth century, there were several schools of medicine and nursing to train future medical professionals, but there were no formal training programs for the field of public health. In an effort to establish education for a separate public health career, the Rockefeller Foundation provided funding to create the first endowed school of public health at the Johns Hopkins University in 1918. At that time the career and formal education for public health was created for individuals to dedicate their career to controlling infectious diseases, improving sanitation, assuring the safety of food and water, and providing immunizations (Gebbie, Rosenstock, & Hernandez, 2003).

Since the creation of formal education for public health, both schools and programs of public health have awarded the Masters of Public Health (M.P.H.) degree and other public health-related degrees and certificates (Gebbie et al., 2003). Presently (4/21/2011) there are 44 accredited schools and 79 accredited programs of public health in the United States. There are also two accredited schools and four accredited programs of public health outside the United States (Council on Education for Public Health, 2011). In general, the curriculum for the M.P.H. degree and other similar degrees consists of courses in epidemiology, environmental health, health services and administration, biostatistics, and social and behavioral sciences.

This coursework provides the appropriate training and education for public health professionals to establish careers in both the private and public sectors. Those working in private sectors typically work as researchers within an academic institution or a pharmaceutical company, while those working in the public sector work as nutritionists, epidemiologists, food safety inspectors, health educators, and policy analysts in local, state, or federal health departments. Public health professionals continue to control infectious diseases, provide immunizations, and assure the safety of food and water, but today they also confrontcomplex health issues such as obesity and cancer, improving access to health care, and reducing environmental hazards (WhatisPublicHealth.?, n.d.).

Multidimensional Health Locus of Control Scales

Kenneth Wallston
School of Nursing, Vanderbilt University, Nashville, TN, USA

Synonyms

Measures of perceived control of health

Definition

Health locus of control beliefs indicates whether individuals believe their health status is under their own control (termed an internal health locus of control orientation) or is under the control of forces external to themselves, such as other people, fate, luck, chance, or "a higher power."

Description

Multidimensional Health Locus of Control Scales

Internal-external locus of control (LOC) of reinforcement is a generalized expectancy construct consistent with Julian Rotter's social learning theory (Rotter, 1954). Rotter (1966) developed the I-E Scale as a means of assessing individuals' dispositional beliefs as to whether their reinforcements (or valued outcomes) were due to their own behavior or enduring characteristics (an internal LOC orientation) or to external factors such as other people, fate, luck, or chance. Ten years later, Barbara Strudler Wallston, Ken Wallston, and two of their students published a health-related version of the I-E Scale termed the Health Locus of Control (HLC) scale (Wallston, Wallston, Kaplan, & Maides, 1976). Like the I-E Scale, the HLC scale was unidimensional; high scores were termed "health externals," and low scorers were designated "health internals." The HLC scale proved to be very popular; even before publication, health researchers started using it in hopes that HLC scores would be related to measures of health behavior and health status. Soon thereafter, however, the Wallstons recognized that the HLC scale was not unidimensional, with internality on one end of the dimension and externality on the other end, but consisted of two orthogonal dimensions; some people could (and did) simultaneously endorse internal *and* external causes of their health status, while others disagreed with either type of HLC orientation.

With the help of a grant from the National Center for Health Services Research, they set

about developing the Multidimensional Health Locus of Control (MHLC) Scales modeled after Levenson's (1973) I, P, and C scales, a three-dimensional alternative to the unidimensional I-E Scale. They developed two equivalent 18-item forms (A and B) of the MHLC scale (Wallston, Wallston, & DeVellis, 1978). Each form (A or B) contains three, more-or-less orthogonal, 6-item subscales. The IHLC subscale assesses the extent to which people believe their health status is due to their own actions. The PHLC subscale assesses the belief that one's health status is due to the actions of "powerful other" individuals, e.g., health-care professionals, family members, or friends. The belief that nobody or nothing controls a person's health status, and that it is all a matter of fate, luck or chance, is assessed by the CHLC subscale. The early research with Forms A and B was reviewed by B. S. Wallston and K. A. Wallston (1981), and recognizing that designating people as internal or external was too simplistic, an 8-cell MHLC typology was proposed by K. A. Wallston and B. S. Wallston (1982). Although some research has been done using the multidimensional, 8-cell typology, it is much more typical to treat the MHLC scores as continuous rather than categorical.

Forms A and B of the MHLC scales assess LOC orientation toward one's health status in general. Many investigators, however, administered those initial forms of the MHLC to patients with specific medical diagnoses. In those instances, when trying to interpret responses to the MHLC items, investigators had no way of knowing whether the patients were responding with their beliefs about their health in general or their beliefs regarding control of one or more of their medical conditions. This ambiguity led many researchers to modify the MHLC scales in an attempt to make the instrument fit their own purposes. This was all well and good, but each of these modifications used different item stems, and there was little comparability among these modified instruments. K. Wallston, therefore, developed and published Form C of the MHLC scales as a generic instrument that could be easily modified into a condition-specific measure of locus of control beliefs by substituting for the word "condition" in each of the item stems (Wallston, Stein, & Smith, 1994). For example, if studying patients with diabetes, Form C can be used as a multidimensional diabetes locus of control scale. Form C has 6-item subscales for the Internal and Chance dimensions, but the Powerful Other dimension is split into two, 3-item subscales: Doctors and Other People. In the ensuing years, Form C is the instrument of choice for researchers wishing to ascertain control beliefs of patient samples. Those who wish to study healthy samples continue to administer either Form A or B. Also, it is not necessary to administer all of the subscales of the MHLC. If an investigator is only interested in knowing whether a group of respondents believe their health (or health condition) is determined by their own actions, it is perfectly OK just to administer the IHLC subscale.

When the Wallstons developed the initial MHLC scales, they attempted to make the two external dimensions, PHLC and CHLC, as uncorrelated as possible. While Levenson's P and C scales correlated >0.6, PHLC and CHLC usually correlated ≤ 0.3. In accomplishing this, all of the items in the original item pool that mentioned God (or a higher power) as the cause of a person's health status were eliminated, because those items correlated too highly with the other external dimensions. Many years later, K. Wallston received feedback from researchers in "bible belt" states that the MHLC items did not "speak to them," because, in their opinion, God was the entity most responsible for changes in their own health or medical condition. Responding to that feedback, K. Wallston and colleagues developed and published the 6-item God Locus of Health Control (GLHC) scale that could be used as a stand-alone instrument or as another external subscale of the MHLC (Wallston et al., 1999). The GLHC can be administered in either a general health version (similar to Forms A and B) or a condition-specific version (like Form C). As with the other external subscales, the GLHC is uncorrelated with internal HLC, but, depending on the respondents' view of God, GLHC scores correlate positively with one or another of the "traditional" external subscales.

All of the MHLC scales are "in the public domain," which means that they can be used freely by health researchers as long as there is no charge for their administration. They can be downloaded from the MHLC website http://www.vanderbilt.edu/nursing/kwallston/mhlcscales.htm where there are scoring instructions and answers to frequently asked questions (FAQs). The MHLC scales were developed to be used in research, but that has not stopped clinicians from administering the MHLC to individual patients in an attempt to gain insight into patients' health beliefs and to use that information to individualize patient care. The Veterans Administration administers both Form A and Form B as part of a battery of tests to prospective candidates for bariatric surgery. To date, there have been no published reports evaluating the use of the MHLC scales to identify good surgical candidates or their use in routine clinical practice, but there are hundreds of publications in refereed journals that report on the use of the measures, and they have been used in innumerable theses and dissertations. The MHLC scales have also been translated into a number of foreign languages, as well as American Sign Language (Athale et al., 2010).

About 7 years ago, K. Wallston guest edited a special issue of the *Journal of Health Psychology* devoted to research with the MHLC scales. This issue included a critical look at the construct of health locus of control (Luszczynska & Schwarzer, 2005), an overview of the validity of the various MHLC scales (Wallston, 2005), and numerous empirically based articles demonstrating the breadth and creativity of the research that has been done with these measures. Many of the articles in the special issue examined interactions among MHLC subscale scores or interactions between MHLC subscale scores and other constructs as predictors of health behavior or health outcomes. Such analyses were congruent with modified social learning theory (Wallston, 1992), although none directly tested the three-way interaction between internal health locus of control, health value, and self-efficacy beliefs.

High scores on the IHLC, PHLC, and GLHC subscales are all indicative of a belief that health (or health conditions) can be controlled, regardless of whether that control is exercised by one's self (IHLC); powerful other people, such as one's doctors (PHLC); or by God (GLHC). High scores on the chance health locus of control subscale (CHLC) indicate an expectancy that only random occurrences, such as fate luck or chance, control health outcomes. Most research has shown that, in the absence of high scores on the IHLC subscale, scoring high on CHLC is a moderately strong predictor of psychological distress and depressive affect. Recently, K. Wallston reported on a set of analyses from a 10-year longitudinal study of patients with rheumatoid arthritis where it turned out that, controlling for baseline IHLC and PHLC beliefs, higher baseline scores on CHLC not only predicted depressive symptoms at T1 but also predicted an increase in depressive symptoms over the subsequent 10-year period (Wallston, 2011). Baseline scores on neither IHLC nor PHLC predicted change in depression or any other variable in the dataset over that relatively long time.

The MHLC scales have been used by health researchers to assess control beliefs related to health for over 30 years. While research with the MHLC scales has slowed down somewhat in the twenty-first century, interest in the construct and its measurement remains high.

Multiethnic Cohort Study

Yori Gidron
Faculty of Medicine and Pharmacy, Free University of Brussels (VUB), Jette, Belgium

Definition

The Multiethnic Cohort (MEC) Study was a prospective study which included people from Hawaii and California. It recruited people from the main cultural groups residing there – Native Hawaiians, African Americans, Latinos, Japanese Americans, and whites. In such MEC studies, researchers sample subgroups of people belonging to one of several preselected cultural groups. These groups were expected to have a different prevalence of a given disease, and the study aimed to investigate which risk factors accounted for such differences. The MEC study included over 215,000 men and women. Generally speaking, by running the study prospectively and simultaneously for all ethnic subgroups, effects of "historical events" (e.g., development of a new treatment for a disease, a known public figure develops an illness) occur for all participants at the same time. Furthermore, by conducting the study prospectively, researchers used similar assessment tools and controlled for the identical confounders, across ethnic groups. This resulted with more methodological rigor and thus greater inferential validity in the results.

Numerous studies emerged from the MEC study, in relation to several health outcomes. Initially planned to examine ethnic differences in cancer, this research found that Native Hawaiians have 65% higher risk of breast cancer than white Americans. One explanation for this excess, which was partly confirmed, was that Native Hawaiians have more frequent polymorphisms in sex steroid pathways (Pike et al., 2002). Another study compared the rates of mortality from myocardial infarction and other cardiac reasons, between those ethnic groups. Native Hawaiians and African Americans had highest death rates, which were mostly explained by their higher prevalence of diabetes and hypertension (Henderson et al., 2007). Such studies enable health policymakers and public health professionals to target specific risk factors in specific ethnic groups, to prevent such outcomes. Furthermore, MEC studies can shed light on "nature-nurture" interactions, where environmental factors (e.g., smoking, diet, psychosocial stressors) and ethnicity (proxy measure of genetic risk) or actual genetic polymorphism may interact in relation to onset of diseases.

Multilevel Intervention

Yori Gidron
Faculty of Medicine and Pharmacy,
Free University of Brussels (VUB), Jette,
Belgium

Definition

This term can refer to two concepts. First, a multilevel intervention (MLI) refers to addressing various risk factors in one intervention, either at the prevention stage or at the treatment stage of an illness. Additionally, an MLI refers to an intervention which involves several levels of people or entities such as individual patients, groups, and communities. Both definitions reflect that illnesses and health are a multifactorial problem, requiring either to modify several risk factors or to involve several levels in one's social and health context. In coronary heart disease (CHD) prevention, the Minnesota Heart Health Project (MHHP) combined both meanings of the MLI concept. First, they aimed to conduct a lifestyle behavior change program, targeting diet, physical activity, smoking, and alcohol. Second, this was achieved by involving individuals, community leaders, teachers, physicians, the media, classes, and schools. Thus, they addressed the multiple risk factor aspect of MLI as well as various levels of intervention units, the social-organizational aspect the MLI. Mittelmark et al. (1986) revealed the implementation of the MLI, in which they conducted the MLI on three towns/cities, and compared that to matched towns/cities, over time. However, follow-up studies found modest effects of the MHHP, mainly due to control communities possibly also receiving health education and due to overall increases in certain risk factors such as obesity overtime. Another MLI is the Ornish lifestyle change program, where CHD patients learned to alter their diet, physical activity, smoking, and stress responses. Compared to controls, the MLI-treated group showed regression in atherosclerosis (Ornish et al., 1990). Other types of public health hazards such as traffic accidents could indeed benefit from an MLI approach, where students, teachers, universities, community leaders, safety authorities, schools, and communities can be involved in risk-factor modification. Thus, an MLI approach is suitable for problems involving multiple risk factors or multiple social contexts.

Synonyms

Hierarchical linear modeling (HLM); Mixed-effects modeling; Random-coefficient regression modeling; Random-effects modeling

Definition

Multilevel modeling is a data analysis technique used to analyze nested data. Nested data refers to data wherein units of analysis at one level are nested within units of analysis at higher levels. Multilevel data are observed in cross-sectional designs which sample individuals nested within groups. An example of this type of multilevel data is patients (level 1) nested within hospitals (level 2). Multilevel data are also found in repeated measures designs (e.g., multiwave longitudinal or experience sampling designs) which sample repeated reports nested within individuals. An example of this type of multilevel data is an experience sampling study where repeated reports of pain (level 1) are nested within individuals (level 2). In multilevel modeling, *level* thus refers to the structure of the data. The lower level (level 1) represents the most detailed unit of analysis and has the greatest number of data points. Level 2 represents the higher level within which level 1 observations are nested.

Description

Why Is Multilevel Modeling Necessary?

Multilevel modeling is necessary because nested data structures violate the assumption of independence required by traditional, single-level data analysis techniques such as analysis of variance and ordinary least squares multiple regression. That is, in nested data, observations at the lower level (level 1) are not independent. For example, individuals (level 1) sampled from the same neighborhood (level 2) may be more similar than individuals sampled from a different neighborhood. Single-level data analysis techniques often fail to take into account such a nested data structure and either ignore the nested data structure (violating the assumption of independence) or collapse across the levels of the nested data structure (ignoring potentially meaningful variability in the data). Violating the assumption of independence may result in underestimation of standard errors and inflation of type I error rates.

In contrast, multilevel modeling allows for data to be analyzed at one level while accounting for variance at other levels. Maximum likelihood algorithms are typically used in multilevel analyses, which allow for simultaneous estimation of multiple error terms. As a result, standard errors are more accurate, and type I error rates are not inflated. In addition, multilevel modeling enables unique types of analyses. Multilevel analyses are similar to single-level regression analyses, where intercepts and slopes are calculated. However, unlike single-level regression analyses, multilevel modeling permits cross-level analyses, wherein a level 2 predictor is used to predict a level 1 outcome. For example, an investigator may test if the neighborhood people live in (level 2) predicts their obesity (level 1). Although such computations are complex, there are many software programs which perform multilevel modeling, including HLM, LISREL, MLwiN, MPlus, R, SAS, SPSS, and Stata.

Considerations When Using Multilevel Modeling

Power. Although sample sizes at both levels warrant consideration, in general, sample size at the higher level has a greater influence on power than sample size at the lower level. For example, in experience sampling studies, the number of participants (level 2) has a greater influence on power than the number of reports per participant (level 1).

Intraclass correlation. It is also necessary to test if multilevel modeling is even necessary. Multilevel modeling is not necessary if there is no variation at higher levels. Variation at higher levels may be computed using the intraclass correlation coefficient. The intraclass correlation coefficient measures the degree to which the lower level units (level 1) belonging to the same higher level unit (level 2) are dependent or clustered. Larger intraclass correlation coefficients indicate more dependence or clustering at higher levels. The occurrence of dependence or clustering at higher levels indicates it is important to use multilevel modeling to protect against inflation of type I error rates and to capture variability at higher levels of the nested data structure.

Missing data. Multilevel modeling is often used to analyze repeated measures data, where missing data are common. Because multilevel analyses typically use maximum likelihood algorithms, participants with missing data may be included in analyses. In multilevel modeling, results are weighted by the amount of data contributed by each participant. That is, participants who provide more data contribute more to the results than participants who provide less data.

Fixed and random effects. Another consideration in multilevel modeling is whether effects are fixed or random. With random effects, the outcome-predictor relationship varies across level 2 units. That is, the slope and the intercept of the regression line are assumed to vary across level 2 units. With fixed effects, the variables of interest do not vary across level 2 units; the slope and the intercept are the same for all level 2 units. If random effects are modeled, the results are assumed to generalize to the population from which cases were sampled, whereas, if fixed effects are modeled, the results are confined to the cases studied. However, random effects models typically require greater sample sizes and may be more complicated to interpret.

Centering. Variables in multilevel modeling may be centered around the group mean (i.e., the mean of each level 1 unit) or centered around the grand mean (i.e., the mean of all the level 2 units). For example, in an experience sampling study involving repeated reports (level 1) nested within individuals (level 2), group mean centering is conceptually equivalent to creating variables that are relative to the individual's own mean based on his/her repeated reports, whereas grand mean centering is conceptually equivalent to creating variables that are relative to the overall mean of all reports provided by all the individuals in the study. Centering aids in interpretation of the results and the choice of centering affects the estimates computed. Decisions regarding centering should be made on a theoretical basis.

Autocorrelation. In repeated measures designs, autocorrelation is an issue. Because of the repeated nature of the data, residual errors in repeated measures data may be correlated (i.e., autocorrelation). The simplest and the most common autocorrelation structure is the first-order autoregressive error structure in which reports closer together in time are more strongly correlated than reports further apart in time. Some software programs (e.g., MPlus or SAS) also model more complex error structures to better account for autocorrelation.

Advantages of Multilevel Modeling

Nested data commonly arises in the field of behavioral medicine. By taking into account the nested structure of the data, multilevel modeling provides more contextualized analyses. For example, multilevel modeling may be used to test neighborhood effects on individuals' obesity, partner effects on patients with cardiovascular disease, and peer influences on adolescents' risky health behaviors. Multilevel modeling may also be used in repeated measures designs, including multiwave longitudinal and experience sampling studies of health behaviors (e.g., smoking, diet, exercise, and medication adherence), chronic illnesses (e.g., pain, diabetes, and HIV), and physiological processes (e.g., cardiovascular reactivity and neuroendocrine levels).

There are several advantages to using multilevel modeling to analyze repeated measures data. Multilevel modeling is able to analyze unbalanced designs, including unequally spaced data and missing data. Using multilevel modeling, it is possible to simultaneously estimate within person and between persons effects. For

example, a researcher could study if on days when a participant experiences more stress, he or she smokes more compared to days when he or she experiences less stress (a within person effect). This effect may then be tested to see if it generalizes across all participants in the study (a between persons effect) or to see whether between person differences, such as personality traits, moderate the relationship between stress and smoking (a cross level interaction).

Limitations of Multilevel Modeling

Multilevel modeling is an advanced statistical technique, which requires a solid grounding in statistics. Increasingly, resources are available to support researchers using multilevel modeling (e.g., Bickel, 2007; Field, 2009; Hox, 2010; Raudenbush & Bryk, 2002). Specialized software is also usually needed to conduct multilevel modeling. However, increasingly, mainstream software also performs multilevel analyses.

New Applications and Developments

Multilevel modeling is not limited to regression analyses. In recent years, researchers are combining multilevel modeling with other data analysis techniques. For example, multilevel modeling may be used in testing moderation, mediation, path models, structural models, growth curves, and meta-analyses. By integrating these data analysis techniques, multilevel modeling is able to analyze a wider variety of research questions.

Conclusion

Multilevel modeling is needed to appropriately analyze the nested data structures that often occur in research on behavioral medicine. Careful consideration of the above issues is critical to appropriately using this data analysis technique.

Multiple Risk Factor Intervention Trial (MRFIT)

Jonathan Newman
Columbia University, New York, NY, USA

Definition

The Multiple Risk Factor Interventional Trial (MRFIT) was a large, randomized primary prevention trial to test the effect of multiple interventions to reduce the risk of premature coronary heart disease (CHD) in 12,866 men, age 35–57, with one or more of three risk factors (hypertension, hyperlipidemia, or cigarette smoking) without a prior history of CHD. The trial was conducted in 22 clinical centers in the United States. MRFIT was conducted by the National Institutes of Health (NIH) and National Heart, Lung, and Blood Institute and was massive in scope, screening 356,222 men for the desired study population. These risk factors were chosen because they are modifiable, and there was an expectation (largely unproven at the time) that reduction of these factors should have beneficial results on the development of premature CHD. A subsample of 3,110 men was recruited to participate in the Behavior Pattern Study, which

investigated the relationship between certain behavior patterns and CHD risk.

Six thousand four hundred and twenty eight participants were assigned to the intervention group, and 6,438 were assigned to the usual care group. Active follow-up was obtained for 6 years, and more than 25 years of surveillance has occurred. The intervention group was instructed to follow a diet designed to result in a nutrient intake of 30–35% of calories from fat, with prespecified intakes of cholesterol and un/saturated fats. This group also received counseling and audiovisual aids to encourage smoking cessation. High blood pressure (BP) was treated with a stepped-care approach using weight loss and medications as validated in prior studies. The usual care group was referred to their individual physician or care provider and received risk-factor management as considered appropriate by these providers. The primary endpoint was CHD death. Participants in both groups had annual assessments of changes in their risk factor levels and were monitored annually for CHD morbidity and mortality.

One of the main findings of the MRFIT study – in both the active follow-up and the 25+ year surveillance – is that the relationship between cholesterol and CHD mortality is continuous, graded, and strong, i.e., that CHD risk is progressively higher at every cholesterol level from normal to higher levels, without a threshold effect. The MRFIT study also clearly demonstrated the importance of dietary cholesterol in CHD risk. This result remained robust after controlling for study factors such as age, systolic BP, diabetes, smoking status, race, and socioeconomic status. MRFIT also demonstrated the near linear relationship between systolic BP and CHD death and the relationship between both systolic and diastolic BP on risk of kidney failure. Importantly, MRFIT participants who stopped smoking had reductions in CHD morbidity and mortality when smoking cessation was implemented along with other risk modification strategies. While failing to demonstrate clear increases in CHD risk associated with type A behavior patterns, the Behavior Pattern Substudy of MRFIT was an important contribution to the field of behavioral cardiology. Lastly, the original 1986 MRFIT paper also introduced the concept of low or optimal CHD risk, proposing a first set of criteria, and emphasized both the rarity and benefit of this phenotype.

Multiple Risk Factors

Yori Gidron
Faculty of Medicine and Pharmacy,
Free University of Brussels (VUB), Jette,
Belgium

Definition

The etiology and prognosis of many diseases is complex, and assuming single causal agents alone could result in scientific and clinical

"ignorance." Most major causes of morbidity and mortality, such as of cancer, coronary heart disease (CHD), dementia, or traffic accidents (TA), are caused by and are predicted by multiple risk factors. In the case of CHD, for example, researchers often distinguish in behavioral medicine between background demographic risk factors such as age, gender, and education level; known biomedical risk factors such as family history of CHD, smoking, hypertension, physical inactivity, cholesterol level, and inflammatory markers; and behavioral risk factors such as hostility, effort-reward imbalance at work, and little social support. Some of the biomedical risk factors can indeed also be conceptualized as behavioral such as physical inactivity or smoking. Simultaneously testing multiple risk factors is then statistically done by multivariate analyses, where statistically significant risk factors from univariate tests are then simultaneously considered, to identify the unique risk factors of a disease, independent of other ones considered.

For example, after finding that hostility is the main "toxic" element from the type A behavior pattern, studies examined extensively the etiological and prognostic role of hostility in CHD, in multivariate analyses, where multiple risk factors named above where considered. Many studies supported the etiological independent role of hostility in CHD in multivariate analyses (e.g., Dembroski, MacDougall, Costa, & Grandits, 1989). However, some studies did find that certain "known" CHD risk factors, such as physical activity, smoking, and alcohol consumption, accounted for the hostility-CHD relationship, since after statistically controlling for their effects, hostility no longer predicted CHD (Everson et al., 1997). Yet, in a recent meta-analysis of all studies on anger, hostility, and CHD, Chida and Steptoe (2009) concluded that anger and hostility have an independent role in the risk of CHD and in its prognosis. The multivariate analysis serves to examine whether a factor has an etiological or prognostic role, independent of established risk factors, and if not, then to identify which factor mediates its role in the disease. At times, consideration of multiple risk factors also enables to identify interactive effects, which can help to point at a particularly high-risk group, who can benefit from scarce intervention efforts. For example, Gidron, Berger, Lugasi, and Ilia (2002) found that hostility synergistically interacted with CHD family history in relation to severity of coronary artery disease. Thus, for prevention at the population level, it may be better to focus on high-hostile people with a first-degree relative with CHD. Thus, the identification of multiple risk factors enables to better estimate one's risk of a disease and to treat people by targeting all significant independent risk factors (e.g., diet, physical activity, hostility reduction). By identifying and modifying multiple risk factors, we can aim to prevent or treat illnesses more effectively.

Demyelinating disease; Quality of life

Definition

Early research into the psychological aspects of multiple sclerosis (MS) focused on an undifferentiated category referred to as "mental symptoms," which included fatigue, sleep, emotional, and cognitive problems. These relatively imperceptible symptoms were initially considered secondary to the more overt physical symptoms believed to be most impairing. However, with improved methodologies for measuring the domains of psychological functioning, impairments in psychosocial functioning are now recognized as a primary and often disabling consequence of the disease.

Description

Disease Characteristics

Pathology

MS is an autoimmune disorder that involves a chronic inflammatory process characterized by neuronal demyelination and inflammation in white matter regions, as well as more subtle tissue damage in diffuse areas of gray matter. The disease causes axonal demyelination in which the fatty myelin sheaths covering the axons of nerve cells are attacked by the body's immune system (Richardson, Robinson, & Robinson, 1997). More specifically, MS attacks oligodendrocytes, glial cells responsible for the production and maintenance of the myelin sheath, causing a thinning of the axonal sheath and transection of axons in the later stages of its more progressive forms (Compston & Coles, 2008). The neuronal damage results in gliosis (i.e., a proliferation of astrocytes) that leads to the formation of glial scars, also referred to as sclerotic plaques or lesions.

Diagnosis

Initial presentation of MS involves one or more of a variety of symptoms that include optic nerve dysfunction (e.g., visual deficits), sensory disturbance (e.g., pain, numbness, and tingling sensations), pyramidal tract dysregulation (e.g., increased muscle tone and hyperreflexia), ataxia, bladder and bowel dysfunction, and sexual problems, as well as cognitive impairment and emotional symptoms (Olek & Dawson, 2002). The varied presentation of MS can make diagnosis difficult, which often requires a combination of clinical symptoms and positive findings from neuroimaging and laboratory tests (see Table 1). Furthermore, the occurrence of one MS attack may be insufficient to make a diagnosis and time between exacerbations can be years. Thus, a definitive diagnosis can sometimes take months to years. However, the existence of disease-modifying agents that can slow progression of the disease makes early diagnosis and treatment particularly important. Multiple sclerosis may have a variable or progressive course. The US National Multiple Sclerosis Society classifies MS phenotypes as relapsing-remitting (RRMS), primary progressive (PPMS), secondary progressive (SPMS), and progressive-relapsing (PRMS).

Course

MS has been estimated to affect between 2 and 150 of every 100,000 people (Rosati, 2001). The majority of patients are diagnosed between 20 and 50 years of age, women are affected 2–3 times as often as men, and its prevalence is greatest in individuals of northern European descent (Prakash, Snook, Lewis, Motl, & Kramer, 2008). RRMS is the most common

Multiple Sclerosis: Psychosocial Factors, Table 1 McDonald criteria for MS diagnosis[a]

Clinical presentation	Additional data needed for MS diagnosis
> = 2 attacks; objective clinical evidence of > = 2 lesions or objective clinical evidence 1 lesion with reasonable historical evidence of a prior attack	None
2 or more attacks; objective clinical evidence of 1 lesion	Lesion(s) dissemination in *space* (DIS) on MRI as demonstrated by: > = 1 lesion in at least 2 of 4 MS typical regions (periventricular, juxtacortical, infratentorial, or spinal cord); or await further clinical attack implicating a different CNS site
1 attack; objective clinical evidence of 2 or more lesions	Lesions dissemination in *time* (DIT) on MRI as demonstrated by simultaneous presence of asymptomatic gadolinium-enhancing and nonenhancing lesions at any time; or a new enhancing lesion(s) on follow-up MRI, irrespective of its timing with reference to a baseline scan; or await a second attack
1 attack; objective clinical evidence of 1 lesion (clinically isolated syndrome)	Lesion dissemination in *space* and *time* (as defined above; or await a second attack
Insidious neurological progression suggestive of MS (PPMS)	1 year of disease progression plus 2 of 3 of the following criteria: 1. Evidence of DIS in the brain based on > = 1 lesion in the MS-characteristic brain regions 2. Evidence of DIS in the spinal cord based on > = 2 lesions in the cord 3. Positive CSF (isoelectric focusing evidence of oligoclonal bands and/or elevated IgG index)

[a]Adapted from Polman et al. (2011)
MRI magnetic resonance imaging, *PPMS* primary progressive multiple sclerosis, *CSF* cerebrospinal fluid, *IgG* immunoglobulin G

subtype and is the initial course of 80% of individuals with MS (Compston & Coles, 2008). Approximately 65% of those with an initial RRMS presentation begin to exhibit progressive neurologic decline classified as SPMS (Lublin & Reingold, 1996). Regardless of subtype, most cases of MS eventually cease to remit and become slowly progressive over time.

Patients with MS have an average life expectancy that is 7 years shorter than the general population, though patients usually die of MS-related disability rather than the disease process itself. Though the disease has no known cure, use of disease-modifying drugs (e.g., interferons, immunosuppressant agents, and cytotoxic agents) has significantly improved outcomes for individuals with MS. Such agents decrease clinical relapses, disability progression, and lesion load, and may also have cognitive benefits, though more research is needed (Amato, Portaccio, & Zipoli, 2006).

Psychosocial Factors

Cognitive Functioning

Cognitive processes rest upon dynamic brain networks that are highly dependent on the integrity of long white matter tracts to facilitate information flow between distant cortical areas. MS lesions can disrupt connections between cortical regions, often resulting in impairments of cognitive functioning. Cognitive deficits have been estimated to be present in up to 65% of patients (Rao, 1997). Impairment can occur even in the early stages of the disease, and complete remission of cognitive symptoms is uncommon across all disease subtypes (Amato et al., 2006).

Although there is no uniform pattern of cognitive impairments in MS, greatest deficits are often seen in learning and memory, with working memory and short-term recall the most significantly impacted (Calabrese, 2006). Other commonly affected domains include information processing speed, complex visuospatial abilities,

conceptual reasoning, and sustained attention, while primary language functions and verbal intellectual skills are usually unaffected. Additional factors that may impact cognition include depression, anxiety, and fatigue, as well as lesion location, size, and medication use.

Psychological Functioning

Individuals with MS are susceptible to emotional problems both as a direct result of disease pathology and as a consequence of coping with its numerous symptoms. Up to 60% of patients seek professional help for emotional problems during the course of their illness. Many MS symptoms are not noticeable to others (e.g., weakness, dizziness, headache, impaired coordination, muscle spasticity, bladder and bowel dysfunction, fatigue, sleep problems, pain, and sexual difficulties), but can result in daily problems and impact emotional functioning (National Multiple Sclerosis Society, 2010).

Given unpredictable exacerbations, symptomatology, and prognosis, it is not surprising that depression and anxiety are commonly associated with MS. The most common mood disorder co-occurring with MS is major depressive disorder, which is present in up to 54% of patients (Patten, Beck, Williams, Barbui, & Metz, 2003). This rate far surpasses those of many other common neurological or medical conditions. Anxiety disorders have also been identified in approximately 25% of MS patients, which is slightly less than their prevalence in the general population (Kessler & Wang, 2008). Comorbid anxiety and major depressive disorders in MS are associated with increased somatic symptoms, suicidal ideation, interpersonal difficulty, and decreased treatment adherence.

Quality of Life

Quality of life (QoL) refers to an individual's subjective well-being as determined by psychosocial, health, economic, and environmental factors. Unsurprisingly, such factors can be significantly impacted by the constellation of cognitive, emotional, and physical symptoms characteristic of MS. MS leads to unemployment in 50–80% of cases within a 10-year disease course, making it the most common cause of neurological disability in young and middle-aged adults in the United States and Europe (Johnson, 2007).

Although physical problems are the most recognizable symptoms of MS, impairments in mental functions appear to be the most important predictor of QoL (Wynia et al., 2008). Mental impairments (including cognitive and emotional problems) are present in more than 80% of patients and are major predictors of disability, unemployment, and caregiver distress. Patients with less impairment in mental functions report better QoL in the domains of mental health, emotional functioning, social functioning, bodily pain, and vitality. All MS patients are at risk for decreased QoL, though QoL is lowest in the more progressive forms of the disease. While fatigue is more prevalent than cognitive and emotional problems and can significantly impact daily functioning, its impact on QOL is limited.

Summary

The demyelinating lesions of MS cause a disconnection of neuronal pathways resulting in a variety of clinical symptoms that tend to be episodic and fluctuate in severity and course. The constellation of symptoms characteristic of the disease often impact physical, cognitive, and psychological functioning, that in turn tend to negatively impact overall quality of life. Further, cognitive impairments (e.g., memory, processing speed, and attention), depression, anxiety, fatigue, and sleep problems are often more functionally impairing than the physical symptoms of the disease, leading to unemployment, disability, and decreased subjective well-being.

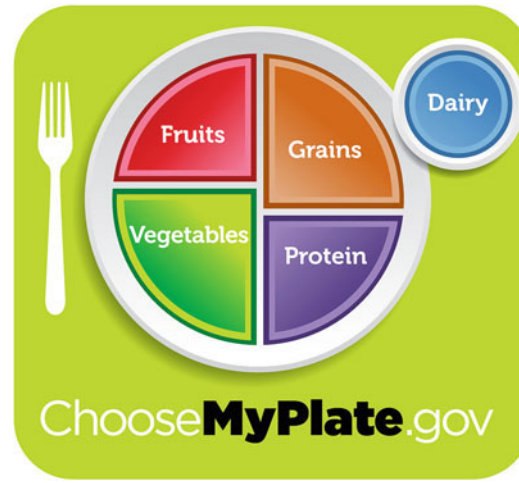
Healthy eating guide

Definition

The Food Guide Pyramid was a visual representation of the recommendations for daily food intake. The Food Guide Pyramid followed the recommendations of the USDA Dietary Guidelines. The Food Guide Pyramid was first published by the United States Department of Agriculture (USDA) in 1992 and was updated approximately every 5 years. In 2005, the Food Guide Pyramid changed to a vertical representation of food groups and emphasized exercise by including a person walking up "stairs" on the side of the pyramid. As the Dietary Guidelines were updated June 2010, the Food Guide Pyramid was eliminated in 2011. The USDA launched a new site in 2011 called Choose My Plate and can be accessed at www.choosemyplate.gov.

Although the Food Guide Pyramid changes every 5 years, the basic message remains the same. Recommendations are to include a variety of foods each day including whole grains, dark-green and orange vegetables, dry beans and peas, fresh or frozen fruit, limited fruit juice, calcium-rich foods such as low-fat and fat-free milk and milk products, and low-fat or lean meats and poultry. There are unique Food Guide Recommendations for preschoolers, children, and pregnant women, as shown in Choose My Plate (Fig. 1).



MyPlate, Fig. 1 The plate is one half fruit and vegetables, a bit over a quarter grains, a bit under a quarter protein and a glass of dairy

National Cancer Institute

Jasmin Tiro and Simon J. Craddock Lee
Department of Clinical Sciences, The University of Texas Southwestern Medical Center, Dallas, TX, USA

Basic Information

The US National Cancer Institute (NCI)

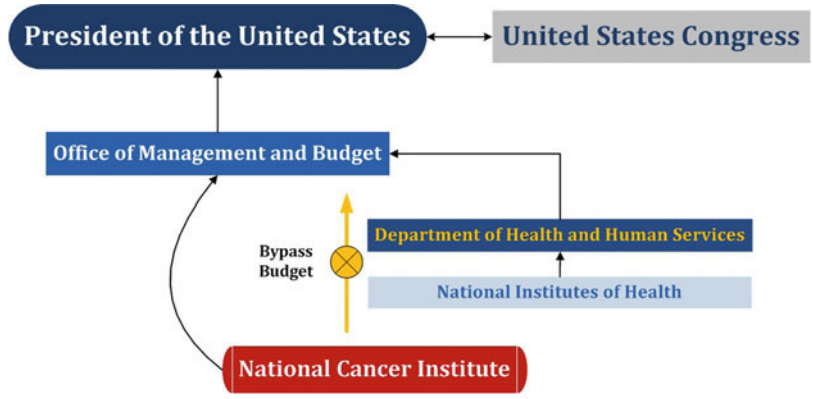
The National Cancer Institute is the oldest and largest of the 27 institutes and 6 centers that comprise the US National Institutes of Health (NIH), which are part of the US Department of Health and Human Services (DHHS) Public Health Service (PHS). First established in 1937 by Congress, NCI's mission and responsibilities were expanded in the *National Cancer Act of 1971*. Currently, the NCI's main responsibility is to coordinate the National Cancer Program, which fosters research, training, and health information dissemination programs with respect to the cause, diagnosis, prevention, and treatment of cancer, rehabilitation from cancer, and survivorship concerns of cancer patients and their families. Through this program, the NCI:

- Supports a national network of regional and community cancer centers
- Conducts and fosters cancer research through intramural (its own laboratories and clinics) and extramural programs (grants and cooperative agreements with universities, hospitals, research foundations, and businesses)
- Reviews, approves, and monitors grants supporting novel research projects on the causes, diagnosis, treatment, and prevention of cancer
- Collects, analyzes, and disseminates cancer research findings
- Trains health professionals in cancer diagnosis and treatment and researchers in basic, clinical, cancer control, behavioral, and population sciences
- Supports collaborative research between US and foreign researchers

Unique Budget Process of the NCI

Unique among the institutes in the NIH, NCI has the authority to submit an annual budget

M.D. Gellman & J.R. Turner (eds.), *Encyclopedia of Behavioral Medicine*,
DOI 10.1007/978-1-4419-1005-9,



National Cancer Institute, Fig. 1 Bypass budget process of the National Cancer Institute (The National Cancer Institute, NIH (Bethesda, MD), http://www.cancer.gov/aboutnci/servingpeople/nci-budget-information/budget-process. Accessed date 7/2011)

proposal directly to the president (called the "Bypass Budget" because it circumvents the NIH/DHHS budget process; see Fig. 1). The White House Office of Management and Budget (OMB) reviews and integrates the NCI proposal into the president's executive branch budget which reflects the administration's fiscal and management priorities for the next year. Then, Congress reviews the president's proposal and makes a recommendation, and final appropriations are enacted into law after approval by both houses of Congress and signature by the president. Every year, NCI publishes online the Bypass Budget Proposal for the coming fiscal year and the Annual Fact Book, which summarizes the distribution of budget among the research programs and funding mechanisms for the past fiscal year. In 2009, NCI's budget was $4.97 billion not including the additional $1.26 billion from the American Recovery and Reinvestment Act (ARRA) funds intended to be distributed in fiscal years 2009 and 2010. Approximately 43% of the total NCI 2009 budget was allocated for 5,461 research project grants, including 543 grants made possible by ARRA funds.

The US government has made cancer a national priority and has allocated significant resources to understand the complexity of cancer as a disease process as well as processes of cancer care. Thus, the NCI has become a leading supporter of behavioral, social, and population research in basic, intervention, and applied science related to cancer.

NCI Organizational Structure and Governance

The NCI's organizational structure consists of the Office of the NCI Director, two intramural divisions/centers, and five extramural divisions. The current NCI director is Dr. Harold Varmus, Nobel laureate. The NCI director receives programmatic and scientific advice and counsel from three national bodies of appointed experts. The *National Cancer Advisory Board* (NCAB) advises the secretary of DHHS and the NCI director with respect to the activities of the Institute. Appointed by the president, members are leading representatives of health and scientific disciplines, including at least two experts in public health and the behavioral or social sciences. NCAB approves research grant award decisions made by NCI program staff who prioritize applications ranked according to scientific merit through independent peer review. The *Board of Scientific Advisors* (BSA) provides scientific advice and guidance on a wide variety of matters concerning scientific program policy, progress, and future direction of the NCI's *extramural* research programs and provides concept review of extramural program initiatives. The BSA charter specifically requires that one or more members have expertise with cancer epidemiology, cancer prevention and control, cancer education, cancer information services, and community outreach. The *Board of Scientific Counselors* (BSC) provides analogous scientific advice and guidance regarding *intramural* research programs.

Major Impact on the Field

Division of Cancer Control and Population Sciences (DCCPS)

The main division charged with fostering behavioral medicine is the extramural Division of Cancer Control and Population Sciences (DCCPS), created in 1997 and currently led by social psychologist, Dr. Robert Croyle. Cancer control science is defined as "basic and applied research in the behavioral, social, and population sciences to create or enhance interventions that, independently or in combination with biomedical approaches, reduce cancer risk, incidence, morbidity and mortality, and improve quality of life" (Cancer Control Program Review Group, 1998-modified). For a history of cancer control and commentary on how to advance the science of cancer control, see Hiatt and Rimer (1999).

DCCPS conducts and supports integrated research in a wide range of disciplines and fields including anthropology, behavioral sciences, demography, epidemiology, genetics, health communication, health policy, health services research, psychology, public health, sociology, and surveillance. DCCPS funds research on the full continuum of cancer control that spans prevention, detection, diagnosis, treatment, survivorship, and end-of-life care to "understand the causes and distribution of cancer in populations; support the development and delivery of effective interventions; monitor and explain cancer trends in all segments of the population." As a result of its mission, DCCPS represents one of the largest concentrations of social, behavioral, and population scientists at the NIH.

DCCPS is organized around five research program areas: Epidemiology and Genetics, Surveillance, Applied, Behavioral, and Survivorship. The latter three programs are of central interest to researchers in behavioral medicine. The Applied Research Program fosters research to understand how and why cancer care and control activities in the USA influence patterns and trends in cancer outcomes (incidence, morbidity, mortality, and survival). The Behavioral Research Program fosters a wide range of research from basic behavioral research to evaluation and dissemination of interventions to promote cancer prevention and control behaviors and informed decision-making. The Office of Cancer Survivorship fosters research on the short- and long-term biopsychosocial effects of cancer and its treatment. An overview of the history and scientific accomplishments of the first 10 years of DCCPS (1997–2007) can be found online at the NCI website (www.cancercontrol.gov).

Current Major Programs and Initiatives of DCCPS

DCCPS is a leader in supporting transdisciplinary research in tobacco control, population health disparities, cancer-related energetics (physical activity), cancer screening, and health communication research (Croyle, 2008; Rebbeck, Paskett, & Sellers, 2010; Stokols et al., 2003). DCCPS has led or partnered with other institutes and offices (e.g., National Heart, Lung, and Blood Institute; National Institute on Minority Health and Health Disparities) on large NIH funding mechanisms to establish research centers to leverage transdisciplinary and team science research in these cancer domains.

DCCPS also collaborates with the NIH Office of Behavioral and Social Science Research (OBSSR) to jointly fund innovative grants and projects. For example, the Grid-Enabled Measures Database enables researchers to share standardized measures of theory-based constructs through OppNet, a trans-NIH initiative to fund and advance research elucidating mechanisms and processes within and among individuals and groups that affect health-related behaviors.

Other key theoretic and methodologic initiatives that engage behavioral medicine include cognitive, affective, and social processes in health, health behavior theory development, measurement of health constructs (e.g., quality of cancer care), questionnaire design and testing, and the integration of behavioral and biomedical scientific approaches (Stefanek et al., 2009). These scientific areas are reflected in networks of individual investigators collaborating with NCI scientific staff, as well as in funding opportunities calling for grant applications to advance these efforts.

Cancer Centers Program

The National Cancer Act of 1971 also established NCI-designated Cancer Centers for clinical research, training, and demonstration of advanced diagnostic and treatment methods for cancer. To be awarded designation, these centers must periodically undergo peer review and meet a national series of competitive standards and demonstrate excellence in cancer research through the operation of formal programs. As of 2010, there are 66 Cancer Centers across the USA that have been awarded NCI designation. Forty of these centers carry *Comprehensive* Cancer Center status, which reflects integration and collaborative research in clinical trials and patient care, as well as programmatic emphases in epidemiology and cancer control. As such, NCI-designated Comprehensive Cancer Centers are often leading proponents of cancer-related behavioral medicine.

Conclusion

The US National Cancer Institute is the largest organization dedicated to supporting cancer research in the world. Through its efforts, it provides vision and leadership to the global cancer community. This is especially true in the area of behavioral oncology and cancer control. The NCI recognizes the importance of transdisciplinary research efforts in addressing the cancer continuum.

Synonyms

NCS

Definition

The National Children's Study (NCS) will be the largest longitudinal study of children's health,

growth, and development ever conducted in the United States. The main study aims to recruit women from randomly selected study locations around the country, and a sample of 100,000 children born to these recruited mothers will be followed from before birth to 21 years of age. "It is the first large birth cohort study in any nation to specifically examine the influence of environmental factors on birth outcomes, child health, and human development and the first designed to systematically examine the influence of gene-environment interactions on children's health" (Landrigan et al., 2006). The NCS defines "environment" broadly, such as air, water, soil, noise, stress, and exposure to natural and manufactured products. By studying children through different phases of growth and development, researchers may be better able to understand the role these factors have on health and disease.

The National Children's Study is led by the *Eunice Kennedy Shriver* National Institute of Child Health and Human Development of the National Institutes of Health (NIH) in collaboration with a consortium of federal government partners. Study partners include the National Institute of Environmental Health Sciences of the NIH, the Centers for Disease Control and Prevention, and the Environmental Protection Agency. The NCS will concentrate on collecting data geared toward the following broad outcomes with key public health significance: pregnancy outcome, neurodevelopment and behavior, lung and airway disease, physical growth and body composition, and injury. Analysis of pilot data from field testing at a subgroup of NCS sites has resulted in modifications to the original study design. The NCS main study is currently scheduled to begin in 2013

National health and nutrition examination survey, The

Definition

The National Health and Nutrition Examination Survey (NHANES) is a program of studies designed to assess the health and nutritional status of adults and children in the United States. The survey is unique in that it combines interviews and physical examinations. NHANES is a major program of the National Center for Health Statistics (NCHS). NCHS is part of the Centers for Disease Control and Prevention (CDC) and has the responsibility for producing vital and health statistics for the nation.

The NHANES program began in the early 1960s and has been conducted as a series of surveys focusing on different population groups

or health topics. In 1999, the survey became a continuous program. The focus of the survey changes based on current health care trends and needs. Each year the survey includes a sample of 5,000 persons representative of the general population.

The NHANES interview includes demographic, socioeconomic, dietary, and health-related questions. The examination component consists of medical, dental, and physiological measurements, as well as laboratory tests administered by medical personnel.

Findings from this survey are used to determine the prevalence of major diseases and risk factors for diseases. Information is available to consider such things as nutritional status and its association with health promotion and disease prevention. NHANES data are also used to set norms for height, weight, and blood pressure and to establish public health policy, to guide health maintenance and prevention program and services and expand what is known about health in our country.

National health survey; NHIS

Basic Information

The National Health Interview Survey (NHIS) is a principal source of information on the health status of the civilian noninstitutionalized population of the United States. The NHIS is one of the major data collection programs of the National Center for Health Statistics (NCHS), a component of the Centers for Disease Control and Prevention (CDC). The NHIS has been in the field continuously since 1957 and is the nation's largest household health survey. The survey was authorized by Congress in order to obtain national estimates on disease, injury, impairment, disability, and related issues for the US population. The NHIS has evolved over the years, with significant questionnaire redesigns in 1982 and 1997.

Major Impact on the Field

Purpose

The main objective of the NHIS is to monitor the health of the United States population through the collection and analysis of data on a broad range of health topics. The NHIS provides data for the analysis of health trends, barriers to care, health status, health-care access and utilization, health-related behaviors, and risk factors. A major strength of this survey lies in the ability to display these health characteristics by many demographic and socioeconomic characteristics. Survey results have been instrumental in tracking health status and health-care access, and monitoring progress toward achieving national health objectives. The NHIS is a major source of data used for *Healthy People*, which provides 10-year national health objectives and tracks progress toward achieving them for improving the health of all Americans.

Sample Design

The NHIS is a cross-sectional household interview survey designed to be representative of the civilian noninstitutionalized population of the United States. The sampling plan follows a multistage area probability design that permits

the representative sampling of households and noninstitutional group quarters (e.g., college dormitories). The NHIS sample design is reevaluated and modified after every US decennial census. The NHIS sample design oversamples selected minority subgroups including African Americans, Hispanics, and starting in 2006, Asians. Persons aged 65+ in these selected minority groups are also oversampled. Since the last NHIS sample redesign was implemented in 2006, the expected annual interviewed sample size has been about 35,000 households with approximately 87,500 persons, although the sample sizes vary appreciably over time.

The NHIS data files contain sample weights based on the unit of analysis (e.g., household, person). The NHIS sample is chosen such that each person in the covered population has a known nonzero probability of selection. These probabilities of selection, along with adjustments for nonresponse and post-stratification to sex, age, and race/ethnicity census population control totals, are reflected in the sample weights provided. It is necessary to utilize the weights provided in analyses of the NHIS data, along with the stratification and primary sampling unit information, for valid statistical inferences.

Content of the Questionnaire

The NHIS collects basic health and demographic data, which can be used to develop prevalence estimates of a wide variety of health measures. The NHIS questionnaire contains a set of Core questions and Supplemental questions. The Core includes questions about chronic conditions, disability, health behaviors, risk factors, health insurance coverage, and health-care use. Core questions have remained largely unchanged since 1997, which allows for trend analysis and for pooling data from more than one NHIS year, thus increasing the sample size for analytic purposes. The Supplemental questions change from year to year and collect additional data pertaining to current health issues of national importance (e.g., cancer, immunization, diabetes).

A 1997 questionnaire redesign separated the Core questions into three main components: the Family Core (collects information on all family members), the Sample Adult Core (collects information directly from one randomly selected adult, aged 18 and over, in each family in the household), and the Sample Child Core, which is only administered if a child resides in the family (collects information on one randomly selected child, aged 17 and under, from a knowledgeable adult family member).

The Family Core questionnaire includes sections on health status and limitations, injuries and poisoning, health-care access and use, health insurance coverage, and sociodemographic characteristics. The Sample Adult Core questionnaire includes sections on health conditions and health behaviors in addition to more detailed questions on some topics included in the Family Core. The Sample Child Core questionnaire includes questions on health conditions and more detailed questions on some topics included in the family core.

Data Collection Procedures

The NHIS data are collected by interviewers who are employed and trained by the US Census Bureau in accordance with procedures specified by NCHS, via personal household interviews. Prior to 1997, NHIS interviews were conducted using paper and pencil. After a questionnaire redesign was implemented in 1997, all data were collected by interviewers using computer-assisted personal interviewing, allowing interviewers to enter responses directly into the computer during the interviews.

Prior to 1997, all adult members of the household aged 18 and over who were at home at the time of the interview were invited to participate and to respond for themselves; however, a proxy respondent often provided responses for all household members. After the 1997 questionnaire redesign, a greater emphasis was placed on self-reporting to improve data quality. Data collection procedures for conducting the household, family, and children interviews remained largely unchanged, but sample adults must respond for themselves (except in rare cases where they are unable to do so).

Confidentiality

All data collected in the NHIS are used for statistical purposes only and are guaranteed by law to be held in the strictest of confidence. Survey participation is voluntary, and the confidentiality of responses is assured under Section 308(d) of the Public Health Service Act, which forbids the disclosure of any information that may compromise the confidentiality promised to its survey respondents.

Record Linkages

The NHIS data are routinely linked to administrative records enabling researchers to examine factors that influence disability, chronic disease, health-care utilization, morbidity, and mortality. The NHIS is linked to death certificate records from the National Death Index; Medicare and Medicaid enrollment and claims data from the Centers for Medicare and Medicaid Services; and Retirement, Survivor and Disability Insurance and Supplemental Security Income benefit data from the Social Security Administration. Immunization data for children in the 1997–1999 NHIS are linked to physician medical records in the National Immunization Provider Record Check Study. Starting with the 1996 Medical Expenditure Panel Survey (MEPS), the NHIS data can be linked to the MEPS data which are drawn from a subsample of households that participated in the prior year's NHIS, allowing users to link, for example, the 1995 NHIS to the 1996 MEPS. The NHIS data are also linked to contextual data including air monitoring data obtained from the Environmental Protection Agency.

Data Availability

The NHIS data are available via public-use and restricted-use data files. Public-use NHIS data files are released annually and are available for download from the NCHS web site. Restricted-use linked NHIS data files, which contain indirect identifiers such as geographical locations or specific dates, are available for use through the NCHS Research Data Center (RDC). The RDC is a secure environment designed to protect the confidentiality of survey respondents, while also allowing researchers the ability to access restricted-use data for research purposes only.

Documentation containing detailed information on the public-use and restricted-use NHIS data files is available on the NCHS web site. Reports providing statistics based on data collected from NHIS and detailed documentation on the NHIS design, sampling procedures, and guidance for analyzing the data are also available. Information on the NHIS Early Release Program which provides very timely estimates of key health and health-related indicators is also provided on the NCHS web site. Harmonized NHIS public-use data and documentation going back to the early 1960s are available in the Integrated Health Interview Series, maintained by the University of Minnesota. (See section G for more information on these resources.)

National Health Survey

► National Health Interview Survey

National Heart, Lung, and Blood Institute

Martica H. Hall
Department of Psychiatry, University of Pittsburgh, Pittsburgh, PA, USA

Basic Information

The National Heart, Lung, and Blood Institute (NHLBI) is one of the National Institutes of Health (NIH). Its mission is the advancement of research on, and the prevention and treatment of, heart, lung, and blood diseases and sleep disorders.

The National Heart Institute (NHI) was established in 1948 as one of the National Institutes of Health (NIH). The National Heart Institute's mission was to advance research and training related to heart disease and functioning. Its functions were broadened in 1969 and 1976 to include lung (National Heart and Lung Institute; NHLI) and blood diseases (National Heart, Lung, and Blood Institute; NHLBI), respectively. The NHLBI is also responsible for the adequacy and safety of the nation's blood supply.

Major Impact on the Field

Organizationally, the NHLBI includes the Office of the Director, an Intramural Research Program, and an Extramural Research Program. The Office of the Director provides strategic planning, policy guidance, program development and evaluation, and institute coordination. It also liaisons with Federal agencies, professional societies, and the public and is responsible for the dissemination of information regarding the prevention of heart, lung, and blood diseases and sleep disorders. The Office of the Director includes divisions, centers, and branches that support bioinformatics development; epidemiological studies of the etiology of heart, lung, and blood diseases and sleep disorders; the translation of scientific evidence into clinical practice; and the elimination of health disparities through the education and career development of a diverse workforce.

The Intramural Research Program includes a multinational team of NIH investigators and clinicians who conduct basic and clinical research and technology development related to heart, lung, and blood diseases and sleep disorders. In contrast, the Extramural Research Program supports heart, lung, and blood diseases and sleep disorders research, research training, and career development of investigators outside of the NIH. These activities are supported through various extramural award mechanisms including research, program project, and center grants; cooperative agreements and research contracts; research career development awards; and institutional and individual national research service awards. Three divisions (Cardiovascular, Lung, Blood Diseases and Disorders) foster research and training in their related areas.

National Institute of Child Health and Human Development

Deborah Lee Young-Hyman
Department of Pediatrics, Georgia Prevention Institute Georgia Health Sciences Universtiy, Augusta, GA, USA

Basic Information

The National Institute of Child Health and Human Development (NICHD) was established by federal law in October 1962. The mission of NICHD encompasses that every person is born healthy

and wanted; no harmful effects are suffered by women in the reproductive process; children have the opportunity to live healthy and productive lives; and to ensure the health, productivity, independence, and well-being of people through optimal rehabilitation (http://www.nih.gov/about/almanac/organization/NICHD.htm).

Major Impact on the Field

This mission statement informs the research programs supported by NICHD as follows:

Projects funded through NICHD adopt a life course perspective, such that conditions are studied prior to and during pregnancy, as well as during childhood, as they impact the health and well-being of children and adults, including person based and environmental factors and their interaction. The process of growth and development is assumed to be continual and evolving, such that research focuses also include cellular, molecular, and developmental biology. Basic, clinical, and epidemiologic research is conducted regarding reproductive science, with emphasis on safe and effective regulation of fertility, solving problems of infertility, and understanding consequences of reproductive behavior and population change. This last focus is behavioral and social science based.

NICHD also supports the research training of clinicians in order to address areas of critical public health concern. A current focus is obesity prevention and treatment throughout the life course, with particular emphasis on the maternal-fetal environment. In 2008–2009, the National Children's Study was launched in concert with the Centers for Disease Control (CDC), a longitudinal study of environmental influences on child health. This study will follow approximately 100,000 subjects across diverse areas the United States, and span over 20 years, mapping multiple environmental influences on children's health status. As the issues addressed by NICHD span biologic systems, NICHD often partners with NIDDK and NHLBI to fund projects which target disease prevention and intervention during childhood, particularly the antecedents of diabetes and cardiovascular disease

The division of intramural research addresses the biological and neurobiological, medical, and behavioral aspects of normal and abnormal human development.

In addition to issues of biology, NICHD supports research that addresses health literacy and numeracy, health maintenance, use of health care and community resources to improve child health, and the interaction between risk behaviors, psychological morbidity, and health outcomes.

NICHD supports a systems approach to discovery, whereby the focus of inquiry can range from the maternal-child dyad, to the family-school or family-health care environment. Therefore, besides a strong commitment to developmental biology discovery, there is emphasis on how health prevention attitudes and behavior translate into public health issues.

National Institute of Diabetes and Digestive and Kidney Diseases

Deborah Lee Young-Hyman
Department of Pediatrics, Georgia Prevention Institute Georgia Health Sciences Universtiy, Augusta, GA, USA

Basic Information

National Institute of Diabetes and Digestive and Kidney Diseases (NIDDK) conducts and

supports research ranging from basic science to translational multidisciplinary studies regarding the *endocrine system***.** This consists of *a system of glands*, each of which *secretes a type of* hormone *into the bloodstream to regulate the body*. In addition, related organs such as the kidney, liver, and gonads are studied as secondary contributors of hormonal input to the endocrine system. An endocrine axis denotes the interrelationship of function between glands and organs caused by reciprocal hormonal and cellular functions, including the brain. Functions regulated by endocrine hormones range from growth and pubertal development to basic metabolism and brain-mediated behavior. The endocrine system has systemic effects on the body, and therefore, NIDDK funds and takes a leadership role in studies encompassing the endocrine system, related organ systems, hormonal dysregulation and chronic disease, lifestyle as it relates to prevention and disease course of metabolic diseases, proteinomics, genomics, and gene environment interactions (http://www2.niddk.nih.gov/AboutNIDDK/).

Major Impact on the Field

In addition to its broader mission, NIDDK is dedicated to the funding of projects which address health disparities. Minorities are disproportionately affected by endocrine disorders, in particular diabetes and obesity, and have poorer disease outcomes. Diabetes is the single largest cause of end-stage renal disease (ESRD). In order to address these multifactorial illnesses, the NIDDK is a proponent of multidisciplinary research, reflecting the bench to bedside application of basic research findings to clinical care. NIDDK has a history of funding large clinical trials and epidemiologic studies which have addressed issues such as disease development and progression (types 1 and 2 diabetes), primary and secondary prevention (type 2 diabetes), and secondary prevention (preserving the health of neonates in mothers with gestational diabetes).

Because treatment of endocrine disorders such as autoimmune and weight-related diabetes is based on individual behavior, the NIDDK has an emphasis on behavioral aspects of disease prevention and management and has funding mechanisms (R18, R34) which emphasize the inclusion of behavior change strategies as primary or secondary treatment of disease prevention and management. Clinical trials, in particular the Diabetes Prevention Program (DPP) and Preventing Type II Diabetes (STOPP-T2D), have had major behavioral components and have helped to establish the clinical superiority of behavior/lifestyle change over pharmacologic intervention in lifestyle-based disease development and treatment (http://www2.niddk.nih.gov/Research/ScientificAreas/Diabetes/Type2Diabetes/CTT2.htm). NIDDK also maintains a network of biobehavioral researchers who conduct studies regarding the prevention and early treatment of type 1 diabetes (http://www.diabetestrialnet.org/) and is dedicated to providing funding to train clinician-scientists across disciplines to carry out this work.

Content areas of current NIDDK-funded behavioral research include hormonal regulation of appetite; associations between inflammation, glycemia, and mood; insulin resistance, exercise, and cognition; psychiatric disorders and risk for diabetes; translation of effective care models to underserved populations; and health-care delivery channels to improve pre-disease risk factors such as obesity in children and adults. Applications for funding behavioral approaches are likely to be assigned to the Division of Diabetes, Endocrinology and Metabolic Diseases (DEM).

National Institute of Mental Health

Jennifer Pellowski
Department of Psychology, University of Connecticut, Storrs, CT, USA

Basic Information

The National Institute of Mental Health (NIMH) is a part of the National Institutes of Health (NIH) which focuses on clinical research associated with mental illness and behavioral disorders through biological and behavioral perspectives. It focuses on the prevention, recovery, and cures of mental illness and is the nation's scientific leader in this area.

NIMH was conceived on July 3, 1946 when President Truman signed the National Mental Health Act. This act acknowledged the plight of World War II soldiers coming back from war with mental illnesses caused or exacerbated by the environmental stress of war. It also recognized that the incidence rate of mental illness in the general population was higher than originally thought. To address this need for psychiatric care, the National Institute of Mental Health was formally established on April 15, 1949.

Since the beginning, NIMH has been at the forefront of mental health research focusing especially on assessing psychiatric needs of the nation, using cutting-edge technologies to determine when, where, and how mental illness occurs and finding treatments to slow or cure these mental illnesses. It commenced this long history of research in the 1950s and 1960s, starting with the Mental Health Study Act of 1955. The purpose of the Mental Health Study Act was to access the mental health issues effecting the American public as well as what resources were available at that time to treat those suffering from illness. This resulted in the report *Action for Mental Illness* which called for a national program to address individual needs on specific mental health problems.

NIMH continued to make strides during the 1970s and 1980s with its focus on the use of cutting-edge biological techniques, technologies, and treatments to aid in attempts to answer the questions of how, when, and why mental illness happens and how to treat those who are suffering. These aims resulted in the creation of the PET scan to measure brain function as well as the use of lithium, a revolutionary treatment for mania.

A resolution later signed by President George H. W. Bush declared the 1990s "The Decade of the Brain," and NIMH continued to focus on the advances in imaging technologies as well as the interaction between brain, behavior, and the environment to gain more knowledge about specific mental health illnesses. Currently, NIMH works to fulfill four objectives aimed at further determining the causes of mental illness, charting the course of mental illness, developing interventions, and the dissemination of knowledge acquired through NIMH-supported research.

To fulfill these objectives, NIMH conducts and funds internal and external research studies. With a budget of upwards of $1.5 billion, NIMH provides many grants to independent researchers, as well as contracts through requests for applications (RFAs). It also provides training grants to pre- and postdoctoral students to encourage entry into biomedical and behavior fields of research.

In conjunction with the goals of obtaining new knowledge through research, NIMH also acts to disseminate this newly found knowledge. It accomplishes this through conferences and lectures open to the general public in addition to providing booklets, brochures, and fact sheets. It also supplies curriculum and educational tools to primary and secondary schools to aid in the teaching process.

National Institute of Mental Health
Parklawn Building, 15C-05
5600 Fishers Lane
Rockville, Maryland 20857

Major Impact on the Field

The National Institute of Mental Health is the nation's scientific leader in research on the causes, treatment, and prevention of mental illness. The NIMH acts to bridge the gap between

research and the larger community by providing leadership in the dissemination of information for clinicians, patients, policy makers, and the general public.

National Institute of Nursing Research

Barbara Resnick
School of Nursing, University of Maryland, Baltimore, MD, USA

Basic Information

The development of NINR has had a major impact on building nursing science as delineated by the many successes and the growing number of doctorally prepared nurses engaged in research. Specifically, NINR has had a great influence on genetics research with a focus on bench to bedside, palliative care and symptom management research, end-of-life research, and research in long-term care.

Major Impact on the Field

The major impact of NINR has been in the development of nurse researchers and nursing science in general.

National Institute on Aging

Natalie E. Bustillo
Department of Psychology, University of Miami, Coral Gables, FL, USA

Basic Information

The National Institute on Aging (NIA) is one of the institutes of the National Institutes of Health (NIH). The mission of the NIA is to conduct research about the aging process, to promote understanding of aging, and to disseminate advances in aging research to the public. The NIA sponsors aging research through the extramural and intramural research programs (National Institute on Aging [NIA], 2009).

The extramural research program consists of aging studies conducted at public and private organizations, such as hospitals and universities. The four extramural research programs supported by the NIA are: Division of Aging Biology, Division of Behavioral and Social Research, Division of Neuroscience, and Division of Geriatrics and Clinical Gerontology. Research conducted by the Division of Aging Biology examines the physiological mechanisms involved in the aging process using humans and animals. Examination of the biological processes involved in aging aid in the understanding of how biochemical changes associated with aging may be risk factors for diseases later in life. The Division of Behavioral and Social Research seeks to understand the aging process at the individual and group level. Emphasis is placed on how individuals change over time and the impact it has on greater society. The Division of Neuroscience supports research related to increasing the understanding of how the nervous system is impacted by the effects of aging. Alzheimer's disease and other dementias are the main research areas in this division. Research studies supported by the Division of Geriatrics and Clinical Gerontology consist of three main areas, which include Geriatrics, Clinical Gerontology, and Clinical Trials. The focus of this division is to examine age-related health concerns and identify risk factors associated with age-related diseases. The four divisions of the extramural research program offer grants and training opportunities to further enhance the aging research field (NIA, 2011).

The intramural research program conducts studies in multiple NIH sites in Maryland. The focus of this research program is to examine the physiological age-related changes that occur throughout the lifespan in order to better understand the physiology of age-related diseases, such as Alzheimer's disease, atherosclerosis, and cancer. In addition to examining the physiology of age-related diseases, the intramural research program also aims to understand the predictors of positive health (NIA, 2010).

Major Impact on the Field

The NIA has made many initiatives in the field of behavioral medicine through their ongoing research studies, clinical trials, and published findings.

Clinical Trials

The NIA supports multiple clinical trials examining multiple age-related conditions. The various medical conditions funded by the NIA-funded clinical trials include atherosclerosis, diabetes mellitus, hypercholesterolemia, hypertension, inflammation, menopause, obesity, and osteoporosis. In addition, the NIA funds clinical research relevant to promoting health behavior and managing psychological stress.

For example, the NIA is committed to understanding more about Alzheimer's disease. One of the clinical trials funded by the NIA tested whether Pioglitazone, a drug traditionally used to treat type 2 diabetes, was effective at slowing the progression of Alzheimer's disease (Geldmaher, 2009). Similarly, the NIA funded a trial to evaluate the effectiveness of antioxidant treatments for patients diagnosed with Alzheimer's disease (Galasko, 2009). Additional clinical trials have been funded by the NIA to assess decision-making abilities of patients diagnosed with Alzheimer's disease and to identify Alzheimer's disease-related brain changes and predictors of memory loss (de Leon, 2009; Karlawish, 2009).

Publications

The NIA has published various resources available to the public that demonstrate its initiatives in the field of behavioral medicine. Published resources include information about the importance of engaging in positive health behaviors such as eating a healthy diet, quitting smoking, exercising, and sleeping well. The NIA has also published resources for issues related to depression, coping with death, memory loss, and sexuality in adulthood.

National Institute on Alcohol Abuse and Alcoholism

Jennifer Pellowski
Department of Psychology, University of Connecticut, Storrs, CT, USA

Basic Information

The National Institute on Alcohol Abuse and Alcoholism (NIAAA) is part of the National Institutes of Health and focuses on research associated with the causes, treatment, and prevention of alcoholism. NIAAA became the leading federal agency to address alcoholism as a public health problem after the passage of the Comprehensive Alcohol Abuse and Alcoholism Prevention, Treatment, and Rehabilitation Act of 1970. Also referred to as the Hughes Act of 1970, this legislation established NIAAA as part of the National Institute of Mental Health (NIMH).

Since its conception, NIAAA has been at the forefront of alcohol-related research starting with its investigation of fetal alcohol spectrum disorder (FASD) at a time when many scientists and physicians doubted its existence. In 1977, it held the first national FASD research conference which highlighted epidemiological and clinical research and led to the issue of the first FASD government health advisory. Since then their research has expanded to include the genetics of alcoholism, benefits of alcohol consumption, neurological examinations of the impact of alcohol, and improving health care and treatment of those that suffer from alcohol abuse and alcoholism as well as other topics.

It conducts and funds internal and external research studies. NIAAA focuses on multidisciplinary efforts including epigenetics, neuroscience, public health, epidemiology, genetics, and public policy. It also acts to relay information to clinicians, patients, policymakers, and the general public in an accessible manner. Notable projects include Project MATCH and Project COMBINE which have developed new ways of approaching treatment and therapy for those suffering from alcoholism. Additional studies have also identified targeted populations, specifically pregnant women and youth, and subsequently focused research efforts to highlight specific needs of these populations to increase prevention. In addition to internal research, NIAAA also provides financial and other forms of support to researchers through requests for applications (RFAs) and program announcements (PAs) as well as through other small grants.

In conjunction with the goal of conducting and supporting research, the NIAAA also works to disseminate this newly found information. It accomplishes this goal through Alcohol Alert, which is published quarterly and aimed at professionals and clinicians. Additionally, the NIAAA also provides information to the general public through pamphlets and brochures as well as educational training programs. NIAAA also sponsors several public health programs that range in topics and targeted populations from pregnant women to youth and young adults.

National Institute on Alcohol Abuse and Alcoholism
5635 Fishers Lane, MSC 9304
Bethesda, MD 20892-9304
URL: http://www.niaaa.nih.gov

Major Impact on the Field

The National Institute on Alcohol Abuse and Alcoholism is the largest funder of research concerning alcoholism and alcohol-related problems in the United States. It is a keystone of alcohol abuse and alcoholism research and provides leadership in the dissemination of information for clinicians, patients, and the general public. The NIAAA acts to bridge the gap between research and the community at large through educational programs and changes in public policy.

National Institutes of Health

Vaughn Bryant[1] and Anne Frankel[2]
[1]Behavioral and Social Sciences, Brown University, Providence, RI, USA
[2]Robert Stempel College of Public Health and Social Work, Florida International University, Miami, FL, USA

Basic Information

Overview

The National Institutes of Health (NIH) is an agency of the United States Department of Health and Human Services. It consists of the Office of the Director (OD) and 27 institutes and centers which make up the largest source of medical and scientific funding in the world (United States Department of Health and Human Services & National Institutes of Health, 2010). The main function of the OD is to "plan, manage, and coordinate" the specific policies and procedures laid out for these institutes (United States Department of Health and Human Services, 2010a). The policies and procedures are developed and implemented through extensive collaboration and input from the OD and NIH staff. Other sources of information include the extramural scientific community, patient advocacy and volunteer organizations, Congress, and the Director's Council of Public Representatives, a federal committee made up of members of the general public. The current director of the NIH is Francis S. Collins. Dr. Collins' job is to efficiently and effectively integrate the information from his advisors and provide direction for specific "Areas of Research Emphasis," the future goals and directions that the NIH identifies as beneficial to science and society. Themes that are to be addressed in the coming years include translational medicine, health-care reform, global health, and empowering and energizing the research community (United States Department of Health and Human Services, 2010a).

Application Process

Sustained funding is a necessary component for advancing science. In order to facilitate innovative projects that support scientific progress, the NIH funds grants, cooperative agreements, and contracts (United States Department of Health and Human Services, 2010b). The NIH lists several key factors in being awarded funding: (1) the project must be of high scientific caliber, (2) it must be investigator-initiated, and (3) the research must be unique and innovative. In order to provide guidance for funding opportunities, NIH notifies researchers of the availability of funds through Funding Opportunity Announcements (FOAs), which are posted in the NIH Guide for Grants and Contracts and on Grants.gov. Other sources of funding information include Parent Announcements, Program Announcements (PAs), and Requests for Applications (RFAs). The NIH also supports research centers and intramural research (United States Department of Health and Human Services, 2010b; United States Department of Health and Human Services & National Institutes of Health: Office of Extramural Research, 2009).

Funding opportunities exist for a variety of research structures, including individuals, domestic institutions, and foreign institutions. Further, the NIH seeks to fund investigators at various points in their scientific careers. For example, special programs and announcements have been created targeting young and early stage investigators in order to help this population establish their career and ultimately flourish in the realm of scientific research. More senior investigators may choose to be mentors for early stage investigators and directors of projects or institutes (United States Department of Health and Human Services, 2010b).

Historically, it has been considered difficult to be awarded an NIH grant. However, competition is critical for improving the level of applications and ultimately the caliber of scholarly research. In order to determine which grants are awarded funding, applications typically go through a rigorous process known as peer review. The peer review process involves multiple readings of each application by credentialed peers in the relevant field and helps to establish the quality of the grants funded. The NIH lists five major review criteria looked at by reviewers when examining and scoring applications: the significance of the project; investigator background; level of innovation, approach, and methodology; proposed environment for the study; and probability of success (United States Department of Health and Human Services & National Institutes of Health: Office of Extramural Research, 2011). Before reviewers meet, they give each application a preliminary score on a scale from 1 (exceptional) to 9 (poor). Applications which receive a score above a predetermined threshold score progress to a full committee meeting. At this meeting, reviewers discuss the strengths and weaknesses of each application and create an impact/priority score, which determines the percentile ranking that will organize applications for possible funding. Program officers then determine how review scores are translated into funding for a certain number of applications. Often, applications are submitted twice: if an initial application is not granted review, comments are provided to the applicant, and they are encouraged to submit an amendment. Grants are reviewed both by the center for the scientific review and the institutes themselves for special initiatives. Special review processes only allow for one submission (United States Department of Health and Human Services & National Institutes of Health: Office of Extramural Research, 2011).

Funding Success

Funding success is an important measure of the level of competition. Success rates are reported as the percentage of reviewed grant applications that receive funding, which is determined by dividing the number of competing applications funded by the sum of the total number of competing applications reviewed and the number of funded carry-overs (United States Department of Health and Human Service & National Institutes of Health, 2009). Success rates are computed on a fiscal year basis and include applications that are peer-reviewed and either scored or unscored

by an Initial Review Group. Applications that have one or more amendments in the same fiscal year are only counted once. Funding success rates are typically between 10% and 20% (United States Department of Health and Human Services & National Institutes of Health: Office of Extramural Research, 2011; United States Department of Health and Human Service & National Institutes of Health, 2009; United States Department of Health and Human Services, 2010c). In 2010, there was an overall success rate of approximately one in five grants, which accounts for both new investigators and established investigators, who may be more likely to get funding based on past awarded grants. Thus, this measure may not be representative of the level of competition for new or less established investigators. After peer review, successful grantees go through the award process in which the grantee is notified of an award and assigned a program officer who manages the distribution and monitoring of the award. Grant awards can range from a few thousand to tens of millions of dollars and depend on numerous factors including the type of grant (known at NIH as the "grant mechanism"), the institution, the structure of the proposal (individual vs. center), the period of time that the award is assigned, and many more. The oldest and most common mechanism applied for is the R01, which cannot exceed $250,000 annually in direct costs, unless a special request is made (United States Department of Health and Human Services & National Institutes of Health, 2010). Other common grant types are K mechanisms, which represent training grants, fellowships, and early stage investigator-initiated research; U mechanisms, which are cooperative agreements; and R21 exploratory grants.

Funding and Scientific Accomplishments

Funding of the NIH has been integral to the progression of innovative scientific discovery. President Obama recently released his 2012 budget proposal, in which he requested a 745 million dollar increase to the NIH budget. When added to the existing budget, the total request for the NIH is 32 billion dollars. Considering the 3.5% rate of inflation, the proposed amount is roughly equivalent to flat funding (Brown, 2011).

The latest scientific accomplishments of NIH-funded projects were highlighted in a recent status report (United States Department of Health and Human Services, 2011). Many of these accomplishments have been in the area of HIV/AIDS, with the development of antiretrovirals (ARVs) to treat the disease as one of the most notable. One large-scale study involved an ARV microbicide for women and found a 50% protection rate against HIV transmission. Future research focuses for the NIH in the field of HIV/AIDS will be on vaccine development and efficacy.

Advances in technology are key to NIH's research success. For example, because of NIH-sponsored research, high-resolution imaging is becoming a critical part of studying disease and disease progression. Findings of a study conducted by the National Lung Society suggest that low-dose CT screening can decrease lung-cancer deaths by 20% among heavy smokers. Another technological innovation becoming increasingly important in the treatment of disease is stem cells. Researchers recently found that mouse embryonic and induced pluripotent stem cells can be used to generate new hair cells, which has implications for hearing loss and deafness in humans. Finally, influenza vaccines have been improved to protect against multiple strains of the virus, which has helped science progress toward the goal of eradicating the virus worldwide.

Future Changes and Directions

There are many areas in the health sciences that are under-researched, including pain control, drug delivery, vaccines, medical informatics, and more that may lead to future initiatives and structural changes. The NIH is currently developing translational research initiatives by creating a clinical and translational research institute, which would help facilitate the process of translating clinical findings to practical applications such as drug development and other health improvements. Another example of a structural change to the NIH is the recent vote by the Scientific Management Review Board to merge the National Institute on Drug Abuse (NIDA) and the National Institute on Alcohol Abuse and Alcoholism (NIAAA) (Mcmanus, 2010). These proposals indicate that the NIH is

responsive to changes in science and attempts to accommodate these changes through reorganization and constant refinement both at the structural level and the scientific level.

Major Impact on the Field

The NIH is the largest source of funding for medical research in the world. Major contributions to various scientific fields linked directly to NIH funding cannot be understated. For example, the increase in lifespan in the United States from 47 to 78 between 1900 and 2009 has been attributed to the long history of NIH funding (United States Department of Health and Human Services & National Institutes of Health, 2010). Diseases such as smallpox, measles, polio, and chronic conditions such as diabetes and cancer, which were once death sentences, are now eradicated, curable, preventable, or treatable. In fact, rates of cancer diagnoses and cancer-related deaths have seen significant drops in recent years (United States Department of Health and Human Services, 2008). The field of mental health has seen advances, including the development of more effective antidepressants as well as improvements in the overall treatment for mental health and substance use disorders. The Human Genome Project, an ambitious campaign that began in 1990 and involved researchers from all over the world dedicated to decoding the mysteries of the human genetic code, resulted in the sequencing of the human genome in 2003. This enormous effort has given researchers unique insight into more than 1,800 disease genes and has played an invaluable role in the development of genetic tests (United States Department of Health and Human Services & National Institutes of Health, 2011). Prevention research has made immense strides due to NIH funding and has resulted in a better understanding of measures that can be taken to reduce the risk of heart disease, stroke, dementia, and many other adverse health conditions.

More than 80 Nobel Prizes have been presented to NIH-funded projects. However, scientific advances resulting from NIH-supported projects extend well beyond the ones receiving special recognition, and often the true impact of such projects cannot be gauged until long after their completion. Additionally, despite major cuts to NIH funding, the latest advances in comparative effectiveness research offer a better understanding of how to best utilize and distribute funds to maximize the long-term impact that projects will be able to have in their respective fields. Each day, NIH-funded projects address the challenges of a changing health climate facing chronic disease, the resurgence of old diseases, and emergence of new, and progress toward a healthier society both across the United States and worldwide.

Natural Killer Cell Activity

Riyad Khanfer[1], Benjamin I. Felleman[2] and G. Alan Marlatt[3]
[1]School of Sport and Exercise Sciences, The University of Birmingham, Edgbaston, Birmingham, UK
[2]Seattle Pacific University, Seattle, Washington, USA
[3]University of Washington, Seattle, Washington, USA

Definition

Natural killer (NK cells) form an important arm of the innate immune system (non specific immunity). They develop in the bone marrow and circulate in the blood. They are called NK cells because they are always active naturally and can kill before they encounter any antigens. They have important roles in eliminating virally infected cells without having specificity against any particular viruses and act as early component of the host response to viral infections. NK cells also play role in fighting cancer cells in the body. NK cells are considered part of the group of lymphocytes; however, they have neither antigen receptor nor antibody receptor, and they are larger in size than T and B lymphocytes.

Upon NK cells activation, they produce cytotoxic granules which contain many molecules like perforins, TNF-α, lymphotoxin-β, INF-α, and many granzymes. NK cells kill virally infected cells by secreting these cytotoxic granules after recognizing the infected cells by lacking MHC molecule (major histocompatability complex) class I, which is not present in the virally infected cells. Also, these granules contain other molecules like TNF (tumor necrosis factor) which can activate apoptosis through death domain of TNF receptor of the target cell; also, NK cells kill by apoptosis via Fas ligand – Fas receptor mechanism upon engagement of the NK cell receptor with the target cell receptor.

NK cells have a mechanism of checking cells by detecting the amount of MHC I protein on the cell

surface; cells which express enough amount of MHC I will escape the killing by NK cells, and cells with reduced amount of MHC I will be targeted and killed by NK cells via programmed cell death after targeted by the cytotoxic granules. NK cells can be activated in response to interferons and macrophage-derived cytotoxins.

NK cells secrete cytokines such as interferon γ and interleukin 12 which help in CD4 T lymphocytes differentiation. NK cells are among the first to encounter cancer cells of the innate immunity components, and they secrete interferon γ which recruit other component of the immune system.

To control their cytotoxic activities, NK cells have two types of receptors on their surface: the first set are activating receptors that induce killing by NK cells and called KAR (killer activating receptors), while the second set of receptors are inhibitory which inhibit NK cells activation and therefore prevent killing to the normal host cells (killer inhibitory receptors KIR), and the KIRs are specific for MHC class I molecule.

Also, NK cells kill cancer cells as well as viral-infected cells by detecting an important specific protein expressed often at the surface of these cells as a result of cellular physiological stresses, such as postneoplastic transformation or viral infection. NK cells express complementary cell surface receptor for the above stress proteins which strongly activate NK cells and the production of the NK cell cytotoxic granules.

Summary: *Specific features of NK cells function and killing*
Part of innate immunity
Kill cancer and virus-infected cells
Killing without specificity
Have two types of receptors: KAR to kill and KIR to avoid killing
Secrete some cytokines like IL12 and IF-γ
Produce cytotoxic molecules to kill target cells by apoptosis
Screen target cells by lack of MHC I expression
Recognize stress proteins on physiologically stressed cells

Needle Exchange Programs

Hansel Tookes
Epidemiology and Public Health, Miller School of Medicine, University of Miami, Miami, FL, USA

Synonyms

NEPs; SEPs; Syringe exchange programs

Definition

In 2006, injection drug users (IDUs) accounted for 12% of the 56,300 new human immunodeficiency virus (HIV) infections in the USA (Hall et al., 2008). In 2007, 15% of the 43,000 new hepatitis B virus (HBV) infections and 44% of the 17,000 new hepatitis C virus (HCV) infections in the USA were among IDUs (Guardino et al., 2010). IDUs are susceptible to infection via sharing injection equipment and high-risk sexual behavior. While the National Institute on Drug Abuse (NIDA) recommends use of a new, sterile syringe each injection, many IDUs contract these viral infections through the sharing of

contaminated syringes. In response to these viral epidemics, syringe exchange programs (SEPs) have been implemented in many countries including the United States (USA) (Mathers et al., 2010). These programs allow IDUs to exchange contaminated syringes for sterile syringes, with the goal of reducing the likelihood of IDUs' sharing used syringes.

The first SEPs in the USA opened in the late 1980s in Tacoma, Washington, followed shortly by programs in San Francisco, California; Portland, Oregon; and New York, New York (Hagan, Des Jarlais, Purchase, Reid, & Friedman, 1991). The North American Syringe Exchange Network (NASEN) estimates that there are currently 184 SEPs operating in the USA (Guardino et al., 2010). In December of 2009, President Barack Obama signed a bill authorizing the use of federal dollars for SEPs. This signing marked the end of a 21-year-long Congressional ban on SEPs instituted in 1988 at the height of the AIDS epidemic (Kerlikowske & Crowley, 2010).

A 1997 Report to Congress by the then Secretary of Health and Human Services Donna Shalala established SEPs as an effective component of a comprehensive strategy to prevent HIV and other blood-borne infectious diseases (Shalala, 1997). Many studies have shown that SEPs help to reduce the sharing of syringes among IDUs, and IDUs have reported no increased unsafe disposal in areas where SEPs were providing more syringe coverage (Bluthenthal, Anderson, Flynn, & Kral, 2007; Neaigus et al., 2008; Watters, Estilo, Cark, & Lorvick, 1994). Further, SEPs provide a range of preventive care services. Most SEPs services include HIV/AIDS counseling and testing, HCV counseling and testing, condom distribution, referral to substance abuse treatment, alcohol swabs, and safe-injection education. Additional services are often available including primary medical care, tuberculosis screening, and comprehensive hepatitis screening services including HAV and HBV vaccination (Guardino et al., 2010).

SEPs help refer IDUs to treatment and do not encourage drug use among IDUs or recruit new users (Vlahov & Junge 1998). SEPs also help IDUs use sterile syringes and share less, reducing risk of blood-borne illness (Des Jarlais et al., 1994; Heimer, Khoshnood, Bigg, Guydish, & Junge, 1998). HIV incidence among IDUs has decreased by 80% from before SEPs (1988–1990) to their maximum coverage (2003–2006) (Hall et al., 2008). These data are of high public health significance because in 2010, the Departments of State and Health and Human Services have issued policy guidance for US and global partners in the President's Emergency Plan for AIDS Relief (PEPFAR) in the implementation of SEPs, but SEP coverage has yet to increase domestically. Despite the evidence, IDUs have limited coverage with SEPs offered in only 36 states, the District of Colombia, and Puerto Rico (Guardino et al., 2010). However, in 2011, the Centers for Disease Control and Prevention will issue guidance on SEPs to all US Health Departments, which will include recommendations relevant to syringe exchange programs.

Negative Affect

Deborah M. Stringer
Department of Psychology, University of Iowa, Iowa City, IA, USA

Synonyms

Emotional distress; Negative emotion

Definition

Negative affect is a broad concept that can be summarized as feelings of emotional distress (Watson, Clark, & Tellegen, 1988); more specifically, it is a construct that is defined by the common variance between anxiety, sadness, fear, anger, guilt and shame, irritability, and other unpleasant emotions. A variety of converging evidence suggests that negative affect is largely statistically independent from positive affect (e.g., Watson, 1988), but it is also clear that there exists a dimension called pleasantness-unpleasantness that has relations to both negative and positive mood terms (e.g., happiness and sadness). Some workers (e.g., Russell & Carroll, 1999) take the existence of the bipolar pleasantness-unpleasantness factor as evidence that negative affect and positive affect form a single dimension.

Negative affect and the dispositional tendency toward negative affect (called neuroticism, negative affectivity, or negative emotionality) are a large component of many forms of psychopathology including mood disorders, anxiety disorders, and personality disorders. Negative affect has also been associated with such important areas in behavioral medicine as coping with illness or caregiving, blood pressure and heart rate, perceived stress, drinking motives, tobacco smoking, drug use, disordered eating, self-reported sleep quality, and cardiovascular disease.

Negative Affectivity

Johan Denollet
CoRPS – Center of Research on Psychology in Somatic diseases, Tilburg University, Tilburg, The Netherlands

Synonyms

Neuroticism

Definition

Negative affectivity (NA) is a broad personality trait that refers to *the stable tendency to experience negative emotions* (Watson & Clark, 1984). Individuals who are high in NA are more likely to report negative affective mood states across time and regardless of the situation. They also report more somatic symptoms and have an attention bias toward adverse stimuli or potentially threatening situations (Watson & Pennebaker, 1989).

NA is closely related to *neuroticism* (Costa & McCrae, 1987) as one of the broad trait domains in the Five Factor Model of personality. Because NA is centrally defined by the tendency to experience negative affect (Watson & Pennebaker, 1989), the label NA is used here to designate dysphoric individual differences that are relatively stable over time. From a cognitive point of view, individuals who are high in NA may take a gloomy view of things and are inclined to be worrying. From an affective point of view, symptoms of depressed mood are often accompanied by other negative emotions like anxiety and anger (Watson & Clark, 1984).

There are a number of reasons why it is important to account for individual differences in NA in clinical research and practice. First, *psychological risk factors tend to cluster together within individuals*; clustering of these factors, in turn, elevates the risk for adverse outcomes. NA is a personality trait that predisposes to clustering of negative emotions as a psychological risk factor (Denollet, 2005; Suls & Bunde, 2005). Second, individuals who are high in NA may *scan the world for signs of impending trouble* and seem to focus their attention on adverse stimuli (Watson & Pennebaker, 1989). This may explain why NA or neuroticism has been associated with more reactivity to stressful events and with more negative appraisals of interpersonal stressors. Third, NA may be related to *difficulties in coping with life stress* (Depue & Monroe, 1986) and is associated with an increased risk of affective disorder (Watson, Clark, & Harkness, 1994) and symptoms of both emotional and somatic distress (Watson & Pennebaker, 1989).

Some have argued that neuroticism or NA is associated with complaints of chest pain but not actual heart disease (Costa & McCrae, 1987). However, one should not overlook potential associations between NA and *decrements in physical health*. There is a substantial overlap among the various negative affective dispositions (anger, anxiety, and depression) that have been associated with an increased risk of cardiovascular disease. This suggests that a general disposition toward negative emotions – the core of NA – may be important as a potential determinant of adverse health outcomes (Denollet, 2005; Suls & Bunde, 2005).

Broad and stable personality traits such as NA may carry with them much potential for scientific and clinical purposes. NA taps into chronic attributes of individuals and has many referent attributes and therefore has much predictive and explanatory power. NA can be reliably *assessed with the 7-item NA measure of the DS14* (Denollet, 2005), a scale that was specifically designed to assess this stable tendency to experience negative emotions.

Negative Thoughts

Louise C. Hawkley
Department of Psychology, University of Chicago, Chicago, IL, USA

Synonyms

Anger; Anxiety; Avoidance; Catastrophizing/Catastrophic thinking; Depression; Hostility; Loneliness; Negative affect; Negative cognitions; Neuroticism; Perceived stress; Pessimism; Rumination; Worry

Definition

Negative thoughts are cognitions about the self, others, or the world in general that are characterized by negative perceptions, expectations, and attributions and are associated with unpleasant emotions and adverse behavioral, physiological, and health outcomes.

Negative thoughts are cognitive components of negative psychosocial variables such as depressive symptoms, anxiety, loneliness, and hostility. Depressive cognitions, for instance, include thoughts of hopelessness, helplessness,

and diminished self-worth. Anxiety is a negative affective state or trait that is accompanied and perpetuated by worry and rumination. Loneliness is a negative state or trait that is characterized by perceptions of social threat, negative expectations in social interactions, and lower self-esteem. Hostility is characterized by derogation of others and thoughts of aggression and revenge. Negative thoughts are often intrusive and unwanted and require effort to suppress.

Negative thoughts are assumed to play a major role, together with related negative emotions, in the associations of negative psychosocial variables with poorer health behaviors, greater physiological reactivity, poorer health, and higher rates of mortality. Negative thoughts tend to co-occur with each other, and their combined contributions may exceed those of any particular negative thought. Alternatively, specific negative thoughts may exert unique effects on health-related outcomes. The effects of loneliness on systolic blood pressure, for example, are independent of the effects of negative thoughts related to perceived stress, depressive symptoms, poor social support, and hostility (Hawkley, Thisted, Masi, & Cacioppo, 2010). On the other hand, worrying and pessimism tend to be correlated, and each has shown a positive prospective association with risk for coronary heart disease (Kubzansky et al., 1997; Kubzansky, Sparrow, Vokonas, & Kawachi, 2001), but it is not known whether the effects of worrying and pessimism on disease risk are independent of each other or confounded with each other. Mechanistic models of health risk employ negative thoughts as precursors to behaviors that have health consequences. For instance, low self-esteem has been shown to prospectively predict health problems through its effect on the quality of social bonds (Stinson et al., 2008).

Neuroticism is a personality trait that is defined as a propensity for negative thoughts and experiences of many kinds and has been associated with mortality (Shipley, Weiss, Der, Taylor, & Deary, 2007). Because neuroticism is associated with a variety of specific negative thoughts, studies sometimes employ neuroticism as a covariate to determine the extent to which health effects are attributable to a specific negative psychosocial variable or negative thought as opposed to negativity more generally.

Synonyms

Nested case-control study

Definition

A nested case-control study is one that is "nested" within a cohort study.

In many cohort studies, all subjects provide a wide range of information at the time of recruitment, e.g., results from a physical examination, answers to multiple questionnaires, blood and urine samples, and results from imaging techniques. Because of the large numbers of subjects in these studies and the cost of analyzing some biological samples, some of these resources are often not analyzed in detail at the time of collection, but are stored for future use. The nested case-control study is performed using subjects who develop the disease of interest in due course, and control subjects who are selected from those who were disease-free at the time the case subjects (those who developed the disease) were diagnosed.

The appropriate data sets and samples are then retrieved and analyzed for these two subsets (cases and controls) of the original cohort recruited into the study. This approach maintains the major advantage of a cohort study in that the exposure data were collected before the development of the disease in the case subjects, while requiring the analysis (and associated costs) for only those who become entered into the nested case-control study (Webb, Bain, & Pirozzo, 2005).

Definition

Neuroendocrine activation is activation of both neuronal and endocrine pathways in situations when either internal or external factors act in a way that disturbs the body's homeostasis.

Description

From its very origin, life has been exposed to a highly dynamic environment. In order to survive, everything, from the simple primordial ribonucleic acid (RNA) molecules to the highly structured organisms that exist in the present world, had to learn how to fight these changes and eventually benefit from them. Nevertheless, no matter how beneficial these changes proved to be in the end, first encountered, they usually provoked a physiological response, commonly known as stress. Often, very hostile environments forced more complex organisms, like vertebrates, to develop a response that Walter Cannon (1914) first introduced as a "fight-or-flight" response, which describes a number of physiological changes involved in regulation of the body's response to stimuli. This response aims to maintain body homeostasis, the mechanism that keeps internal environment in the body as constant and balanced as possible (Pacák & Palkovits, 2001).

One of the key features in this adaptive response is neuroendocrine activation (Miller & O'Callaghan, 2002), which includes activation of two systems, the hypothalamic-pituitary-adrenal (HPA) axis and the sympathetic nervous system (SNS). Neuroendocrine activation can be triggered in two ways: as a feedback signal from peripheral receptors that have recognized the altered homeostasis or by the direct simulation from an activated brain regulatory center (Vigas & Jezová, 1996). Even though different stressors activate different pathways and circuits within an organism, they will always result in the series of neural and endocrine adaptations known as the stress cascade (Miller & O'Callaghan, 2002). The key site involved in neuroendocrine activation is the hypothalamus (Barrett, 2005). Activation of both HPA axis and SNS starts from this very small but extremely important part of diencephalon. The hypothalamus consists of large number of nuclei and fiber tracts situated in three prominent features: supraoptic (anterior) region, tuberal or middle region, and mammillary or posterior region. From its posterolateral nuclei, the hypothalamus establishes strong, direct connections with autonomic nuclei in the brain stem and spinal cord. In this way, this part of central nervous system (CNS) structure controls SNS functions (Barrett). At the same time, and as a response to stress, the hypothalamus releases a neuropeptide called corticotrophin-releasing hormone (CRH) (Griffin & Ojeda, 2004), which stimulates the anterior pituitary gland to release another hormone, adrenocorticotropic hormone or ACTH, into general circulation. ACTH in turn stimulates the adrenal cortical cells of the adrenal glands to synthesize and release species-specific glucocorticoids into blood. The tight control of these glucocorticoids (mainly cortisol in humans) is sustained via negative feedback that controls and, in the end, terminates the release of CRH (Griffin & Ojeda). The necessity for this very subtle regulation of HPA axis at different levels is well represented by adverse health consequences caused by its dysregulation (Tsigos & Chrousos, 2002). For example, increased HPA axis activity and the hyperproduction of cortisol can lead to melancholic depression which can be accompanied by atherosclerosis, suppression of immune cells, infectious diseases, deposition of visceral

fat, and enhanced resistance to autoimmune/inflammatory disease (Tsigos & Chrousos). Hypo-production of cortisol, on the other hand, will lead to the state of the relative resistance to infectious but increased susceptibility to inflammatory and autoimmune diseases, and, in its more severe form, a serious condition known as Addison's disease (Griffin & Ojeda, 2004). Clearly, one of the very important consequences of HPA axis activation is immunosuppression (Nance & Meltzer, 2003) that includes changes in leukocyte trafficking and function, decreased production of inflammatory cytokines, and inhibition of their effects on target tissues. However, although glucocorticoids can express variable effects on different systems, resulting sometimes in activation and sometimes in their suppression, their primary goal is always to act as the guardians of body homeostasis (Munck, Guyre, & Holbrook, 1984). Therefore, it is not stress that glucocorticoids fight against, it is altered homeostasis that triggers their secretion and activation.

Stress triggers the activation of both pituitary gland and adrenal cortex, as well as specialized "neuroendocrine tissue" in the hypothalamus, but it can also act via sympathetic neurons responsible for presence of the circulating catecholamines, adrenaline, and noradrenaline, (epinephrine and norepinephrine) secreted from adrenal medulla (Barrett, 2005). This is known as the sympatho-adrenal-medullary axis or SAM axis/system. Stress can also cause an integrated response that originates entirely within the central nervous system, where activation of cortical and hypothalamic brain centers acts via postganglionic sympathetic neurons, innervating the smooth muscles of blood vessels, heart, skeletal muscles, kidney, gut, and other organs (Barrett). In other words, both short-term physiological changes (such as acute exercise) and chronic pathophysiological disorders (chronic heart failure) will lead to CNS-mediated SNS activation (Goldstein, 1987). SNS activation involves the release of noradrenaline at the end of the postganglionic neurons, but through its preganglionic fibers of splanchnic nerves, it also regulates hormone secretion from adrenal medulla (Barrett, 2005). The cells of this endocrine gland, chromaffin cells, synthesize and secrete adrenaline, and, to a lesser extent, noradrenaline. The presence of these catecholamines in the blood stream (e.g., in response to the exercise-induced stress) will lead to cognitive arousal, cardiac stimulation and vasoconstriction of peripheral blood vessels with preserved skeletal muscle blood flow, and relaxed bronchial smooth muscle, increasing oxygen delivery to the exercising muscle, and it will also affect gastrointestinal, renal, endocrine, and other systems (Barrett). On the other hand, a rise in plasma glucocorticoid levels activates different hormones, prostaglandins and other arachidonic acid metabolites, lymphokines, and bioactive peptides which in turn challenge homeostasis through different physiological mechanisms again affecting endocrine, renal, nervous, as well as the immune systems. However, unlike components of HPA axis, secretion of adrenal medullary hormones is not regulated by endocrine feedback loop, but it is controlled by CNS instead (Barrett).

In sum, activation of the autonomic and neuroendocrine system during stress has been developed as a protective mechanism in "flight-or-fight" situations where it serves to mobilize the metabolic resources necessary to support the requirements of the organism (Havel & Taborsky, 2003). The problem arises when neuroendocrine activation exceeds the body's metabolic requirements, typical in situations of chronic psychological stress, large amounts of caffeine uptake, as well as the pathological condition of chronic myocardial infarction. One example of this negative effect of neuroendocrine activation in humans today is stress-induced hyperglycemia (Havel & Taborsky). Clearly, neuroendocrine activation during stress through sympathoadrenomedullary system triggers the release of neuropeptides such as adrenaline and noradrenaline and, via activation of HPA axis, causes an increase in secretion of cortisol and the pancreatic hormone glucagon (Havel & Taborsky), with a simultaneous decrease in insulin production. As the pancreatic hormone glucagon raises blood glucose levels, and insulin acts as its antagonist, this neuroendocrine pattern will

cause an increase in hepatic glucose production in situations that demand increased muscular activity (Havel & Taborsky). In other words, increased physical activity present in the "flight-or-fight" response will increase the demand for the glucose consumption and effectively balance higher glucose production, therefore maintaining glucose plasma level (Havel & Taborsky). Among modern types of stress, exercise-induced stress is the only one that parallels somatic motor activation present during "flight-or-fight" response (Havel & Taborsky). Other common types of stress such as hypoxia, trauma, myocardial infarction, etc., will trigger neuroendocrine activation and secretion of glucose-mobilizing hormones without adequate glucose utilization and therefore will lead to the state of hyperglycemia (Havel & Taborsky).

Caffeine intake (Lane, Pieper, Phillips-Bute, Bryant, & Kuhn, 2002) can also mimic stress-induced activation of neuroendocrine system and lead to a rise in plasma levels of adrenaline, noradrenaline, as well as glucocorticoids such as cortisol. Similar to stress situations, it not only enhances cardiac output, diastolic blood pressure and heart rate, as well as skeletal muscle blood flow but can also potentiate already stress-induced increases in cardiac output and plasma concentration of adrenaline and cortisol (Lane et al., 2002).

One of the important protective roles of neuroendocrine activation is sustaining circulation in vital organs (such as heart, brain, kidney), in the situations of extensive volume loss, e.g., hemorrhage (Swedberg, 2002). In order to sustain its role, neuroendocrine activation causes tachycardia, constriction of peripheral blood vessels, and volume expansion. Unfortunately, what is beneficial in one situation can become detrimental in other pathological conditions such as chronic heart failure (Swedberg). Direct consequences of chronic neuroendocrine activation in this case are sodium and water retention that leads to congestion, vessel constrictions that will increase demand of oxygen, and toxic cellular effects, all of which combined together may cause cardiac dysfunction and higher morbidity and death in chronic heart failure patients (Swedberg).

Hence, neuroendocrine activation is an adaptive response to changing and demanding external and internal environment, and another example of the complex structure of living organisms, so carefully and subtly regulated that exposure to any new phenomenon, can turn this strong protector into a very dangerous enemy.

Neuroendocrine Theory of Aging

Emil C. Toescu

Hormone theory of aging

Definition

The neuroendocrine hypothesis of aging proposes that aging results from the functional perturbations, both in neuronal control and in endocrine output, of the hypothalamic-pituitary-adrenal axis. These perturbations result in dysfunction in the activity of various endocrine glands and their target organs. The other consequence is a developing imbalance in hormonal cross-communication between various endocrine axes.

Description

The neuroendocrine system has two central components: the hypothalamus, a structure that is part of the central nervous system (CNS), and the pituitary gland, situated in an anatomical bone depression at the base of the skull, just behind the crossing of the optical nerves (optic chiasm). The two components, forming the hypothalamo-pituitary (HP) axis are extensively linked, though a stalk that contains both vascular and neuronal connections.

The activity of the system is regulated both by neurotransmitters and neuropeptides secreted locally in the CNS and by circulating hormones. Together, these factors control the secretion by the hypothalamus of hormonal factors that induce or inhibit the downstream release of hormones from the pituitary gland. In addition to this central role in the control of the endocrine system, the hypothalamus has also an important role in the control and integration of activities in the sympathetic and parasympathetic branches of the autonomic nervous system, thus influencing a wide array of essential physiological functions such as heart beat, blood pressure, and vascular reactivity or glucose metabolism. By changes in neuronal activity in specific discrete nuclei, the hypothalamus also regulates the food intake and the distribution and regulation of fat metabolism, in response to peripheral appetite-inducing, orexigenic (ghrelin), or appetite-reducing, anorexigenic (e.g., leptin) agents.

Aging is associated with multiple endocrinological changes, including a decrease in estrogens in women (menopause) and testosterone in men (andropause), dehydroepiandrosterone (DHEA) and DHEA sulfate (adrenopause), as well as decreases in growth hormone (GH) and insulin-like growth factor (IGF-1) (somatopause).

The general form of the neuroendocrine hypothesis of aging proposes that aging results from the functional perturbations, both in neuronal control and in endocrine output, of the HP axis, that result in a dysfunction in the activity of the endocrine glands and their target organs, as well as imbalances in the hormonal and signaling cross communication between the various components of the endocrine axes. A relevant feature of the activity of the neuroendocrine system is that the secretion of many of the hormone-releasing factors controlling individual endocrine

systems is cyclical, integrated mainly in diurnal (24 h), but also in monthly or longer cycles, through activity in the hypothalamic suprachiasmatic nucleus (SCN). Thus, the neuroendocrine hypothesis of aging proposes that with aging, through yet to be defined mechanisms, the activity of the body clock is perturbed resulting in a gradual and progressive dys-synchronization of the hormonal output. Similar disruptions in SCN activity affect other processes showing a diurnal cycle, such as the sleeping.

Several examples can illustrate this effect of aging on the endocrine system and the resulting functional effects. Thus, with increasing age, there is a decreased secretion of hypothalamic gonadotrophin-releasing hormone (GnRH) and a significant change in the pulsatile rhythm of its secretion that results in a decreased and more erratic secretion of luteinizing hormone (LH). This desynchronization, together with the decrease in the ovarian secretion of regulatory factors, leads, over a period of time, to the loss of reproductive cycles in females. The associated decrease in number of ovarian follicles contributes also to the decline in estrogen levels in aged women, leading to some of the of age-associated changes in postmenopausal women, such as the atrophy of the secondary reproductive tissues, reductions in bone density, or alterations in various cognitive functions. Decreased secretion of GnRH in males results in changes in LH and consecutive decrease in androgen levels, with corresponding loss of skeletal muscle and reproductive functions.

In many instances, the term "neuroendocrine theory of aging" is used in a much more restricted meaning and refers to the consequences of the age-related changes in the hypothalamo-pituitary-adrenocortical gland (HPA) axis. At the top of this axis, the parvocellular neurons in the paraventricular nucleus of the hypothalamus secrete corticotrophin-releasing hormone (CRH) that stimulates the anterior pituitary secretion of the adrenocorticotropic hormone (ACTH). The target organs for this latter hormone are the adrenal glands (situated above each kidney), where it activates the secretion of the glucocorticoids (GCs; cortisol, in humans, corticosterone, in rodents) from specific cortical cells in the cortex of the gland. The GCs have a wide range of effects – some are related to glucose metabolism, inducing through various mechanisms increases in glucose concentration in the blood, while others are related with the immune response, up-regulating overall the expression of anti-inflammatory proteins and decreasing the levels of pro-inflammatory proteins. In addition to these effects, and very relevant to the mechanisms linking glucocorticoids with the aging process, the GCs hormones play a vital role in regulating the stress response. Together with other stress-sensitive systems (e.g., the sympathetic response mediated by secretions from the medullar part of the same adrenal gland), GCs prepare the body for adaptation by mobilizing energy stores, suppressing nonessential physiological systems (e.g., feeding, reproduction), and generating behavioral responses to stimuli perceived as stressful. In the various target organs, including the brain, GCs act through two types of receptors. The glucocorticoid receptor (GR) is expressed throughout the brain, with relatively higher density in the hippocampus and prefrontal cortex. The mineralocorticoid receptor (MR) has a more restricted distribution, mainly in the hippocampus. The existence of both types of receptors in hippocampus is very relevant since the hippocampus, while being a central node in the networks controlling learning and memory, is also exerting an inhibitory effect on the hypothalamic release of CRH and, thus, can exert significant control on the HPA axis.

Two interrelated concepts are important for understanding this formulation of the neuroendocrine theory of aging, particularly in respect to brain aging: (1) chronic stress is associated with increases in circulating GC concentrations and (2) such increases in GCs induce an enhanced vulnerability of neurons to a variety of neuro- and excito-toxic agents. Thus, in a simple scheme, the decrease in the number of GRs and MRs observed with increasing age would contribute to an impaired regulation of the HPA axis, enhanced basal levels of circulating GCs, neuronal death and hippocampal atrophy, and cognitive impairment (the glucocorticoid hypothesis of brain aging).

Experimental evidence indicates that, in fact, the age-dependent changes in HPA axis activity are of a much subtler nature. With age, there are variable changes in the effects of GCs (cortisol) on ACTH secretion or of ACTH on cortisol secretion, while the capacity of the adrenal gland to produce GCs is not affected. Whereas the physiological cortisol circadian rhythmicity is maintained in essence, a significant age-related increase in the peak cortisol levels in physiological aging and an advance shift in the onset of the circadian cortisol rise result in an overall elevated serum GC level. With the important role of the GCs in mediating the stress response, one of the important functional consequences of these changes in the activity of the HPA axis is an increased responsiveness and an impaired ability to terminate stress responses, resulting in prolonged GCs exposures.

Further difficulties in tracing a simple causal relationship between dysregulation in the HPA axis, aging, and behavioral and cognitive impairment have been generated by recent data indicating that not all types of cognition are impaired, such that both encoding and consolidation of emotional learning is, in fact, facilitated by GCs or that in certain conditions, such as the caloric restriction model in rodents, increased GCs levels can be present while cognition performance is better than in the aged-matched control groups on a normal diet. Such results led to the recent proposal that the relationship between GCs, aging, and cognition represents a divergent imbalance between an age-dependent increase in GCs efficacy on some cell types, such as neurons in the hippocampus, enhancing the catabolic processes, and a decreased efficacy on other cell types, resulting in a decreased protective, anti-inflammatory response.

It is still unknown whether the age-associated reduction in hippocampal volume is the primary event leading to elevated levels of cortisol or the other way around, elevated levels of cortisol causing hippocampal atrophy. It is also possible that both events reflect a broader syndrome, often observed during aging, called the metabolic syndrome, and characterized by reduced glucose tolerance, hypertension, obesity, and elevated levels of cortisol. In addition, the actual role of circulating GCs in controlling the aging process is further complicated by the fact that the concentrations of active GC forms (cortisol, in humans, and corticosterone, in rodents) that interact with the intracellular receptors are controlled not only by the circulating levels of GCs but also by powerful pre-receptor mechanisms in the cytosol, such as the enzyme 11b-hydroxysteriod dehydrogenase I (11-HSD I), that is able to convert inactive forms of GCs (cortisone) into active forms (cortisol). Recent experiments indicate that modulation of 11-HSD I expression and activity has effects both on the aging phenotype and on the age-associated cognitive changes.

An important line of support for a neuroendocrine theory of aging comes from studies in the last few decades on the powerful effect of caloric restriction (CR) in delaying aging and increasing life span, in species ranging from yeast and worms to mice, rats, and monkeys (the results in humans are promising but not yet conclusive). From an evolutionary viewpoint, the effect of CR appears to be explained by organisms having evolved adaptation mechanisms in their neuroendocrine systems to maximize survival during periods of food shortage. Although CR induces wider endocrine modifications (fall in thyroid hormones (T_3), increased circulating corticosterone (in rodents), with little change in the secretion of the central regulator factors on the HPA axis, and decreased gonadal hormones), the proposed central mechanism of action of CR is through insulin signaling. It is known that aging is associated with increases in insulin resistance and adiposity, and it is becoming clear that long-time exposure to insulin resistance accelerates biological aging. For example, in diabetes, there is early onset of certain diseases of aging, such as dementia, as well as signs of general body aging such as frailty. Chronic stress may accelerate these age-related metabolic changes. Stress is related to obesity, especially abdominal obesity, and insulin resistance in both animal and human models.

Lifting the veil as to the endocrine mechanisms involved, the positive effects of CR are reproduced, to a large extent, in animal models

that have spontaneous or genetically engineered reductions in the activity of the GH/IGF-1 axis, starting with the initial reports of antiaging effects of hypophysectomized animals, more than 50 years ago. The nature of the processes involved was discovered by genetic studies, initiated in worms (*C. elegans*), showing that mutations in some genes in this pathway confer resistance to environmental stress, enhanced resistance to starvation, and, most importantly, extended longevity. Many of these same genes are conserved in humans: the insulin/insulin-like growth factor-I (IGF-I) peptide and *daf-2* gene (in worms) are homologs of the human insulin and IGF-I receptor, while *age-1* (worms) is related to a conserved phosphoinositol-3-kinase that responds to insulin receptor activation, and *daf-16* (worms) is a homolog of a human transcription factor.

The endocrine mechanisms of the antiaging effects of CR highlight also some of the subtleties of the complex set of processes that regulate the process of normal aging and the resultant potential pitfalls in designing and offering rejuvenation cures. Insulin/IGF-1 signaling is one of the most crucial cellular pathways regulating protein synthesis, glucose metabolism, and cellular proliferation and differentiation. The somatotropic axis in mammals, having the growth hormone (GH) as the major peripheral hormone, can stimulate the expression and secretion of IGF-1 in the liver and modulate the metabolism of several target tissues directly via different GH receptors. Several endocrine mutants, expressing either elevated or reduced levels of GH/IGF-1 hormones, highlight the significance of this axis in the regulation of growth and body size since the deficiencies in the function of GH/IGF-1 axis invariably lead to decreased anabolic capacity and reduced growth. The fact that the GH circulating levels are reduced with age could thus account for many of the features of the aging phenotype and form one face of the so-called GH/IGF-1 paradox of aging. The other face of it is the demonstration of the significant antiaging effects of reducing IGF/insulin signaling, as exemplified by the CR process. To date, the paradox does not have a satisfactory resolution, and it is difficult to decide whether reduced activity in the GH/IGF-1 axis should be viewed as a cause or a simple effect of aging. Furthermore, it can be argued that the decline in GH secretion with age represents a protective mechanism against insulin resistance and/or cancer or even an activation of survival mechanisms rather than simply reflecting a progressive failure of the hypothalamus-somatotrope axis. One way to reduce the conceptual tension generated by this neuroendocrine paradox is to invoke one of the most powerful evolutionary theories of aging, the antagonistic pleiotropy theory, which argues that, from an evolutionary perspective, aging results from the action of a number of physiological and/or homeostatic systems that exert several effects (pleiotropic), some of which being positive and beneficial at early stages of individual development, while others being negative and detrimental at later stages of development. Against this backdrop, opinions about the potential use and benefits of GH or GH secretagogues as antiaging agents differ widely and are highly controversial. Overall, data from well-designed clinical studies reported to date indicate unfavorable risk–benefit ratio for treatment of normal elderly subjects with GH. Prescribing GH to individuals who are not GH deficient in an attempt to slow aging is not supported by the available evidence, is not included among its approved uses, and, in the US, is specifically disallowed.

The same cautious view should be taken in respect to the adrenal sex steroid, dehydroepiandrosterone (DHEA) proposed as another antiaging fountain of youth hormone. With age, there is a large and abrupt decrease of estrogens in postmenopausal women and a slower and gradual decrease of testosterone in men. In a similar fashion, DHEA and its sulfate ester also fall progressively with age. The fact that the changes in DHEA correlate well with other age-induced modifications, such as increased fat mass and visceral adiposity, reduced bone mineral density, reduced muscle mass, and increased frailty, led to proposals for DHEA treatments or even sex hormones, in elderly individual otherwise

endocrinologically well. However, well-controlled clinical trials have repeatedly failed to show significant improvements in either the biological parameters tested or in the overall quality of life reporting.

Definition

Neurogenomics is the interface of neurobiology and genome sciences. It is the study of how the genome as a whole contributes to the evolution, development, structure, and function of the nervous system. Neurogenomics research employs genetic strategies, including investigations of the genome sequence and products (transcriptomes and proteomes), to identify genes involved in the nervous system and to understand their gene-product function and the biological mechanisms through which they contribute to brain development, function, plasticity, and disease. A major goal in neurogenomics is the isolation of genes linked to neurological diseases such as Alzheimer's and Parkinson's diseases. Outcomes of such research programs will improve the ability to diagnose neurological disease even before it strikes and will advance the development of novel therapeutic targets to prevent and/or halt the progression of these diseases.

Description

Trends toward large-scale interdisciplinary research projects advance the neurosciences and provide firm foundation the vigorous exploration of the frontier between neurobiology and genome sciences. Neurogenomics field includes, but is not limited to, research of genes that cause neurological disorders; molecular mechanisms through which disease genes act; animal models

and in vitro techniques for studying pathways of gene function; genetically based studies of neuronal patterning, migration, connectivity, and cognitive/behavioral function; and the genetic basis of normal neural development and function. These studies promote also the development of preclinical disease biomarkers, gene-based therapeutics for neurological disorders, and pharmaceuticals targeted to specific gene products.

Genetic methodologies are having a rapidly increasingly impact on studies of the normal and diseased nervous system. The recent advances in genomic and other high-throughput "omic" technologies have allowed an expansion from single-gene to genome-wide analyses, providing a step forward toward a global understanding of neurological and neuropsychiatric disorders. To date, more than 200 genes have been identified that cause or contribute, in various extents, to neurological disorders. Examples of recent milestone advances are the following: (1) A meta-analysis of genome-wide association studies in Parkinson's disease identified 11 Parkinson's risk loci that surpassed the threshold for genome-wide significance. Six were previously identified loci (*MAPT, SNCA, HLA-DRB5, BST1, GAK*, and *LRRK2*), and five were newly identified loci (*ACMSD, STK39, MCCC1/LAMP3, SYT11*, and *CCDC62/HIP1R*). (2) Large Alzheimer's GWAs and replication studies reported genome-wide significant association with the strongest most established genetic risk factor for sporadic late-onset Alzheimer's disease, the *APOE* genomic region, and with three novel loci (*CLU*, *CR1*, and *PICALM*). (3) Using comparative genomics approach, it was found that rare structural variants (CNV) disrupt multiple genes in neurodevelopmental pathways in schizophrenia.

Furthermore, the development of new model organisms (such as the *C. elegance*, honeybee, *Drosophila*, and zebra fish) for neuroscience research is being accelerated by extensive genome sequencing and the application of comparative and functional genomics technologies.

These modern technologies also impact the availability of information and data sharing. Resources for neurogenomics research – such as tissue and information registries, gene expression and function atlases of the brain of animal models, human brain transcriptomes, and whole genome genotypes from neurological affected subjects and control – have been rapidly developed and are becoming publicly available for investigators to use.

Synonyms

Brain imaging; Computerized tomography (CT); Diffuse optical imaging (DOI); Event-related optical imaging (EROI); Functional magnetic resonance imaging (fMRI); Imaging; Magnetic resonance imaging (MRI); Positron emission tomography (PET)

Definition

Neuroimaging broadly refers to the relatively noninvasive technologies and techniques for localizing, measuring, and visualizing central nervous system function and structure. Common neuroimaging methodologies include magnetic resonance imaging (MRI), positron emissions tomography (PET), and computerized tomography (CAT/CT).

Description

Neuroimaging refers to a collection of techniques used to noninvasively view structure and function of living brain tissue. The methods used to visualize brain tissue have evolved significantly over the last several decades from using x-ray technologies to the more recent and increasingly ubiquitous (nuclear) magnetic resonance imaging.

Contrast X-Rays and Computerized Axial Tomography (CAT/CT)

X-ray photography creates images by passing x-rays through the body and onto a photographic plate by taking advantage of variation in x-ray radiation absorption of different tissues. Certain molecules and denser materials absorb more radiation and thus less reaches the photographic plate. This method is excellent for seeing skeletal bones that appear on the photographic plate with a high degree of contrast compared to surrounding tissues. It is less useful for tissues that do not strongly differ in x-ray radiation absorption such as parts of the brain. One method to get around this is to introduce a radiopaque agent to increase contrast by differentially absorbing x-rays. This allows for the visualization of the cerebral ventricular and circulatory systems. Pneumoencephalography involves injecting air into the cerebral ventricular system to briefly displace cerebral spinal fluid (CSF), and cerebral angiography involves injecting a radiopaque dye into a cerebral artery. These methods are limited in the information they produce but can be used to examine general brain atrophy, damage, or displacement of blood vessels.

The next step in the evolution of x-ray imaging of the living brain was the introduction of computed tomography (CT) which is sometimes referred to as computerized axial tomography (CAT). However, CT is more appropriate because "axial" merely refers to the plane of image acquisition, and images can just as easily be acquired in the coronal or sagittal planes. CT utilizes an x-ray detector rather than a photographic plate. The x-ray source and detector are mounted opposite one another on a rotating ring inside a tube that encircles the person being scanned. The CT scanner captures numerous images of the brain from several angles as the x-ray source and detector rotate around the head. These images are then reconstructed by a computer to make three-dimensional multislice images of the living brain. The brighter and darker areas of the images are described as "hyperdense" and "hypodense," respectively, with grayish components of the images as "isodense." Water and CSF appears almost black, white matter darker than gray matter, and skull as nearly white. Variation in image intensity is more carefully delineated in Hounsfield units (HU) with water having an HU of 0, CSF and HU between 8 and 18, gray matter and white matter HU = 37–41 and 30–34, respectively, and bone

HU = 600–2,000. CT scans have the benefit of being relatively inexpensive and having very fast acquisition times, making them particularly valuable tools for detecting recent brain trauma and intracranial lesions in emergency situations. Limitations of CT scanning include poorer contrast between brain tissue types, and the number of CT scan any one person can have at a given time is limited because of safety requirements to limit exposure to x-ray radiation. Furthermore, while CT can be used to visualize brain structure, it is not useful for measuring brain function while engaging in a process or activity. Other methods allowing for accurate localization of brain function include positron emissions tomography (PET) and functional magnetic resonance imaging (fMRI). Imaging equipment that combine CT and PET technologies in one package are now commonly available and increase information yield and utility with the practical benefit of taking up less space than dedicated CT and PET scanners.

Single-Photon/Positron Emissions Tomography (SPECT/PET)

Positron emissions tomography (PET) and single-photon emission computerized tomography (SPECT) are used to image brain activity. This method also uses radiation and radiation detectors, but rather than shooting an x-ray through the material to be imaged, PET utilizes radiolabeled tracers in the form of chemicals that have specific actions within the brain. For example, fluorine-18-labeled 2-fluoro-2-deoxy-D-glucose (18 F-FDG) is a commonly used radiotracer. When 18 F-FDG is injected into the carotid artery, it is rapidly taken up by metabolically active neurons during an experimental task as it very similar to glucose. However, it cannot be metabolized like glucose and thus accumulates in active brain regions where it slowly breaks down. The radioactive label (or ligand) gives off photons (i.e., S*P*ECT) as a result of a nuclear process where a proton in the nucleus is converted into a neutron, neutrino, and a positron (i.e., *P*ET). Both the neutrino and the positron are then ejected from the nucleus. The kinetic energy of the ejected positron both varies and declines at a rate that depends on the nature of the surrounding material. When an ejected positron meets an electron, it creates an annihilation reaction where the electron and the positron turn into two photons that travel in opposite directions (180°) of each other. These photons are measured as a line by two of a series of scintillation detectors mounted in opposition from one another. The images created by the PET scanner are not images of the brain itself; rather, they are images created from the relative distributions of detected amounts of radioactivity in brain regions of interest.

PET is powerful methodology that can be used to study hemodynamics, drug action localization, receptor function, metabolism, and even molecular processes including DNA synthesis. PET is particularly valuable in detecting disease processes that may be evident as metabolic variation but not are yet manifested as anatomical abnormality that could be detected using CT or MRI. However, PET images can be effectively combined with CT or MRI images, providing accurate localization of accumulated radioactivity. PET is also advantageous in that radiation exposure is relatively limited. The primary limitation of PET is the necessity for local access to a cyclotron to produce radiotracers. The radiotracers have a very short half-life and thus must be made in close physical proximity to the PET scanner and utilized quickly. The limitations of PET and CT have led to a significant increase in application of methods that do not utilize hard radiation like x-rays or radiolabels that are expensive to produce. Structural and functional magnetic resonance imaging (sMRI and fMRI, respectively) and the recent emergence of near infrared spectroscopic imaging (NIRSI) allow for detailed analyses of both brain structure and function in the living brain.

Magnetic Resonance Imaging (MRI)/ Functional Magnetic Resonance Imaging (fMRI)

Magnetic resonance imaging (MRI) methods produce images of the brain and other bodily regions that are high in both contrast and resolution. Although some MRI methods utilize contrast agents, MRI does not expose patients or study participants to ionizing radiation. Rather,

this technique utilizes a very powerful homogeneous and stable electromagnetic field.

This brief description of how MRI works is limited to "classical"/Newtonian physics, but quantum mechanical descriptions are available elsewhere. Protons are found in all of the nuclei of the atoms that make up the body, but conventional MRI utilizes hydrogen protons. Hydrogen protons spin randomly with their magnetic moments "pointing" in random directions until they are in the influence of the strong magnetic field of the MRI scanner where they all align in parallel with the direction (z-axis) of the external field generated by the electromagnet. Application of a radiofrequency (RF) pulse is applied to the z-axis aligned hydrogen protons with an excitation/receiver coil. As a result of absorbed energy from the RF pulse, the hydrogen protons move or "flip" into a higher energy state that is antiparallel to the z-axis toward the x-y plane. With the removal of the RF pulse, the hydrogen protons "relax" or move back into alignment with the external electromagnetic field along the z-axis and release the absorbed energy form the RF pulse as electromagnetic waves that are detected by the excitation/receiver coil and other magnetic gradient coils in three dimensions.

Static contrast methodologies are used to generate anatomical images of the brain. Depending on the type of RF pulse applied, the images highlight different types of tissue or fluids. Static contrast between tissue types is achieved by three properties of protons in tissues: (1) the proton density (i.e., how many hydrogen protons are in the region), (2) proton relaxation times along the z-axis (i.e., the longitudinal relaxation time or T1), and (3) proton relaxation times along the x-y plane (i.e., the transverse relaxation time or T2). Motion contrasts detect dynamic properties of protons in tissues and fluids to generate images of blood flow, capillary irrigation, perfusion, and diffusion of water.

Functional MRI (fMRI) refers to MRI methodologies that estimate brain activity. Brain slices are repeatedly imaged over time, allowing for statistical contrast of experimental manipulations. The most common is blood oxygen level-dependant (BOLD) fMRI. BOLD fMRI methods exploit changes in levels of oxygen in the blood that result from the metabolic demands of brain tissue during neural activity. Active brain tissue utilizes oxygen, and the change from an oxygenated state to a deoxygenated state can be detected because deoxygenated blood is paramagnetic. Other methods include perfusion or dynamic-contrast MRI, which measures changes in blood volume using an injected paramagnetic contrast agent such as gadolinium, or magnetic resonance spectroscopy (MRS), which measures localized levels of brain metabolites. There is also diffusion MRI that measures diffusion coefficients of water in brain tissue. Diffusion tensor imaging (DTI) examines the water diffusion coefficients in neighboring voxels to estimate the shapes and directions of white matter tracts.

MRI possesses advantages over CT and PET including very high-resolution images that can be acquired without ionizing radiation. In most MRI procedures, no contrast agent is needed, and the procedures are completely noninvasive. MRI still requires significant safety procedures though. The magnet is always active, and any objects that are susceptible to magnetism can become dangerous projectiles within the boundaries of the field. Furthermore, patients and study participants must be screened for metallic objects or medical devices such as pacemakers in and on their bodies.

Diffuse Optical Imaging or Tomography (DOI/DOT) and Near Infrared Spectroscopy (NIRS)

Diffuse optical imaging (DOI) and near infrared spectroscopy (NIRS) are relatively new applications for measuring relative changes in blood volume and oxygenation via hemoglobin levels as a proxy for cellular metabolism. These methods exploit changes in the properties of near IR light projected through tissue in the absorptive spectra and light scattering properties of water, oxygenated hemoglobin, and deoxygenated hemoglobin. Like BOLD fMRI, DOI measures the hemodynamic response as blood flows to the active tissue supplying oxygen to satisfy the metabolic needs of neurons in the active

region. Changes in the way that light moves through brain tissue from the IR source to the IR detector can be computationally modeled, and blood flow to particular brain regions can be examined based on the placement of the IR source and detectors.

Modeling how light moves through the various tissues of the head is a complex process that contributes to DOI and NIRS limitations. One method of simplifying the model is to assume the brain region being scanned is essentially "flat" and that the tissues do not differ in their optical properties. However, anatomical MRI can be combined with DOI/NIRS to provide a better model of absorption and scattering of light with bone and other head tissues. Advantages of this technology include a high degree of portability, rapid data acquisition, relative low cost, and complete noninvasiveness. The primary disadvantages result from the lack of robust spatial resolution and that imaging is limited to surface and near-surface brain tissue.

Neuroimmunology

Yori Gidron
Faculty of Medicine and Pharmacy, Free University of Brussels (VUB), Jette, Belgium

Definition

This term refers to the interdisciplinary field merging neurology, immunology, and aspects of neuroscience. It is a scientific and clinical domain. Scientifically, neuroimmunology tries to understand the bidirectional links between the nervous and immune systems, and their implications to illnesses. Clinically, various "classical" neuroimmune diseases (e.g., multiple sclerosis – MS) and recently more diseases are being recognized for their influence by both the nervous and immune systems, including cancer and coronary heart disease. The biological underpinnings of neuroimmunology include the descending pathways from the brain to the immune system, manifested by innervation of lymph nodes, effects of stress hormones on immunity, and the presence of neurotransmitter receptors on immune cells (Dantzer, Konsman, Bluthé, & Kelley, 2000). In parallel, ascending pathways include the vagus nerve, expressing receptors for interleukin-1, brain regions lacking the blood–brain barrier (BBB), and a "domino-like" effect of prostaglandins, an end point of inflammation, on both sides of the BBB (Dantzer et al., 2000; Tracey, 2009). MS, for example, represents an inflammatory autoimmune insult on nerves, which eventually leads to the episodic and degenerative characteristic of this disease (Compston & Coles, 2002). Understanding neuroimmune interactions has been pivotal for developing treatments for MS. Another extraordinary example is the work of Schwartz and colleagues who demonstrated that due to the "immune privilege" status of the brain, closed brain injuries may not undergo immune protection, while in contrast, following a homing intervention of T cells to the brain, recovery is accelerated (Schwartz & Moalem, 2001). The relevance of neuroimmune interactions to other diseases has

recently been claimed by researchers in relation to coronary heart disease (Gidron, Kupper, Kwaijtaal, Winter, & Denollet, 2007) and cancer (Gidron, Perry, & Glennie, 2005), based on multiple converging evidence. Ongoing scientific efforts may hopefully reveal the clinical implications of such neuroimmune associations for such and other diseases.

Neuroimmunomodulation

Yori Gidron
Faculty of Medicine and Pharmacy, Free University of Brussels (VUB), Jette, Belgium

Definition

This term refers to the modulating role of the nervous system in relation to immune functions. This modulation reflects part of the bidirectional communication between the nervous system and the immune system. Neuroimmunomodulation is possible due to existence of receptors for neurotransmitters (e.g., norepinephrine, acetylcholine) on immune cells and due to innervation of lymph nodes by sympathetic nervous system (SNS) fibers (Felten et al., 1984). These innervating fibers influence the trafficking and proliferation of immune cells, all evidence for neuroimmunomodulation. Another more recently discovered form of neuroimmunomodulation includes the one by the vagus nerve, where its descending (efferent) branches inhibit cytokine synthesis in peripheral monocytes, via the alpha-7 nicotinic acetylcholine receptor (Tracey, 2009). The neuroimmunomodulating role of the vagus may have clinical implications since the inflammatory response is in the core of the etiology of severe chronic diseases such as cancer and coronary heart disease. Thus, vagal activity is hypothesized to possibly modulate the progress of such diseases (Gidron, Kupper, Waijtaal, Winter, & Denollet, 2007; Gidron, Perry, & Glennie, 2005), a matter under current investigation. Neuroimmunomodulation is also manifested by the differential effects of the cerebral hemispheres on peripheral immunity. Studies have shown that the left hemisphere has immune-potentiating effects while the right hemisphere has immunosuppressive effects (Davidson, Coe, Dolski, & Donzella, 1999; Meador et al., 2004). These effects were found in animals and humans and were found to be mediated by the sympathetic response, since blocking beta-adrenergic receptors abolished differences in immunity between the hemispheres. Here too, the neuroimmunomodulatory effects of the hemispheres may have clinical roles since a shift from left to right hemisphere activity during stressful periods correlated with more reported illness (Lewis, Weekes, & Wang, 2007). Furthermore, in a matched prospective design, people with right hemisphere lateralization were at significantly higher risk of reporting the common cold than those with left hemispheric lateralization, independent of confounders (Gidron, Hall, Wesnes, & Bucks, 2010). Neuroimmunomodulation has

a central role in behavior medicine, by possibly explaining how psychological factors influence the risk of disease, since the SNS, vagal nerve activity, and hemispheric lateralization are each related to psychological factors as well as to immunity and risk of certain illnesses. Research is only at the beginning of understanding these neuromodulatory links and of possibly utilizing them in the service of preventing or treating diseases.

Neurological

Yori Gidron
Faculty of Medicine and Pharmacy,
Free University of Brussels (VUB), Jette,
Belgium

Definition

Neurological refers to any process or disorder involving the nervous system or its components. The nervous system includes the central and peripheral nervous systems (CNS, PNS, respectively). These systems are composed of neuronal fibers (axons and dendrites) which transmit neurological information to and from neurons, cell bodies that process neurological information, as well as other types of cells (e.g., astrocytes, microglia). The CNS, the "headquarters" of the body, processes and regulates multiple bodily responses and psychological responses to external and internal stimuli. These numerous neurological processes are carried out by various levels of the CNS including the brain stem (basic vital signs), limbic system (memory, sensory, autonomic, immune, hormonal, and emotional processes), and the cortex (executive function and information processing, overall modulation of multiple systems). Neurological disorders are a heterogeneous group of disorders that involve abnormal functioning of the nervous system, PNS or CNS, or both. These could be manifested motorically (as in Parkinson's disease and stroke), behaviorally (as in Alzheimer's disease), or in neurophysiological tests (as in epilepsy or stroke). Neurological diseases caused by genetic mutations are often congenital (e.g., congenital insensitivity to pain with anhydrosis), developmental disorders of the nervous system (e.g., spina bifida), neurodegenerative diseases (e.g., Alzheimer's disease), diseases due to cerebral ischemia (e.g., stroke), injuries to the PNS or CNS, seizures (e.g., epilepsy), cancers (e.g., glioma), and infections (e.g., meningitis). These disorders are treated by

neurologists, physicians who specialize in neurological disorders, their etiology and treatment. A major consequence of neurological disorders is their psychosocial impact, both on the patient and on his or her social environment. Often, the social stigma associated with certain neurological problems is quite severe (de Boer, 2010) and has the potential to isolate patients. This is of great importance for behavior medicine and includes the assessment of the health-related quality of life affected by such conditions. The accumulating evidence linking neuroimmune processes (e.g., inflammation, vagal nerve modulation) to peripheral and central pathways (Tracey, 2009) and to diseases reveals the importance of the interdisciplinary nature of the neurologist's work, encompassing basic biology, medicine, and behavioral sciences.

Neuromuscular Diseases

Robert J. Gatchel and Matthew T. Knauf
Department of Psychology, College of Science, The University of Texas at Arlington, Arlington, TX, USA

Synonyms

Neuromuscular disorders

Definition

Neuromuscular disease is a broad term that encompasses many different specific diseases and ailments that, in general, impair the functioning of the muscles, the neuromuscular junction, and/or the peripheral nervous system (LaDonna, 2011; National Institute of Neurological Disorders and Stroke [NINDS], 2011).

Description

Many different specific diseases fall under the broad spectrum of neuromuscular diseases. Because it would be impossible to list each and every disease in this brief section, the most prevalent ones are included here: (1) motor system disorders (e.g., amyotrophic lateral sclerosis, Parkinson's disease), (2) central nervous system disorders (e.g., multiple sclerosis), (3) muscular dystrophies (e.g., Steinert's, Duchenne, Becker), (4) autoimmune disorders (e.g., myasthenia gravis), (5) neuropathies (acquired or inherited), and (6) hereditary muscular disorders (e.g., spinal muscular atrophy). There are also numerous other diseases that fall under each of the above categories. For example, muscular dystrophies include a group of more than 30 diseases, but the most common are myotonic (i.e., Steinert's, which primarily affects adults) and Duchenne (which primarily affects children) [NINDS, 2011]. Neuromuscular diseases may present symptoms at any time during an individual's lifetime, some may be present while an individual is an infant or child, but others may not be present until mid- to later portions of an individual's lifetime. Reported overall prevalence rates for all individuals that may be affected by an inherited neuromuscular disease at sometime during their life (infancy to adulthood) are approximately 1 in 3,500 individuals (Emery, 1991).

Many of the neuromuscular diseases are chronic and/or inherited, as well as progressive in nature, and individuals with these disorders tend to require specialized care in dealing with them (LaDonna, 2011; Seesing, Drost, van der Wilt, & van Engelen, 2011). In addition,

adjustment of the current treatment may be required if new symptoms arise at any time or if the existing symptoms begin to aggregate over time (Seesing et al., 2011). Many of the common symptoms of neuromuscular disease may include fatigue, muscle weakness, loss of motor control, and spasticity. Recent studies have shown that chronic pain may also be considered a common symptom of neuromuscular disease (Engel, Kartin, Carter, Jensen, & Jaffe, 2009; Hoffman et al., 2005; Jensen et al., 2005; Tiffreau et al., 2006). It has been reported that the rates for adults with neuromuscular diseases who have chronic pain range from 70% to 96% of those affected (Engel et al., 2009). One interesting point that should be noted is that chronic pain is not only present for adults with neuromuscular disease but is also present in children with neuromuscular diseases (Engel et al., 2009). It has been reported that the rate for children with neuromuscular diseases who have chronic pain is over 70% (Engel et al., 2009).

In addition to the physical impact of neuromuscular disease, there may also be a psychosocial impact as well. While individuals with neuromuscular diseases may experience a lower quality of life due to the effects of the disease, there is evidence that there are some activities, such as employment, recreational physical activity, and social outlets (peer support), that may improve quality of life (LaDonna, 2011). Also, the more independence that individuals with neuromuscular diseases are able to maintain, (i.e., the more activities that individuals can do by/for themselves), the better their quality of life (Abresch et al., 1998).

Once an individual has been diagnosed with having a neuromuscular disorder, the appropriate treatment plan may begin. While there is currently no "cure" for neuromuscular diseases and current treatments are limited (LaDonna, 2011), various treatments aimed at managing the diseases have included (1) drug therapy, (2) referral to specialists for potential surgical intervention (e.g., stimulator implants), (3) patient and familial education and counseling, (4) massage therapy, (5) acupuncture, (6) biofeedback or relaxation training, (7) chiropractic manipulation, (8) nerve blocks, and (9) hypnosis (Jensen, Abresch, Carter, & McDonald, 2005). Drug therapies may include giving the patient immunosuppressive drugs, analgesic medication (e.g., nonsteroidal anti-inflammatory, narcotic), muscle relaxants, anticonvulsants, and/or antidepressants. Any one of the treatments listed may be used to manage the neuromuscular disease itself, and they may also be employed to manage the pain that is associated with neuromuscular disease. Patients may go to many different specialists, ranging from occupational/physical therapists to physiatrists to surgeons, depending on the severity of the disease. Patient and familial education may be done individually or with family present, and patients and family members also have the option to go to counselors and support groups.

Currently, there is little evidence to suggest that any one treatment provides either significant and/or permanent reprieve of pain, as patients with neuromuscular disease who reported using any one or combination of pain treatments still report some pain (Jensen et al., 2005). Because there is currently no cure for the diseases, disease management approaches must be employed. It is important to attempt to identify the cause of the neuromuscular disease and any pain associated with the disease in order to provide the best method of management (Jensen et al., 2005). However, research is still needed to examine the etiology of the diseases, and, in addition, more research is needed to examine the underlying mechanisms of the pain that is associated with neuromuscular diseases. If new symptoms arise over the course of the disease, physicians and other specialists may conduct appropriate further testing and adjustment of treatments as warranted.

Definition

Neurons are the basic building blocks of the nervous system, which includes the brain, the spinal cord, and the peripheral nervous system. These specialized cells are the information-processing units responsible for receiving, processing, and transmitting information by electrical and chemical signaling. Chemical signaling occurs via synapses, specialized connections with other cells.

Structure

Although the morphology of various types of neurons differs in some respects, they all contain four distinct regions with differing functions in the communication of information: the cell body (soma), the dendrites, the axon, and the axon terminals. Most neurons have multiple dendrites, which receive chemical signals from the axon termini of other neurons. Dendrites convert these signals into small electric impulses and transmit them in the direction of the cell body. The cell body contains the nucleus and is the site of synthesis of virtually all neuronal proteins. Almost every neuron has a single axon, which is specialized for the conduction of a particular type of electric impulse, called an action potential, away from the cell body toward the axon terminus. When an action potential reaches a chemical synapse, a neurotransmitter is released into the synaptic cleft. The axon terminals are the small branches of the axon that form the synapses, or connections, with other cells. A single axon in the central nervous system can synapse with many neurons and induce responses in all of them simultaneously (Lodish, Berk, & Zipursky, 2000).

Classification

Neurons can be classified by their morphology and function. Functionally, we can distinguish afferent neurons, efferent neurons, and interneurons. Sensory neurons are afferent neurons that convey information from tissues and organs to the central nervous system. Motor neurons are efferent neurons that transmit signals from the central nervous system to the effector cells. The interneurons connect neurons within specific regions of the central nervous system.

Neurons can also be classified anatomically into unipolar, bipolar, and multipolar neurons. Unipolar neurons are those where the dendrite and axon merge into a single process of the cell body. Bipolar neurons are those where axon and single dendrite are on opposite ends of the soma, while multipolar neurons consist of more than two dendrites.

Functions

Neurons connect to each other to form networks. Neurotransmitters are used to carry the signal across the synapse to other neurons (Lodish et al., 2000). The shape, structure, and connectivity of nerve cells are important aspects of neuronal function. Genetic and epigenetic factors that alter neuronal morphology or synaptic localization of pre- and postsynaptic proteins contribute significantly to neuronal output and function and may underlie clinical states. Furthermore, neuronal loss is one of the major pathological hallmarks of neurodegenerative disorders including Alzheimer's disease (AD), Parkinson's disease, Huntington's disease, and amyotrophic lateral sclerosis. In daily mental functioning and psychiatric conditions, the pathways and amounts of neurotransmitters crossing between neurons influence and represent at the neuronal level such conditions. Examples include reduced serotonin in depression and aggression. Numerous studies have shown that neuronal stimulation can also influence behavior. For example, a study in rats showed that the stimulation of one single neuron in the somatosensory cortex can change the animal's detection behavior (Houweling & Brecht, 2008). Thus, the neuron is the basic unit of the nervous system, and understanding its multiple functions is of pivotal significance in health and disease.

Hormones

Definition

Neuropeptide Y (NPY) is a 36-amino acid hormone expressed in multiple sensory, cerebral, and autonomic pathways. It is a highly conserved peptide reflecting its important role in the body.

In 1982, NPY was isolated from the hypothalamus, and early studies to characterize specific locations and functions of this neuropeptide documented the presence of NPY neurons within the paraventricular nucleus (PVN) of the hypothalamus. Subsequent experiments using a technique called in situ hybridization also found the highest cellular levels of NPY messenger RNA within the arcuate nucleus of the hypothalamus. Research has also demonstrated the presence of NPY in other areas within the brainstem, monoaminergic neurons, and GABAergic neurons in the cortex. Peripherally, NPY is present in sympathetic nerve fibers and innervated organs including the blood vessels, heart, gastrointestinal tract, thyroid gland, and sensory nerves.

Several receptors are targeted by NPY and these receptors are widely distributed throughout the body. These include subtypes Y1 and Y5 receptors which mediate effects of NPY on appetite stimulation, and receptors Y2 and Y4 which mediate NPY effects on appetite reduction.

The wide distribution of these receptors results in various effects on multiple central and peripheral functions. These effects can be a result of direct NPY action or indirect though influencing other neurotransmitters, such as norepinephrine and glutamate.

NPY Functions

NPY plays a significant role in a number of physiological and behavioral processes. It is involved in regulating emotions, energy balance, and cognitive functions. NPY increases food intake while also increasing rate and proportion of nutrients storage as fat. It may also interrupt pain processing leading to analgesic effects. Administering NPY by injecting it directly into the PVN leads to increases in the release of corticotropin-releasing hormone (CRH). Because CRH is involved in regulating various psychological and stress-related processes, it is thought that NPY is indirectly involved in these processes.

NPY and Appetite Regulation

The involvement of NPY in appetite regulation has received significant attention over the last 20 years, with animal research documenting NPY orexigenic effect. Studies on rats and using multiple methodologies, including immunochemical and in situ hybridization techniques, have shown that activation of NPY neurons increases food intake. Injecting the NPY agonist dexamethasone into the third ventricle or the hypothalamus increases appetite. Consistent results were also found when using antagonists that block NPY receptor. The blocking effect led to reduction in NPY neuron activity and reduction in food intake. When the receptors that inhibit the release of NPY (called autoreceptor Y2) were activated in the arcuate nucleus reduction in appetite was noted. Blocking these autoreceptors also led to the reverse effect of increased food intake. Studies that used genetically obese rats have also been conducted to investigate the role of NPY and found that NPY contributes to obesity through direct and indirect pathways. For example, both NPY mRNA and NPY release are high in obesity animal models. Factors that contribute to obesity, such as glucocorticoids, also increase NPY release. Other hormones that block NPY, such as leptin, have also been found to reduce appetite and reduce risk for obesity.

NPY and Emotion Regulation

NPY is involved in the regulation of emotional and affective behaviors. It also influences cognition functions and pain perception. For example, several of the NPY hypothalamic functions have been found to be dysregulated in depression. Hypothalamic-pituitary-adrenal (HPA) axis functions and disruption of appetite regulation in addition to disrupted circadian rhythm occur in depression and have been attributed to certain abnormalities of NPY functions. When NPY is administered into the hypothalamic PVN, it increased ACTH and corticosterone. It is also known that NPY fibers directly innervate CRH-producing neurons within PVN, and injection of NPY increases CRH levels. Patients with depression show decreased levels of NPY in CSF. Similar observation was found in suicide victims. Pharmacological treatment for depression using tricyclic antidepressants and treatment using electroconvulsive shocks were associated with increased NPY in multiple areas of the brain. Research also suggests that depressive symptoms associated with withdrawal from a stimulant like cocaine may be related to reduced levels of NPY caused by chronic drug use.

Studies related to anxiety have also shown a negative association between the level of anxiety and NPY levels in cerebrospinal fluid. Observational research using electrophysiological and behavioral approaches in multiple models of anxiety has demonstrated anxiolytic effects of NPY when administered intracerebroventricularly. This research has also been advanced toward pinpointing specific structures that are involved in this effect of NPY and has shown that localized microinjection into the central nucleus of the amygdala was specifically effective in producing NPY anti-anxiety effects. NPY anxiolytic effect in the amygdala appears to be mediated by Y1 receptor. Considering that this

location is where multiple stress-response factors and neurochemical pathway also interact suggests that NPY plays a significant role in regulating the stress response.

Studies both in humans and in animals indicate the possibility that NPY is directly involved in regulating the stress response and emotional reactivity. In humans, observational studies have indicated that NPY may have anxiolytic effects and may help in coping with stress by facilitating speedy recovery after exposure to intense stressors. Related to this, one study in veterans with posttraumatic stress disorder (PTSD) measured plasma NPY and compared them with veterans with no PTSD. The study found that veterans who did not suffer from PTSD had higher NPY levels than those with PTSD, suggesting that NPY may be a marker of the ability to recover from stress. On the other hand, studies in both mice and monkeys have demonstrated that exposure to repeated stress leads to increased NPY release. This is a similar effect to that seen when the animal ingests a high fat, high sugar diet. It is possible that the increased NPY concentrations contribute to increased fat buildup, especially around the waist and abdomen, and the effects of chronic stress on metabolism function are mediated by NPY.

Synonyms

Brain-behavior relationships; Neurobehavioral assessment; Neurocognitive assessment; Neuropsychological assessment

Definition

Neuropsychology is a subdivision of the field of psychology that is concerned with the investigation of brain-behavior relationships. The broad category of neuropsychology can be further divided into experimental neuropsychology and clinical neuropsychology, with this latter specialty definable as an applied science focusing on the behavioral sequelae and manifestations of brain dysfunction.

Description

Neuropsychology is currently one of the fastest growing scientific specialty areas in the field of psychology, and the subspecialty area of human clinical neuropsychology is of direct relevance to behavior medicine practitioners as well as physicians in clinical practice, especially neurologists and neurosurgeons. Neuropsychologists in clinical practice use a variety of specially constructed tests and test batteries to assess the functional effects of brain trauma, infection, neoplasias, and structural changes to the brain (including

vascular abnormalities and strokes) as well as degenerative central nervous system disorders, cortical and subcortical dementias, and progressive disorders of the nervous system, such as multiple sclerosis, Huntington's disease, and Parkinson's disease. Specialized neuropsychological test batteries have been constructed to investigate the neurocognitive effects alcohol and drugs of abuse, assess the functional effects of epilepsy and diabetes, and assess the effects of neurotoxins and hypoxia. In the field of neuropsychiatry, the neuropsychology of schizophrenia and the mood and affective disorders has been extensively studied and neuropsychological impairments have been identified that are independent of medication effects or the psychiatric illnesses themselves.

Modern clinical neuropsychology is very much a hybrid specialty, with influences from – and ties to – neurology, neurosurgery, neuroimaging (especially functional neuroimaging), neuropsychiatry, cognitive psychology, neuroscience, and clinical psychology as well as the significant advances that have been made in experimental neuropsychology, particularly in the areas of memory and learning. This is

Neuropsychology, Table 2 Common diagnostic questions that neuropsychological assessment can help answer

Does the patient have an impaired memory and, if so, what does that mean for that patient and for the treating physicians?
Is dementia present and, if so, what kind of dementia and how severe is it?
Can the patient understand and follow health-care provider instructions regarding their medical care?
What is the patient capable of doing vocationally and can the patient return to work following a neurological injury? What components need to be included in the patient's rehabilitation plan? Is the patient a candidate for a cognitive rehabilitation program and what should be included in this program?
Does the patient have only psychological or psychiatric problems, or do they have brain problems as well?
What problems remain for the patient following successful physical recovery from a head injury, stroke, or other brain injury?
What is the patient's capacity in a legal sense (can they drive a car safely, manage their money adequately, participate fully in legal matters such as criminal or civil trials, can they maintain professional licensure)?
What are the cognitive and functional effects of progressive illnesses as time progresses (dementias, brain tumors, progressive deteriorating disorders such as Huntington's, etc.)?
What is normal aging versus neurological disease/dementia?
Is the temporal lobe epilepsy patient a candidate for resection surgery?
Does the patient have specific learning disabilities/attention deficit disorder? What needs to be included in educational programming and follow-up?
Is the patient in need of a conservator or guardian? Are there neuropsychological deficits that require supervision, additional support, or placement out of the home (such as nursing home placement)?

reflected in the broad range of functional domains that are examined in neuropsychological assessment, as noted in Table 1.

Specialized neuropsychological test batteries have been developed for child and pediatric populations in addition to the adult and aged adult populations, and neuropsychological assessment is great value in the assessment of developmental and learning disorders of childhood. Child and pediatric neuropsychology has close ties to both child neurology and behavioral pediatrics, in addition to child psychiatry and contemporary learning models in child psychology.

Neuropsychology is a relatively new area of scientific inquiry. Sir William Osler first used the term "neuropsychology" in 1913, but neuropsychology as an emerging scientific discipline can trace its roots to the contemporary psychology, experimental/cognitive psychology, and neurology of the mid-1930s. In 1935, Ward Halstead at the University of Chicago – in close collaboration with neurologists and neurosurgeons – carefully observed the behavior of brain-damaged patients and constructed a battery of ten functional tests or neuropsychological tests designed to provide a comprehensive assessment of the functional impairment seen in individuals with known injury to the brain. This was the first true battery of neuropsychological tests, later refined by Ralph Reitan at the University of Indiana (working closely with neurosurgery colleagues), culminating in the Halstead-Reitan neuropsychological test battery, which is still in use today. A contemporary of Halstead's in Russia, the neurologist and psychoanalyst A.R. Luria, was carefully studying aphasia in the 1930s and later did extensive single-case studies in the 1940s of the effect of brain injury on the behavior of individuals, many who were injured in World War II. The legacy of Luria is reflected in contemporary neuropsychological assessment that emphasizes an individualized, hypothesis-testing approach to neuropsychological assessment, including careful observation of the qualitative responses of the patient examinee.

There are currently a wide variety of specialized neuropsychological test batteries that have been constructed to examine specific diseases or disorders, many of which are designed to be administered following one or more cognitive screening tests. There are also dozens of single neuropsychological tests designed to assess very specific areas of brain functioning. Many of the

newer test batteries are hypothesis driven and symptom specific such that individual patients with the same medical diagnosis or disorder may be given different component subtests depending upon their specific presenting symptoms and performance on the initial tests given (the flexible battery approach). There also remain several fixed neuropsychological test batteries where all patients – or all patients with a given diagnosis or disorder – are given the same tests. Irrespective of whether a fixed or flexible battery approach is employed, the performance of the examinee is customarily compared relative to normative data of individuals without neurological disorder matched by age, gender, and education in order to arrive at reliable and valid conclusions. The earliest neuropsychological test batteries were designed to accurately and efficiently assess the type and extent of specific brain problems and the area or areas of the brain affected and were quite successful in doing so. At the present time, neuropsychological assessment can extend localization information already available from neuroimaging studies and also address in addition many more issues related to treatment planning, educational planning, and the impact of brain problems on a variety of tasks of daily living, some of which are listed in Table 2.

Neurotensin

Yori Gidron
Faculty of Medicine and Pharmacy,
Free University of Brussels (VUB), Jette,
Belgium

Definition

Neurotensin (NT) is a multipotent 13-amino acid neuropeptide, originally found in the hypothalamus of cattle. It plays multiple physiological and pathological roles since it affects the nervous, cardiac, immune, and gastrointestinal systems, among others. NT is found in the central nervous system (CNS) and in the gastrointestinal system. It seems to play a role as an endogenous antipsychotic peptide and a role in colorectal cancer (Mustain, Rychahou, & Evers, 2011). In cancer, NT and its receptor neurotensin receptor 1 have been found to play oncogenic roles. They mark prognosis in breast, lung, and head and neck cancers. Furthermore, NT seems to play a role in tumor growth as it acts as a growth factor as well as in metastasis (Dupouy et al., 2011). These have important implications for drug development in the treatment of cancers as well. Dysregulation of NT also plays a role in schizophrenia and in the sensitizing reaction toward drugs, thus playing a possible role in addiction

as well. Given this knowledge, NT can be a target in the treatment of such diseases (Caceda, Kinkead, & Nemeroff, 2006). NT is closely related to the dopaminergic system and has thus been studied in relation to diseases related to dopamine including Parkinson's disease. NT is widely distributed in the CNS and is projected in numerous circuits including the mesocorticolimbic circuit, implicated in pain and in the stress response. Given its multipotent roles in regulation of behavior and in onset of diseases, it requires further research in behavior medicine as well.

Neurotic Anger, Subcategory of Anger

Yori Gidron
Faculty of Medicine and Pharmacy, Free University of Brussels (VUB), Jette, Belgium

Definition

This term refers to a type of anger which mainly reflects the affective component of anger. Neurotic anger (or neurotic hostility) is contrasted with antagonistic anger (or antagonistic hostility), which refers mainly to the behavioral component of anger (Dembroski & Costa, 1987). Neurotic anger includes feelings of anger and is associated with the personality dimension of neuroticism-emotional stability, with neuroticism being the tendency to attend to, experience, and report negative affect. In contrast, antagonistic anger refers mainly to the agreeable-antagonism dimension of personality and includes disagreeable behavior, argumentativeness, rudeness, being evasive, and lack of cooperation. This distinction is of great importance in behavior medicine because studies have shown that mainly antagonistic, but not neurotic anger/hostility, is the element of anger/hostility predictive of cardiovascular reactivity to stress and of coronary artery disease (Felsten, 1996). Furthermore, some studies even suggest that neuroticism (which includes neurotic anger) may be a factor unrelated to survival (Costa & McCrae, 1987). The latter authors suggested that neuroticism (and neurotic anger) is related mainly to self-reported but not to objective indices of health, primarily because self-reported indices are biased by perceptions and reporting of physical and emotional symptoms, strongly related to neuroticism. These perceptions are thought to involve less physiological overactivity, while antagonistic anger/hostility is thought to involve greater physiological reactivity, explaining its prediction of cardiac disease (Felsten, 1996). It has been suggested that use of objective measures of disease could partly solve this issue as well as use of measures of antagonistic anger/hostility. On the other hand, clinically, while individuals with neurotic anger may not always be more ill on objective measures, they suffer from excessive distress, for which they require psychological assistance.

Neuroticism

Leigh A. Sharma
Department of Psychology, University of Iowa, Kenosha, WI, USA

Synonyms

Negative affectivity; Negative emotionality

Definition

Neuroticism, broadly defined, refers to an individual's tendency to experience negative affect or negative emotional states (e.g., anger, anxiety, hostility, sadness); those high in neuroticism react more strongly to negative stimuli (e.g., threat, frustration, loss) than those low in neuroticism. Structural models of personality establish that neuroticism is linked to Digman's alpha, composed of negative emotionality and disinhibition, in a two-factor model; negative affectivity/negative emotionality splits from disinhibition in three- and four-factor models and emerges as neuroticism in a five-factor model (Markon, Krueger, & Watson, 2005). Most broad personality measures include a neuroticism scale (e.g., measures of the five-factor model of personality), and as early as 1984, authors were demonstrating the high levels of relations among these scales (Watson & Clark, 1984). Neuroticism scores tend to peak in adolescence and decline moderately through adulthood (Roberts & Mroczek, 2008), and evidence demonstrates that females tend to score slightly but significantly higher than males (Costa, Terracciano, & McCrae, 2001).

Neuroticism is a dimension of normal personality, though it is linked to several psychological phenomena and behavioral tendencies. Evidence demonstrates neuroticism acts as a nonspecific vulnerability to the internalizing disorders (e.g., anxiety, depression) and that it can account for a portion of the comorbidity among them (Malouff, Thorsteinsson, & Schutte, 2005). Further, after controlling for sociodemographic variables, neuroticism has been linked to higher rates of smoking, drinking alcohol, and using illegal drugs; poor physical health; lower quality of life; and mortality from all causes (Lahey, 2009).

Neurotransmitter

Susan Dorsey
School of Nursing, University of Maryland, Baltimore, MD, USA

Definition

A neurotransmitter is a naturally occurring (endogenous) chemical messenger that passes a message from one neuron to the next by being released into the synaptic gap from the axon of the presynaptic neuron and then attaching itself to the receptor on the dendrite of the postsynaptic neuron.

Neurotransmitters allow neurons to pass on both excitatory and inhibitory messages when they fire. Excitatory messages mean that the next neuron is more likely to fire having received the message, while inhibitory messages mean that the next neuron is less likely to fire.

Some chemicals act as both neurotransmitters and hormones. Neurotransmitters can only influence neurons that come into contact with by traveling over the very small gaps at synapses. In contrast, hormones are secreted by endocrine glands into the blood stream, which carries then around the body and enables them to affect cells that are distant from their point of origin. Another major difference is that neurotransmitters exert their influence for a very brief time: reuptake or chemical decomposition takes place very quickly. In contrast, once released into the blood stream, hormones remain present, and hence active, for much longer.

Nicotine

Motohiro Nakajima and Mustafa al'Absi
University of Minnesota Medical School, University of Minnesota, 235 School of Medicine, Duluth, MN, USA

Synonyms

Cigarette; Smoking; Tobacco

Definition

Nicotine is a psychostimulant alkaloid that is addictive and heavily used in cigarettes and other tobacco-related products. It is primary metabolized by the liver to cotinine, and the average half-life is 2 h.

Description

Upon administration, nicotine binds to nicotinic cholinergic receptors (nAChRs), ligand-gated ion channels composed of several subunits, that are located in central and peripheral nervous systems. Stimulation of nAChRs by nicotine leads to the release of various neurotransmitters. Of those, dopamine secreted in the mesolimbic area and the frontal cortex mediates pleasurable experience and rewarding pathways linked

to the positive reinforcement of nicotine (Benowitz, 2010). Other neurotransmitters, such as norepinephrine, acetylcholine, glutamate, serotonin, beta-endorphin, and gamma-aminobutyric acid (GABA), are also released in response to nicotine and mediate its effects on attention, tension reduction, and appetite suppression. These symptoms are commonly cited motivators of tobacco use by smokers. Nicotine activates the sympathetic nervous system which leads to the release of epinephrine from the adrenal medulla, eventually increasing heart rate, blood pressure, and cardiac output. Nicotine excites paraventricular nucleus in the hypothalamus leading to the release of corticotrophin-releasing factors (CRF), causing the release of adrenocorticotropin (ACTH) from the anterior pituitary, promoting the production of cortisol in the adrenal cortex (i.e., hypothalamic-pituitary-adrenocortical (HPA) axis). Nicotine-induced activation of cardiovascular and HPA functions are very similar to those changes observed during stress. Nicotine modulates pain perception: It induces analgesia via endogenous opioid system. Nicotine may also play a role in stress-induced analgesia through increased activity in the cardiovascular system. Taken together, acute exposure to nicotine activates multiple central nuerochemical regulatory systems that influence psychological and physiological processes and behavior. Pharmacological effects of nicotine play an important role in the development of nicotine dependence and addiction.

Repeated exposure to nicotine leads to tolerance or neuroadaptation to the effects of nicotine. Desentization of nAChRs in the central system may contribute to abstinence-related withdrawal symptoms and craving. Nicotine withdrawal is associated with negative affect including anger, tension, depression, difficulty in concentration, impatience, insomnia, and restlessness (Hughes, 2007). Absence of nicotine may also be linked to reduction of cardiovascular and adrenocortical activity. These symptoms typically peak within a few days of nicotine abstinence and may last for 2–4 weeks and are powerful determinants of smoking lapse and relapse (al'Absi, Hatsukami, & Davis, 2005).

Maintenance of nicotine intake may result from the combination of positive and negative reinforcement. Smokers may take up cigarettes to enhance subjective mood and pleasure (positive reinforcement) but also consume them to maintain levels of nicotine in the body to prevent withdrawal symptoms (negative reinforcement). Certain environmental cues associated with smoking may facilitate subsequent smoking behaviors due to conditioning. Genetic component may also contribute to these processes. Furthermore, chronic nicotine use may be related to structural and functional changes in various stress and emotion-regulations systems as well as endogenous pain modulation mechanisms, which may lead to increased withdrawal symptoms and risk for early smoking relapse.

Nicotine Patch

Jed E. Rose
Department of Psychiatry, Duke Center for Nicotine & Smoking Cessation Research, Durham, NC, USA

Definition

Nicotine skin patches are drug delivery systems that are worn on the skin and provide the user with a controlled dose of nicotine to assist in smoking cessation, by replacing the nicotine previously obtained from cigarettes. The ability of nicotine to permeate intact skin has been known for decades, but the first published study exploring the therapeutic potential of transdermal nicotine to ameliorate tobacco withdrawal symptoms appeared in 1985 (Rose, Herskovic, Trilling, & Jarvik, 1985). Previous work in the 1970s had developed transdermal patches for the delivery of medications such as scopolamine and nitroglycerin. Theoretically, transdermal drug administration has the advantages over oral delivery in providing a more uniform blood level of a therapeutic agent and avoiding first-pass liver metabolism. However, other theoretical considerations initially argued against the efficacy of providing a steady level of nicotine in treating tobacco dependence, since it was widely believed that smokers were addicted to rapid bolus delivery of nicotine from inhaled smoke, which could not be duplicated using a nicotine patch. Nonetheless, transdermal nicotine has been shown to be efficacious in aiding smoking cessation, approximately doubling success rates over placebo. In 1991, nicotine patches were approved for marketing in the United States as a prescription drug, and they have been available over the counter since 1996. Despite well-established efficacy (Stead, Perera, Bullen, Mant, & Lancaster, 2008), however, long-term success rates (1 year following treatment) are often only 10–15%.

The standard nicotine patch dose is 21 mg/day, similar to that of a pack of cigarettes; however, the delivery is more uniform than with cigarettes. After 6–8 weeks of wearing 21 mg/day patches, weaning doses are often recommended providing 14 mg/day for 2–4 weeks and 7 mg/day for 2–4 weeks. Combination therapy, entailing adding other forms of nicotine replacement, such as nicotine polacrilex (nicotine chewing gum) or nicotine lozenge, to supplement nicotine patch treatment, increases success rates beyond treatment using the nicotine patch alone.

Interestingly, the mechanism of action of nicotine patch therapy has still not been fully elucidated. One hypothesis holds that successful abstinence is facilitated by nicotine replacement due to the alleviation of nicotine withdrawal symptoms. However, while withdrawal alleviation is clearly obtained from nicotine replacement using nicotine patches, other mechanisms may be more important, such as the attenuation of the rewarding effects of cigarette smoking. When a cigarette is smoked after nicotine blood levels have been elevated from wearing nicotine patches, cigarettes are rated less enjoyable (Levin et al., 1994). Moreover, the odds ratio of preventing the first "lapse" following an attempt to quit smoking is only marginally increased by nicotine patch treatment. In contrast, the progression from an initial lapse to a relapse is markedly reduced (Shiffman et al., 2006). These results suggest that nicotine patch treatment helps smokers remain abstinent largely by affecting their reaction to the first cigarette smoked in a way that discourages the subsequent reuptake of smoking.

In a similar vein, studies in the last several years have shown that initiating nicotine patch treatment before a target quit date, while smokers temporarily continue to smoke, significantly enhances efficacy (Rose, Herskovic, Behm, & Westman, 2009). Thus, as the rewarding effects of smoking are attenuated, smoking behavior declines, and smokers are better able to succeed in quitting when they reach their target quit date. Although not yet approved in the United States, pre-cessation use of nicotine

patch has been approved in Australia, Canada, and the United Kingdom.

[2]Sleep Medicine Institute and Department of Psychiatry, School of Medicine, University of Pittsburgh, Pittsburgh, PA, USA

Synonyms

Grave yard shift

Definition

Shift work refers to a job schedule in which employees work hours other than the standard hours of 8 a.m. to 5 p.m. or a schedule other than the standard workweek – Monday through Friday in the USA.

Description

Human beings are by nature a diurnal species with a natural tendency among adults to sleep at night and be most active during the day. Society is largely structured to facilitate such tendencies, with most social interactions, familial gatherings and work hours during the daylight hours. However, there is often occasion to diverge from these norms especially for work purposes. Today's society is driven by a 24 h mentality which demands that over 8.6 million people (in the USA) perform shift work (Kryger, Roth & Derent, 2005).

Circadian factors are a primary determinant of one's ability to cope with shift work. Humans are biologically wired to sleep during the night and be most active during the day. Certain biological processes determine the body's natural sleep-wake cycle, particularly the secretion of melatonin in response to the light-dark cycle. Such processes are not easily changed so as to shift the natural cycle. Some evidence indicates that sleep phase adjustment for a night worker, as measured by urine melatonin, can take as long as 5–6 days (90 min phase delay per day) before melatonin onset is readjusted to the new schedule.

In addition to endogenous determinants of the sleep cycle, there are other factors known as zeitgebers (time givers) that contribute to one's perceived normal sleep-wake cycle. Such zeitgebers include social factors like meal times and social gatherings and natural factors like daylight and night. These timing cues help orient the body to a certain time schedule and to encourage humans to be active during the day. However, for a night-shift worker who must be awake during the night, these zeitgebers can work

against an individual's inclination to remain awake at night resulting in dysregulated immune, hormonal, and cardiovascular function, thereby contributing to poor health.

Domestic factors also play a big role in sleep and subsequent health of the shift worker. For the night worker, social, familial, and societal obligations often impinge on sleep time since they occur in opposition to the night worker's schedule. Moreover, many shift workers have families and homes to care for that often require significant attention during daylight hours. Not only do these domestic factors inhibit a shift worker from obtaining adequate sleep during the day but they often impact the quality of the sleep he/she does get. Several consequences can arise from poor coping with a shift-work lifestyle, including a predisposition to depression and anxiety (Akerstedt, 2003).

Not surprisingly, shifting of one's sleep to the daytime hours can have negative consequences (Akerstedt, 2003). Not only is shift work (and daytime sleep) in contradiction to most of the biological system's circadian rhythms, but it is a strong predictor in the development of chronic sleep disorders. For instance, shift workers have been found to have sleep maintenance insomnia as opposed to sleep onset insomnia, which results in a constant state of sleep deprivation. Surveys in Europe and in the USA have found that night workers get approximately 10 h less sleep per week than day workers. Akerstedt and colleagues found that there is a significant loss of Stage 2 and REM sleep among shift workers. Although a night worker's sleep loss can be partially attenuated by sleeping longer on days off, they are unable to "repay the debt" and still experience chronic sleep deprivation and its consequences.

Health consequences of shift work include cardiovascular disease, diabetes, and obesity. There are also associations with stomach problems and ulcers, increased depression, and risk for injury or accidents. Many of these adverse outcomes stem from dysregulation of metabolic, digestive, and immune processes that maintain alignment with the circadian rhythm. While important and often necessary for many people to perform shift work, it is imperative to understand and appreciate the significant toll that shift work can have on health and social relationships (Akerstedt, 1990).

Nitric Oxide Synthase (NOS)

Sarah Aldred
School of Sport and Exercise Sciences,
The University of Birmingham, Edgbaston,
Birmingham, UK

Synonyms

Endothelial nitric oxide synthase (eNOS); Inducible nitric oxide synthase (iNOS); Neuronal nitric oxide synthase (nNOS)

Definition

Nitric oxide synthase (NOS) is an enzyme which catalyzes the formation of nitric oxide (NO).

NO is a free radical gas, which acts as a vasodilator, and is formed from the amino acid arginine. NOS comprises a family of enzymes which were first described in 1989. NOS is present in the human body in three distinct isoforms: neuronal NOS (nNOS) found predominantly in neuronal tissue, inducible NOS (iNOS) being inducible in a wide range of cells and tissues, and endothelial NOS (eNOS) which was first found in vascular endothelial cells.

Description

Three distinct genes for the human NOS isoforms exist, with 51–57% homology between the human isoforms in primary amino acid sequence. The similarity in genomic structure indicates a common ancestral NOS gene. The isoforms are classified by the tissue in which they were originally found, although it is now known that expression of these enzymes also occurs in other cell types, such as cardiac muscle, skeletal muscle, and blood platelets. The NOS enzymes are dimeric in their active form, and function is facilitated by the cofactors NADPH (nicotinamide adenine dinucleotide phosphate-oxidase) and tetrahydrobiopterin (BH_4). Other cofactors are calmodulin/calcium, heme, flavin mononucleotide (FMD), and flavin adenine dinucleotide (FAD). A summary of the reaction catalyzed by NOS can be written as:

$$\mathrm{L-arginine} + 2\mathrm{NADPH} + \mathrm{O_2} = \mathrm{L-citrulline} + \mathrm{NO} + 2\mathrm{NAPD^+}$$

The enzyme consists of two domains, an oxygenase and a reductase domain, which both have catalytic activities. Binding sites for heme and BH_4 reside on the oxygenase domain and are linked to the reductase domain through a binding site for calmodulin. The binding sites for FAD and FMD are also found on the reductase domain. To allow production of NO, the enzyme must be fully coupled through BH_4. Deficiencies in any of the cofactors can influence NO biosynthesis.

iNOS and nNOS are soluble and found predominantly in the cytosol, while eNOS is a membrane-associated protein, docked to regions of the plasma membrane called calveolae.

nNOS

nNOS was initially identified in neuronal cells, but has since been identified in the many other cells including those of the gastrointestinal tract. It has a role in NO production for sphincter relaxation and blood flow and modulates the response to glutamate.

iNOS

iNOS as its name suggests is inducible. It is calcium insensitive, in contrast to the calcium-sensitive isoforms nNOS and eNOS. iNOS is linked with the immune response. Previous research in this field has identified that iNOS is expressed as a result of inflammation, but its role in inflammatory disease is a complex one. iNOS has also been implicated in attenuation or suppression of inflammatory tissue injury. In addition, NO forms part of the nonspecific immune defense mechanism against invading microorganisms. NO and superoxide ions are produced in response to microorganisms and react together to form the reactive ion peroxynitrite which, with NO, has the ability to react with and kill invading cells.

eNOS

eNOS is present in the cells of the endothelium, and its main function is to regulate blood flow and blood pressure. eNOS is activated by the pulsatile flow of blood causing a small release of NO with every heart beat. When intracellular levels of calcium increase, eNOS detaches from the plasma membrane and becomes activated. The requirement for calcium is significantly reduced if the enzyme becomes phosphorylated on one of its serine residues, and phosphorylation is now recognized as a common mechanism for activation of eNOS.

More details can be found in Packer (1996).

Nocebo and Nocebo Effect

Magne Arve Flaten
Department of Psychology, University of Tromsø, Tromsø, Norway

Synonyms

Anxiety; Context effect; Expectancy

Definition

A nocebo is any inert substance, procedure, apparatus, or similar that alone has no effect in the body. The nocebo effect is the psychological and/or physiological response to the nocebo when it is administrated with a suggestion that the substance, procedure, apparatus, or similar will increase pain or unpleasantness, or otherwise harm the individual.

Description

Placebo comes from the Latin word "nocere" which means "I will harm" and has been used in medicine to describe treatments that worsen or induce symptoms in the patient, without having a specific effect on the symptom.

A nocebo effect may occur when a substance, procedure, or other stimulus is administrated to a person together with a suggestion that this will increase pain or unpleasantness, or in some way harm the person. The nocebo effect occurs whether or not the substance or procedure is harmful or painful. Thus, a substance or procedure that induces a placebo effect may, when administrated with the opposite suggestion, induce a nocebo effect (Flaten, Simonsen, & Olsen, 1999). The nocebo effect may consequently be considered the opposite of the placebo effect.

Nocebo effects have mostly been studied in the field of pain. The effect may be observed as an increase in pain report to a painful stimulus after suggestion that the pain will increase, although the stimulus is kept at constant levels. The nocebo effect may also be observed as the induction of pain by a non-painful stimulus that is administrated with information that it will induce pain (Colloca, Sigaudo, & Benedetti, 2008). Nocebo effects have also been observed in asthmatic patients and in nausea, but are not well researched outside the field of pain.

Brain imaging studies have shown that nocebo effects are associated with further increases in brain regions activated by painful stimulation, i.e., a painful stimulus activates certain brain regions (often the anterior cingulate cortex and insula), the activation of which have been found to be further increased by expectation that the pain will become more intense. These effects are the opposite of those observed during placebo analgesia.

One mechanism underlying nocebo effects is most likely anxiety. Information that a procedure or substance will induce pain or may harm induces anxiety, which in turn increases pain. Administration of an anxiolytic reduces nocebo hyperalgesia. Furthermore, blockade of cholecystokinin, a hormone associated with anxiety, has been found to block completely nocebo hyperalgesia (Benedetti, Lanotte, Lopiano, & Colloca, 2007).

Nocebo effects are clinically relevant for diagnostic or therapeutic medical procedures. Injections of anesthetics, e.g., may be made painful, or more painful, if the information provided by health personnel performing these procedures induces nervousness or anxiety in the patient (Varelman, Pancaro, Capiello, & Camann, 2010).

Nonexperimental Designs

J. Rick Turner
Cardiovascular Safety, Quintiles, Durham, NC, USA

Synonyms

Observational designs; Observational studies; Observational study

Definition

There are two fundamental types of study design: experimental and nonexperimental (Piantadosi, 2005). Experimental designs (discussed in their own entry) involve a series of measurements (observations) made under conditions in which the influences of interest are controlled by the research scientist. Nonexperimental studies are often called observational studies, but this term is inaccurate; it does not definitively distinguish between nonexperimental studies and experimental studies, in which observations are also made.

The term "nonexperimental" is not a relative quality judgment compared with experimental. This nomenclature simply distinguishes methodological approaches. In some cases, nonexperimental studies are the only type of medical study that can legitimately be used. If one wishes to examine the potentially negative health impact of a specific influence, such as exposure to nicotine via smoking cigarettes or living close to an environmental toxin, it is not appropriate for the research scientist to exert control over the influence of interest by asking some individuals to smoke or to live in a certain location. Rather, the research scientist makes use of naturally occurring cases of individuals who have and have not smoked and individuals who live close to and far from an environmental toxin to examine a potential relationship between the influence of interest and a specific health outcome.

Case-control studies and cohort studies are examples of nonexperimental designs.

Non-REM Sleep

Salvatore Insana
Western Psychiatric Institute and Clinic, Pittsburgh, PA, USA

Synonyms

N1, N2, N3; Quiet sleep; Sleep stages 1, 2, 3, and 4

Definition

Sleep can be measured with polysomnography (PSG) (see review, Keenan & Hirshkowitz, 2011). Polysomnographically measured sleep can be classified into distinct behavioral categories. Non-Rapid Eye Movement (NREM) sleep is a distinct sleep behavior classification. NREM sleep is a term used to describe, as the name suggests, sleep stages that are not Rapid Eye Movement (REM) sleep. NREM sleep includes sleep stages N1, N2, and N3 as defined by the 2007 American Academy of Sleep Medicine (AASM) sleep scoring manual (Iber, Ancoli-Israel, Chesson, & Quan, 2007). NREM sleep is otherwise known as the combination of sleep stages 1, 2, 3, and 4 as identified by the Rechtschaffen and Kales "classic criteria" (Rechtschaffen & Kales, 1968).

General descriptions of AASM scoring criteria for each NREM sleep stage are briefly stated. N1 is characterized by the expression of slow rolling eye movements, decreased muscle tone, and low-amplitude, mixed-frequency brain activity (4–7 Hz). N2 is characterized by K-complexes (a negative vertex sharp brain wave immediately followed by a positive wave that lasts $\geq$0.5 s) and sleep spindles (a train of brain waves with high frequency [11–16 Hz] and low amplitude that last $\geq$0.5 s). N3 is characterized by slow brain waves that are high amplitude (>75 V), low frequency (0.5–2 Hz), and occur throughout $\geq$20% of a given epoch. N3 sleep includes stages 3 and 4 sleep in the Rechtschaffen and Kales' classification and is also frequently called "delta" or "slow-wave" sleep.

NREM sleep has been observed among all mammals (Siegel, 2009). The function of human sleep, and particularly NREM sleep, is complex and unknown (e.g., Rector, Schei, Van Dongen, Belenky, & Krueger, 2009; Siegel, 2009). Theories about the function of each NREM sleep stage are briefly mentioned. N1 serves as the transitional stage from wake to sleep. N2 components (spindles and K-complexes) are thought to integrate new memories and regulate arousal from sleep (Halász, 2005; Tamminen, Payne, Stickgold, Wamsley, Gareth, & Gaskell, 2010). N3, or rather

the amount of N3, is thought to reflect the homeostatic sleep drive, or one's escalating need for sleep with increasing time awake (Dijk, Brunner, Beersma, & Borbély, 1990). NREM sleep appears central to memory formation; specifically, NREM sleep and REM sleep complement each other to process and consolidate various types of memory (Diekelmann & Born, 2010).

Human development: From birth to approximately 6 months post-term, infant sleep patterns are classified into either REM or NREM; during this period, these classifications are also referred to as active sleep and quiet sleep, respectively (Grigg-Damberger et al., 2007). Following 6 months post-term, infant NREM sleep patterns become more complex, and then can be categorized into N1, N2, and N3 sleep stages – in addition to REM sleep. Across the life span, generally, the percentages of N1 and N2 sleep increase, whereas N3 and REM sleep decrease (Ohayon, Carskadon, Guilleminault, & Vitiello, 2004).

Nonverbal Communication

Elizabeth Galik
School of Nursing, University of Maryland, Baltimore, MD, USA

Synonyms

Body language; Kinesics

Definition

Nonverbal communication is a complex system of communication that involves sending and receiving messages without the use of words. Nonverbal communication consists of a combination of (1) body movement (kinesics), such as gestures, posture, stance, and facial expressions; (2) touch (haptics); (3) eye contact and gaze, (4) bodily use of physical space, position, and proximity (proxemics), and nonverbal vocalizations that convey emotions or attitudes (paralanguage), such as laughing, crying, whistling, speech hesitancy, and tone. Research has indicated that 50–90% of social meaning is transmitted through nonverbal communication (Knapp & Hall, 2007). Functions of nonverbal communication include expression of emotion and attitude, communication of interpersonal relationships, support or contradiction of verbal communication, reflection of personality, and performance of social rituals, such as greetings and farewells (Argyle, 1988; Argyle & Hinde, 1972). Nonverbal communication is particularly influenced by the function of culture (Agliati, Vescovo, & Anolli, 2006). An understanding of nonverbal communication can be applied widely in a variety of fields such as medicine, business, politics, psychology, education, and the criminal justice system.

Norepinephrine/Noradrenaline

Sabrina Segal
Department of Neurobiology and Behavior, University of California, Irvine, CA, USA

Definition

Norepinephrine/noradrenaline is a catecholamine that is released as a stress hormone in the peripheral sympathetic nervous system via the adrenal medulla and initiates the fight or flight response. It is released as a neurotransmitter in the central sympathetic nervous system via noradrenergic neurons.

Norepinephrine is synthesized from dopamine by dopamine beta-hydroxylase through a series of enzymatic steps, beginning with tyrosine hydroxylase. This enzyme converts tyrosine to L-dihydroxyphenylalanine (L-DOPA), which in turn is transformed to dopamine by dopa-decarboxylase and packaged into storage vesicles. The membrane-bound enzyme, beta-hydroxylase, converts dopamine to norepinephrine within storage vesicles.

Norms

Chad Barrett
Department of Psychology, University of Colorado Denver, Denver, CO, USA

Synonyms

Social norms

Definition

In the context of psychological assessment, norms refer to sets of scores from well-defined samples that are used for standardizing and interpreting assessments. Norms are derived from sampling one or more groups of individuals and obtaining the distribution of scores on a particular assessment for each group. These sets of scores make it possible to interpret the scores of individuals who are assessed. The score of individual test takers can be compared to the scores from the group to which they belong. This provides a basis for comparison and makes it possible to interpret a person's score. For example, if a high school student obtains a certain score on an aptitude test, there is no way to interpret their score without comparing it to the scores of other high school students. If only 5% of their peers scored better than them, this would indicate that they demonstrated exceptional aptitude on the test relative to their peers. However, if 95% of their peers scored better than them, this would indicate that they demonstrated a diminished aptitude relative to their peers. Given that norms are essential for interpretation, it is important that norms be based on samples that are sufficiently representative of the populations they represent and large enough to minimize standard error (Kaplan & Saccuzzo, 2008; Kline, 2000).

Norms, also called social norms, refer to rules or standards of expected behavior that are shared by members of a certain group. Social norms shape individual group members' perceptions about the acceptability of certain behaviors (injunctive norms) as well as the type, and frequency, of behaviors that other group members perform (descriptive norms). A person's perceptions of social norms are often constructed by observing the behavior of other group members, by communicating with other group members, and by exposure to normative messages through media outlets and from explicit or implicit instruction (Dubios, 2003; Hechter & Opp, 2005). Social norms have been found to influence a variety of health-related behaviors, such as eating and exercise habits, alcohol consumption, smoking, drug use, and seeking medical help (Berkman & Glass, 2000; Borsari & Carey, 2003; McNeill, Kreuter, & Subramanian, 2006; Shaikh, Yaroch, Nebeling, Yeh, & Resnicow, 2008; Sorensen et al., 2007). According to the social norms approach, individuals who engage in unhealthy behaviors often overestimate the extent to which others engage in those unhealthy behaviors and underestimate the extent to which others engage in healthy behaviors. Such misperceptions predict the likelihood of engaging in unhealthy or healthy behaviors. Many interventions that focus on correcting such misperceptions by providing normative feedback have been successful in correcting such misperceptions and in promoting healthier behaviors (Berkowitz, 2003, 2004).

Nurses' Health Study

William Whang
Division of Cardiology, Columbia University Medical Center, New York, NY, USA

Definition

The Nurses' Health Study is a long-term cohort study that has collected information about cardiovascular and other disease risk factors, in addition to lifestyle factors, since its beginning in 1976 (Belanger, Hennekens, Rosner, & Speizer, 1978). At the onset, 121,701 female

registered nurses, aged 30–55 years, completed a questionnaire about their medical history and disease risk factors. The cohort has been followed up every 2 years with mailed questionnaires that update exposure information and inquire about newly diagnosed medical illnesses. Numerous analyses involving NHS data have been performed, including investigation of the impact of smoking cessation on long-term risks of coronary artery disease (Kawachi et al., 1994) and relationship between phobic anxiety and coronary heart disease events (Albert, Chae, Rexrode, Manson, & Kawachi, 2005).

Nutrient Intake

► Nutrition

Nutrition

Steven Gambert
Department of Medicine, School of Medicine, University of Maryland, Baltimore, MD, USA

Synonyms

Dietary requirements; Nutrient intake

Definition

Nutrition is the process by which living organisms obtain nutrients and use them for proper growth and development, cellular metabolism, and repair. It is a process that involves the ingestion, digestion, absorption, transport, assimilation, and excretion of essential nutrients.

Description

Nutrition is the process by which living organisms obtain nutrients and use them for proper growth and development, cellular metabolism, and repair. It is a process that involves the ingestion, digestion, absorption, transport, assimilation, and excretion of essential nutrients. In order to insure an adequate "nutrition," there are a variety of macro and micro-nutrients that must be obtained. While the body has the ability to utilize certain nutrients obtained through nutrition to provide the building blocks for cellular growth, maturation, and repair, some are essential and must be part of one's nutrition. This is illustrated by the fact that although animal and plant protein contain 20 amino acids, 9 are considered "essential" and not able to be produced by the body itself.

Recommended Dietary Allowances are established by the Food and Nutrition Board of the National Research Council and represent the nutrient allowances thought to be necessary for the maintenance of good health (National Research Council, NRC, 1989). Malnutrition is the state associated with either an under or over intake of essential components of one's nutritional requirements including calories and specific nutrients such as protein, fat, minerals, and vitamins. Examples include obesity (an excess intake of calories), marasamus (a deficiency in caloric intake), kwashiorkor (a deficiency in protein intake), among other examples. Certain individuals will require intake above the minimum daily requirement of certain nutrients. One example is calcium. The RDA is 800–1,500 mg of elemental calcium daily. Individuals who are breast-feeding, pregnant, or who have metabolic bone disease should be at the higher range of intake.

Each individual utilizes nutrients differently based on genetic and environmental factors. Muscle has a higher metabolic utilization than fat and individuals with more muscle have a higher caloric requirement to maintain their body weight. Catecholamines and thyroid hormone play a role in our ability to up and downregulate our metabolism as well as the type of food we consume. For example, individuals who "nibble," eating multiple meals throughout the day are metabolically different from those who "gorge" (one meal a day) their dietary intake even at the same level of caloric consumption . Eating only one meal a day (gorger) causes the body to function the rest of the day as it is starving and metabolically downregulating metabolism. Not all foods are also handled the same in the body with only 78% of protein utilized by the body due to the increase in metabolic work needed to break down the protein bonds as compared to fat and carbohydrate that are utilized by the body at 99% and 98%, respectively.

Nutritional assessment may be done by assessing a variety of measures including body mass index. This is a calculated value that is determined by taking the weight in kilograms divided by the height in meters squared. A value of 19–25 is considered to be normal and values over 30 are considered to be obese. Another measure of nutritional status is pre-albumin with values of 20 or greater indicating adequate protein stores. A questionnaire (mini-nutritional assessment) can provide information to predict who is at risk of malnutrition (Kaiser et al. 2009).

Nutrition Data System for Research (NDSR)

Lisa Harnack
Division of Epidemiology and Community Health, School of Public Health, University of Minnesota, Minneapolis, MN, USA

Definition

Nutrition Data System for Research (NDSR) is a Windows-based dietary analysis program designed for the collection and analyses of 24-h dietary recalls and the analysis of food records, menus, and recipes. The system is developed and maintained by the University of Minnesota Nutrition Coordinating Center (ncc.umn.edu).

Description

Overview of NDSR

NDSR is a software application that may be used to quantify the food and nutrient intake of individuals, analyze the nutrient composition of menus, and calculate the nutrient composition of food recipes. Consequently, the program has both research and practice applications in the arena of behavioral medicine. Examples of its use include collection and analysis of 24-h dietary recalls from study participants to evaluate the effect of a nutrition intervention on food and nutrient intake. In clinical settings, NDSR is used to analyze food records kept by patients as a behavioral monitoring tool. Institutions such as hospitals, prisons, and colleges use NDSR in planning nutritionally balanced menus. The program is also used to calculate the nutrient content

of recipes for publication in health promotion pamphlets, cook books, etc.

Food and Nutrient Database

The University of Minnesota Nutrition Coordinating Center (NCC) Food and Nutrient Database serves as the source of food composition information in the software. This database includes over 18,000 foods, including 7,000 brand-name products. Ingredient choices and preparation methods provide more than 160,000 food variants. Values for 162 nutrients, nutrient ratios, and other food components are generated from the database. Also, food group assignments are provided so that intake of food categories such as fruits and vegetables may be calculated. Missing nutrient values are kept to a minimum by obtaining nutrient composition information from a variety of sources and utilizing standardized imputation procedures (Schakel, Sievert, & Buzzard, 1988; Schakel, Buzzard, & Gebhardt, 1997; Westrich, Buzzard, Gatewood, & McGovern, 1994). The database is updated annually to reflect marketplace changes and new analytic data.

24-H Dietary Recall Collection and Analysis

Dietary recall data gathered by interview are entered directly into NDSR. The software searches for foods and brand products by name. Sophisticated search algorithms locate the food, and the interview prompts standardize requests for more detail. Dietary intake data gathered by interview are governed by the multiple-pass approach interview methodology. Four distinct passes provide multiple opportunities for the participant to recall and clarify food intake.

Dietary supplement use may be assessed in conjunction with collection of 24-h dietary recalls using the Dietary Supplement Assessment Module included in NDSR. Use of all types of dietary supplements and nonprescription antacids is queried in the module. The database linked with the module includes over 2,000 dietary supplement products. A "missing product" feature in the software allows the user to add products to the database. The coding of foods and dietary supplements occurs automatically as data are entered. Calculation of nutrients occurs immediately and yields data per ingredient, food, meal, and day in report and analysis file formats.

Food Record, Menu, and Recipe Analysis

Data entry windows tailored for direct entry of food records, menus, and recipes are provided in NDSR. The coding of foods occurs as data are entered. Calculation of nutrients occurs simultaneously, allowing for generation of reports and analysis files immediately following completion of data entry.

Background and History

NDSR was developed and is maintained by the University of Minnesota Nutrition Coordinating Center (NCC). NCC was established in 1974 by the National Heart, Lung, and Blood Institute (NHLBI) to support the food-coding and nutrient-analysis needs of two historically significant national collaborative research programs – the Multiple Risk Factor Intervention Trial (MRFIT) and the Lipid Research Clinics (LRC). For these studies, a standardized mainframe computer-based food-coding and nutrient-analysis system was created by NCC in collaboration with NHLBI and outside experts in nutrition, statistics, computer science, and education (Dennis, Ernst, Hjortland, Tillotson, & Grambsch, 1980). This system was designed for in-house use, with NCC staff responsible for using it to code foods for nutrient calculations.

By 1977, NCC services were made available to other researchers studying the impact of diet and nutrition on various health conditions, including cardiovascular disease, cancer, hypertension, obesity, diabetes, age-related eye disease, and acquired immune deficiency syndrome (HIV/AIDS). In 1988, NCC released Nutrition Data System (NDS), a DOS-based software program designed to provide a standardized interview and direct data entry for collection of dietary intake (Feskanich, Sielaff, Chong, & Bartsch, 1989). For the first time, coding of foods and amounts was computerized, providing immediate calculation of nutrient data. The software was developed for distribution to researchers for use on their own computers. A user manual, technical support, and

training were among the services developed by NCC to support those using NDS.

Since 1998, NCC has worked to keep NDSR up-to-date with computer hardware and software advances, and dietary intake assessment methodological improvements. In addition, major expansion to the nutrients and foods in the NCC Food and Nutrient Database has been made to keep the database current, with the ever-expanding food marketplace and the growing number of nutrients and other food components of interest to researchers and of importance to human health.

Nutritional Supplements

Steven Gambert
Department of Medicine, School of Medicine, University of Maryland, Baltimore, MD, USA

Synonyms

Dietary supplement; Food supplement; Nutritional supplement

Definition

A nutritional supplement is a product available in any form that is intended to provide nutrients that are considered to either be lacking or insufficient in the diet. These may contain one of more of the following: vitamins, minerals, fiber, fatty acids, amino acids, and herbs or other botanicals. It is intended for ingestion in pill, capsule, tablet, powder, or liquid form and is not to be used as a conventional food or as a primary form of meal.

Description

A nutritional supplement is a product available in any form that is intended to provide nutrients that are considered to either be lacking or insufficient in the diet (US Food and Drug Administration). These may contain one of more of the following: vitamins, minerals, fiber, fatty acids, amino acids, and herbs or other botanicals. It is intended for ingestion in pill, capsule, tablet, powder, or liquid form and is not to be used as a conventional food or as a primary form of meal. While various countries regulate nutritional supplements in different ways, in the United States, nutritional supplements are regulated by the Food and Drug Administration (FDA) as a category of foods, not drugs, and are not regulated by the National Academy of Sciences that provides the Recommended Dietary Allowances (RDA's) (National Research Council, 1989). Anyone wishing to market a dietary/nutritional supplement that

contains a "new dietary ingredient" as defined as "a vitamin, mineral, herb or other botanical (Goldman, 2001), amino acid, or dietary substance for use by man to supplement the diet by increasing total dietary intake or a concentrate, metabolite, constituent, extract, or combination of any of these must notify the FDA prior to marketing and receive approval as per the provisions of the Dietary Supplement and Health Education Act of 1994. Nutritional supplements must not be used for diagnosis, treatment, cure, or prevention of any disease. In 2007, the FDA implemented a 'current good manufacturing practices' policy to ensure that nutritional supplements are produced in a 'quality manner,' do not contain contaminants or impurities, and are accurately labeled." There are a wealth of products available that are characterized as nutritional supplements with a majority of persons in the USA reporting intake of at least one. While some nutritional supplements may have benefits based on limited studies, many have not been proven to have clinically significant benefits (Blendon, DesRoches, Benson, Brodie, & Altman, 2001).

Synonyms

Overweight

Definition

The prevalence of obesity has increased dramatically in the USA and worldwide over the past 30 years. Obesity and its consequences represent a significant public and individual health concern. Generally, obesity results when there is a sustained energy imbalance such that caloric intake (i.e., through food and beverages) exceeds caloric output (i.e., body functions, physical activity). In adults, obesity is defined as a body mass index (kg/m^2) of 30 or higher and overweight is defined as a BMI between 25.0 and 29.9. In children and adolescents, obesity is defined as a BMI at or above the 95th percentile for age and gender, and overweight is defined as a BMI at or above the 85th percentile. Current estimates suggest that 32% of men and 35% of women in the USA meet criteria for obesity (Flegal, Carroll, Ogden, & Curtin, 2010). Similarly, almost 17% of US children and adolescents (ages 2–19) are obese and 32% of youth are either overweight or obese (Ogden, Carroll, Curtin, Lamb & Flegal, 2010). Although increases in prevalence may have slowed over the past 10 years, researchers estimate that if the trajectory of obesity prevalence continues at present rates, almost half of US adults will meet criteria for obesity by 2020 (Stewart, Cutler & Rosen, 2009).

Obesity confers significant risk for individual medical, psychological, and social risks. Deleterious health effects strongly associated with obesity include cardiovascular disease, type 2 diabetes, certain types of cancers, sleep apnea, asthma, joint problems, depression, and suboptimal quality of life. Additionally, obesity represents a sizeable economic burden on society. The direct costs of medical care for adult obesity-related illness have been estimated to exceed $147 billion annually (Finkelstein, Trogdon, Cohen & Deitz, 2009). Moreover, estimates suggest that increases in obesity-related illness explain 27% of the increase in overall health-care spending in the USA between 1987 and 2001 (Thorpe, Florence, Howard, & Joski, 2004). Direct costs of childhood and adolescent obesity-related illness are estimated at 14.1 billion for prescription, outpatient, and emergency costs (Trasande & Chatterjee, 2009) in

M.D. Gellman & J.R. Turner (eds.), *Encyclopedia of Behavioral Medicine*,
DOI 10.1007/978-1-4419-1005-9,

addition to 237.6 million for inpatient treatment (Trasande, Liu, Freyer, & Weitzman, 2009).

Given the high prevalence of obesity in children and adults, prevention and treatment approaches have received increasing attention. Individual and group interventions for obesity have adopted behavioral (i.e., "lifestyle"), pharmacological, and surgical approaches (Wilfley, Tibbs, Van Buren, Reach, Walker & Epstein 2007; Wadden, Webb, Moran & Bailer, 2012). Establishing a healthy eating plan and attaining recommended levels of physical activity are key lifestyle components for both obesity prevention and treatment.

[2]Department of Pediatrics, University of Miami Miller School of Medicine, Miami, FL, USA

Synonyms

Overweight children

Definition

Obesity in children is defined as having a body mass index (BMI) at or above the 95th percentile compared to peers of the same age and gender.

Description

BMI is calculated from height and weight and plotted on a growth chart according to the child's age and gender. Obesity occurs when over time more calories are consumed than expended. Many factors affect obesity including poor eating habits, lack of exercise, family history, and psychosocial problems. Very few cases of obesity can be attributed to a specific disease.

Recent estimates indicate that nearly 10% of infants and toddlers and 12% of children and adolescents aged 2 through 19 years meet criteria for obesity in the United States (Ogden, Carroll, Curtin, Lamb, & Flegal, 2010). Correlates of childhood obesity include genetics, environment, metabolism, behavior, culture, and SES. Children from ethnic minority backgrounds and lower

socioeconomic status are at an increased risk of being obese. Obesity has a strong familial component: if a child's parent is obese, there is a 50% chance that the child will be obese; if both parents are obese, the likelihood of the child being obese increases to 80% (Whitaker, Wright, Pepe, Seidel, & Dietz, 1997). Obese children have a high likelihood of remaining obese as adults (Freedman et al., 2005).

The consequences of being obese are potentially severe, including higher risk for cardiovascular disease, hypertension, dyslipidemia, stroke, impaired glucose tolerance, type 2 diabetes, cancer, breathing problems, joint problems, and fatty liver disease. In addition to health consequences, there are also psychosocial and emotional consequences of being obese. Obese children often experience bullying and teasing in school which is associated with poor self-esteem and low self-confidence.

Obesity: Causes and Consequences

Chad D. Jensen[1], Amy F. Sato[2] and Elissa Jelalian[3]
[1]Department of Psychology, Brigham Young University, Provo, UT, USA
[2]Department of Psychology, Kent State University, Kent, OH, USA
[3]Department of Psychiatry, Rhode Island Hospital, Brown Medical School, Providence, RI, USA

Description

Obesity results from a complex interplay of biologic, environmental, genetic, and psychosocial factors that influence appetite, satiety, and food storage in the form of body fat. At a fundamental level, obesity results from a sustained positive energy balance; that is, consuming more energy than one expends over an extended period of time. Weight gain results from excess caloric intake, and weight loss results from greater caloric expenditure than intake. Thus, excessive caloric intake and insufficient physical activity are the primary contributors to obesity.

Biologic Influences

Research has demonstrated that energy balance is highly influenced by a complex biological system. This system balances the amount of fat in the body, partially by regulating the unconscious drive to eat (Friedman, 2009). This drive to eat is adaptive in times of food scarcity but has become problematic given the relative abundance of high-calorie foods and limited physical activity participation in today's society.

Genetic Contributors

Although the dramatic increase in obesity is not genetic in origin, genes interact with environmental factors to give individuals in the same environment significantly different risks of becoming obese. Estimates of the heritability of obesity – the percentage of variability due to

genetic factors – range from 70% to 80%, indicating that genetics play a clear role in increasing one's vulnerability to becoming obese (Walley, Asher, & Froguel, 2009).

Perinatal Influences

Recent research has also highlighted the important contribution of the perinatal environment to development of obesity. Studies have demonstrated that severely obese mothers are much more likely to have obese children than previously obese mothers who lost weight prior to conception (Kral et al., 2006). These results highlight the significance of gene-environment interactions: Epigenetic influences play a critical role in one's likelihood of becoming obese.

Environmental Factors

There is increasing recognition of the extent to which environmental factors contribute to the rise in obesity. Indeed, American society has been characterized as an *obesogenic environment* that promotes excess eating and physical inactivity (Swinburn, Egger, & Raza, 1999). Energy expenditure has decreased for most individuals in the developed world, largely because employment primarily consists of sedentary work, energy-saving devices limit physical exertion, and transportation requires little physical effort. In concert with decreases in physical activity, access to highly palatable, inexpensive food that requires little or no preparation has increased dramatically. These foods are often high in caloric content and contain high amounts of fat and sugar. Additionally, the food industry promotes consumption of these foods through aggressive advertising and promotion, a practice that has been shown to increase their consumption (Kumanyika et al., 2008).

Research has consistently demonstrated that attributes of the "built" environment (i.e., buildings such as homes, schools, and shopping centers, as well as the ways in which these buildings are configured within space) also contributes to the prevalence of obesity. Individuals who live in walkable neighborhoods with access to recreation facilities are more likely to be physically active and less likely to be obese. Residents of communities with ready access to healthful foods tend to have healthier diets and lower incidence of obesity. Furthermore, environmental characteristics that contribute to obesity affect low-income and racial minorities disproportionately, contributing to higher levels of obesity among these groups (Sallis & Glanz, 2009). Fast-food restaurants in particular have been identified as a key contributor to the rise in obesity, and these restaurants are more prevalent in low-income neighborhoods, a characteristic thought to partially explain the higher incidence of obesity among the poor (Powell, Auld, Chaloupka, O'Malley, & Johnston, 2007).

Consequences of Obesity

A broad spectrum of medical, psychological, social, and behavioral consequences result from obesity. These consequences have been shown to arise from one of two factors: the increased mass of fat in the body of the obese individual and the risks resulting from metabolic changes associated with excess fat.

Consequences Due to Metabolic Changes

One of the most well-known risks associated with metabolic changes arising from excess fat is the higher incidence of type 2 diabetes mellitus. Associated conditions include insulin insensitivity and metabolic syndrome, a concurrence of elevated blood pressure, cholesterol, centrally deposited fat, and elevated blood sugar. Cardiovascular disease including hypertension is also a frequent consequence of obesity. Estimates suggest that as many as 50% of obese individuals suffer from hypertension. Excess body weight also increases the risk of heart failure. Increased cardiac work resulting from higher body mass raises the likelihood of cardiomyopathy and heart failure in obese individuals. Obese individuals are also at risk for nonalcoholic fatty liver disease, a constellation of liver abnormalities associated with obesity. Certain forms of cancer, including colorectal, prostate, and female reproductive and breast cancers, are more prevalent among obese individuals (Bray, 2004).

Consequences Due to Increased Fat Mass

Medical comorbidities associated with increased fat mass include osteoarthritis, cartilage and bone

metabolism problems independent of weight bearing effects, and skin pigmentation and stretch marks. Obstructive sleep apnea risk is also greatly elevated in obese individuals.

Equally concerning are the psychosocial consequences associated with obesity. Obese individuals experience significant social stigmatization, including difficulty obtaining employment, education, and health care in addition to difficulties establishing and maintaining social relationships. Obese children are also more likely to have academic problems and to experience social difficulties, such as peer victimization and increased loneliness. Furthermore, obese individuals are more likely to report poor quality of life, depression, and disordered eating (Bean, Stewart, & Olbrisch, 2008).

Obesity Shortens Life

The detrimental effects of obesity combine to shorten life for individuals with this condition. Although estimates of life-shortening effects vary, obesity has been shown to shorten life on a population level. Indeed, the rise in rates of obesity has overwhelmed the positive effects of reduced rates of smoking on a population level (Stewart, Cutler, & Rosen, 2009). Individuals with obesity (BMI 30–39.9) have a reduced median survival rate of 2–4 years, while for those with extreme obesity (BMI 40–45), survival is reduced by 8–10 years (Prospective Studies Collaboration, 2009).

Conclusion

In summary, obesity is caused by energy imbalance resulting from excess caloric input relative to expenditure. The increased rate of obesity observed in the USA over the last three decades has been attributed primarily to an interaction between biologic risk for obesity and an *obesogenic environment* that provides limited opportunity for physical activity and ready access to calorie-dense foods. There are a number of medical and psychosocial consequences associated with obesity, including cardiovascular disease, joint problems, type 2 diabetes, depression, social stigmatization, poorer quality of life, and abbreviated life expectancy. These consequences underscore the importance of prevention and intervention efforts to ameliorate the negative consequences of obesity.

[3]Department of Psychiatry, Rhode Island Hospital, Brown Medical School, Providence, RI, USA

Description

Obesity prevention and treatment approaches have been developed for individuals across the developmental continuum, from childhood through adulthood. The basic goal of obesity prevention and treatment approaches is to shift energy balance (i.e., calories consumed versus calories expended) in order to reduce the presence of, or risk for, excess weight.

Obesity Prevention

Obesity prevention efforts include attention to both promoting healthy dietary intake and achieving adequate physical activity. The NIH Obesity Research Task Force outlines three levels of obesity prevention (US Department of Health and Human Services, 2004). Primary prevention is aimed at all individuals regardless of weight or obesity risk status. Secondary prevention seeks to prevent further weight gain in individuals who are already overweight or obese. The goal of tertiary prevention is to prevent complications due to co-occurring health problems (e.g., type 2 diabetes) in individuals who are already overweight or obese. A staged, or tiered, approach to obesity prevention and treatment has been recommended for child and adolescent overweight and obesity, with the appropriate level of intervention determined based on degree of overweight and presence of comorbidity (see Spear et al., 2007). With respect to youth, it is recommended that children ages 6 and older be screened for obesity, and then referred to multicomponent behavioral interventions to promote improvement in weight status (US Preventive Services Task Force, 2010). Obesity prevention programs are aimed at fostering a healthy lifestyle (e.g., consumption of fruits and vegetables, minimizing sugar-sweetened beverages, obtaining 60 min daily physical activity, and limiting screen time).

Environmental factors, such as the high cost of healthy foods and lack of access to safe places to exercise, are key contributors to the increased prevalence of obesity (Hill & Peters, 1998; Sallis & Glanz, 2009). For this reason, obesity prevention efforts are also aimed at community and population level change (Khan et al., 2009). Environmental- and policy-level changes can be divided into six categories aimed to (1) promote availability and affordability of healthy food/beverages (e.g., improve geographic availability of supermarkets in underserved areas), (2) support choice of healthy foods and beverages (e.g., restrict availability of high-calorie, high-fat, high-sugar, and high-sodium content foods and beverages in public service areas), (3) encourage breastfeeding (e.g., support for breastfeeding in the workplace), (4) encourage physical activity/limit sedentary activity in youth (e.g., require physical education in schools), (5) create safe communities that increase physical activity through changes in the built environment (e.g., increase access to outdoor recreational facilities), and (6) encourage communities to organize for change (e.g., participate in community coalitions or partnerships to address obesity) (Khan et al., 2009).

Obesity Treatment

The treatment of overweight and obesity in children and adults shares the same fundamental

principal, which is to increase energy expenditure and decrease caloric intake. However, the goal of treatment may differ somewhat depending on age. For adults, obesity treatment seeks to reduce body weight. For children, the goal of obesity treatment may be either reduction of body weight or deceleration of weight gain (Oude Luttikhuis et al., 2009). The most appropriate mode of treatment is based on several considerations, including initial degree of overweight, previous intervention efforts, co-morbid health problems, and age.

Lifestyle Intervention

There is a strong evidence base for multicomponent lifestyle intervention approaches that combine dietary restriction, physical activity prescription (increasing physical activity, limiting sedentary behaviors), and behavioral modification approaches for the treatment of obesity in adults and youth (Oude Luttikhuis et al., 2009; Shaw, O'Rourke, Del Mar, & Kenardy, 2005). Behavioral modification components for adults and youth typically include goal setting, self-monitoring, stimulus control, reinforcement, and problem solving (Jelalian & Hart, 2009; Oude Luttikhuis et al., 2009; Shaw et al., 2005). Research supports including parent involvement as part of lifestyle intervention approaches for pre-adolescent children (Spear et al., 2007).

A comprehensive review of behavioral treatments for overweight and obese adults (18 years and older) revealed that the combination of behavioral or cognitive-behavioral techniques with dietary and exercise interventions was effective in producing short-term and long-term (12-month) weight loss (Shaw et al., 2005). However, maintenance of weight loss following behavioral intervention continues to be poor, with participants typically gradually discontinuing changes in exercise and diet and consequently regaining weight (Perri et al., 2001). For overweight and obese children and adolescents, a comprehensive review of randomized controlled trials utilizing lifestyle intervention found that the combination of dietary intervention, physical activity, and behavior modification components was effective compared to standard care and self-help (Oude Luttikhuis et al., 2009). This is consistent with a previous meta-analysis which found that lifestyle interventions for pediatric obesity yield significant decreases in obesity immediately posttreatment, compared to no treatment or education-only controls (Wilfley et al., 2007).

Pharmacological Intervention

Pharmacological intervention approaches have been utilized for the treatment of obesity in both adults and adolescents (i.e., 12 years or older). In adults, the most commonly studied antiobesity medications have been orlistat and sibutramine. Results of a comprehensive review of these medications in adults suggested that, combined with lifestyle modification, orlistat and sibutramine resulted in greater weight loss than placebo with maintenance of weight loss at long-term follow-up (i.e., 12+ months; Padwal, Li, & Lau, 2004). The majority of the research in adolescents has focused on metformin, orlistat, and sibutramine as antiobesity drugs, with preliminary support for these pharmacologic interventions in adolescents (Delamater, Jent, Moine, & Rios, 2008; US Preventive Services Task Force, 2010). Orlistat is approved by the FDA for use in children ages 12 and older (US Preventive Services Task Force). However, recently, sibutramine was withdrawn from the US and Canadian markets due to concerns arising from research finding that it was associated with an increased risk of cardiovascular events (e.g., myocardial infarction; James et al., 2010). Finally, attrition rates with pharmacological interventions are somewhat high and there is a need for more methodologically rigorous studies of pharmacological treatments for obesity, with longer-term follow-up (Padwal et al., 2004).

Surgical Intervention

Surgical interventions for obesity have increased as the prevalence of obesity and morbid obesity (BMI $\geq$ 40) has increased in adults as well as in children and adolescents. Bariatric surgery, a surgical intervention for obesity, seeks to reduce weight and maintain weight loss via restriction of dietary intake, malabsorption of food, or a combination of these mechanisms (Colquitt, Picot, Loveman, & Clegg, 2009). Gastric bypass (i.e., Roux-en-Y, resectional gastric bypass) and adjustable gastric

banding have been the most commonly performed types of surgery, although other methods are available (e.g., biliopancreatic diversion, sleeve gastrectomy, vertical banded gastroplasty) (Colquitt et al., 2009). A comprehensive review of surgical interventions found that bariatric surgery was more effective in producing short- and long-term weight loss relative to nonsurgical interventions (e.g., dietary intervention) (Colquitt et al.). However, this may be due in part to the fact that most adult and adolescent bariatric surgery patients have a high BMI (i.e., BMI $\geq$ 40), and therefore have more weight to lose (Colquitt et al.; Delamater et al., 2008). Though results are mixed, overall, the available evidence suggests that gastric bypass yields greater weight loss than adjustable gastric banding or vertical banded gastroplasty, but similar to banded gastric bypass and isolated sleeve gastrectomy (Colquitt et al., 2009). Gastric bypass surgery has been found to be efficacious for the treatment of obese adolescents, and preliminary evidence supports the use of adjustable gastric banding in severely obese adolescents, with promising short-term and long-term weight reduction (Delamater et al., 2008).

Summary

A range of obesity prevention and treatment approaches have been implemented in adults as well as in children and adolescents. Prevention and intervention efforts involve attention to achieving a healthy diet and maintaining adequate levels of physical activity and, at the most basic level, seek to shift energy balance toward achieving weight loss or decelerating the rate of weight gain. Behavioral lifestyle interventions have traditionally received the most attention, with support for use in both adult and child populations; however, pharmacologic and surgical interventions have increasingly received support in adults and adolescents.

Obrist, Paul A

J. Rick Turner
Cardiovascular Safety, Quintiles, Durham, NC, USA

Biographical Information

Paul A. Obrist was born on June 17, 1931. He received his B.S. degree from Cornell University in 1953 and his Ph.D. from the University of Rochester in 1958. His graduate training included 2 years of clinical psychology at the Veterans Administration and a 2-year teaching assistantship, assisting in the teaching of introductory personality, child, and abnormal psychology. He also had extensive predoctoral research experience, culminating in his thesis research, "An Investigation of the Claim of Autonomic Discrimination Without Awareness and the Relationship of GSR Conditioning to Measures of Skin Conductance."

Obrist held a postdoctoral fellowship at the Fels Research Institute from June 1958 to June 1960. His specialty area was psychophysiology, working under the guidance of John Lacey. He then moved to the University of North Carolina, Chapel Hill, in 1960 as an assistant professor of psychology in the department of psychiatry. He progressed to associate professor in 1965 and full professor in 1970. His primary focus was developing the department's psychophysiology laboratory and guiding research (both chronic dog preparation and young human adults) on the role of behavioral stress in the etiology of hypertension.

Major Accomplishments

From the time of his arrival at UNC-Chapel Hill until his death in 1987, Obrist established and maintained one of the most prominent and productive psychophysiology research laboratories in the world. From his earliest studies, he sought to identify the cardiovascular mechanisms responsible for inducing variations in cardiovascular performance and to understand the functions that these cardiovascular responses serve in the context of behavior. His bringing behavior and physiology together in this manner generated a comprehensive view of cardiovascular psychophysiology.

Obrist was particularly proud of being president of the Society for Psychophysiological Research from 1974 to 1975. Additional honors included being the recipient of the 1985 Award for Distinguished Contributions to Psychophysiology from the Society for Psychophysiological Research and being conferred the honor of fellow by the Academy of Behavioral Medicine Research, the American Association for the Advancement of Science, and the American Psychological Association (Divisions 3, 6, and 38).

Obrist received numerous National Institute for Mental Health (NIMH) and National Heart, Lung, and Blood Institute (NHLBI) grants from 1963 to 1987. He was the recipient of continuous NIMH R01 grant funding from 1963 to 1976 and continuous NHLBI funding from 1976 to 1987. During his career, he published over 100 papers, one authored book, and one edited book.

Many outstanding psychophysiologists (including some who went on to make their mark in the fields of health psychology and behavioral medicine) had the good fortune to be trained in his laboratory. Among his trainees who later became department chairs were James Lawler (University of Tennessee-Knoxville), Kathleen Lawler-Row (East Carolina University), James McCubbin (Clemson University), and Michael T. Allen (University of Mississippi). P. Murali Doraiswamy became head of the Division of Biological Psychiatry at Duke University, where Andrew Sherwood continued his research. Kathy Light joined Obrist's laboratory in 1976, collaborating as a research scientist and assuming directorship of the lab in 1987. The coeditor of this encyclopedia, J. Rick Turner, also trained under Obrist and Light. Light also trained her

own graduate students there, including Susan Girdler who is now professor and director of the university's Stress and Health Research Program.

One of Obrist's central themes was that psychophysiologists (and, by extension, those in behavioral medicine and health psychology) should become better biologists. The depth of biological discussions in this encyclopedia attests to the usefulness of this approach.

Organizational health; Work-related health

Definition

"Occupational health" is defined as the field of research and intervention that deals with work- and employment-related influences on people's health and health-related behaviors and their modification. The field of occupational health is broader than the academic discipline of occupational medicine as it includes organizational, psychosocial, and behavioral aspects in addition to the more traditional physical and chemical hazards, thus incorporating research and expertise from social and behavioral sciences.

Description

Generally, behavioral medicine is interested in two approaches toward occupational health. The first approach considers the organizations, companies, and businesses where large population groups can be met recurrently and simultaneously as an ideal setting of implementing programs of behavioral modification. In these programs, health-adverse behaviors such as smoking, unhealthy diet, or lack of physical exercise are targeted with the aim of promoting a healthy lifestyle. These individual- or group-based interventions are often supported by employers and health insurance organizations as they were shown to produce benefits to both employees and employers. The second approach focuses on those aspects of work and employment that directly affect the health of working people. Here, scientific analyses of these associations and interventions based on respective evidence are of central interest.

As the nature of employment and work has changed significantly over the last half century, psychological and socio-emotional demands and threats evolving from an adverse psychosocial environment have become more widespread in all advanced societies (Schnall, Dobson, & Rosskam, 2009). Technological progress and economic growth in the context of globalized markets and trades result in new types of tasks (e.g., information processing, occupations, and professions in the service sector). Chronic exposure to an adverse psychosocial work environment affects the health of working people by triggering negative emotions and by eliciting recurrent stress responses in the organism that may compromise different bodily systems in the long run and increase the susceptibility to stress-related physical and mental disorders (Siegrist & Marmot, 2006).

To measure a health-adverse psychosocial work environment a theoretical model is needed that identifies "toxic" components within complex and diverse work settings at a level of high

generalization. Several such models were proposed, but the following three concepts are considered being the most established as they have been supported by a substantial body of empirical research (Cartwright & Cooper, 2009). First, the "demand-control model" posits that a specific job task profile characterized by high quantitative demands in combination with a low degree of decision latitude or control elicits recurrent stress reactions. These effects are moderated by the presence or absence of social support at work (Karasek & Theorell, 1990). Second, the "effort-reward imbalance model" is based on the basic principle of reciprocity of contractual social exchange. High efforts spent at work that are not reciprocated by adequate rewards trigger recurrent stressful experience. Rewards include salary or wage, promotion prospects and job security, and esteem or appreciation from significant others. Effort-reward imbalance is frequent among employees who have no alternative choice in the labor market or who work in highly competitive jobs. Stressful experience is reinforced among those who are overcommitted to their work (Siegrist, 1996). Third, the "organizational justice model" claims that unfair procedures within organizations and inappropriate interpersonal relationships, in particular within the hierarchies of organizations, are experienced as stressful (Greenberg, 2010).

These complementary theoretical models offer opportunities of health-promoting behavioral interventions at three levels. At the personal level, the individual workers' coping resources are strengthened by different approaches of stress management (e.g., relaxation and meditation techniques, cognitive-behavioral interventions). At the interpersonal or group level, social relationships at work are improved (e.g., communication, leadership, esteem, social support). At the organizational or structural level, interventions target changes in the division of work, work time, work load, task content, promotion prospects, or monetary and non-monetary rewards. Evidence indicates that interventions which combine these levels produce stronger and more sustainable effects than single-level interventions (Bourbonnais, Brisson, & Vézina, 2010; Semmer, 2008). Moreover, integrating health-promoting behavioral change into programs of stress management and organizational change seems particularly promising in an attempt of reducing social inequalities in health where those in lower socioeconomic positions suffer from a higher work-related burden of disease.

Behavioral interventions in occupational health are commonly located at the level of primary prevention where they are directed either at the workforce as a whole or at specific vulnerable subgroups. However, behavioral interventions at the level of secondary prevention are becoming more important as working populations are aging. Improving return to work in chronically ill and disabled people is considered a major challenge of occupational health, particularly with regard to mental health problems. There is a strong business case in terms of sickness absence reduction and productivity gain for introducing such secondary prevention measures where behavioral medicine expertise can be successfully implemented (e.g., individual placement and support models) (Black, 2008).

Despite these promises, occupational health from a behavioral medicine perspective still has to face substantial challenges. So far, only a minority of companies and organizations is committed to promote healthy work. There is a lack of resources, personnel, and management incentives. In view of financial pressures and heavy competition priorities are diverted from long-term concern about workers' health to short-term profit. The impact of legal regulations and labor policies at national level is limited by transnational trade and labor markets in a globalized economy (Blouin, Chopra, & van der Hoeven, 2009). Therefore, diffusion and promotion of excellent research findings and successful models of good practice in the field of behavioral occupational health is needed in an attempt to reduce the burden of work-related disease and disability.

Occupational Prestige

► Occupational Status

Occupational Science

Clare Hocking
Faculty of Health and Environmental Sciences, Auckland University of Technology, Auckland, New Zealand

Definition

Occupational science is the systematic study of the things that people do (their occupations). Occupations include everyday activities undertaken to care for self and others, animals and living and inanimate objects; secure shelter and sustenance; raise children; develop and test abilities, learn, and experience a sense of competence; contribute to family and community; create or distribute material wealth; play and enjoy life; pursue interests; celebrate significant life events; express creativity and spirituality; preserve or regain health; and the things people do for rest and restoration. In brief, occupation is everything people do to occupy themselves (Townsend, 1997). Research is undertaken at the level of individuals, groups, or populations, with an emphasis on understanding what occupations mean to people, occupational patterns, the factors that influence people's participation in occupation, and the relationship between occupation and health.

Description

Occupational science is concerned with the nature, performance, and outcomes of the ordinary and extraordinary things people do in their everyday lives. It is an interdisciplinary synthesis of basic knowledge (Yerxa, 1993), which draws from the human sciences, population studies, engineering, economics, ecology, and political sciences (Dickie, 2010).

Occupation

Within occupational science, various definitions of occupation have been proposed. While no consensus is sought, many definitions have included notions of occupation being self-initiated, intentional, and self-directed; meaningful; and organized, goal-directed, or purposeful (Crabtree, 1998; Yerxa et al., 1989). These characteristics, and the fact that occupations are identifiable and named within their cultural context, differentiate occupations from actions (such as brushing hair out of one's eyes) (Yerxa, 1993). Occupations command some level of attention, energy, time, and interest (Gray, 1997), are a means of fulfilling needs or meeting environmental demands, and lead to development and competence (Crabtree, 1998; Yerxa, 1998). They are variously described as discrete chunks of activity or as enfolded – indicating that people might be doing more than one occupation at a time, as in directing

children's play while preparing a meal. Occupations are also considered unique, in that an occupation cannot be repeated exactly as it was done before and each person performs an occupation in his or her own way (AOTA, 1997). Occupations are patterned, in that many occupations occur on a regular and repeated basis, and expected to change over time in response to maturation and over the lifespan.

Occupational Science Perspective on People

Occupational scientists view people as occupational beings (Yerxa et al., 1990), meaning that engaging in occupation is part of the essential nature of being human. Accordingly, occupation is positioned as the mechanism by which people develop and exercise their innate capacities; fulfill basic needs for food, water, and shelter; "adapt to changes in the environment, and flourish as individuals" (Wilcock, 1993, p. 17). Because she considered the need for occupation to be innate, Wilcock argued that lack of engagement in occupation is experienced as a discomfort that warns of a problem, manifesting as boredom, anxiety, depression, loneliness, tiredness, or tension; as a protective energy surge, triggering use of one's capacities; and as a sense of pleasure, satisfaction, or competence, which rewards and prompts engagement in occupation. While these assertions remain largely untested, adoption of the concept of flow into the occupational science literature suggests acceptance of these premises (Csikszentmihalyi, 1993).

Emergence of Occupational Science

Occupational science was founded by scholars at the University of Southern California (Yerxa et al., 1989), who initiated the discipline to "support the practice of occupational therapy" (Yerxa et al., 1990, p. 1) by generating a unique and substantive knowledge base for the profession, and to consolidate occupational therapy's place in academia by demonstrating its field is worthy of scholarly investigation (Yerxa, 1993). The discipline's focus on occupation is described as providing an alternative conceptualization of health to the biomedical focus that predominates in post-industrial societies. Occupational science rejects the mind-body split of physical disability and mental illness (Yerxa, 1993), instead emphasizing that occupation (doing) is a determinant of health and well-being, as well as being the mechanism through which people "learn to be competent, participating masters of their environments" (Yerxa, 1993, p. 3) and experience being, becoming, and belonging (Wilcock, 2006).

Primary Focuses

Occupation is a complex concept. Within the diverse topics addressed, much of the occupational science research has coalesced around several key concerns; the relationship between occupation and health, the meanings occupation holds, and occupation as a means of identity construction.

Large-scale empirical studies to establish the influence occupation has on health have been conducted by researchers from the University of Southern California, targeting lifestyle redesign™ for elders living in the community and for individuals at risk of decubitus ulcers and other health conditions (Clark, Jackson, & Carlson, 2004; Clark & Lawlor, 2009). In the Well Elderly Study, elders who were assisted to incorporate meaningful occupations into their everyday lives achieved global improvements in physical and social functioning, vitality, and mental health. Delivery of the intervention was cost-effective, and participants reported substantially reduced health costs. Smaller-scale studies have investigated the impact of various health conditions on individuals' occupations, explored the concept of occupational balance, and identified patterns of engagement in occupation associated with self-reported stress levels or health status.

Exploration of the relationship between occupation and well-being utilizing a history of ideas methodology has generated theoretical understandings of using occupation to both promote health and well-being, and to prevent illness and disability (Wilcock, 2006). These perspectives align with the Declaration of Alma Ata and the Ottawa Charter, which call for the reorientation of health services toward the pursuit

of health, and point to the need for widespread reform of occupational therapy to address population health (Wilcock & Hocking, 2004).

In addition to the focus on health, multiple small-scale qualitative studies have explored the meaning and experience of engaging in occupation. Perspectives range from meaning making through participation in cultural and mundane occupations (traditional forms of Indian dance, making a cup of tea) to the meaning of specialized occupations, such as teaching in a tertiary setting. Meaning has been explored through studies of participation in solitary and group occupations, such as cake decorating or singing in a choir, in relation to ritual, and from the perspective of making and using objects (Dickie, 2010; Hocking, 2009). An emerging perspective, grounded in Deweyan pragmatism, is that occupation is a transaction between the environment, self, and others. This strand of discussion draws attention to the ways internal and external changes mediate the meanings experienced and conveyed through occupation, and implicitly critiques earlier studies of individuals' engagement in occupation that paid little attention to environmental influences (Dickie, Cutchin, & Humphry, 2006).

A third focus has been the construction of identity and sense of self through occupation (Phelan & Kinsella, 2009), including the ways identity is strengthened or claimed (Christiansen, 1999; Rudam, 2002). Occupational identity is frequently discussed in relation to roles or role loss, gender, ethnicity, group membership, place or living with a chronic illness. In vulnerable groups, including older adults, refugees, migrants, and asylum seekers, restrictions and disruptions in occupation have been associated with identity change or preservation.

Key Concepts in Occupational Science

Occupational Deprivation

Grounded in the belief that "unused skill or capacity . . . can become a disease centre or else atrophy or disappear" (Maslow, cited in Wilcock, 1993, p. 21), Wilcock proposed that insufficient engagement in occupations has detrimental effects on health. Occupational deprivation is the term used to refer to situations where people experience chronic or permanent health problems due to lack of access to the range of occupations required to sustain health, because of cultural, political, economic, or social factors outside of themselves. Examples include the deliberate occupational deprivation of prisoners; sex role stereotypes, and cultural and religious sanctions that curtail women's participation in culturally meaningful occupations; the displacement and containment of refugees and asylum seekers (Whiteford, 2010), and the lack of opportunity to engage in occupation experienced by older people living in care facilities.

Occupational Justice

An aspect of social justice, occupational justice hinges on the equitable distribution of resources "as part of fair, enabling and empowering societies" (Wilcock, 2006, p. 245). Four occupational rights have been proposed, centering on (a) experiencing occupation as meaningful and enriching; (b) participation in occupations that foster development, health and social inclusion; (c) having choice in occupations, at individual or population levels; and (d) deriving fair privileges from participation in diverse occupations (Townsend & Wilcock, 2004). Systematically depriving people of occupation, to the extent that individual and population health are undermined (Stadnyk, Townsend, & Wilcock, 2010), is termed an occupational injustice. Such injustices are thought to manifest at the individual level as chronic stress, fatigue, and immune deficiencies and at a population level as civic disturbance and social disintegration. The concept of occupational justice has been taken up by the World Federation of Occupational Therapists in its Position Statement on Human Rights (n.d.). Related concepts including occupational marginalization and occupational apartheid have been proposed.

Occupational Potential/Possibilities

While occupational potential has been defined as "a vision of future possibilities for engagement in occupations, or structuring of society to enable people to participate as fully as possible"

(Christiansen & Townsend, 2010, p. 421), it is more usually considered to refer to the human potential that emerges through participation in occupation (Asaba & Wicks, 2010). Assumptions include that people naturally strive to develop their potential, employing creativity and constructive means across the life course. Human potential is not seen as predetermined; rather it is responsive to both the person and the social environment, relates to participation in occupation, and emerges over time as human capacities are exercised. The concept of occupational potential relates to the notion of possibilities, viewed as the interaction between experiences, actions, skills, and contexts.

Co-occupation

First published in 1996, the concept of co-occupation refers to those occupations where the shared participation of two or more people is requisite, such as playing on a see-saw, feeding an infant, or playing "peek-a-boo" (Zemke & Clark, 1996). In relation to infants, co-occupation is discussed in terms of promoting development, adaptation, and interaction. Researchers have sought to establish psychological, physiological, and behavioral differences between people engaged in solitary occupations and co-occupations, with some statistically significant differences identified.

Scope of Occupational Science

The scope of the discipline has been described as encompassing the substrates, form, function, and socio-cultural and historical context of human occupation (Clark et al., 1991). The substrates comprise humans' capacity to engage in occupation, including:

- Neuromuscular and other bodily structures, which both give the potential for and delimit human's capacities (e.g., physical strength, dexterity, and reaction times)
- Metabolic functions to maintain homeostasis despite exertion, which manifest as fitness, endurance, recovery times, and so on
- Cognitive and psychological processes such as information processing, memory, and regulation of emotions, which provide the capacity to maintain attention and monitor performance, and to remember, interpret, and apply the culturally accumulated and individually acquired knowledge of occupations
- Learned motor patterns and ways of responding.

Humans' stereoscopic vision, opposable thumbs, upright posture (which frees the hands to manipulate objects), and the size of humans' cerebral cortex (thus, the capacity for language, judgment, problem solving, and self-consciousness) have been identified as particularly important physical characteristics (Wilcock, 2006), which underpin these substrates.

The form of an occupation is its observable features. Depending on the occupation, different characteristics will be important. Those might include the capacities required to carry out the occupation (e.g., sufficient strength to wield a hammer), where the occupation usually takes place, who typically participates in the occupation (age, gender, socioeconomic status, ethnicity), whether the occupation is completed alone or with others, the time of day it is usually performed, how long it takes and the sequence of steps involved, how rigidly the steps or timeframes must be adhered to, the pace or tempo of performance required, and what tools or resources are used.

Other sources have included aspects that are not observable in their definition of an occupational form, such as the cultural meanings the occupation holds, the rules that govern performance, and the cognitive processes involved in monitoring performance (Nelson, 1999).

The function of an occupation is what is achieved by participating in it. There may be a concrete product, such as the vegetables growing in the garden, in addition to individual gains (a child learns about caring for seedlings), group outcomes (a family conserves its financial resources), and societal consequences (horticultural knowledge is preserved and disseminated).

The sociocultural context of an occupation shapes the meanings associated with it. For instance, expectations related to individuals' socioeconomic status, gender, age, and ethnicity influence who does what and how people respond to people acting within and outside of those

norms. The sociocultural context also influences the value placed on different occupations, with playing football being more acceptable to mainstream society than driving a stolen car, and programming a computer likely to be better remunerated than cleaning a bathroom – even though keeping bathrooms clean has an important role in preserving people's health. The historical development of an occupation can influence the meaning attributed to it, as in an occupation attributed the status of a tradition, as well as how widely dispersed it is across different cultures and people of different ages. Making bread and baskets, cleaning, building, weaving, raising crops, and fishing are occupations present in many cultures, albeit using different technologies. Reading a book is a more recent occupation, although its history spans several centuries, that is encouraged in school-aged children and an assumed ability in adults, even if they prefer not to participate. Playing interactive games on a computer has a shorter history, and younger rather than older people tend to have higher levels of proficiency in that occupation.

Critical Perspectives in Occupational Science

A range of critical discourses are emerging in the literature (Whiteford & Hocking, 2012). It is acknowledged that Western assumptions of the centrality of occupations in people's lives, the meanings occupations hold, and individualist rather than collectivist understandings predominate, and indigenous perspectives, such as the things people do to care for the land or in relation to the spiritual world, have not received much attention. One review of the discipline's research has also identified a gender inequity, with "adult, white women without disabilities" (Pierce et al., 2010, p. 209) being the group most studied by presenters at conferences convened by the Society for the Study of Occupation: USA between 2002 and 2007. A similar bias is evident in the Journal of Occupational Science.

In response to such critiques, a derived emic method was developed to generate cross-cultural understandings of occupation (Shordike, Hocking, Pierce et al., 2010), a transactional perspective has been advocated (Dickie et al., 2006), and governmentality has provided a critical lens through which to consider people's occupational choices (Rudman, Huot, & Dennhardt, 2009).

Synonyms

Employment status; Job prestige; Occupational prestige

Definition

Occupational status is the "collective term encompassing occupational performance components, occupational performance, and occupational role performance" (Jacobs & Jacobs, 2009).

Occupational performance components are "any subsystem that contributes to the performance of an occupation" (such as self-care, leisure, work, education, etc.) (Jacobs & Jacobs, 2009).

Occupational performance is "the act of doing and accomplishing a selected activity or occupation that results from the dynamic transaction among the client, the context, and the activity" (Jacobs & Jacobs, 2009).

Occupational role performance is the "rights, obligations, and expected behavior patterns associated with a particular set of activities or occupations, done on a regular basis, and associated with social cultural roles" (Hillman & Chapparo, 1995).

Overall, occupational status can be thought of as the various roles that a person identifies through participation in occupations. Occupational status may be impacted by other factors such as socioeconomic status. However, in general, it is being engaged in an occupation for wages.

Definition

World Federation of Occupational Therapists (WFOT) defines occupational therapy as a "client-centered health profession concerned with promoting health and well being through occupation. The primary goal of occupational therapy is to enable people to participate in the activities of everyday life. Occupational therapists achieve this outcome by working with people and communities to enhance their ability to engage in the occupations they want to, need to, or are expected to do, or by modifying the occupation or the environment to better support their occupational engagement" (World Federation of Occupational Therapists [WFOT], 2010, para. 1)

Description

Occupational therapy, founded in 1917, has become a well-established profession within the

areas of health and rehabilitation with over 60 member countries in the WFOT. Occupational therapists use a variety of interventions including the therapeutic use of everyday activities to enable persons to improve or regain the ability to participate in meaningful and satisfying activities that are necessary to support everyday life. Occupational therapy is applied at individual, group, community, and population levels (Christiansen, Baum, & Bass-Haugen, 2005; Söderback, 2009).

The term "occupation," as used by occupational therapists, refers to more than paid work; it refers to engagement in all life activities and includes activities necessary to care for self and others, education, work, play, leisure, and social participation. The discipline holds a number of key values and assumptions; in particular, it views people as occupational beings, believes in the positive relationship between occupation and health, holds that all people have the need for, and right to, engagement in meaningful occupation of their choice, and experience the health and well-being it brings (Townsend & Polatajko, 2007).

Occupational therapy is an applied discipline with theoretical underpinnings related to occupation and its enablement. The practice of occupational therapy draws from occupational science and neuroscience, as well as the behavioral, biomedical, neurological, psychological, social, and environmental sciences. The integration of knowledge from these diverse sciences and its application to daily life places the profession in a key position to contribute to translation of science to everyday living to improve the human condition (Carey & Baum, 2011).

The Practice of Occupational Therapy

As an applied science, occupational therapy is focused on the role occupation plays in the everyday lives of those who experience difficulties in engaging in their occupations. Occupational therapists become involved when everyday living is compromised or is at risk of being compromised by impairments or potentially disabling conditions. They help people overcome occupational restrictions or limitations by identifying barriers to occupational engagement and by evaluating the process that supports it. Occupational therapy interventions are designed to promote engagement; restore function; and enable important activities, tasks, and life roles. Occupational therapists rely on valid and reliable tools that assist in their inquiry and promote their unique roles as members of a team supporting a person's development or recovery, health, and well-being. Occupational therapy practitioners understand performance and engagement from a holistic perspective and address all aspects of performance when providing interventions.

Occupational therapists use a client-centered approach. They use a detailed analysis of the fit between personal capacity, occupational demands, and environmental demands and support to determine the best approaches to improving capacity and/or modifying occupations and environments to facilitate change and enable performance and engagement (Law, Baum, & Dunn, 2005). Eriksson, Kottorp, Borg, and Tham (2009) describe the limitations to daily occupations caused by disruptions of health and social situation as "occupational gaps" – the gaps that occur between what the individual wants, needs, and is expected to do, and what he or she actually does. The process of enabling change is driven by a variety of approaches to intervention, most especially learning-based models that draw on skills in activity analysis and problem solving.

Occupational therapy is practiced in a wide range of settings, including hospitals, rehabilitation settings, health centers, mental health centers, community centers, homes, workplaces, schools, and residences for seniors and those living with chronic disability. Clients are actively involved in the therapeutic process, and outcomes of occupational therapy are measured in terms of occupational performance and engagement, participation, or well-being (WFOT, 2010). Occupational therapists bridge between the medical perspectives focused on impairment management or recovery and the sociocultural perspective focused on the contexts in which people live their lives. Occupational therapists are committed to promoting inclusion, diversity, independence,

and safety for all recipients in various stages of life, health, and illness; and are guided by an Occupational Therapy Code of Ethics (American Occupational Therapy Association, 2005).

The day-to-day practice of occupational therapy is guided by the self-appointed World Federation of Occupational Therapists (WFOT, 2010). All schools worldwide must meet minimum standards established by WFOT. Many countries have additional standards and some have registration standards that must be met by therapists to be allowed to practice. There are also self-appointed national and international bodies, such as the American, Australian, Canadian, British, and Swedish Associations of Occupational Therapists.

The Science of Occupational Therapy

The science of occupational therapy provides a unique contribution to the understanding of occupational performance and participation in the activities of daily life. Occupational therapy is based on the premise that individuals can support their own health through meaningful and purposeful engagement in occupations. Occupation is a primary source of meaning (Christiansen, 1999; Hasselkus, 2002) and a determinant of life satisfaction (Eriksson et al., 2009). A number of empirical studies have supported occupational engagement as a determinant of health and well-being (Clark et al., 1997; Glass, de Leon, Marottoli, & Berkman, 1999; Herzog, Franks, Markus, & Holmberg, 1998; Horgas, Wilms, & Baltes, 1998; Hultsch, Hertzog, Small, & Dixon, 1999). Absence of engagement in occupation may lead to physiological decline and negatively impact health (Kielhofner, 2004; Townsend & Polatajko, 2007). Importantly, occupation has the potential to be therapeutic.

The science of occupation seeks to understand the mechanisms that support *function* (e.g., postural control, grasp, pinch, problem solving, attention, strategy development, endurance), *activity* (e.g., writing, dressing, feeding, grooming, learning), *participation* (e.g., education, work, community life, leisure), and the *environmental enablers and barriers* that make function, activity, and participation possible (e.g., social support, assistive technology, accommodations). Occupational scientists study the full range of phenomena that contribute to human occupation. From basic mechanisms of body function and structure to sociocultural influences, they address measurement, intervention, and translational and health services research.

Occupational therapy is a discipline as it has an established literature testing the theoretical underpinnings of the profession, such as occupation, as well as empirical studies of the practice using scientific methods (Carey & Baum, 2011). The science of occupational therapy contributes to occupational science, neuroscience, and environmental science and furnishes evidence to support recovery and/or adaptive or compensatory strategies that improve the lives of people, support development, or maintain health and well-being.

Odds Ratio

Elizabeth M. Maloney
Formerly of the Viral and Rickettsial Division, Centers for Disease Control and Prevention, Atlanta, GA, USA

Definition

An odds ratio (OR) is a measure of association between an exposure and an outcome (i.e., disease) and is commonly derived from data collected in a case–control study design. When the outcome is rare, the OR is a good estimate of the relative risk of the outcome. The absolute value of the OR varies in size from 0 to infinity; its size is an indication of the magnitude of the association. An OR >1.0 indicates that the likelihood of the exposure is increased in the presence of the outcome. For example, an OR of 3.00 is interpreted as meaning that those with the outcome are three times as likely to be exposed compared to those without the outcome. An OR <1.0 indicates that the likelihood of the exposure is decreased in the presence of the outcome, which is often referred to as a "protective effect." For example, an OR of 0.70 is interpreted as meaning that persons with the outcome are 1.00–0.70, or 30%, less likely to be exposed compared to persons without the outcome. Since a case–control design is cross-sectional in nature, an OR cannot be used to assess causation between an exposure and an outcome.

The precision of the OR is determined based on the computation of a 95% confidence interval (CI) around the OR, and is greatly affected by the sample size. A narrow CI indicates greater precision, and conversely, a wide CI indicates less precision and more variability. The larger the sample size, the greater the precision of the OR. A CI that *does not* include 1.0 indicates that the OR is statistically significant. An unadjusted OR and 95% CIc can be computed using the simple chi-square statistic, or logistic regression analysis if preferred. However, logistic regression analysis is typically used to generate an OR and 95% CI that is adjusted for the effects of one or more confounders.

Oldenburg, Brian

Brian Oldenburg
Department of Epidemiology and Preventive Medicine, Monash University,
Melbourne, VIC, Australia

Biographical Information

Brian Oldenburg was born in Sydney, Australia, on October 23, 1953. He received his Bachelor of Science (Honors in Psychology) degree from University of New South Wales (UNSW) in 1975, and he then worked in a community mental health center in Sydney before living and working in the United Kingdom for 2 years. He returned to Australia in 1978 to the Department of Psychiatry at Prince Henry Hospital and University of NSW, before completing a Masters of Clinical Psychology in 1983. He completed his Ph.D. degree in the UNSW Schools of Medicine and Psychiatry in 1987. He was employed as a lecturer – and then, senior lecturer – in the Department of Public Health, University of Sydney (1987–1994) before becoming professor and head of the School of Public Health at Queensland University of Technology in Brisbane (1994–2006). In 2006, Oldenburg became the inaugural professor and director of International Public Health and Associate Dean International at Monash University in Melbourne, Australia. Since 2006, he has also been a visiting professor at University of Queensland, as well as the Finnish National Public Health Institute (KTL) and also at China's Beijing Centers for Disease Control. He has been a regional director of the Asia Pacific Academic Consortium for Public Health since 2004 and a regular consultant for the World Health Organization since 2003. He was a public health consultant in China for the 5 years leading up to the Beijing Olympic Games in 2008. He also undertook a review for the South African Human Sciences Research Council of their research program on the "Social Aspects of HIV/AIDS and Health" in 2008.

He has chaired grant review panels for Australia's National Health and Medical Research Council and other research organizations since 1990, and he has also served on grant review panels for US NIH. He has served on many national and international committees and advisory boards related to health psychology, behavioral medicine, and public health. He has held senior editorial appointments on *European Journal of Health Psychology*, *International Journal of Behavioral Medicine*, *Health Psychology Review* and *Translational Behavioral Medicine*. He has held senior appointments on many national and international organizations, for example, he has served as secretary, president, local program chair, and congress program chair for the International Society of Behavioral Medicine over the past 20 years. He received the Public Health Recognition Award from Asia Pacific Academic Consortium for Public Health in 2004, and in 2006, he was awarded Lifetime Fellow Membership of US Society for Behavioral Medicine, 2006, for his contribution to "building evidence-based population health interventions that can guide practice and change policy globally." He also has invited membership of the United Kingdom Faculty of Public Health for his achievements in global public health.

Major Accomplishments

Oldenburg's research has made a substantial contribution to evidence development, practice,

and policy in the fields of public health, prevention, and behavioral medicine in Australia and internationally over the last 30 years. He has a very distinguished and internationally recognized track record in the design, implementation, and evaluation of behavioral, psychosocial, and environmental interventions for the prevention and management of chronic disease and the promotion of health and well-being in community, clinical, workplace, school, and other settings. Conducted with one of his academic mentors, Gavin Andrews, his earliest intervention trials conducted in the early 1980s focused on psychosocial and behavioral interventions to improve rehabilitation and health outcomes for patients following myocardial infarction. Conducted with another of his mentors, Graham Macdonald, in the early 1980s, he investigated how psychosocial and behavioral factors were important for treatment adherence and quality of life in people on renal dialysis. His interest in the complex interplay between biological, psychosocial, and behavioral factors in the development, course, and outcomes of chronic conditions is one that has continued throughout his research over the last 30 years. For example, his research team is currently examining the comorbid relationship between negative emotions and both cardiovascular disease and diabetes in order to develop new approaches to interventions.

Since 1990, most of Oldenburg's intervention trials have had a "real-world" focus, and they have emphasized implementation and policy and practice uptake. He has undertaken recent prevention and chronic disease management trials in China, Malaysia, South Africa, and Finland, and his team is currently undertaking a large trial of diabetes prevention in Kerala, India (K-DPP). His interventions have involved both "soft touch" (peer support, socio-behavioral, and environmental interventions) as well as more "high-tech" (ICT) interventions. In collaboration over the past 10 years with Dr. Rob Friedman and other colleagues from Boston University, his research team has developed one of the first automated telehealth programs in the world to improve diabetes management (*Australasian TLC Diabetes*). The results demonstrate that people living with diabetes in the community can significantly improve their self-management of diabetes by using this interactive telehealth program. His research has also focused on chronic disease and socioeconomic health inequalities and social disadvantage as well as interventions with Aboriginal and Torres Strait Islander populations in Australia and disadvantaged people in other countries.

He is the current recipient of a 5-year capacity building and training grant from the US National Institutes of Health (*Millennium Promise Grant Award*) to establish the ASCEND Network in Asia (*Asian Non-Communicable Chronic Disease Research Network)*2010–2015. This program will establish the first comprehensive and cross-country research training program for early career researchers in the prevention and control of chronic diseases in the Asia Pacific Region. He regularly provides significant evidence-based advice to government and nongovernment organizations in Australia and internationally, about how governments and countries can more effectively prevent and manage chronic conditions, thereby improving the health of their people.

Omega-3 Fatty Acids

Matthew Muldoon
Department of Medicine, University of Pittsburgh, Pittsburgh, PA, USA

Synonyms

Alpha-linolenic acid; DHA; EPA; Fish oil; n-3 fatty acids; Omega-3 polyunsaturated fatty acids

Definition

Fatty acids are fat molecules that are ubiquitous in the diet and all living organisms. The long-chain, omega-3 fatty acids, eicosapentaenoic and docosahexaenoic acids (EPA, DHA) are known to be effective in reducing recurrence of heart disease events and in the treatment of depression. EPA and DHA are being studied in relation to heart disease prevention, various psychiatric disorders, eye health, cancer, immune function, and arthritis.

Description

Basic Science

Biochemistry and Nutritional Sources

Triglycerides are the classic fat molecule and consist of three fatty acids bound to a 3-carbon glycerol backbone. Phospholipids are triglycerides in which a phosphate group has replaced one of the fatty acids. Phospholipids are the primary building block of all cell membranes.

Fatty acids are simple chains of carbons atoms of lengths between 6 and 22 with a carboxylic acid group at one end. Saturated fatty acids have all single bonds between carbon atoms, monounsaturated fatty acids have a single double bond, and polyunsaturated fatty acids (PUFAs) have multiple double bonds. PUFAs are classified as omega-6 when the terminal double bond is present at the sixth carbon atom, and omega-3 when is occurs at the third carbon.

The principle long-chain omega-6 fatty acid is arachidonic acid (AA), and the omega-3 polyunsaturated fatty acids of interest are EPA and DHA. Humans synthesize AA from the essential fatty acid, linoleic acid, and EPA and DHA from the essential fatty acid, alpha-linolenic acid. However, the efficiency of these synthetic steps is limited for EPA and more so for DHA. As a result, EPA and DHA are viewed as "conditionally essential" in the diet. Only seafood has significant quantities of EPA and DHA, and within seafood oily fish such as salmon, trout, tuna, and mackerel are the richest sources of these nutrients. In North America and Europe, median EPA and DHA intake is under 200 mg/day, substantially less than earlier and more primitive cultures.

Functional Roles

The multiple actions of the long-chain, omega-3 fatty acids in biological chemistry establish their importance generally to health and disease and,

therefore, the biological plausibility of various sequelae of nutritional deficiency. Phospholipids are the basic building block of cell and organelle membranes, and most have an AA, EPA, or DHA in sn-2 position of the glycerol backbone. DHA and AA are highly concentrated in brain phospholipids, and DHA edges out AA as the most prevalent PUFA in human brain gray matter and synaptic membranes. As a highly unsaturated fatty acid, DHA increases the fluidity of cell membranes relative to other fatty acids. Fluidity is a physicochemical property of membranes that modulates the location and activity of membrane-bound proteins, including enzymes, ion transporters, and neurotransmitter receptors.

PUFAs are released by phospholipases and then serve as precursors to eicosanoids – families of prostaglandins, thromboxanes, and leukotrienes regulating inflammation, vasomotion, and hemostasis. AA-derivatives are pro-inflammatory while EPA-derived eicosanoids are relatively anti-inflammatory. Increased EPA availability competes with, and reduces the production of, AA-derived eicosanoids. Additionally, EPA and DHA serve as precursors of resolvins which temper inflammation, vasoconstriction, and thrombogenesis. Finally, DHA both affects brain-derived neurotrophic factor production and forms nitro-fatty acids that are reactive electrophilic species which modulate oxidative stress.

Acting through the preceding mechanisms, the long-chain n-3 PUFA exert neurotrophic effects. These include promotion of neurogenesis, dendritic arborization, selective pruning, and myelination. In a complementary fashion, neural tissue degeneration may be reduced by neuroprotective or anti-apoptotic effects of DHA. Logically, the foregoing cellular roles of PUFA may be expected to affect neurotransmission, either generally or selectively. Evidence from laboratory experiments and humans studies indicates that omega-3 fatty acid exposure affects serotonergic and dopaminergic neurotransmission.

Clinical Investigation

Early Brain Development

From the last trimester through the second year of life, the human brain undergoes very rapid growth and during this period DHA accretion is rapid and depends upon maternal delivery across the placebo and via breast milk. Infants of mothers reporting low perinatal maternal fish consumption have low early childhood intelligence and increased risk of suboptimal outcomes for prosocial behavior, fine motor, communication, and social development scores. Similarly, the effects of breast-feeding on IQ may be moderated by genetic variation in fatty acid metabolism. Randomized clinical trials suggest that supplementing the diets of either pregnant mothers or infants with DHA improves cognitive development.

Affective Disorders

Evidence from numerous observational studies links low intake of omega-3 fatty acids with greater risk of major depressive disorder and, more generally, depressive symptomatology. Randomized and placebo-controlled trials of fish oil supplementation indicate efficacy in treating this disorder. Treatment benefit appears after 2–3 months of supplementation and appears to be most robust for EPA. In persons not suffering from major depression, supplementation has not been found to affect mood symptoms.

Cognitive Functioning, Decline, and Dementia

Cross-sectional studies and small randomized trials in children and non-elderly adults using dietary data, blood levels, or supplementation suggest that higher intake enhances cognitive performance. However, absent more strongly designed investigations, it is unclear whether such effects are robust and which aspects of cognitive functioning are affected. A comparative wealth of studies finds omega-3 fatty acids to correlate inversely with age-related cognitive decline. Clinical trials to date have provided only inconsistent evidence that taking a fish oil supplement ameliorates cognitive decline among elderly individuals.

Dementia risk in large cohort studies is greatest in persons with relatively low omega-3 fatty acid intake. However, no clinical trial has tested supplementation effects on dementia incidence, and two trials of disease progression found no benefit.

Nonetheless, omega-3 fatty acids may be protective in persons not carrying the gene conveying risk for Alzheimer's disease, APOE ε4.

Other Psychiatric Disorders

Other major conditions such as schizophrenia and attention-deficit/hyperactivity have also been linked to low consumptions of EPA and DHA. Preliminary evidence of efficacy from supplementation exists, and additional studies are underway.

Public Health

Potential Health Benefits and Risks of Consumption of Fish or Omega-3 Fatty Acid Supplements

As summarized above, a variety of common and serious chronic health conditions are associated with low dietary consumption of the omega-3 fatty acids, EPA, and DHA. To date, clinical trials providing 2–6 months of supplementation have yielded mixed evidence of intervention efficacy, although dose and/or duration may not have been sufficient. National intake levels are low, and long-term diet modification has the potential to affect the incidence of various disorders and, accordingly, have substantial public health benefit.

Risks of fish consumption require consideration. Mercury is toxic to the brain in high doses and may have mild effects on the central and peripheral nervous systems with more modest exposure. Mercury bio-accumulates in aquatic food chains, reaching potentially dangerous concentrations in large, predatory fish with long life spans (e.g., swordfish, shark, and king mackerel). Caution against consumption of these fish during pregnancy is particularly emphasized, whereas consumption of other fish and any shellfish three times a week is widely considered to be safe. PCBs and dioxin are organochlorine compounds produced by commercial and industrial processes. Although they contaminate many foods (e.g., beef, chicken, butter, and fish), their levels are decreasing in recent years and PCBs and dioxin have not been clearly linked to adverse health outcomes in contemporary clinical studies. Fish oil capsules can contain varying amounts of PCBs and dioxins, but typically have no mercury.

Public Health Recommendations

To the extent that EPA and DHA can be synthesized by humans, albeit at low rates, these nutrients are not absolutely required in the diet and this complicates attempts to arrive at consensus regarding dietary recommendations. Nonetheless, a variety of expert bodies have issued recommendations and these generally suggest minimum daily intake of 250–500 mg of EPA and DHA. In order to achieve putative health benefits, persons with lifelong low intake of EPA and DHA consumption may need to increased consumption well above these recommended targets.

Oncology (Oncologist)

Yu Yamada
Department of Psychosomatic Medicine, Kyushu University, Fukuoka, Japan

Definition

Oncology is the branch of medicine dealing with the biological and chemical properties of cancer, in addition to its prevention, development, diagnosis, and treatment. An oncologist is a medical professional who practices oncology. In general, oncology mainly consists of three primary disciplines: surgical oncology, radiation oncology, and medical oncology.

Surgical oncology is the field of surgery dedicated to the operative ablation of cancer. Surgery is the oldest treatment for cancer and the only treatment that can cure a patient with cancer, although chemotherapy for hematological malignances has also been known to be an effective cure. Recently, laparoscopy has emerged as a valuable tool in surgical oncology. Radiation oncology is the study of the use of radiation to destroy cancer. Radiation kills cancer cells by radiating the cells with either photons (i.e., x-rays and gamma rays) or particles (i.e., protons and electrons). Medical oncology is a subspecialty of internal medicine concerned with the study of cancer, especially chemotherapy involving treatment with anticancer drugs (see "► Chemotherapy" for more information).

There are other subspecialties within oncology. Gynecologic oncology focuses on cancers of the female reproductive system. Pediatric and geriatric oncology is the branch of medicine that studies benign and malignant tumors in children and the elderly, respectively.

Behavioral medicine may be closely related to psycho-oncology, which is the study of psychological aspects of the treatment and management of patients with cancer. Psycho-oncology addresses two major psychological dimensions of cancer: the emotional reactions of the patients, families, and staff to cancer and its treatment (psychosocial) and the psychological and behavioral factors that influence cancer risk and survival (psychobiological). While great advances have been made in the fields of psycho-oncology in general, further research is needed (1) to improve the assessment and treatment of psychiatric syndromes in cancer patients, (2) to understand the nature of distress in all stages of disease and survival, (3) to assess the needs of special subgroups such as geriatric cancer patients, (4) to understand the mechanisms and implications of cognitive changes associated with cancer treatment, (5) to integrate basic science insights into clinical practice, and (6) to continue the development and study on intervention modalities for the full range of psychological and psychiatric symptoms and syndromes encountered in the oncology setting.

Operant Conditioning

Misato Takada
Department of Health Economics and Epidemiology Research, School of Public Health, The University of Tokyo, Bunkyo-ku, Tokyo, Japan

Synonyms

Instrumental conditioning

Definition

A type of learning in which the probability of a behavior recurring is increased or decreased by the consequences that follow upon occurrence of the behavior. The three-term contingency represents the simplest conceptual model of operant conditioning (Holland & Skinner, 1961).

Description

Operant conditioning applies many techniques and procedures first investigated by E. L. Thorndike (1898), but was later refined and extended by B. F. Skinner (1938). Although operant conditioning is built on the classical conditioning work of Ivan Pavlov (1927), it is distinguished from classical conditioning in that operant conditioning deals with the modification of "voluntary" (operant) behavior. The operant is behavior that acts on the environment to produce a consequence, which is meted out by the environment in response to the operant. This response encourages the operant to either repeat or cease the behavior. Operant conditioning techniques are currently used in clinical therapy, although they are typically applied as part of cognitive behavioral therapy.

Three-Term Contingency

Three-term contingency consists of discriminative stimulus, operant response, and consequences of behavior (reinforcer/punisher). Discriminative stimulus is an antecedent stimulus and is defined as a cue that signals the probable consequence of an operant response. That is, it signals whether the operant response will be reinforced or punished. Certain types of results occur after an organism performs a response to a discriminative stimulus. If the results are advantageous or favorable, the response increases; however, the response decreases when the results are disadvantageous or unfavorable.

In an example of operant conditioning, a hungry pigeon is caged in an operant box, which contains a feeder that can be activated to dispense feed by the pecking of a lighted key. Initially, the pigeon walks around the inside of the box and accidentally pecks at the key, which then releases feed. Although the pigeon does not comprehend the relation between the lighted key and feed, gradually, the frequency that the pigeon moves to the location where the feed is dispensed after pecking the lighted key increases. In this case, the pigeon learns the three-term contingency, consisting of the operant box (discrimination stimulation), pecking a lighted key (operant response), and feed (reinforcer). The change in frequency with which the pigeon pecks the lighted key represents the process of operant conditioning.

Reinforcement

Reinforcement is the process of increasing or sustaining a behavior by its consequences. Two kinds of reinforcement exist: positive and negative reinforcement.

Positive reinforcement occurs when the frequency of a behavior is increased as a result of the presentation of favorable events or outcomes, known as positive reinforcers. This form of conditioning is termed reward training.

Negative reinforcement occurs when the frequency of a behavior is increased because it is followed by the removal of unfavorable events or

outcomes, known as negative reinforcers. This form of conditioning is termed escape training.

Punishment

Punishment is a process by which a behavior is decreased by its consequences. There are two kinds of punishment: positive and negative.

Positive punishment occurs when a behavior is decreased because it is followed by the presentation of unfavorable events or outcomes, which are known as positive punishers. This form of conditioning is termed punishment training.

Negative punishment occurs when a behavior is decreased because it is followed by the removal of favorable events or outcomes, which are known as negative punishers. This form of conditioning is termed omission training.

Although punishment is more effective if combined with reinforcement, as appropriate and alternative behaviors can be learned, it is less effective without reinforcement because it only suppresses inappropriate behavior.

Extinction

Extinction is a process whereby the positive reinforcement of a previously reinforced behavior is discontinued. Organisms may exhibit resistance to extinction, by which a response continues even after the reinforcement ceases. The greater the resistance to extinction, the longer the response will continue.

Notably, extinction may produce adverse side effects; two commonly noted effects are an increase in the frequency of the target response and an increase in aggression.

Shaping

Shaping is a method for conditioning an organism to perform a new behavior. It is well described by its technical name: the method of successive approximations. To approximate something is to get close to it, and successive approximations condition an organism in small steps. Shaping works by starting with whatever the organism can already do and subsequently reinforces with closer and closer approximations to a goal.

Five simple rules for shaping are as follows: (1) Ensure the target behavior is realistic and biologically possible. (2) Specify the entering and target behaviors. (3) Plan a small chain of behavioral changes leading from the entering behavior to the target behavior. (4) If a step proves too large, break it into smaller, more manageable steps. (5) Use reinforcers in small quantities to avoid satiation.

Schedule of Reinforcement

Several types of reinforcement schedules exist. If reinforcement occurs after each desired behavior, the situation is termed continuous reinforcement. However, if reinforcement occurs only after certain desired behaviors, it is referred to as partial reinforcement. A response learned under the latter conditions is more resistant to extinction, a phenomenon called the partial reinforcement effect.

Fixed-ratio schedules are those where a response is reinforced only after a specified number of responses, while variable-ratio schedules occur when a response is reinforced after an unpredictable number of responses. Fixed-interval schedules are those where the first response is rewarded only after a specified amount of time has elapsed. Variable-interval schedules occur when a response is rewarded after an unpredictable amount of time has passed.

The response styles of subjects, whether they are pigeons in an operant box or employees in a workplace, vary based on the schedule used. Other factors being equal, a variable-ratio schedule produces the greatest number of responses from a subject in a given time period, whereas a fixed-ratio schedule fosters rapid learning of the desired response; the number of responses then remains steady, but is lower than those produced by a variable-ratio schedule. Fixed-interval schedules produce relatively few responses overall and a drop in number of responses immediately following reinforcement, although the number increases as the time for reinforcement nears. Variable-interval schedules result in slower learning of the response, followed by a steady number of responses, but produce fewer than those resulting from the fixed-ratio schedule.

Notably, the type of reinforcement schedule will have an impact on how quickly a behavior is extinguished.

Operant Conditioning Therapy

Operant conditioning therapy is a form of behavioral therapy that utilizes the procedures of shaping, token economy, chaining, response cost, time out, and stimulus control.

Token economy uses a token as a reinforcer. Tokens begin as essentially neutral stimuli and are of minor significance in and of themselves. However, as tokens become increasingly associated with the reinforcers for which they are exchanged, the tokens themselves can become mildly reinforcing. Chaining is yet another procedure that is based on shaping, but it is used to condition an entire complex series of different responses, not just one.

Response cost represents the removal of a positive reinforcer after the occurrence of an undesirable response. Time out is the time during which a discriminative stimulus is not available. Stimulus control is the process of controlling discriminative stimulus.

Opponent Process

Leah Irish
Department of Psychiatry, School of Medicine, University of Pittsburgh, Pittsburgh, PA, USA

Definition

Opponent process is a general theoretical model applied to several psychophysiological concepts, whereby a conditioned response is followed by its opposite, and this opponent process becomes stronger and more efficient with repeated exposure.

Description

Opponent process is a general theoretical model that has been applied to a number of psychological experiences and their underlying neurological processes. It was initially proposed as a theory of color vision (Hurvich & Jameson, 1957), but was later modified by Solomon and colleagues (1973, 1974, 1980) to apply to emotion and motivation. In a basic opponent process model, a stimulus elicits an unconditioned response referred to as "*a* process." After a latency, a "*b* process" is activated, which opposes the *a* process and reduces its intensity. Over repeated exposures, the strength of the *a* process does not change, but the *b* process becomes stronger and more efficient with a reduced latency period. The theory suggests that it is possible for the *b* process to become a conditioned response to neutral stimuli associated with the *a* process. Therefore, with repeated exposures, it is possible for the *b* process to occur before the *a* process, thus suppressing the experience of *a* altogether.

One classic demonstration of opponent process theory is a study of skydivers performed by Fenz and Epstein (1967). Prior to their first jump, novice skydivers reported feelings of terror (*a* process). After landing safely, the terror subsided and was replaced by feelings of exhilaration (*b* process). After several jumps, the terror became less intense because the feelings of exhilaration were stronger and came on more quickly. Measures of sympathetic nervous system activity (i.e., skin conductance, heart rate, respiration rate) before and after the jump paralleled these findings and further supported the opponent process theory (Fenz & Epstein, 1967). According to opponent process theory, after many jumps, the neutral stimuli associated with skydiving (e.g., the plane, the parachute) may activate feelings of exhilaration that suppress the experience of terror, thus making skydiving a very positive experience for veteran skydivers.

Opponent process theory has been applied most notably to the study of addiction (Koob, Caine, Parsons, Markou, & Weiss, 1997; Koob, Markou, Weiss, & Schuteis, 1993; Solomon & Corbit, 1973). In these models, the pleasurable "high" of drug use (*a* process) is followed by an affective low during withdrawal (*b* process). After repeated use, the highs become shorter and less intense because the lows begin to occur more quickly. This motivates drug users to take more drugs in order to sustain the high, and this pattern leads to tolerance and addiction. These experiences are accompanied by biochemical alterations during and after drug use (Koob et al., 1993). Similar models have been proposed to explain motivation for a variety of behaviors including blood donation, breastfeeding, exercise, and workplace satisfaction. Opponent process theory has also been applied to the affective experience of attachment and separation anxiety.

Although the opponent process theory has been successful at modeling motivation for a variety of behaviors, it is not capable of explaining all human behaviors. For example, the model is notably less effective at explaining motivation for more primary or biological needs. Further, not all motivated behaviors are accompanied by opponent processes. Despite these limitations, the opponent process theory continues to serve as an effective model for conceptualizing conditioning of motivation and emotion.

Definition

Measures assessing optimism and pessimism have been developed from two perspectives. The first is from the expectancy perspective which reflects the expectations an individual has about their future. From this perspective, dispositional optimism is described as the tendency for an individual to have positive expectations about the future, whereas dispositional pessimism is the tendency to have negative expectations about the future. The second perspective is based on attributional style. Conceptually, attributional style refers to an individual's habitual manner of explaining the cause of negative events. Explanatory styles can be internal/external, stable/unstable, and global/specific. An optimistic explanatory style is when negative events and their causes are viewed as external, unstable, and specific. A pessimistic explanatory

style is when a negative event and its cause are construed as internal, stable, and global.

Several different measures exist to assess optimism and pessimism from an expectancy perspective, and are primarily derived from the Life Orientation Test (LOT). The current standard for measuring optimism and pessimism in adults is the Revised Life Orientation Test (LOT-R). The LOT-R consists of ten items: three assessing optimism (e.g., "In uncertain times, I usually expect the best."), three assessing pessimism (e.g., "If something can go wrong for me, it will."), and four filler items to disguise the purpose of the test (e.g., "It's easy for me to relax"). In principal component factor analysis, all six items of the LOT-R yielded one factor accounting for 48.1% of the variance, with factor loadings of at least 0.58. The LOT-R has sufficient internal consistency (Cronbach's alpha = 0.78), and test-retest reliability as administered between 4 and 28 months apart (0.68–0.79 respectively). The LOT and LOT-R are considered to be measures of "trait" dispositions while the Optimism Pessimism Scale (OPS) measures "state" dispositions. The Extended Life Orientation Test (E-LOT) is a longer measure comprised of items from the LOT and OPS measures, and was developed specifically to evaluate optimism and pessimism as independent constructs. The Youth Life Orientation Test (Y-LOT) is used in adolescent populations, while the Parent-rated Life Orientation Test of children (P-LOT) is a newer instrument designed to obtain parent's reports of their child's levels of optimism and pessimism.

Attributional measures of optimism and pessimism include the Attributional Style Questionnaire (ASQ) and Expanded Attributional Style Questionnaire (EASQ). The ASQ is comprised of six positive and six negative events, while the EASQ contains only negative events. These measures assess appraisals of internality, stability, and globality. The ASQ attempts to assess attributional style through presenting an individual with 12 events, and asks them the cause of each event if they were to happen to them, and then rate the cause of the event on scales representing internality, stability, and globality. Half of the events are good events (e.g., "You become very rich.") and half are bad events (e.g., "You have been looking for a job unsuccessfully for some time."). The ASQ has shown good internal consistency for good events and bad events (Cronbach's alpha = 0.75 and 0.72, respectively), and test-retest reliability over a 5-week time period (with scores ranging from 0.58 to 0.70).

There has been considerable debate in the literature regarding expectant measures of optimism and pessimism and whether optimism and pessimism should be regarded as a single-dimension or two-dimensional constructs. Research findings are varied, with some studies identifying the LOT and LOT-R as two dimensional (i.e., optimistic and pessimistic items load on two different dimensions during factor analysis), while others support a single-dimension interpretation (i.e., both optimistic and pessimistic items load on one dimension). Given the nature of the literature surrounding this topic, it is prudent to determine which orientation will best capture the construct of interest for the research question posed (e.g., expectant versus attributional), and to carefully consider issues surrounding the interpretation of test findings (e.g., the dimensionality of optimism and pessimism).

Dispositional optimism; Dispositional pessimism

Definition

Optimism is a dispositional variable characterized by a generalized positive expectation about the future, while pessimism reflects a generalized negative expectation about the future. Although optimism and pessimism were originally viewed as occupying opposite ends of a single dimension, they have also been considered as independent variables. However, the dimensionality of these two constructs continues to be an ongoing debate in the literature. Each has been associated with different outcomes. Optimism has been associated with better psychological and physiological health outcomes, and these relationships are thought to be mediated by a coping style characterized by problem and emotion approach coping strategies. In contrast, pessimism has been associated with poorer psychological and physiological health outcomes, which is believed to be mediated by the reliance upon problem and emotion avoidance coping strategies.

Description

Optimism is a dispositional variable that involves a propensity to foster positive expectations for the future. Pessimism, on the other hand, involves a propensity to foster negative expectations for the future. Optimistic and pessimistic beliefs are conceptually based on theories of coping and behavioral self-regulation, and are thought to influence behavior in the service of goal pursuit. Optimism is theorized to provide motivation for sustained goal pursuit, which is demonstrated by continued active and productively guided effort and behavior both in daily living and in stressful situations. Pessimism is thought to undermine active goal pursuit and effort, and to contribute to suboptimal outcomes. Other factors theorized to underlie optimistic and pessimistic coping strategies include confidence, doubt, engagement, and disengagement.

High levels of optimism have been associated with several positive physiological outcomes among adults coping with acute and chronic illness, including cardiac patients, and HIV + and AIDS patients. In cardiac patients, high levels of optimism have been associated with minimal increases in carotid intima thickness (an index of atherosclerosis in the carotid

artery and a marker for heart disease) over a three-year period, and a decreased likelihood for developing coronary heart disease. Following coronary artery bypass surgery, high optimism has been associated with a quicker recovery and a significantly decreased chance of rehospitalization. In HIV + and AIDS patients, high optimism has shown associations with delayed symptom onset, slower disease progression, and decreased mortality.

High optimism has also been associated with psychosocial benefits among patients with chronic illness and those experiencing major life changes. Patients recovering from coronary artery bypass surgery report fewer negative mood states and higher satisfaction with medical care and quality of life after surgery, while adults with type 2 diabetes reported experiencing less depression and anxiety. Similar positive psychosocial outcomes have been found in cancer and HIV + populations, and ante- and postpartum mothers. Overall, pessimism is less beneficial for physiological and psychosocial outcomes in health contexts. Evidence suggests individuals high in pessimism experience more fatigue, depression and anxiety, and poorer outcomes and adjustment following illness and illness recovery. Strong support for the associations observed between optimism and pessimism, and physiological and psychosocial health outcomes was demonstrated in a recent meta-analysis of the literature on coping and health outcomes (see Rasmussen, Scheier, & Greenhouse, 2009).

Coping styles have largely been investigated as mediating the associations between optimism, pessimism, and their observed outcomes. Thus far, research investigating coping styles among optimists and pessimists during times of distress has generally supported that optimists who experience physiological and psychological benefits rely on approach coping strategies, while pessimists rely on avoidant coping strategies. Additional support for these coping styles among optimists and pessimists was shown in a meta-analysis in which general patterns emerged; problem and emotion approach coping strategies appear to characterize the coping styles of those high in optimism, while problem and emotion avoidance coping strategies characterize the coping styles of pessimists (Solberg-Nes & Segerstrom, 2006). Also, perceptions of control have been considered to contribute to the types of coping strategies optimists and pessimists use. Optimists seem to rely on problem approach coping strategies when confronted with controllable stressors and emotion approach coping strategies when dealing with uncontrollable stressors. This is thought to underlie an overall engagement and persistence in dealing with their problems, whether it be directly (e.g., active/instrumental coping or planning) or indirectly through cognitive strategies such as acceptance and positive reinterpretation and growth. On the other hand, pessimists seem to show the opposite response in similar situations and rely more on problem avoidance and emotion avoidance coping strategies such as avoidance, distraction, denial, escapism, or substance use. Pessimistic coping reflects an overall disengagement and withdrawal from dealing with stressors, regardless of their level of controllability. For a more detailed discussion about optimism, pessimism, and coping styles, please refer to Solberg Nes & Segerstrom, 2006.

Oral Glucose Tolerance Test (OGTT)

Adriana Carrillo
Department of Pediatrics, Miller School of Medicine, University of Miami, Miami, FL, USA

Synonyms

Glucose test

Definition

The OGTT test is used for the diagnosis of prediabetes, diabetes, and rare disorders of carbohydrate metabolism. The OGTT is a procedure in which a standardized load of glucose is provided and plasma glucose levels are drawn at different times over a 2-h period. Insulin levels could be also obtained to determine insulin resistance. Normal values for fasting glucose levels are below 100 mg/dL. Impaired fasting plasma glucose levels are considered between 100 and 125 mg/dL, and fasting plasma glucose levels above 126 mg/dL are considered in the diabetes range. The 2-h glucose level will help in the definitive diagnosis of diabetes. Plasma glucose levels above 200 mg/mL are diagnostic for diabetes mellitus. Levels between 140 and 200 mg/mL at 2 h are considered in the prediabetes range.

Procedure

A diet that includes at least 60% of calories as carbohydrates should be provided at least for 3 days before the test. The test should not be performed if there is a history of a physiological stress such as infection, acute illness, trauma, or surgery over the past 2 weeks. Medications that could affect glucose levels should also be discontinued. Patient should be fasting for at least 10–12 h. A baseline sample is obtained, followed by administration of an oral glucose solution of 1.75 g/kg to a max of 75 g within 5 min. Samples are generally obtained at 30, 60, and 120 min after the glucose administration (Lifshitz, 2007).

Organ Replacement Therapy

▶ Organ Transplantation: Psychological and Behavioral Aspects

Organ Transplantation: Psychological and Behavioral Aspects

Mary Amanda Dew, Kristen R. Fox and Andrea F. DiMartini
School of Medicine and Medical Center, University of Pittsburgh, Pittsburgh, PA, USA

Synonyms

Organ replacement therapy

Definition

Organ transplantation involves the surgical implantation of an organ or section of an organ into a person whose own organ is failing. The donor organ may come from a deceased individual or, in some cases, from a living donor. Psychological and behavioral aspects of the organ transplantation process encompass transplant patients' emotional responses and mental health, as well as their behavior in adhering to the medical regimen both before and after transplantation. The living donor's psychological response to donating an organ (most commonly for kidney and liver segment transplantation) is also an aspect to consider in the transplantation process.

Description

Individuals with end-stage diseases of the kidney, pancreas, intestines, liver, heart, or lung may receive organ transplantation in order to extend their lives and/or to improve the quality of their lives. Organs typically are transplanted from deceased individuals or, in the case of kidney and liver transplantation, may come from living donors. Organ transplantation is one of a growing range of organ replacement therapies. Dialysis for end-stage kidney disease and mechanical circulatory support systems for end-stage heart disease are examples of alternatives to organ transplantation. Organ transplantation remains the optimal strategy for organ replacement because it is often less economically costly both to the patient and to payers (Medicare, private insurance companies) and because it often provides higher quality of life for a longer time period. However, like other organ replacement strategies, it is associated with numerous stressors that may take a psychological toll on patients and their families (Dew & DiMartini, 2011; Rodrigue, 2001; Trzepacz & DiMartini, 2000). It also has specific behavioral consequences: patients must adhere to a complex, lifelong medical regimen involving multiple medications, routine monitoring of the functioning of the transplanted organ, requirements for medical follow-up care, and permanent lifestyle changes in areas such as diet and exercise. Finally, because some types of organ transplantation are increasingly reliant on living donors, it is important to recognize that these donors also face significant stressors associated with medical and surgical risks of surgery, potential financial issues, and longer-term physical health concerns (Dew, Switzer, DiMartini, Myaskovsky, & Crowley-Matoka, 2007c; Dew & DiMartini, 2011).

In the sections below, we summarize the psychological and behavioral issues that are most prominent for organ transplant patients both before and after organ transplantation. We also describe psychological issues relevant for living donors. Lastly, we comment on interventions that have been developed to treat or prevent psychological or behavioral problems during the transplantation process.

Psychological Factors in Organ Transplant Patients

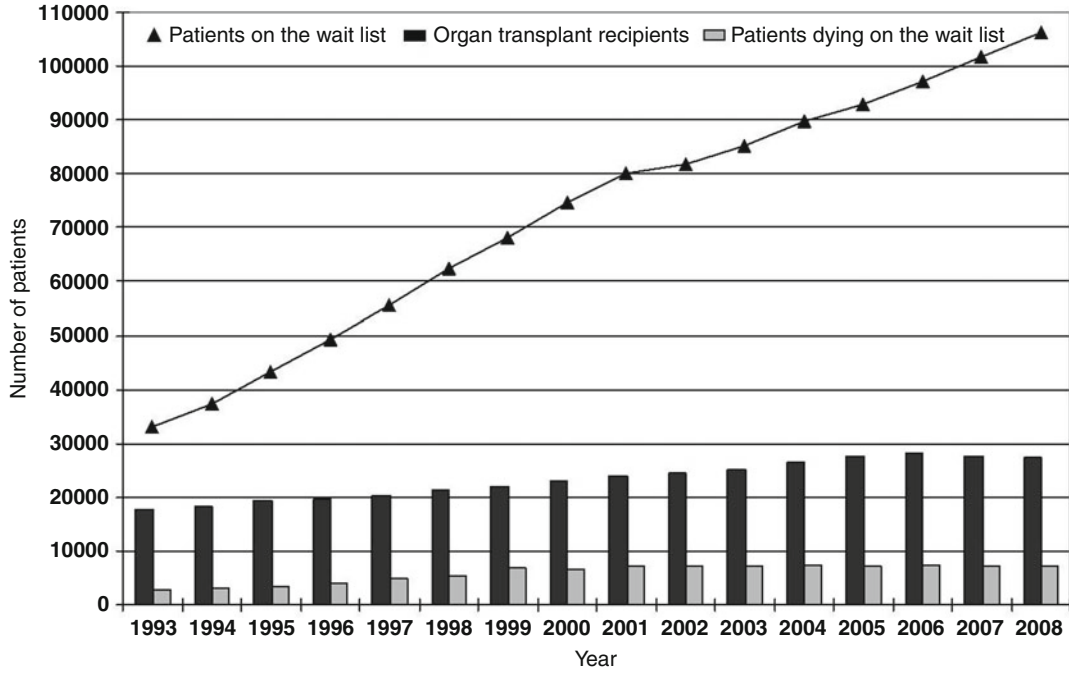
The evaluation for transplant eligibility and the wait for an organ transplant are two of the chief stressors associated with the transplantation process (Craven & Farrow, 1993; Dew, DiMartini, & Kormos, 2007b). These stressors occur in the context of patients' physical morbidity and declines in physical functioning, and this physical decline is a potent chronic stressor as well. The evaluation for transplantation includes both

medical and psychosocial components (DiMartini, Dew, & Crone, 2009; Olbrisch, Benedict, Ashe, & Levenson, 2002). Patients often fear that their health status is too poor for a transplant or that they may be judged to be ineligible for psychological or psychosocial reasons. As part of the evaluation process, patients' psychiatric history, substance use, intellectual functioning, medical adherence history, and psychosocial status are thoroughly reviewed by most transplant programs, and these areas do influence decisions about whether or not to approve patients for transplantation. However, there is substantial variability across transplant programs in whether or not problems in these areas (e.g., current mood disorders, substance abuse history, and current status) are viewed as contraindications to transplantation. In many circumstances, patients are not permanently ruled out for transplantation due to such problems but instead are required to undergo psychological or behavioral interventions, or demonstrate that certain problems are being addressed. For example, many programs require evidence of abstinence from alcohol or drug use for a period of months before an individual will be approved for transplantation. The need to complete interventions in order to be approved for transplantation can be viewed by patients as one more hurdle to complete in the face of their significant medical illness. However, to the extent that they develop stronger coping skills or feelings of control as a result of these interventions, patients may become better prepared for life posttransplant.

In the USA and most other countries, after individuals are approved for transplantation, they are entered into a national wait list for deceased donor organs. Because there are too few organs for the number of individuals in need, the waiting time for transplantation may be months to years (Organ Procurement and Transplantation Network, 2009). Figure 1 shows the number of individuals waiting for transplantation in the USA, as well as the number of organs available for transplantation during each of the past 15 years. It also shows the numbers of patient deaths on the wait list. Thus, in 2008, while 27,281 individuals received transplants, another 7,182 died on the wait list. Fear of not surviving to transplantation is a looming and unfortunately very realistic concern among transplant candidates. Although strategies such as dialysis for end-stage kidney disease and mechanical circulatory support systems for end-stage heart disease can keep patients alive for extended periods during the wait for a transplant, these therapies bring their own risks for health problems and even death. Indeed, the development of complications from these therapies (e.g., infections) can result in an individual being removed from the transplant waiting list. Other stressors during the waiting period for transplant also stem from transplant candidates' declining physical health status: they may have to reduce or give up family and social roles (e.g., parental, household, work, or community responsibilities), and they may eventually become dependent on others for daily care.

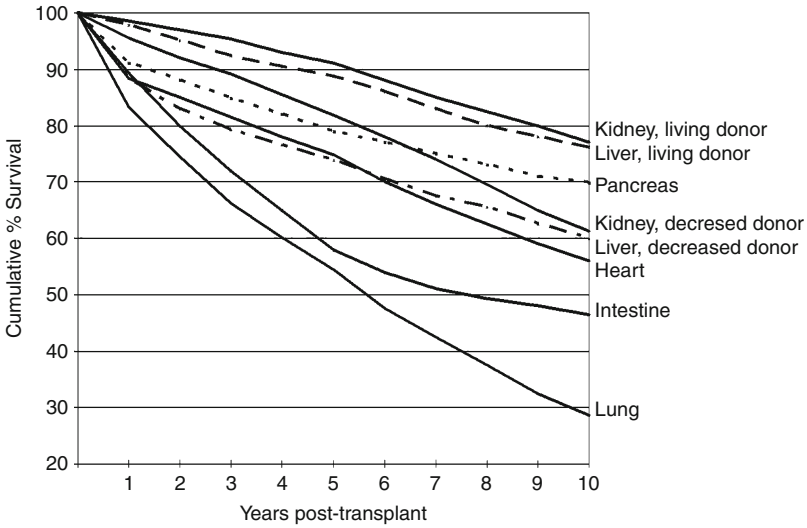
The presence of these powerful stressors during the waiting period explains why patients show high rates of psychological distress and diagnosable episodes of mental illness during this time. Mood and anxiety disorders are the most commonly diagnosed problems in these individuals (Dew & DiMartini, 2011). Transplant candidates show higher rates of these disorders than do other chronic disease populations. Among the chief correlates of psychological distress and disorder in transplant candidates are physical symptom severity and physical functional impairments, as well as poorer social supports. History of psychological disorder is another important risk factor, suggesting the importance of taking steps to prevent new episodes of depression and anxiety as patients face the stressors associated with the evaluation and wait for transplantation.

After transplantation, there is overwhelming evidence that recipients' quality of life and their overall sense of well-being improve (Dew & DiMartini, 2011). In particular, transplant recipients show marked gains in physical functioning. Gains in mental health appear to be somewhat smaller. In the early months posttransplant, recipients typically voice high levels of optimism for the future and great relief that the uncertainties associated with the waiting period are over.



Organ Transplantation: Psychological and Behavioral Aspects, Fig. 1 Size of wait list, number of transplants, and deaths on the wait list, United States (Source: 2002 and 2009 Annual Reports, U.S. Organ Procurement and Transplantation Network and the Scientific Registry of Transplant Recipients (http://optn.transplant.hrsa.org))

Nevertheless, they remain at high risk for mood disorders (including major depression, dysthymia, and adjustment disorders) and anxiety disorders (including posttraumatic stress disorder, panic disorder, generalized anxiety disorder, and adjustment disorders) during the first several years posttransplant. The risk appears to be highest during the first year posttransplant, perhaps because of the major psychosocial adjustments required of patients during this period. For example, they must psychologically incorporate the fact that they have an organ from another person and – in many cases – that the donation was only possible because donor had died. Patients must also adapt to new routines for medical follow-up care and to a new regimen of medications and permanent lifestyle changes related to diet, exercise, limited to no alcohol consumption, and no use of other substances. Patients themselves often comment on the stressfulness of making these psychological and behavioral adjustments. They also report that they have developed significant depression or anxiety as a result of psychosocial stressors related to the financial burdens associated with transplantation (because insurance coverage is often inadequate), attempts to return to former social roles (e.g., returning to employment or parenting activities), and ongoing medical factors related to the transplant. For example, they may develop complications such as infection or they may experience acute rejection (i.e., their bodies may mount an immunologic reaction to the transplanted organ), despite the powerful immunosuppressant medications that they take. Additional personal or dispositional characteristics also appear to increase patients' vulnerability to both distress and diagnosable disorder early posttransplant. These include poorer perceived social supports, use of avoidant coping strategies, a poor sense of mastery or control, and low levels of characteristics such as optimism or hope.



Organ Transplantation: Psychological and Behavioral Aspects, Fig. 2 Patient survival rates by type of organ transplant, United States, 1997–2007 (Source: 2009 Annual Reports, U.S. Organ Procurement and Transplantation Network and the Scientific Registry of Transplant Recipients (http://optn.transplant.hrsa.org))

After the first year posttransplant, the risk for psychological disorders appears to decline. Over the next several years, patients may experience high levels of overall well-being. Their psychological distress levels are low, and this is likely because their physical functional status is at its peak: they have fully recovered from the transplant surgery, and they have been able to resume activities that were impossible during their earlier end-stage organ disease. Most patients express high degrees of appreciation that they were given this "second chance" at life.

There is some evidence that recipients' psychological distress levels begin to rise once again as they enter the later years of posttransplant life expectancy (Dew & DiMartini, 2011). The typical survival time posttransplant varies across the different types of transplantation (Organ Procurement and Transplantation Network, 2009). Survival rates for the major forms of organ transplantation are shown in Fig. 2. In the later years of transplant survivorship, patients are likely to have developed chronic rejection of the transplanted organ, a condition characterized by a progressive deterioration of the organ's function. They are also likely to experience problems secondary to their immunosuppressant medication, including cancers and kidney damage. Some patients may be entered on the wait list for another transplant, with its consequent uncertainties as to whether another organ will become available. Other patients may be ineligible for retransplantation because of conditions such as cancer. All of these stressors emerging during the late-term years increase patients' risk for renewed psychological distress. Research has not yet established whether symptoms of depression or anxiety are more prominent during these later years or whether psychosocial factors related to coping, poor social supports, low levels of optimism, etc., serve as additional risk factors for distress among late-term survivors.

Behavioral Factors in Organ Transplant Patients

Adherence to the medical regimen is the principle behavioral issue for patients (Denhaerynck et al., 2005; Rodrigue, 2001). We noted earlier that patients' medical adherence history is routinely considered during their evaluation for transplantation. Before they are approved for transplantation, patients may be required to demonstrate that they are willing and able to adhere to medical recommendations (including abstaining from substance use if this has been identified as an issue). After transplantation, patients must follow a lifelong regimen that includes (a) taking immunosuppressant and other medications,

(b) attending medical follow-up evaluations and completing required tests, (c) monitoring vital signs and symptoms related to organ function, (d) following lifestyle recommendations regarding diet and exercise, and (e) limiting or abstaining from alcohol use and abstaining from other substance use. This regimen is designed to promote survival and optimal health, and growing evidence shows that nonadherence to its various components is indeed associated with morbidity and mortality posttransplant (Butler, Roderick, Mullee, Mason, & Peveler, 2004).

The majority of transplant recipients are able to maintain adherence to their multifaceted regimen. However, some individuals have difficulty with one or more areas, and this difficulty may begin as soon as they are discharged from the hospital after the transplant. Among the most common areas of nonadherence is medication taking: across many studies, the average rate of nonadherence to immunosuppressant medications is approximately 23% of patients annually (Dew et al., 2007a). Lifestyle and health monitoring requirements are also areas of difficulty, with 19–25% of patients nonadherent annually. Nonadherence to substance use restrictions is less common, occurring in 1–4% of patients annually (Sabaté, 2003). As with other chronic diseases, nonadherence to the posttransplant regimen appears to worsen with time posttransplant.

The correlates and risk factors for nonadherence to the transplant-related medical regimen have been difficult to identify. The World Health Organization has proposed a set of five categories of risk factors for nonadherence to chronic disease treatment regimens (Sabaté, 2003). These categories include demographic factors, health-care system and treatment provider factors (e.g., access to insurance and provider communication skills), disease-related factors (e.g., perceptions of health), treatment-related factors (e.g., medication side effects), and patient-related psychosocial factors (e.g., social supports). There is some evidence in support of each of these categories of factors in transplant recipients, although their impact has often been found to be relatively modest. The most important factor appears to be history of nonadherence before transplant. For example, smoking or alcohol use/abuse before transplant is very strongly associated with posttransplant return to use of these substances, as would be expected given the powerful nature of most addictions. Nevertheless, return to substance use (or abuse) occurs in only a minority – less than 10% – of individuals who receive transplants (Dew et al., 2008).

Psychological Factors in Living Donors

Living donors give an invaluable gift to others. Their gift is all the more remarkable since they face major stressors associated with donation surgery and recovery. They may experience significant pain and discomfort, as well as time lost from work or other responsibilities, financial costs that cannot be reimbursed, and longer-term health risks linked to the donation surgery itself or the loss of organ mass. When a donor has a close emotional connection to the intended recipient, additional stressors arise from watching the patient's health decline gradually or facing a crisis situation of rapid health deterioration.

Like transplant candidates, living donors undergo an extensive medical and psychosocial evaluation (DiMartini, Sotelo, & Dew, 2011; Olbrisch, Benedict, Haller, & Levenson, 2001). Donor candidates may be as fearful as transplant candidates that they will not be approved as a suitable donor. However, other potential donors may find the evaluation stressful because they are ambivalent about or uncertain that they should or want to donate. The evaluation process is designed to ensure that donors do not have major medical or psychological problems that would preclude safe donation, as well as to ensure that they understand the risks associated with donation, are not experiencing coercion or undue pressure from others to donate, and are able to make an informed choice to proceed with the surgery or not. As for transplant candidates, potential living donors may be required to undergo interventions to address any mental health or substance use issues before they are approved as donors.

A chief goal of living donation is to provide needed organs for patients yet protect the living donor from undue harm. This includes protection

from psychological harm. Most donors, in fact, show very favorable quality of life outcomes, and extremely few express any regret associated with donating. The vast majority (up to 95%) also perceive the donation to have been a very gratifying experience that benefitted them personally (by helping them to reframe, e.g., what was important in their lives) (Clemens et al., 2006). Nonetheless, some donors do experience psychological difficulties, including mood and anxiety disorders or heightened nonspecific psychological distress. Some of this distress appears to be linked to ongoing worries about the long-term impact of the donation on donors' physical health, as well as financial strains or family relationships that became strained in the aftermath of the donation. Pre-donation ambivalence about whether or not to donate has also been linked to the occurrence of psychological difficulties postdonation (Dew, Switzer, DiMartini, Myaskovsky, & Crowley-Matoka, 2007c).

Interventions for Psychological or Behavioral Problems During the Transplantation Process

Transplant programs employ strategies found effective in other chronic disease and medically healthy populations in order to address psychological and adherence-related difficulties in organ transplant patients. To care for psychological distress, psychotropic medications may be prescribed, and referrals may be made for individual or group psychotherapy or supportive care. Some programs have attempted to offer brief individual or group psychoeducational programs. There has been little attempt to formally develop and evaluate the effectiveness of interventions in transplant patients due to major constraints that these programs face. For example, many transplant candidates and recipients reside long distances from their transplant center and would not be available to participate in face-to-face interventions except during periods of hospitalization around the time of the transplant. Medical follow-up appointments are generally too brief for intensive interventions. Similar constraints exist for any living donors who develop psychological difficulties after donation because they are even less likely to return to the transplant center after donation.

Some alternatives have been developed that do not require face-to-face contact, including telephone- or internet-based psychotherapeutic or educational strategies or the use of home-based self-monitoring tools. These alternatives have targeted both psychological distress as well as difficulties with adherence. Evaluation of these experimental interventions has yielded promising results in transplant patients, including the abatement of psychological distress and improvements in medical adherence, relative to comparison groups receiving only standard care from the transplant program (De Bleser, Matteson, Dobbels, Russell, & De Geest, 2009; Dew & DiMartini, 2011). Most studies have examined relatively short time periods of well less than 1 year. Whether these interventions' effects would be maintained over longer time periods is an important issue. Work is underway to test brief psychological interventions to prevent psychological distress and associated quality of life decrements in living donors.

Orleans, C. Tracy

C. Tracy Orleans
Robert Wood Johnson Foundation, Princeton, NJ, USA

Biographical Information

Carole Tracy Orleans (nee Schornagel) was born in Holland, Michigan, and obtained her B.A. degree in Psychology (summa cum laude) from Wellesley College in 1970. She completed her Ph.D. in Clinical Psychology at the University of Maryland, including a clinical internship in Medical Psychology at Duke University Medical Center in 1978.

Orleans is an internationally recognized leader in behavioral medicine, health and behavior, and tobacco control research. In the area of tobacco control, she has contributed to four *Surgeon General's Reports* and, with John Slade, coedited the first text on the management of nicotine addiction. She has led or co-led the development of several effective population-level national tobacco cessation programs which remain in wide use nationally (including *Free & Clear*, the first national proactive telephone quitline, the *Clear Horizons* quit smoking guide for older adults, the *Pathways to Freedom* guide for African American smokers). In addition, she played a leading role in the development of the NCQA's first HEDIS tobacco measure, which has been adopted as a standard metric for national health-care quality improvement, and in early efforts to reduce smokeless tobacco use in Major League Baseball. In 1995, she was named by *Tobacco Control* as one of the 100 most widely cited tobacco control researchers.

Prior to joining the Robert Wood Johnson Foundation's (RWJF) professional staff in 1995, Orleans served as vice president for Research and Development, Johnson & Johnson Applied Behavioral Technologies (1993–1995); associate and full member (professor) and director of Tobacco Control Research at the Fox Chase Cancer Center (1985–1993); and assistant professor of Medical Psychology/Psychiatry at Duke University Medical Center (1978–1984) with an adjunct appointment as research associate with the Cecil B. Sheps Center for Health Policy Research at the University of North Carolina.

Major Accomplishments

As the senior scientist for the RWJF since 1998, Orleans has led numerous national efforts to identify and spread evidence-based clinical, public health (policy/environmental), and health-care systems interventions for health promotion, disease prevention, and chronic disease management. As RWJF's only behavioral medicine specialist, Orleans developed and led the Foundation's first Health and Behavior team, catalyzed the development of its first chronic disease management team, and made significant contributions to its substance abuse prevention, tobacco control, and childhood obesity prevention

teams and initiatives. Her work has advanced RWJF's public policy and health-care systems grant-making in the areas of tobacco control, physical activity promotion, substance abuse prevention and treatment, chronic disease prevention and management, and childhood obesity prevention.

Orleans has developed and/or overseen a broad portfolio of RWJF research grants, initiatives, and competitive research programs, including: Active Living Research, Addressing Tobacco in Managed Care, Bridging the Gap (youth tobacco/substance use/and childhood obesity prevention), Healthy Eating Research, Improving Chronic Illness Care, Substance Abuse Policy Research, and Prescription for Health (multiple risk health behavior change in primary care). She also has directed several RWJF program evaluations (e.g., Health e.Technologies, Reducing Underage Drinking through Coalitions, SmokeLess States), led numerous projects deigned to translate evidence-based behavioral medicine interventions into policy and practice, and helped to organize and co-led four national research "collaboratives" designed to coordinate and strengthen the collective impact of the nation's major tobacco control and childhood obesity prevention research, practice, and policy initiatives, including those funded by the CDC, NIH, RWJF, USDA, HRSA, and Legacy Foundation.

Orleans has been PI or Co-PI on numerous NIH research grants and has authored or coauthored more than 225 publications in the areas of behavioral medicine, tobacco control, health promotion, disease prevention and management, and public health. She has served on many journal editorial boards throughout her career and is currently associate editor for policy for the *American Journal of Preventive Medicine*. In addition, she has been a member of numerous influential national scientific, health policy, and evidence review panels, including:

- The Community Preventive Services Task Force (2009–present)
- The *Healthy People* 2020 Prioritization Sub-Committee (2009–2010)
- Agency for Healthcare Research and Quality (AHRQ) Tobacco Control Clinical Practice Guideline Panel (2006–2008)
- Partnership for Prevention's Expert Panel on Worksite Wellness and Chronic Disease Management (2006–2008)
- The National Commission on Prevention Priorities (2003–present)
- The Cessation Subcommittee, Surgeon General's Interagency Committee on Smoking and Health (2002–2003)
- The Institute of Medicine Committee: Identifying Priority Areas for Healthcare Quality Improvement (2002–2003)
- The US Preventive Services Task Force (1998–2004)
- Several National Cancer Institute Research Advisory Committees including for the Working Well Study (1990–1994), the Tobacco Research Implementation Group (1998–2000), and the Behavioral Science Research Division (1996–1997; 2010).

Orleans was honored to receive several awards and recognitions for her work in behavioral medicine. She is a fellow of the Society of Behavioral Medicine, the American Psychological Association Health Psychology Division, and the Academy of Behavioral Medicine Research. A past-president of the Society of Behavioral Medicine (2000), she has received the Society's Distinguished Service Award (2000, 2006) and its Distinguished Scientist Award (2008). In recognition of career contributions to tobacco control research, Orleans received the 1992 Joseph Cullen Tobacco Memorial Award from the American Society of Preventive Oncology and the 2007 John Slade Award for tobacco control policy research leadership from the Society for Research on Nicotine and Tobacco. In 2006, Orleans was named RWJF's first Distinguished Fellow, and in 2010, she received the American Psychological Association Meritorious Research Service Commendation and the US Department of Health and Human Services Innovators Award, a group award.

Throughout her career, Orleans has been inspired and enriched by opportunities to address important health and health-care problems at the population level and to work with outstanding leaders and colleagues – including at Duke University Medical Center, the Fox Chase Cancer

Center, the Robert Wood Johnson Foundation, and in every professional organization she has been part of. Their example and friendship, and the vital support and inspiration of her family (her husband Jeffrey, their sons Jesse and Alexander, and her mother) are the bedrock of all her professional accomplishments.

Ornish Program and Dean Ornish

Manjunath Harlapur[1] and Daichi Shimbo[2]
[1]Center of Behavioral Cardiovascular Health, Division of General Medicine, Columbia University, New York, NY, USA
[2]Center for Behavioral Cardiovascular Health, Columbia University, New York, NY, USA

Synonyms

Dean Ornish

Definition

Dr. Dean Ornish is currently the president of the Preventive Medicine Research Institute in California and clinical professor of Medicine at University of California, San Francisco.

Description

Dr. Ornish is the founder and president of Preventive Medicine Research Institute in Sausalito, California, and on faculty at the University of California, San Francisco, as a clinical professor of medicine. Dr. Ornish received a medical degree at Baylor College of Medicine and underwent internal medicine training at Massachusetts General Hospital. His major contribution to medicine is his examination of the lifestyle modification/stress reduction approach to cardiovascular prevention and also cancer. He has published several seminal studies in this area. A few of these studies are described here.

In 1990, Ornish and colleagues published results (Ornish et al., 1990) from a landmark but small randomized trial (The Lifestyle Heart Trial) showing that intensive lifestyle changes for 1 year (10% fat vegetarian diet, exercise, stress management, and smoking cessation) was associated with regression in coronary artery disease on angiogram in cardiac patients (N = 28), whereas usual care was associated with coronary artery disease progression (n = 20). None of the patients were taking lipid-lowering medications.

In 1998, Ornish and colleagues published results of a longer follow-up period (i.e., 5 years) of the The Lifestyle Heart Trial (Ornish et al., 1998). The study results were similar to the 1-year results. Patients with coronary disease assigned intensive lifestyle changes had regression in coronary artery disease on angiogram at 5-year follow-up, whereas a group that received usual care had coronary artery disease progression. The group assigned to the intensive lifestyle changes also had a lower cardiac event rate during the 5-year follow-up.

In 2005, Ornish and colleagues (2005) demonstrated that in comparison to usual care group, comprehensive lifestyle changes for 1 year reduced the progression of early, low-grade prostate cancer in 93 men who had not chosen to undergo any conventional cancer treatment.

More recently, in 2008, Ornish and colleagues (2008) showed that comprehensive lifestyle changes for 3 months increased peripheral blood mononuclear cell telomerase activity (an enzyme that inhibits cellular aging) in 30 men with low-risk prostate cancer. This study was not randomized and did not have a control group.

Orth-Gomér, Kristina

Kristina Orth-Gomér
Department of Clinical Neuroscience, Karolinska Institute, Stockholm, Sweden

Biographical Information

Born in Stockholm, Kristina Orth-Gomér was educated with a focus on classic and modern languages at Whitlockska Samskolan, where she obtained baccalaureate in Latin, French, English, and German. After a short period of literature and civilization studies at the University of Lille, France, she began her studies of medicine at the Karolinska institutet, Stockholm. There, she obtained an M.D. in 1972 and a Ph.D. in 1979. She specialized in Internal Medicine in 1980 and later also in Social Medicine/Public Health Sciences.

With an interest in alternative therapies, she spent a semester at the Psychosomatische Kinderklinik, Eppendorf in Hamburg, where she also became involved in the 1968 students movements, which were particularly intense in France and Germany. She married in 1969 and welcomed her first child Johanna in 1973.

Trying to combine motherhood with medicine, Orth-Gomér was appointed an intern in internal medicine at the Seraphimer Hospital, Karolinska institutet. Before that, she served for a year as a research associate at the Cornell Medical School, Human Ecology Laboratory at the New York Hospital, learning from scratch the research methodology of cardiovascular epidemiology and 24-h ambulatory ECG monitoring. She also spent a happy year with her young family in Manhattan, NYC.

Back in Stockholm, as an intern in internal medicine, with regular work hours from 8 to 18 h and night/weekend duties in the emergency room in between, Orth-Gomér did not see much of her daughter. She just barely obtained the admission for her daughter into the day care center, and she learned to appreciate the difficulties of fulfilling several multiple roles in a satisfactory manner at the same time.

Major Accomplishments

Research on Social Support

Her next research position, starting in 1980, offered a solution to the time puzzle. As an associate professor at the National Institute for Psychosocial Medicine (IPM) at the Karolinska Campus in Stockholm and head of the Unit for Social Factors and Health, she worked the same number of hours, but she could choose when and where.

Under the guidance of Lenart Levi, the IPM offered great opportunities to pursue the line of alternative therapies, while Töres Theorell at the IPM focused his research on stress and strain at work – and Torbjörn Akerstedt at IPM concentrated on odd work hours, sleep problems, and circadian rhythms – there was less knowledge about stress and strain during leisure time

activities. To find research outside the work environment, the social network studies of Alameda County offered possibilities for scientific exchange with Lisa Berkman, Len Syme, and Jim House.

A question of considerable interest was the following: Are social networks as crucial for the maintenance of health in Sweden as in the USA? With the help of Statistics Sweden, a Swedish social network instrument, the social interaction index was constructed and applied in 17,400 men and women.

In a 6-year follow-up of the population, it was found that men and women who had more and better social contacts lived longer. Age was a strong confounder and controlling for age was crucial. With increasing age, mortality increased – and social contacts decreased dramatically. The remaining risk was smaller but statistically significant (Orth-Gomer & Johnson, 1987).

In subsequent years, the quality and function of social contacts and their role in health promotion and disease prevention became the focus. A measure of social support with two subscales was constructed: attachment (close emotional ties) and social integration (social contacts in the society). These measures were then applied in populations and patients and almost invariably found to matter for health maintenance.

Behavioral Medicine

Behavioral medicine had evolved as a useful concept in the USA, but was unknown in Europe. Initially, introducing behavioral medicine met with some criticism. To launch another term and another society within this field, beside "psychosomatics," "psychosocial medicine," or "stress research," was thought to be redundant. However, when the Swedish Society of Behavioral Medicine was inaugurated under the auspices of the Swedish Society of Medicine in Stockholm, in the presence of some 300 interested colleagues from medicine and behavioral sciences, it felt natural and appropriate. With the support by Arne Öhman, Karin Harms-Ringdahl, Christina Mats Fredriksson, Gösta Tibblin, and Stephen Weiss, Orth-Gomér served as president of the Swedish Society of Behavioral Medicine, 1986–1990.

A few years later, the International Society of Behavioral Medicine (ISBM) was formed and held its first conference in Uppsala in June 1990. It was a very successful conference, with an excellent faculty, which provided the right framework and starting point for the ISBM. It is not inappropriate to say that the success has been ongoing ever since. During the first years, ISBM expanded rather quickly, and there were many new societies formed. At the end of her term as president elect and president in 1990–1994, Kristina Orth-Gomér reported that from five founding societies (USA, Netherlands Germany, Czech Republic, Sweden), ISBM had grown into 15 societies. The second conference in Hamburg in 1992 and the third conference in Amsterdam in 1994 were equally successful and raised a lot of interest and promise. With the fourth conference in Washington, the international nature of behavioral medicine was settled! Every researcher with a name within the field had gathered to make international behavioral medicine known and respected.

Interdisciplinarity and Integration

Collaboration with the European Society of Cardiology

The first step toward practical interdisciplinarity was taken when introducing behavioral medicine to the European cardiology community. To present scientists and practitioners of both fields and make them understand each other and talk to each other was more difficult than one could imagine.

In February 1999, Orth-Gomér presented her behavioral medicine ideas to the 50 member countries of the European Cardiology Forum at the Heart House in Nice, France. From studies in Canada and the USA, the European cardiologists were aware of the importance of depression – and of the impact of social disadvantage. They wanted to know how to interpret and how to treat their patients. Her handout of two pages with common behavioral medicine knowledge was quickly gone.

Kristina Orth-Gomér was then elected to collaborate with the European Society of Cardiology as a scientist, but she asked to do this as

a representative of ISBM. This led to the formation of a multidisciplinary task force, which included not only behavioral medicine but also diabetes research, nutrition, physiology and rehabilitation, etc. The next step was to integrate this knowledge into the European Guidelines of Cardiovascular Disease Prevention in Clinical Practice (De Backer et al., 2003b).

Having attended the European Cardiovascular Epidemiology meetings for many years and presented her research, Kristina Orth-Gomér knew there was an interest of cardiologists in behavioral medicine methodology. She was included as an ordinary member in the task force for CVD prevention and asked to work on several cardiology committees within the field. This led to ISBM being positioned and recognized as the appropriate partner among all the other psychosocial organizations in Europe.

A behavioral working group was formed which included the most experienced colleagues in the field. This group met at the first European meeting of the American Psychosomatic Society (APS) in Barcelona in 2002. This psychosocial working group described the contribution of behavioral factors to CHD, and they were accepted as such by the medical/cardiological community. A special psychosocial chapter was written and included in the full text of the guidelines (De Backer et al., 2003a).

This was a time of enthusiastic belief in the cross-fertilization that would come out of interdisciplinarity and internationalization.

There was firm resistance within the third task force to recognizing behavioral/psychosomatic processes as in any way being related to heart disease. It was argued that the evidence was just not there. The solution was to avoid the concept of etiology and instead talk about depression, social isolation, and other psychosocial risk factors as "barriers" to health promotion.

"Negative emotions. . .may constitute barriers to preventive efforts, both in patients and in high risk people. . ." (De Backer et al., 2003a). The barrier concept was more easily accepted. Furthermore, only empirical studies that had integrated both medical/cardiological and behavioral/psychosomatic contribution to risk of CHD were cited.

The European guidelines became a turning point, which made the behavioral/psychosomatic map change in Europe. It paved the way for several collaborative interdisciplinary efforts in Europe, Germany, the Netherlands, Scandinavia, and Hungary to name a few countries that saw a profound change in interest and attitude to this field. With the guidelines, the theories and findings in behavioral medicine had been empirically founded and widely accepted (2003).

Women's Cardiovascular Disease

The Stockholm female coronary risk study is a comprehensive study of women's risk factors, mechanisms, and pathways to CHD. It had full financial support from the NIH.

In a community-based case control design, women in Stockholm who were under 65 years and hospitalized at any of the ten coronary care units for an acute coronary event during a 3-year period were included. These 292 women patients were compared to 292 same-aged women, randomly obtained from the public census, who were thus representative of normal Stockholm women of the same age. The first publication (Orth-Gomér et al., 1997) demonstrated that lipoprotein (a), a genetically determined lipid compound, was a risk factor in women, as had previously been found in studies of men. The accompanying editorial observed that "Orth-Gomer et al. made a wise decision in using a case control design. . ., for what is, in women of this age, a rare disease" (Fortman & Marcovina, 1997).

As part of the study protocol, Orth-Gomér developed a flowchart for integrating behavioral with medical risk factors, which has, since then, been used as a model for the first conference on Women, Stress, and Heart Disease held in Stockholm in 1993 (Orth-Gomér, Chesney, Wenger, 1998).

It appears that one important characteristic of the female risk factor profile is the social support provided – or not provided – by family and friends and other members of the social network. This factor was consistently associated with several of the relevant mediators and pathways: with depressive symptoms with disturbed sleep patterns (Leineweber et al., 2003), with low heart

rate variability and with disturbances of clotting and lipid profile (Wamala et al., 1999).

A further line of research was that of progression/regression of coronary artery disease (CAD) as assessed by quantitative coronary angiography. In a subsample of about a 100 women with CHD, two identical coronary angiograms were done with a 3-year interval, after initial hospitalization.

Richard Kirkeeide, from the Texas Medical Center, Houston, came once a year to the angiographic laboratory at the Karolinska in Stockholm to calibrate the lab in order to ensure comparability between the two examinations. The subsequent evaluation of cine films, i.e., blinded comparison of pre- and post-angiograms was performed in Houston. In brief, we found that lack of social support as a psychosocial predictor was consistently related to progression of coronary artery disease. The better support, the slower was the progression (Orth-Gomér et al.,1998). Indeed we found one small group of women who said they had both a good job and a happy marriage. This group showed a widening of the mean luminal diameter of the entire coronary tree – a regression of CAD over the 3 years. The magnitude of the change was about that seen as a result of medication with statins over a similar time period. In fact, this methodology had first been developed for use in statin trials (Wang et al. (2007)).

Conclusion

We now take for granted that women and men share leadership in professional societies. This is so only because of the efforts by an initially small cadre of female researchers who were pioneers in their male-dominated fields. Orth-Gomér has been a leader and pioneer in examining social factors in cardiovascular disease, particularly in women. She has led the Stockholm Female Coronary Risk Study and showed for the first time that marital stress in women increased risk of coronary events (e.g., cardiac death, recurrent MI) threefold, whereas work stress did not increase this risk in women (Orth-Gomer et al. (2000)). Her findings suggest that risk factors for adverse outcome in women are different from those of men. Kristina Orth-Gomér has now gone on to conduct intervention studies (e.g., SWITCHD) that specifically target stress reduction in women with coronary disease, and she has demonstrated a threefold reduction in mortality with this intervention (Orth Gomer et al., 2009). Her work has contributed to the sea change in cardiovascular medicine in the past decade in which it is now accepted that risk factors, clinical manifestations, and interventions in coronary disease differ between women and men. Her many grants, publications, and scientific presentations demonstrate the depth and breadth of her work for behavioral medicine throughout her career.

Osteopenia/Osteoporosis

Eun-Shim Nahm
School of Nursing, University of Maryland, Baltimore, MD, USA

Definition

Osteopenia. Osteopenia is a condition where bone mineral density is lower than normal. It is considered to occur before osteoporosis. However, not every person diagnosed with osteopenia will develop osteoporosis. Osteopenia is not a disease but is a marker for the risk of fractures (Torpy, Lynm, & Glass, 2011).

Osteoporosis. Osteoporosis ("porous bone") is a systemic skeletal disease characterized by decreased bone mass, a loss of microarchitectural bone tissue, and a failure of the bone modulus (Cranney, Jamal, Tsang, Josse, & Leslie, 2007; Gardiner, El Miedany, & Toth, 2007; Osteoporosis Education, 2011). The individuals affected by this illness are susceptible to fracture.

In the United States, an estimated 44 million adults are living with either osteoporosis (ten million) or low bone mass (Osteoporosis Education, 2011; U.S. Dept. of Health & Human Services PHS, 2004). Several risk factors can influence the development of osteoporosis, including age (older age), race (White), family history (heredity/genetics), weight (low body weight/being small and thin), estrogen level (low), rheumatoid arthritis, and personal fracture history (National Osteoporosis Foundation, 2007; U.S. Dept. of Health & Human Services PHS, 2004). Postmenopausal women are at a high risk for osteoporosis because they lose bone mass faster than men as their estrogen level decreases after menopause (Camacho & Miller, 2007; MacLean et al., 2008; The North American Menopause Society, 2010). Although men are less affected than women, osteoporosis is also common among older men as approximately two million male older adults have osteoporosis (Qaseem et al., 2008). Osteoporosis in men, however, remains underdiagnosed and underreported (Qaseem et al., 2008; National Osteoporosis Foundation, 2011a; Rochira et al., 2006; Szulc, 2006).

Bone mineral density (BMD) refers to the amount of matter per square centimeter of bone. The BMD test is the only way to diagnose osteoporosis. This test can predict the chances of fracturing bones. The National Osteoporosis Foundation recommends a bone density test of the hip and spine by a central DXA (dual energy X-ray absorptiometry) machine to diagnose osteoporosis (National Osteoporosis Foundation,

Osteopenia/Osteoporosis, Table 1 Interpretation of T-score (National Osteoporosis Foundation, n.d.)

Category	T-score range
Normal bone density	−1 to +1
Low bone density (osteopenia)	Between −1 and −2.5
Osteoporosis	−2.5 and below

2011b). BMD test results are compared to the ideal BMD of a healthy 30-year-old and reported using T-scores. A score of 0 means the BMD is equal to the norm for a healthy young adult. Differences between the norm and the BMD test results are measured in standard deviations (SDs). The lower the BMD score, the higher the risk for fracture (Table 1).

Definition

Traditional research and evaluation methods, including randomized clinical trials, are powerful techniques for determining the efficacy of health and behavioral interventions. Randomized clinical trials, however, have practical and ethical

limitations when applied to many research questions important to the field of behavioral medicine (Concato, Shah, & Horwitz, 2000). Alternative methods are needed to fully examine the effectiveness of treatment techniques for individual patients and to document clinical accountability. This entry examines outcomes for the individual or single case.

Description

In this entry, three approaches are discussed that focus on evaluating outcome at the level of the *individual* person or patient: the *Reliability Change Index*, *Single-subject designs*, and *Goal Attainment Scaling*. These approaches are consistent with the client-/patient-centered focus in behavioral medicine. The assumption is made in presenting these procedures that systematic documentation of patient/client performance is the first step in the process of developing an evidence-based science for clinical practice. It is important to note that the procedures described are designed primarily to document clinical change and not to demonstrate causality.

Reliability Change Index (RCI)

The RCI, originally proposed by Jacobson, Follette, and Revenstorf (1984), is a general purpose measure that is useful with outcomes that are expected to remain relatively stable over time. Jacobson et al. (1984) argued that for a change in performance to be clinically significant it must be "statistically" reliable. That is, there must be a way to determine that the change in performance is not due to chance variation or measurement error. To make this determination, Jacobson et al. proposed the use of the *Reliability Change Index* (RCI). To compute the RCI, the following information is required: (a) pre-test score for an outcome measure, (b) the post-test score following treatment, and (c) the standard error of measurement (S_E) for the test. The S_E may be computed from the following formula: $S_E = S_1\ [sq\ root(1 - r)]$ where S_1 equals the standard deviation for the test and r is the reliability coefficient. The RCI is calculated as: $\text{RCI} = (X_2 - \text{X}_1)//S_E$ where X_2 is the post-test score, X_1 is the pre-test score, and S_E is the standard error of measurement as defined above (Jacobson et al.).

In a subsequent article, Jacobson and Truax (1991) revised the *Reliability Change Index* and replaced the S_E with the standard error of difference $S_{diff.}$ The S_E in the original formula is an index of the dispersion of an obtained score about a "true" score. The RCI, however, makes use of two *obtained* scores. The use of the S_E in the RCI formula assumes that the pre-test score is the "true" score and the Post-test score an obtained score (Jacobson & Truax, 1991). This does not reflect the actual situation. The revised formula is $\text{RCI}' = (X_2 - \text{X}_1)//S_{diff}$. The S_{diff} can be computed as: $S_{diff} = S_1[\sqrt{2(S_E)^2}]$. The S_{diff} represents the amount of difference that would be expected between two scores obtained on the same test by the same individual as a function of measurement error alone. This assumption is consistent with obtaining pre- and post-test scores from a person in a clinical setting.

As an example, a student receiving education intervention for low academic performance might have an initial (pre-test) IQ score of 75 on the Stanford Binet test. Following 9 months of specialized instruction, the child's IQ may increase to 85. The S_E for the IQ test is 5 points. Using the revised formula provided above: $\text{RCI}' = (X_2 - \text{X}_1)/S_{diff}$ or $\text{RCI}' = (85 - 75)//7.07 = 1.41$. This value is not statistically significant and indicates the change from 75 to 85 is within the range of measurement error.

Practitioners using the *Reliability Change Index* to document a clinically significant change in an individual client/patient should use the revised method (RCI′) rather than the original formula (Jacobson & Truax, 1991).

Single-Subject Design

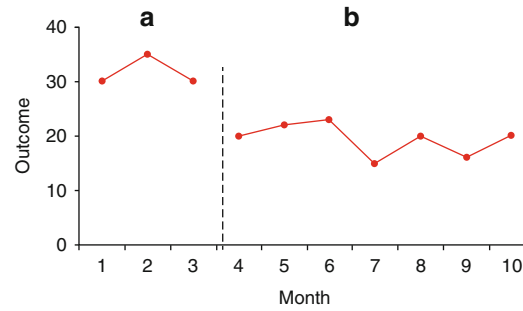
Bloom, Fischer, and Orme (2009) argue that single-system designs, also referred to as single subject, small-N, single-case experimental, or N of 1 clinical trials, represent the preferred method of evaluating clinical change in many behavioral medicine environments. The basic steps followed in using single system designs to assess individual client/patient outcomes are presented below.

Step 1. Specifying the Problem. It is important that the clinical problem be clearly stated and behaviors associated with the problem that can be observed and measured be identified. Traditionally, standardized norm-referenced tests are used to measure research outcomes when comparing persons in treatment versus control groups. Standardized norm-referenced assessments may be of limited value in single system designs where the same person(s) is assessed repeatedly. The ability to measure the person's repeated behavior is essential to implementing the single-system approach. Each outcome can be defined in terms of how often it occurs (frequency) or how long it occurs (duration) and also in terms of qualitatively desirable components (Bloom et al., 2009).

The behavior to be recorded must be clearly defined, and the rater must be familiar with how, when, where, and how long the behavior should be observed and recorded. Procedures have been developed to train raters and observers to determine the consistency and accuracy of their recording (Ottenbacher, 1986).

Step 2. Selecting a Design. The logic of single-system designs rests on a comparison between phases when the intervention is present and when it is not, or when two or more treatments are compared. This comparison is generally made over time within one person (or a small group of participants). The sophistication of single-system designs has increased dramatically over the past two decades (Bloom et al., 2009). The discussion of designs presented here is meant to be illustrative rather than exhaustive. Readers should consult the references for more detailed information.

AB Designs. The AB design is the basic form of single-system design. The A represents the baseline or no treatment condition (phase A). Subsequent interventions are indicated by different letters of the alphabet. If an intervention baseline is repeated, then the same letter is used to represent the repeated phase. For example, Fig. 1 displays the effect of an exercise program on the weight loss of a cardiac patient. Phase A represents the baseline period where the person's weight was recorded on a monthly basis. A program of graded exercise and diet control was initiated at the end of month three and represents start of phase B. The vertical axis of the graph indicates the patient's weight loss in pounds.



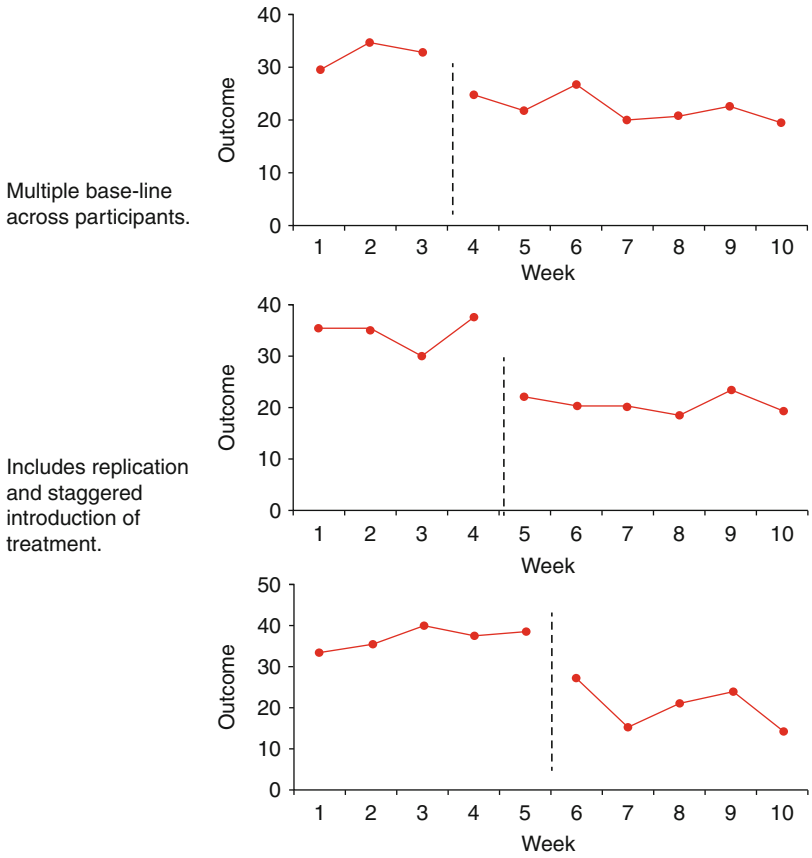
Outcome for the Single Case: Random Control Index, Single Subject Experimental Design, and Goal Attainment Scale, Fig. 1 Example of *AB* design with baseline (*A*) and treatment (*B*) phases

Other design variations are easily developed from this basic design pattern. Bloom et al. (2009) advocate the AB design as the cornerstone for conducting single-system evaluation and research. They contend that the fundamental step in becoming an accountable professional is to start counting with the AB design.

Variations of the AB Design. An extension of the AB design, in which the treatment is withdrawn in the third phase, is the ABA design. The withdrawal of the intervention provides greater confidence in determining the effect of the treatment. With each successive pattern change corresponding to the introduction or withdrawal of the treatment, it becomes increasingly unlikely that the change can be attributed to a coincidence. One disadvantage of the ABA design is that the patient is left in the absence of intervention. Another treatment phase (phase B) may be added to reintroduce the intervention effects resulting in an ABAB design.

Multiple Baseline Designs. In some cases, the treatment or intervention cannot be withdrawn, or withdrawing the treatment may not result in a return to pre-intervention performance levels. In a multiple-baseline design, baseline and intervention data are collected on several individuals for a similar behavior or setting. The most common version of this design is the multiple

Outcome for the Single Case: Random Control Index, Single Subject Experimental Design, and Goal Attainment Scale, Fig. 2 Example of multiple baseline design across three individuals



baseline across participants where data are collected across several different individuals (Bloom et al., 2009). In a multiple baseline design, the intervention phase is introduced in a staggered manner across individuals, behaviors, or settings. Figure 2 illustrates a multiple-baseline across individuals. The intervention is introduced to each participant in a sequential, staggered manner, and the outcome measure recorded repeatedly. The consistently changing performance of each individual as the intervention is introduced strengthens confidence in the relation between the intervention and outcome. The multiple baseline design across individuals is a particularly useful single-system design because it does not require the withdrawal of treatment and has the additional benefit of including replication of the finding across participants.

Graphic analysis and visual inspection are the traditional analytic tools used to present and interpret the results of single-system research (Bloom et al., 2009). Kazdin (1982) has observed that as single-system designs have become popular in applied research areas, there has been an increased emphasis on the need for statistical analysis of the data. The use of statistical procedures with single-system designs is controversial (Kazdin, 1982). Several authorities feel it is inappropriate to use statistical techniques with single-system designs and contend that the application of statistical procedures confuses the issue of clinical and statistical significance. However, Edington (1996) argues that statistical and visual methods should be partners in the analytic endeavor to provide a clearer interpretation of single-system outcome research.

Goal Attainment Scaling (GAS)

The basic idea of GAS is not new. The practice of setting measurable goals for intervention is well

established. Goals should be client/patient-centered and established in relation to the person's home, work, and community environments (Rockwood, Stolee, & Fox, 1993).

The process of establishing goals in GAS is accomplished in series of steps (Kiresuk, Smith, & Cardillo, 1994).

Step 1 is to identify an overall objective in collaboration with the person and his/her family.

Step 2 is to identify specific problem areas that should be addressed. This involves prioritizing areas and then identifying observable, reportable components.

Step 3 is to define specific behaviors or events that will indicate improvement in each of the areas selected in Step 2. The purpose is to provide the operational detail required to make the scale a useful instrument to evaluate performance.

Step 4, the clinician must determine the methodology that will be used to collect the desired information. A plan is developed that will determine how the information will be collected, who will collect it, and in what setting the data will be gathered.

Step 5 involves selecting the expected level of performance. This step relies on professional judgment and realistic appraisal of the client – it simultaneously is one of the strengths and liabilities of GAS. If the expected levels are at variance with actual performance, then the GAS score will reflect this inaccuracy. Step 5 is based on the assumption that experienced practitioners will be able to "predict" treatment outcome with input from the client, family members, and other health care providers. For example, if the clinician and others judge that it is realistic that the client loses 5 lbs in a month as part of a cardiac rehabilitation program, then this is a satisfactory operational criterion for the goal of weight reduction. This operational criterion relies heavily on the practitioner (and others) knowledge of the client, the intervention (e.g., cardiac rehabilitation program), and the environment.

Step 6 involves identifying the most favorable outcome, the least favorable outcome, and intermediate levels of client performance. Kiresuk et al. (1994) suggest that the practitioner develop five levels of performance that range from the most favorable to the least favorable. The most favorable outcome should reflect what the client could accomplish if everything in the program goes smoothly. In the weight loss example, the most favorable outcome may be that the client loses 10 lb in 1 month. The least favorable outcome might be that the client gains 5 lb during the intervention. The expected outcome is to lose 5 lb. Each of the five levels is operationally defined and assigned a numeric value with 0 indicating the expected level of performance and −2 and +2 indicating the least and most favorable outcomes, respectively.

Step 7 involves checking to ascertain whether there are overlapping levels, gaps between levels, or more than one indicator in a problem area. The scale should also be checked to make sure that the definitions of behaviors are clear and that the instructions on how to collect data are not ambiguous. The final step (*Step 8*) is to ascertain the current status of the individual and determine when the client will be evaluated again to document if she or he has progressed. The selection of the time period between evaluations is related to the type of intervention provided, the expected level of performance, and external criteria imposed by third party payers, accrediting agencies and others.

The most commonly used system of scoring relies on the five-point scale of performance (see Step 6) with scores ranging from −2 to +2 for each scale. In this scheme, a rating of −2 is associated with the least favorable outcome; −1 less than expected; 0 expected level of performance; +1 greater than expected outcome; and +2 most favorable outcome. These ratings are used for each of the levels across all goals.

In scoring the GAS, *relative weights* are assigned to each of the goals identified for the client. There is no standard procedure for determining how each goal is weighted. The weighting is (ideally) achieved by consensus among the patient, clinician, family members, and other persons concerned with the patient's performance. The weighing reflects a prioritizing or ranking of

the goals. If four primary goals are prioritized, for example, then the most important goal is given a ranking (weight) of +4 and the least important goal a weight of +1. The weights (rankings) must be determined in the goal planning stage and not in the final assessment phase.

Evaluation Formula. After the intervention has been administered, the weights for the goals and the rating of each level of performance are used to compute a GAS score (Kiresuk & Sherman, 1968). This score represents a numeric index of the client's improvement (or lack of improvement). The formula used to compute the goal attainment score is as follows:

$$T = 50 + \frac{(10\Sigma W_i X_i)}{(1 - r)\Sigma W_i{}^2 + r(\Sigma W_i)^2}$$

X_i represents the outcome score for each behavior (a value from −2 to +2).

W_i represents the weighting for a particular goal.

r-value in the formula reflects the estimated average intercorrelation between outcome scores. Kiresuk et al. (1994) suggest that an r-value of 0.30 can safely be assumed and used as a constant in the formula.

T-value is a standardized score with a mean of 50 and a standard deviation of 10.

A T-score of 50 corresponds to the 0 point on the original profile, that is, the expected level of performance ranging from −2 to +2. A T-score of greater than 50 represents performance above the expected level and a T-score of less than 50 reflects performance below the expected level.

The T-score is a better reflection of client performance than the simple raw score because it combines the outcome scores for all the goals to provide an overall measure of client improvement (or lack of improvement) (Kiresuk & Sherman, 1968). Another advantage of the T-score is that it allows the weighting given to the individual goals to be incorporated into the final outcome.

An advantage of GAS is that it is not bound to any theoretical orientation or type of treatment or outcome measure. Another strength is that goals can be individualized and designed to represent realistic expectations concerning client performance. The GAS strategy actively encourages cooperative person-centered goal setting. Input from clients, family members, and other health service providers is important in establishing and prioritizing (weighting) the goals and in determining realistic levels of expected performance (Kiresuk & Sherman, 1968).

As Rockwood et al. (1993) accurately note "Goal Attainment Scaling can, quite properly, be viewed as an accountability system" (p. 450) it is not a research method. The procedures associated with GAS can, however, be incorporated into many standard research designs (Khan, Pallant, & Turner-Stokes, 2008). If GAS is used in a research context then attention must be devoted to ensuring the internal validity of the investigation by blindly recording and establishing the reliability of the outcome measures. Khan and associates (Khan et al., 2008) provide valuable suggestions and guidelines to practitioners interested in using GAS in a research context.

Implications for Practice and Research

The *Reliability Change Index*, *Single-subject designs* and *Goal Attainment Scaling* can assist practitioners in systematically evaluating change. It may not be realistic to expect behavioral medicine practitioners to complete complex and time-consuming research studies based on experimental procedures or randomized clinical trials. Practitioners do, however, have the opportunity and obligation to assess client/patient performance, document change, and report the results to consumers and colleagues. Increasingly, this obligation includes providing an opportunity for the patient and family to have a role in the assessment, intervention, and evaluation process. *Goal Attainment Scaling* and other patient-centered methods focused on individual outcomes can help improve the evidence-based services provided to persons with disabilities and chronic disease.

Overweight

Elizabeth R. Pulgaron
Department of Pediatrics, University of Miami, Miami, FL, USA

Synonyms

Excess weight

Definition

Being overweight is defined as being heavier than is healthy given a person's height, gender, and age. This includes having more body fat than is desired. Being classified as an overweight adult consists of having a body mass index (BMI) between 25 and 29.9. BMI is calculated by taking a person's weight in kilograms and dividing it by the square of the person's height in meters. For adults, a BMI of 25 is considered the 85th percentile. A similar calculation is computed to determine a child's BMI; however, gender and age are also added into the equation to account for differences in expected body fat at different

developmental levels according to gender. Although BMI is a generally accepted measure for obesity, it is not diagnostic since it is not a direct measure of body fat. Other measures of body fat distribution include skinfold thickness tests, waist circumference, calculation of waist-to-hip circumference ratios, ultrasound, computed tomography, and magnetic resonance imaging (MRI; CDC, 2009b).

Data from the United States National Health and Nutrition Examination Survey (NHANES) indicate that between 2005 and 2006, nearly 33% of adults 20 years and older were classified as overweight according to their BMI. From that same survey, 34.3% and 5.9% of adults were classified as obese and extremely obese, respectively. Thus, 72.9% of adults in the USA were overweight or obese. Data from 2007 to 2008 indicated that 32% of children aged 2–19 years old met criteria for being overweight according to BMI (Ogden et al., 2010). These rates are much higher than those reported 10 years ago, which were significantly higher than the rates reported 10 years before that. High rates of obesity have been reported in other countries outside of the USA as well.

Being overweight is a result of chronic caloric imbalance, with more calories being consumed than expended each day. Genetics, environment, metabolism, behavior, culture, and SES all play a role in being overweight. The consequences of being overweight may be severe, including but not limited to higher risk for cardiovascular diseases, type 2 diabetes, cancer, hypertension, dyslipidemia, stroke, and sleep apnea (CDC, 2009a). In addition to health consequences, there are also psychosocial and economic consequences of being overweight. These include morbidity and mortality, medical prevention and treatment expenses, and physical and psychological distress. For example, one study conducted by Gortmaker, Must, Perrin, Sobol, and Dietz (1993) followed obese adolescents for 7 years. Results indicated that young obese women completed less years of school, had lower household incomes, experienced higher rates of poverty, and were less likely to be married than women who had not been obese.

Oxidative Stress

Sarah Aldred

Birmingham, UK

Synonyms

OS

Definition

Oxidative stress is an environment where the balance of prooxidant species to antioxidant species is altered in favor of the former. Prooxidant species include free radicals (e.g., the superoxide ion; O_2^-) and nonradical species (e.g., hydrogen peroxide; H_2O_2), which together are classified as reactive oxygen and nitrogen species (RONS). RONS are produced as a consequence of normal cellular oxidation processes. Sources include the mitochondrial electron transport chain, peroxisomes, endothelial or hepatic xanthine oxidase, and leukocytes. RONS have a variety of roles in normal homeostasis, including respiration and cellular signaling: RONS are reported to act as transient signaling molecules in the Ras GDP/GTP cycle and MAP kinase cascades, through modification of protein-bound redox-sensitive thiol groups.

Antioxidants serve to delay or prevent the oxidation of substrates or cellular constituents. They may be endogenous, for example, the enzymes superoxide dismutase, glutathione peroxidase, and catalase, or exogenous and taken in via the diet such as vitamin A, C, and E.

RONS can increase to high levels in some disease processes or where there is antioxidant deficiency and may react with cellular constituents to cause damage, disruption of function, or degradation resulting in an oxidative stress.

Oxidative stress has been implicated in a number of diseases including Alzheimer's disease, vascular dementia, cardiovascular disease, rheumatoid arthritis, and diabetes.

Indices of Oxidative Stress

Proteins are highly susceptible to free radical insults, and such events can lead to irreversible oxidative modification. Free radicals can oxidize a protein's backbone and the side chains of particular amino acids (e.g., lysine, arginine, proline, and threonine), as well as induce protein fragmentation. In all of these instances, carbonyl groups (C═O) may be introduced into the protein's structure. In addition, the reaction of proteins with aldehyde compounds produced by lipid peroxidation (e.g., 4-hydroxynonenal (4-HNE) and malondialdehyde (MDA)) can lead to carbonyl formation.

Peroxynitrite (ONOO-) is a highly potent reactive nitrogen species (RNS) formed during the reaction between nitric oxide ($NO^{\bullet}$) and $O2^{\bullet -}$. In addition to oxidizing proteins, $ONOO^-$ has the ability to nitrate proteins: a nitro group ($-NO_2$) replaces a hydrogen atom at the 3′ position of a tyrosine residue, forming a 3-nitrotyrosine adduct. This posttranslational modification can impact upon protein function.

Polyunsaturated fatty acids (PUFA) are components of cell membranes which are highly susceptible to oxidative damage by free radicals: such damage is referred to as free radical-mediated lipid peroxidation (LPO). The initial step of LPO involves the free radical-mediated abstraction of hydrogen atoms from PUFA to form lipid radicals which react with molecular oxygen to form the highly reactive peroxyl radical. This extremely unstable species can further oxidize lipids to produce new lipid radicals and thereby propagate a chain reaction. LPO can be terminated if lipid radicals (e.g., lipid peroxides) react with themselves to form stable lipid peroxide products, or if lipid-soluble antioxidants (e.g., vitamin E) are available to reduce peroxyl radicals to lipid hydroperoxides.

Damage to DNA in peripheral blood lymphocytes and tissues of the human body is a highly sensitive and specific marker of oxidative stress. The use of DNA repair endonucleases (e.g., formamidopyrimidine glycosylase; FPG) allows the direct quantification of damage caused specifically by oxidative stress. Free radicals, and in particular the hydroxyl radical ($OH^{-\bullet}$), cause sugar and base modifications, strand breaks, and DNA-protein cross-links.

Oxytocin

Laura D. Kubzansky
Department of Society, Human Development, and Health, Harvard School of Public Health, Boston, MA, USA

Synonyms

Pitocin; Syntocinon (synthetic forms)

Definition

Oxytocin is a peptide that is produced in the supraoptic (SON) and paraventricular nuclei (PVN) of the hypothalamus and released into circulation from the magnocellular neurons that extend to the posterior pituitary (peripheral system). It is released into the systemic bloodstream in pulsatile form by sensory and other stimuli. Oxytocin is also produced and released from parvocellular neurons in the PVN that project to numerous areas within the brain. It is a hormone but also functions as a neurotransmitter. Oxytocin is found in both males and females. Circulating levels of oxytocin and the number of oxytocinergic neurons in the hypothalamus are independent of sex, and oxytocin release and receptors are similarly induced and distributed in males and females.

Description

Oxytocin has well-known physiological functions during labor and in milk letdown in humans. However, animal research has also demonstrated effects of oxytocin on a broad range of social and affiliative behaviors, as well as on physiological and developmental outcomes. For example, oxytocin plays an important role in the ability to form normal social attachments and is involved with social recognition and social interaction behaviors for both males and females of a number of animal species (Carter, 2003; Insel & Young, 2001; Uvnas-Moberg, 1998). Administering oxytocin has been shown to facilitate maternal behaviors among rodents such as grooming and licking pups, as well as other affiliative behaviors.

Research in both rodents and humans has found that oxytocin activity is elicited by various conditioned and nonconditioned sexual and social behaviors such as olfactory stimuli, touch, hair stroking, warmth, and pleasant vocal sounds (Depue & Morrone-Strupinsky, 2005). As a result, investigators now posit that positive social behaviors and social bonding, characterized by repeated physical contact, can lead to the release of oxytocin (Uvnas-Moberg, 1998). Additional research in animals and humans suggests that oxytocin is involved in general central nervous arousal, with effects that oppose stress-related activation by inhibiting sympathetic nervous system activity and increasing parasympathetic activity, as well as inhibiting the release of glucocorticoids. Some animal work has also demonstrated that oxytocin seems to shift energy use toward more positive health-promoting internal activities like storing nutrients and increasing the rate of wound healing. These findings have led to strong interest among investigators in behavioral medicine, as to whether research on oxytocin in humans may provide new insights into the neurobiology of resilience and health.

The role of oxytocin in social, mental, and physical aspects of health in humans is an area of active investigation. Preclinical research suggests that oxytocin facilitates bonding and approach behaviors partly by inhibiting stress-related maladaptive cognitive, affective, and biological activation. Because of its potential role in mediating human social behavior, ongoing research is focused on whether oxytocin may lead to improved social and emotional functioning for a range of disorders including autism, schizophrenia, and anxiety or depression (Averbeck, 2010; Bartz & Hollander, 2006). Other studies in nonclinical populations have found that exogenously administered oxytocin reduces fear-related activation in the amygdala, reduces cortisol levels and distress in response to social stress, increases prosocial behaviors, and modulates social memory (Heinrichs, Baumgartner, Kirschbaum, & Ehlert, 2003;

Heinrichs, Meinlschmidt, Wippich, Ehlert, & Hellhammer, 2004; Kirsch et al., 2005; Kosfeld, Heinrichs, Zak, Fischbacher, & Fehr, 2005). However, effects of oxytocin do not appear to be uniformly positive and prosocial; other research has found that under certain conditions oxytocin may actually enhance negative responses to social stress in humans (Shamay-Tsoory et al., 2009).

Measuring oxytocin and its effects in humans presents some challenges. Oxytocin release into peripheral circulation is pulsatile, and it has a very short half-life. In addition, plasma oxytocin does not easily cross the blood–brain barrier and therefore may not be informative about oxytocin activity and effects in the brain. As a result, research on the role of oxytocin in human health is still in an early period with investigators developing new assays and protocols for addressing these methodological challenges.

As with any biological substrate, oxytocin is likely to have a multiplicity of effects, and potential therapeutic and mechanistic insights will be enhanced as we achieve a greater understanding of the range of effects possible and the conditions under which they occur.

[2]Department of Psychiatry and Behavioral Sciences, Clinical Psychology Division, Feinberg School of Medicine, Northwestern University, Chicago, IL, USA

Synonyms

Pain management/control; Pain: psychosocial aspects; Pain threshold

Definition

Pain is a noxious sensory phenomenon that provides information to organisms about the occurrence or threat of injury. Pain is also a multidimensional experience that results from a complex interaction between biological and psychological components and is further influenced by behavioral and social factors. The temporal course of pain can range from acute, or time-limited states in response to injury, to chronic states in which pain persists beyond the point of tissue repair or healing. Although the Gate Control Theory (Melzack & Wall, 1967) provides a unified model of pain, a variety of pain subtypes exist that have different underlying mechanisms.

Description

Neurobiology of Pain

A primary function of the nervous system is to communicate information to alert organisms to the experience or threat of injury. Therefore, the noxious qualities of pain function to capture our attention and motivate action to minimize the risk of harm. Nociceptors are a specialized class of primary afferent nerves. Myelinated nociceptors signal sharp pain from heat and pressure stimuli on skin with hair. Unmyelinated nociceptors signal burning and pressure-induced pain on hairless skin. Both unmyleinated and myelinated nociceptors signal pain from chemical stimuli. Injury leads to increased pain sensitivity or hyperalgesia caused by inflammation.

CNS Mechanisms of Pain Modulation

At the level of the spinal cord, pain modulation occurs in the substantia gelatinosa (SG) of the dorsal horn. The SG serves an inhibitory or gating function that modulates pain signal transduction. Pain modulation also occurs in the periaqueductal gray (PAG) and rostral ventromedial medulla (RVM) of the midbrain, which

M.D. Gellman & J.R. Turner (eds.), *Encyclopedia of Behavioral Medicine*,
DOI 10.1007/978-1-4419-1005-9,

function as a bidirectional relay station. The system is involved in the suppression of ascending responses to harmful stimuli and enhances nociceptive responses. The PAG-RVM system has connections to the hypothalamus and limbic forebrain structures including the amygdala, anterior cingulate cortex, and anterior insula. Consequently, fear, attention, and pain expectancies exert top-down processes that influence pain perception.

Clinical Classifications of Pain

Postoperative Pain and its Management

Acute postoperative pain is a product of a range of physiological mechanisms. It comprises a constellation of sensory, emotional, and psychological experiences that follow surgery and is associated with autonomic, endocrine-metabolic, physiological, and behavioral responses. Considerable progress has been made to understand the functions of the peripheral and central nervous systems, mechanisms of acute postoperative pain, side effects of analgesic drugs, and techniques and interventions in surgical patients. However, improvements in the management of acute postoperative pain are needed. Specifically, the use of acute pain management services may help to ensure that evidence-based analgesic techniques are implemented. Furthermore, improved collaboration would be useful between interdisciplinary care teams including anesthesiologists, surgeons, nurses, and mental health professionals to optimize postoperative pain management.

Deep Somatic Tissue Pain Deep tissue pain encompasses pain from the joints and muscles. The pain is often diffuse and characterized by dull and aching sensations. Major sources of deep somatic tissue pain are inflammatory diseases, trauma, overload, and degenerative diseases. Under normal conditions, these nociceptors are activated by stimuli that can lead to structural damage including overload, twisting, pressure, and ischemic contraction. Under conditions of inflammation or trauma, nociceptors of joint and muscle become increasingly sensitized, particularly to mechanical stimuli.

Two types of spinal cord neurons process nociceptive input from joint and muscle. These neurons show two distinct properties: (1) They converge inputs from the skin and deep tissue, and (2) they are activated by mechanical stimuli. Neurons in the thalamus and cortex process inputs from deep tissue.

Arthritis Osteoarthritis (OA) is a degenerative joint disease that results in pain localized to the joint cartilage and subchondral bone. It affects approximately 30% of adults 75 years and older. OA is classified by the location of the affected joints (e.g., hip or knee) and whether the pain is primary or secondary to other conditions or disease processes. OA pain may occur in response to mechanical stimuli but may be chemically mediated when joint tissues fail to adequately repair. Consequences of OA include loss of articular cartilage, new bone formation in the subchondral region, and formation of new cartilage and bone in the joints and are characterized by pain, stiffness, functional limitations, and impaired quality of life.

Rheumatoid arthritis (RA) is an autoimmune disease that results in significant joint inflammation and pain. It affects nearly 1% of the adult population. RA involves both the small and large joints and is distributed symmetrically. RA may eventually progress to joint failure, which can result in secondary OA. Age, sex, family history, and tobacco use are significant risk factors for RA.

Treatment for arthritis is multidimensional. Components may include education about the disease process, weight loss to minimize joint stress, increased physical activity and/or physical therapy, analgesics, anti-inflammatory drugs, and local steroid or hyaluronic acid injections. Specific to RA, antirheumatic drugs (DMARDs) may be used to reduce inflammation and slow the disease progression. In severe or advanced cases, surgical intervention including joint replacement may be indicated.

Fibromyalgia Syndrome Fibryomyalgia syndrome (FMS) is a persistent pain condition involving the soft tissues. It affects approximately 2% in

the general population and is significantly more prevalent among women than men. Although its etiology is unknown, significant advances have been made in understanding its clinical presentation. Pain is believed to result from central sensitization of somatosensory pathways that induce enhanced pain perception. This includes persistent, diffuse pain to touch at localized areas in soft tissues. Other systemic symptoms include recurrent headaches, dizziness, fatigue, morning stiffness, irritable bowel syndrome, irritable bladder syndrome, insomnia, cognitive dysfunction, depression, and anxiety.

Treatment for FMS is similar to that of other persistent pain conditions and includes education, physical activity and/or physical therapy, cognitive-behavioral therapy, and pharmacological interventions that act on central neural pathways.

Low Back Pain Low back pain (LBP) is defined as pain, muscle tension, or stiffness that is localized between the costal margin and inferior gluteal folds. It also presents with or without radiating leg pain. It can also be classified as specific, or in response to a known pathology (e.g., hernia, fracture), or nonspecific or idiopathic. Nonspecific LBP accounts for 90% of all cases. Physical exercises are currently the only empirically supported intervention to prevent LBP. Many randomized controlled trials and systematic reviews have been published that examine its treatment. Physical activity, nonsteroidal anti-inflammatory drugs (NSAIDs), and muscle relaxants are effective treatments for acute LBP. Physical therapy and CB therapy in the context of interdisciplinary pain treatment programs are recommended for persistent LBP.

Visceral Pain Visceral pain is diffuse. It results in referred pain (pain perceived in sites other than the site of injury or pain stimuli). Unlike somatic nociceptors, the activation of visceral nociceptors does not require tissue damage. Rather, it can be caused by the distension of hollow organs, traction on the mesentery, ischemia, and endogenous chemicals associated with inflammatory processes.

Thorax Pain Angina pectoris is the most frequently occurring form of thorax pain. It is caused by myocardial ischemia but often produces chest pain that is distal to the ischemic event. Cardiac pain is mediated by interplay between autonomic reflexes and peripheral cardiac nerves. The thalamus and hypothalamus transmit cardiac pain to the prefrontal cortex. The occurrence of pain is slow and lacks spatial localization. The clinical presentation of myocardial ischemia can be different in men and women. Pharmacotherapy is the primary intervention for angina pectoris and acute myocardial infarction (MI) including beta-blockers, nitroglycerin, morphine, and antithrombotic agents. Percutaneous transluminal coronary intervention (PCI) and coronary artery bypass graft surgery (CAGB) are surgical interventions that improve coronary blood flow. Other forms of thorax pain include esophageal chest pain, aortic aneurysms, and pulmonary events including embolism.

Abdominal Pain Abdominal pain can be caused by chronic functional disorders or acute life-threatening conditions. Chronic disorders, such as irritable bowel syndrome, account for the majority of diagnoses that account for abdominal pain. Most chronic disorders result in enhanced pain perception in response to visceral stimuli, which results from central pain modulation mechanisms. In contrast, acute abdominal pain is caused by an identifiable stimulus or pathology (e.g., gastric ulcer). Although interventions for acute abdominal pain are highly effective, the development of efficacious treatments for chronic conditions is needed.

Orofacial Pain Orofacial pain is defined as pain experienced in the motor or sensory aspects of the trigeminal nerve system. Pain signals are transmitted to the nucleus caudalis in the medulla and project onward to the thalamus and cortex via the trigeminothalamic tract. Orofacial pain is exacerbated by central convergence, inflammation of the oral mucosa, and central sensitization to pain (increased spontaneous firing of nerves). Prevention strategies include preoperative administration of NSAIDs to block inflammatory

processes and local anesthetics to reduce central sensitization. However, due to common adverse events when using systemic opioids, their outpatient use is limited. The etiology of persistent (unremitting or recurrent) orofacial pain is poorly understood. Consequently, pain management is imprecise, and the majority of therapies are not validated.

Neuropathic Pain Neuropathic pain occurs in response to injury (lesion or dysfunction) of the nervous system. Numerous animal models have been proposed to account for the underlying mechanisms. One of the earliest models originated from the observation that animals attack a limb in which the axons of neurons have been severed following injury. This model suggests that a central sensitization process occurs, such that severed nerves exhibit greater spontaneous firing frequencies than healthy intact nerves. Individuals experiencing neuropathic pain describe their pain as "electric shocks, burning, tingling, itching, and prickling." Examples of neuropathic pain conditions include neuropathies (e.g., peripheral, autonomic) and neuralgias (e.g., trigeminal). Pharmacological treatments may include topical analgesics, tricyclic antidepressants, anticonvulsants, and opioids.

Phantom Limb Pain This is a form of neuropathic pain and refers to perceived pain sensations in the anatomical space of a limb that has been amputated. Although the majority of individuals experience sensations related to the shape, posture, or movement of the missing limb, 60–80% of individuals experience intermittent or persistent pain. Although the specific mechanisms underlying phantom limb pain are not entirely understood, both the peripheral and central nervous systems are involved. Additional treatments may include sodium channel blockers, physical therapy, and transcutaneous electrical nerve stimulation.

Cancer Pain The neurobiology of cancer pain is poorly understood. However, new models have identified mechanisms that both produce and maintain cancer pain. Tumor cells and tumor-associated cells (macrophages, neutrophils, T-lymphocytes) are believed to sensitize primary afferent neurons in the periphery. Findings from these studies may lead to the development of novel therapies that act on these peripheral mechanisms and could improve the quality of life of individuals living with cancer.

Pain Assessment and Intervention Pain is a complex and subjective experience characterized by sensory-discriminative, motivational-affective, and cognitive-evaluative dimensions. Pain can be evaluated using a variety of tools including verbal and numerical self-report scales, visual analogue scales (VAS), self-report measures, behavioral observation, and physiological markers. A combination of these measures is recommended to yield the most valid information about this phenomenon.

Within clinical and research settings, the VAS, the McGill Pain Questionnaire (MPQ), and the Multidimensional Pain Inventory (MPI) are examples of commonly used instruments. Using a VAS, individuals are asked to rate their current pain intensity on a numeric scale that is anchored by 0 (no pain at all) and 10 (the most pain you could imagine experiencing). The McGill Pain Questionnaire was developed Melzack and Wall (Melzack, 1975). It evaluates the specific location(s), intensity, and qualities of pain that individuals currently experience. It contains four domains including sensory, affective, evaluative, and miscellaneous. It can either be clinician-administered or completed independently by patients in a self-report manner. The McGill Pain Questionnaire is a reliable and valid tool to assess the multidimensional nature of pain experience. For research applications where time is limited to obtain information, a short-form McGill Pain Questionnaire (SF-MPQ) is also available. The MPI is a comprehensive self-report instrument designed to evaluate a full range of experiences with persistent pain conditions. It includes dimensions of pain intensity, emotional distress, cognitive and functional adaptation, and social support. It has also been shown to have solid psychometric properties.

Cognitive-Behavioral Approaches to Pain Management In the context of persistent pain conditions, cognitive-behavioral (CB) interventions focus on developing adaptive pain coping skills. These skills are intended to minimize the experience of pain, prevent or minimize pain exacerbations, and limit pain-related disability. A CB intervention addresses the subjective and contextual aspects of pain. First, patients receive education about theories of pain (e.g., Gate Control Theory) to foster an understanding of why pain persists beyond the point of tissue repair. Understanding this conceptual framework provides the foundation for deploying a series of related cognitive and behavioral interventions. Cognitive interventions may include cognitive restructuring to minimize pain catastrophizing, attention diversion and distraction techniques, and problem solving exercises. Behavioral interventions may include relaxation, paced diaphragmatic breathing, goal setting, behavioral activation, and graded exposure to feared physical activities. In the management of persistent pain, CB interventions are often most effective when implemented in the context of interdisciplinary care teams and can be used as an adjuvant to other physical, pharmacological, or surgical therapies.

Pain Anxiety

Michael James Coons
Department of Preventive Medicine, Feinberg School of Medicine, Northwestern University, Chicago, IL, USA

Synonyms

Pain-related fear

Definition

Pain anxiety is a future-oriented state of autonomic arousal that is triggered by the anticipation of pain. Similar to the tripartite model of anxiety, it is comprised of cognitive, physiological, and behavioral components. Pain anxiety is an affective manifestation of the autonomic nervous system that occurs in response to the anticipation of pain. Albeit to a lesser degree than that triggered by fear, the sympathetic nervous system becomes activated by the septo-hippocampal brain regions. Pain anxiety is characterized by cognitive, physiological, and behavioral symptoms. Cognitively, individuals become hypervigilant for pain-related cues by internally scanning their body (for internal signs and symptoms of pain) and the environment (for pain-inducing contexts or stimuli). They also anticipate experiencing pain in the future and may often expect their pain to be catastrophic (e.g., "Having to get my tooth fixed at the dentist will be excruciating"). In turn, individuals become motivated to engage in avoidance behaviors to minimize the likelihood of experiencing future pain. According to fear-avoidance models of pain, behavioral avoidance (typically of situations involving physical activity or movement) leads to physical deconditioning and muscle atrophy, which in turn, may result in greater pain intensity. Pain anxiety and related avoidance behavior greatly contributes to the progression of acute to persistent pain.

The most common mode of assessment of pain anxiety involves the administration of well-validated self-report instruments. Several published scales are available that assess the nature and extent of pain-related cognitions (e.g., "When I hurt, I think about pain constantly"), pain-related avoidance (e.g., "I try to avoid activities that cause pain"), and physiological symptoms (e.g., "When I sense pain, I feel dizzy or faint"). Examples of self-report instruments include the Pain Anxiety Symptom Scale (PASS) and the Burn-Specific Pain Anxiety Scale. Alternative modes of assessing pain-related fear include semi-structured clinical interviews and the direct observation of patient behavior.

Cognitive behavior therapy (CBT) is the most well-validated intervention for pain anxiety. Treatment components include psychoeducation and introduction, demonstration, and practice of a variety of adaptive coping skills (i.e., progressive muscle relaxation, diaphragmatic breathing, mental imagery, behavioral activation and pleasant activity scheduling, activity-rest cycling, physical therapy/exercise, problem-solving, cognitive restructuring, and calming self-statements). In treating pain-related fear, special emphasis is placed on graded in vivo exposure with behavioral experiments. These latter components allow individuals to identify situations through which they can gather information to test and challenge their distorted pain-related cognitions.

Pain Anxiety Symptoms Scale (PASS) and Short Version PASS-20

Lance M. McCracken
Psychology Department, Institute of Psychiatry, King's College London, London, UK

Definition

Short self-report questionnaires designed to measure aspects of pain-related anxiety and avoidance for use in clinical assessment and research.

Description

The 40-item Pain Anxiety Symptoms Scale (PASS) (McCracken, Zayfert, & Gross, 1992) and a shorter 20-item version of the same assessment instrument (PASS-20) (McCracken & Dhingra, 2002) measure pain-related anxiety, fear, and avoidance. They were designed for clinical and research purposes and mostly for use with adults with recurrent or chronic pain conditions. However, they have been validated and used in people without identified pain conditions, such as university students and people recruited from community settings (Abrams, Carleton, & Asmundson, 2007). The original PASS was developed at a time during the late 1980s and early 1990s when clinicians and researchers were beginning to focus greater attention on processes of fear and avoidance in relation to chronic pain. Since that time a model of chronic pain referred to as the "fear-avoidance" model has become a popular organizing framework guiding research and treatment development (Vlaeyen & Linton, 2000). The PASS and PASS-20 have been used in research investigating models and mechanisms of pain-related disability, and in treatment process and outcome research (McCracken & Gross, 1998; Vowles & McCracken, 2008). They are also routinely used in clinical practice for analyzing and conceptualizing cases and in treatment-related decision making.

Both versions of the PASS include four subscales that reflect aspects of avoidance behavior (e.g., I will stop any activity as soon as I sense pain coming on), cognitive anxiety (e.g., During painful episodes it is difficult for me to think of anything else besides the pain), fear (e.g., When I feel pain I am afraid that something terrible will happen), and physiological anxiety (e.g., I find it hard to calm my body down after periods of pain). The four subscales are equal length in each version of the measure. All items are rated on a scale from 0 (never) to 5 (always). In the 40-item version five items are reverse-keyed and must be recoded before calculating summary scores. Summary scores for both versions are calculated by summing assigned items and then by summing the subscales to derive an overall score. There are no set cutoffs for interpreting scores from the instruments. One method to facilitate interpretation is to convert raw scores to standard scores or percentile ranks. As an example, a table of raw scores and percentile rank equivalents has been constructed from a large consecutive sample of patients seen at a tertiary care center in the UK ($N = 339$). From this raw scores of 15.0, 33.0, 60.0, and 78.0 from the PASS-20 correspond to the 5th, 25th, 75th, and 95th percentile, respectively.

The PASS and PASS-20 have been extensively validated. They both show very good

internal consistency and temporal consistency (McCracken & Dhingra, 2002; Roelofs et al., 2004) and a factor structure that generally matches the a priori subscale structure (Abrams et al., 2007; Larsen, Taylor, & Asmundson, 1997; Roelofs et al., 2004). Both versions of the instrument demonstrate adequate construct validity in relation to variables such as general anxiety and depression (e.g., Roelofs et al., 2004) and show mostly moderate to large correlations with important criterion variables, such as measures of physical and psychosocial disability (e.g., McCracken & Dhingra, 2002). The original PASS (McCracken & Gross, 1998) and the 20-item version (Vowles & McCracken, 2008) both appear sensitive to the effects of multidisciplinary treatment for chronic pain.

For most uses currently the PASS-20 is preferred as it appears equivalent to the longer version in most important respects. The PASS-20 has been translated into Chinese, Dutch, French, Icelandic, Iranian, Polish, and Spanish, among other languages.

The fear-avoidance model of chronic pain has been a very useful model for understanding pain-related disability and for guiding the current generation of treatment developments for chronic pain. At the same there are other theoretical and treatment developments that appear wider in scope and possibly more progressive than the fear-avoidance model. These developments include contextual approaches within cognitive behavior therapy, approaches such as Acceptance and Commitment Therapy (ACT) (Hayes, Strosahl, & Wilson, 1999) and mindfulness-based approaches. In this work measures such as the PASS-20 remain useful. Other variables that are known to have strong relations with pain-related fear and avoidance are also now frequently studied, such as acceptance of pain and values-based action, among others, and a wider process called psychological flexibility (e.g., Vowles & McCracken, 2008). The point is that the PASS-20 and its focus on fear and avoidance remains relevant and the field is also evolving so that these process are being examined in a broader and well-integrated cognitive behavioral framework. These theoretical and treatment developments may be important to those who are hoping to assess pain-related fear and avoidance and may be seeking to use an instrument such as the PASS-20.

Pain: psychosocial aspects

Definition

Pain is a multidimensional phenomenon. Pain management refers to the physiological (i.e., pharmacological, surgical), psychological, and behavioral interventions that are aimed at minimizing pain perception and alleviating pain-related interference and disability.

Description

Historically, pain was conceptualized using a disease model and was considered to be a purely sensory experience resulting from injury, inflammation, or tissue damage. However, limitations to this model became evident after observing diverse responses to pain across individuals despite objectively similar physical stimuli or trauma. In 1965, Melzack and Wall published a seminal paper in *Science* that outlined a revolutionary theory of pain (Melzack & Wall, 1965).

Gate Control Theory

The Gate Control Theory emphasized central neural mechanisms at the level of the spinal cord that modulate afferent signals from peripheral nerves en route to the brain. This sensory modulation and subsequent pain perception is influenced by sensory input, cognitive processing, affective states, neural inhibitory capacities, activities of the stress-regulation system, and subsequent behavioral responses. Therefore, interventions targeting these multiple mechanisms provide opportunity to achieve effective pain management.

Pharmacological and Surgical Interventions

Pharmacological interventions are often the first-line treatments for pain. Systemic analgesics are the focus of both acute and persistent pain management and include nonsteroidal anti-inflammatory drugs (NSAIDs), including acetaminophen (ASA), and opioid analgesics (pure or in combination with NSAIDs). Combination opioid analgesics are typically administered orally; however, other routes of administration include rectal and sublingual. Pure opioids can be administered through the skin (with a transdermal patch), subcutaneously, or intravenously. These latter routes of administration are typically used when adequate pain relief is not achieved with the use of NSAIDs or combination opioids. In cases of neuropathic pain (i.e., pain due to dysfunction of the nervous system, in the absence of tissue damage), antiepileptic medications are often used (e.g., pregabalin). In light of their misuse and abuse potential of opioids, individuals with persistent pain should be evaluated to determine if chronic opioid management is clinically appropriate. Individuals with a history of medical non-adherence or individuals with severe axis I or axis II pathology may require close monitoring if opioid medications are prescribed.

Surgical procedures for pain management range in their degree of invasiveness. Minimally invasive procedures include steroidal injections and nerve blocks (of the peripheral and sympathetic nerves). Maximally invasive procedures include radiofrequency ablations (for the local destruction of nervous tissue), spinal cord stimulator implantation (for the neuromodulation of afferent pain signals), and intrathecal pump implantations (for the direct administration of opioids and other analgesics into the cerebral spinal fluid when pain relief using other modalities has been unsuccessful). Particularly with these more invasive surgical interventions, individuals must adhere to medical recommendations to avoid potentially life-threatening adverse

medical events. Consequently, candidates for these procedures also require careful evaluation and selection by qualified professionals to ensure patient safety.

Cognitive Behavioral Interventions

Cognitive behavioral interventions focus on developing adaptive pain coping skills to minimize the experience of pain, prevent long-term exacerbations in pain, and minimize pain-related disability. For individuals with persistent pain (either intermittent-recurrent pain or unremitting pain), they often become anxious and fearful of the pain experience and avoid engaging in physical activity to minimize the experience of pain. However, over time, this behavioral avoidance contributes to the loss of physical strength, physical deconditioning, and muscular atrophy (i.e., loss of muscle mass) that exacerbates pain perception. In essence, the avoidance of physical activity *because* of pain results in pain intensification. This behavioral avoidance reinforces the fear of pain, resulting in greater anxiety and propensity to avoid physical activity. Furthermore, avoidance of pain often leads to avoidance of activities through which individual's derive meaning and value (e.g., participation in one's profession, spending time with family/friends). Over time, avoidance may contribute to a sense of isolation, undermine one's confidence in their ability to manage their pain, and increase the focus of their attention to the perception of pain. This process contributes the development or exacerbation of depression, the intensification of pain, and pain-related interference and disability.

Components of cognitive behavioral interventions for persistent pain include psychoeducation and introduction, demonstration, and practice of a variety of adaptive coping skills (i.e., progressive muscle relaxation, diaphragmatic breathing, mental imagery, behavioral activation and pleasant activity scheduling, activity-rest cycling, physical therapy/exercise, problem-solving, cognitive restructuring, and calming self-statements). Within a CBT protocol, the relaxation procedures reduce sympathetic arousal to both "close the gate" to minimize the transmission of afferent pain signals to the brain and reduce muscle tension associated with pain. The attention procedures (i.e., mental imagery, pleasant activity scheduling) function to distract individuals from their pain experience and facilitate positive experiences and positive affect. The behavioral interventions (i.e., activity-rest cycling, behavioral activation, physical therapy/exercise) are intended to help individuals learn how to engage in activities despite experiencing pain and to both minimize pain-related interference and maintain their physical conditioning. While initial behavioral engagement often results in pain exacerbations, and over time, it is associated with reductions in pain intensity. In cases where individuals experience high degrees of pain-related fear and anxiety, graded exposure in vivo to physical movement may be required to minimize their affective response. Cognitive interventions (i.e., cognitive restructuring, calming self-statements, problem-solving) are intended to address pain catastrophizing (e.g., "This pain is so horrible I *cannot* do anything"), maladaptive pain beliefs (e.g., "Walking *should not* be painful"), and enable adaptive problem-solving skills. These cognitive behavioral interventions can be effectively delivered in individual or group formats, can be modified for family or system-based interventions, and can be augmented with the use of biofeedback equipment (e.g., superficial electromyography and monitoring of heart rate, respiration rate, peripheral temperature, and skin conductance). These applications are intended to provide individuals with physiological data that is used to help modulate sympathetic nervous system arousal using the coping skills outlined above.

Pain is a complex and multidimensional experience. In cases of persistent pain, individuals may benefit from clinical management by interdisciplinary teams. Although in some cases complete pain relief is not feasible, a combination of the approaches described above can minimize pain-related interference, disability, and the impact and potential for comorbid psychiatric conditions to maximize the quality of life experienced by individuals.

Pain Threshold

Michael James Coons[1] and Jeremy Steglitz[2]
[1]Department of Preventive Medicine, Feinberg School of Medicine, Northwestern University, Chicago, IL, USA
[2]Department of Psychiatry and Behavioral Sciences, Clinical Psychology Division, Feinberg School of Medicine, Northwestern University, Chicago, IL, USA

Definition

Pain threshold is defined as the minimum intensity of a stimulus that is perceived to be painful. Previously, this threshold was believed to be uniform across individuals, such that given intensity of a stimulus was thought to produce a given pain

response. However, it is now understood that the experience of pain is a subjective phenomenon, which is influenced by a complex interaction of biopsychosocial factors.

Historically, Specificity Theory and Pattern Theory posit that pain results from the direct transmission of peripheral stimuli to the brain, and stimulus response occurs in a reproducible relationship. However, limitations to these theories became evident after observing divergent responses to pain across individuals despite objectively similar physical stimuli or trauma. Consequently, Melzack and Wall proposed the Gate Control Theory of pain, which revolutionized our understanding of this phenomenon.

According to this theory, peripheral small diameter nerve fibers (i.e., pain receptors) and peripheral large diameter nerve fibers (i.e., normal receptors) project to the substantia gelatinosa (SG) in the dorsal horn of the spinal cord. The SG serves an inhibitory or gating function that modulates signal transduction. The SG also projects afferent fibers to the first transmission (T) cells. Activation of the T cells "activates the neural system" via the spinothalamic tract to facilitate pain perception.

In part, pain perception is determined by this bottom-up process. In the absence of sensory input, inhibitory neurons in the SG prevent projection neurons from transducing signals to the brain (i.e., maintaining a closed gate). When there is a preponderance of stimulation of pain receptors, the inhibitory neurons in the SG becomes inactivated (opening the gate), permitting the afferent projection neurons to transduce pain signals to the T cells and to the brain. However, pain perception is also influenced by top-down processes that include cognitive processes (e.g., attention), neural inhibitory capacities, affective states, and activities of the stress-regulation system. These processes transduce efferent signals to the dorsal horn in the spinal cord that further modulate the spinal gate and subsequent pain perception. Pain threshold is determined by variation in spinal gate modulation from both bottom-up and top-down processes that facilitate pain perception.

Definition

Researchers and clinicians have begun to map the trajectory of pain from acute to persistent states. These outcomes are influenced by a complex interaction of biological, psychological, behavioral, and social components, which can be clustered into intrapersonal factors (factors affecting the level of the individual) and interpersonal factors (factors affecting the interaction between the individual and their environment). These factors influence both pain perception and responses to treatment.

Description

Pain is a universal phenomenon experienced by most individuals. However, pain sometimes

persists beyond a reasonable time during which tissue typically heals following injury. Several researchers have developed and articulated conceptual models to understand how and why for some individuals pain transitions from acute to persistent states.

Fear-Avoidance Models of Pain

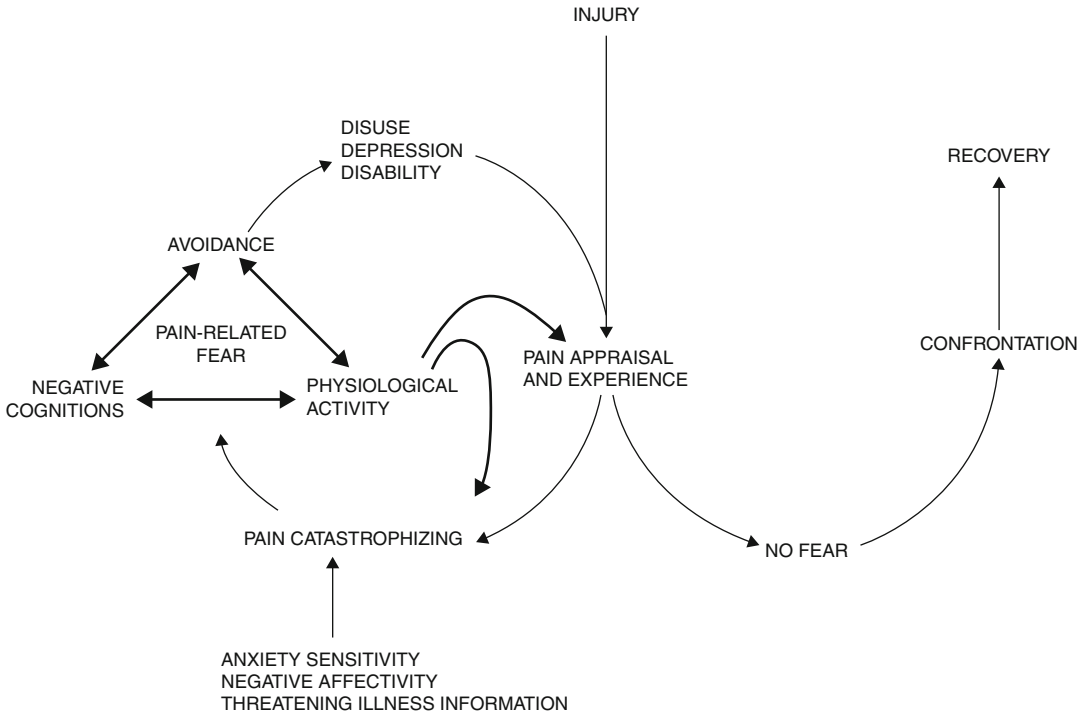
Fear-Avoidance Models posit that following the onset of pain (from injury or disease process), individuals appraise and evaluate their experience (see Fig. 1 Norton & Asmundson, 2003). For those who perceive their pain in a realistic manner, they do not experience excessive fear of pain, are able to engage in activities following a reasonable healing period, and subsequently recover from their experience. However, for others, a more complicated course of recovery ensues triggering a variety of cognitive, physiological, and behavioral symptoms. For those that progress to develop persistent pain (either recurrent intermittent pain or unremitting pain), they interpret their pain to be catastrophic in nature (e.g., "This pain is so excruciating I cannot function"). This overinterpretation triggers a state of autonomic arousal and pain-related fear. This fear is accompanied by a variety of somatic symptoms and negative cognitions about pain that motivates are variety of escape-avoidance behaviors (e.g., prolonged periods of rest, avoidance of physical activity). Over time, the anticipation of experiencing pain in the future motivates continued avoidance of activity, which in turn, leads to loss of physical strength, physical deconditioning, and muscle atrophy. These consequences result in increases in pain intensity, which continues to fuel this fear-avoidance cycle. Several individual difference variables have been identified that seem to place individuals at risk for developing persistent pain and include negative affectivity (i.e., trait experiences of negative emotions) and anxiety sensitivity (i.e., the propensity to experience fear of somatic sensations). Individuals that experience higher levels of these traits have been shown to be at greater risk for developing persistent pain conditions.

Intrapersonal Factors in Persistent Pain

Regardless of the nature of the pain experience (i.e., headache pain; orofacial pain), psychosocial factors have been shown to moderate pain intensity and progression. Specifically, depression, anxiety disorders (e.g., post-traumatic stress disorder, panic disorder, generalized anxiety disorder), substance use disorders, and somatoform pain disorders commonly co-occur with persistent pain conditions and are significantly higher than rates found in the general population. Furthermore, personality disorders also appear to occur more frequently among patients with persistent pain than among the general population; however, precise estimates in the general population are not available. These psychiatric phenomenon may share similar underlying processes to pain (that may account for their co-occurrence), are associated with more negative perceptions of pain, and influence individual's behavioral responses (e.g., are associated with greater pain-related avoidance). It has also been shown that heightened emotional reactivity, particularly when coupled with concurrent psychosocial stressors, further exacerbates negative perceptions of pain and predisposes individuals to pain-related disability. Furthermore, active coping skills (e.g., continuing to engage in activities, distraction from pain) are associated with lower pain intensity and minimize the risk of pain persistence. In contrast, passive coping skills (e.g., pain-related avoidance behavior, reliance on others) are associated with higher pain intensity and increase the risk of pain persistence.

Interpersonal Factors in Persistent Pain

Beyond the individual, several interpersonal factors are associated with pain severity, persistence, and pain-related disability. Within the context of intimate relationships, displays of pain-related behavior solicit responses from others that become reinforced over time and may perpetuate negative outcomes. For instance, an individual with persistent low back pain may display grimacing and guarding behaviors in response to pain experienced while attempting to dress them self. However, their partner may respond by providing physical assistance to help this



Pain, Psychosocial Aspects, Fig. 1 Amended fear-avoidance model of chronic pain (Copyright (2011) by the Association for Behavioral and Cognitive Therapies. Reprinted by permission of the publisher)

individual put on their clothes. Although this physical assistance helps to minimize the pain experienced, and facilitates the timely completion of this task, it reinforces the need for assistance contributing to more significant pain-related disability. Over time, such pain-related behaviors become negatively reinforced (since the assistance provided minimizes the experience of pain), which increases the likelihood of similar future behavioral responses. Furthermore, the need for assistance may undermine an individual's self-efficacy (i.e., their confidence in their ability to manage pain) and contribute to greater pain intensity, more frequent pain-related behavior, physical inactivity, and pain-related disability.

Psychosocial Factors and Treatment Response

Following the progression from acute to persistent pain, psychosocial factors have also been shown to influence responses to a variety of treatments. Across different categorical subtypes (i.e., low back pain; headache pain), the presence of axis I pathology (e.g., depression, anxiety, somatization) is associated with lower response to treatment (i.e., greater frequency and intensity of pain reports, greater perceived functional impairment), and may interfere with individual's ability to engage in the treatment process (e.g., depression interferes with treatment attendance and adherence to interventions). Furthermore, it has been shown that the continued use of maladaptive coping skills (i.e., pain-related avoidance behaviors), positive attitudes and expectations about pain and disability (i.e., pain facilitates the maintenance of supportive relationships; pain prevents the return to unsatisfactory employment), and unresolved worker's compensation/personal injury cases are further associated with lower treatment response. Therefore, a comprehensive assessment of these psychosocial factors is imperative at the outset of any pain-related intervention. This can be accomplished by obtaining a detailed medical and

psychosocial history, conducting semi-structured clinical and diagnostic interviews with both patients and their caregivers, the administration of self-report instruments, and consultation with current and past health-care providers.

Considered together, persistent pain conditions arise from a complex interaction of biological, psychological, social, and environmental factors. Understanding these relationships will help to identify factors that maintain and reinforce persistent pain across time and will provide insight into the development of effective pain management interventions.

Pain-Related Fear

Michael James Coons
Department of Preventive Medicine, Feinberg School of Medicine, Northwestern University, Chicago, IL, USA

Synonyms

Pain anxiety; Pain, psychosocial aspects

Definition

It is an affective manifestation of the fight-or-flight system in response to pain perception. The sympathetic nervous system becomes activated by the amygdala, resulting in cognitive, physiological, and behavioral symptoms. Following pain perception subsequent to injury or pain-inducing stimuli, pain is interpreted catastrophically by inferring more harmful or

life-threatening outcomes to its underlying cause. For instance, when an individual experiences acute pain after rolling over on their ankle, they might infer that the pain is caused by a broken bone, rather than by a sprain. This negative cognitive bias is predisposed by trait-like factors including anxiety sensitivity (i.e., fear of interoceptive experiences) and negative affectivity (i.e., the propensity toward experiencing negative emotions). This cognitive process prompts hypervigilance toward interoceptive cues (e.g., pain or muscle tension consequent to their injury) and illness information in the internal of external environment (continued or exacerbated pain). This motivates a constellation of defensive behaviors (e.g., guarding, rest) that are intended to provide relief or escape from the pain-inducing state. Fear-avoidance models of pain, and the empirical evidence supporting such models, suggest that pain-related fear is a predisposing factor to the development of persistent pain conditions.

Assessment of Pain-Related Fear

The most common mode of assessment of pain-related fear involves the administration of well-validated self-report instruments. Several published scales are available including the Fear of Pain Questionnaire-III (FPQ-III) and the Fear-Avoidance Beliefs Questionnaire (FABQ). These measures assess the nature and extent of pain-related fear by asking individuals to rate how much they fear the pain associated with a variety of situations (e.g., "having someone slam a heavy car door on your hand," "biting your tongue while eating") or the nature and extent of a variety of pain-related beliefs (e.g., "Physical activity might harm my back," "I should not do physical activities that (might) make my pain worse"). Alternative modes of assessing pain-related fear include semi-structured clinical interviews and the direct observation of patient behavior.

Treatment of Pain-Related Fear

Cognitive behavior therapy (CBT) is a mainstay in the treatment of pain-related fear. Treatment components include psychoeducation, and introduction, demonstration, and practice of a variety of adaptive coping skills (i.e., progressive muscle relaxation, diaphragmatic breathing, mental imagery, behavioral activation and pleasant activity scheduling, activity-rest cycling, physical therapy/exercise, problem-solving, cognitive restructuring, and calming self-statements). In treating pain-related fear, special emphasis is placed on graded in vivo exposure with behavioral experiments. These latter components allow individuals to construct situations in which they collect information to test and challenge their distorted pain-related cognitions.

Hospices; Palliative medicine; Supportive care; Terminal care

Definition

The World Health Organization (WHO) defines palliative care as "an approach that improves the quality of life of patients and their families facing the problems associated with life-threatening illness, through the prevention and relief of suffering by means of early identification and impeccable assessment and treatment of pain and other problems, physical, psychological and spiritual" (World Health Organization, 2002).

Description

The goal of palliative care is to achieve the best possible quality of life for both the patients and their families.

Palliative care:

- Is a multidisciplinary task and uses a team approach by physicians, nurses, psychologists, social workers, and other health professionals to address the needs of patients and their families
- Offers a support system to help patients and their families in the community
- Is applicable at any age and at any stage in the course of illness, in conjunction with other therapies such as chemotherapy or radiation therapy which may prolong life
- Provides relief from distressing symptoms such as pain, shortness of breath, depression, drowsiness, and nausea
- Alleviates the adverse side effects, such as relieving the nausea related to chemotherapy
- Influences positively in the course of illness (Temel et al., 2010)

Dying is a normal event; however, many people feel uncomfortable discussing their own death as well as the death of someone close. A book "Hagakure," written by a samurai warrior, who was keenly aware of the events of the day, teaches us how to cope with spiritual pain within the framework of our own insight. "There is something to be learned from a rainstorm. When meeting with a sudden shower, you try not to wet and run quickly along the road. But doing such things as passing under the eaves of houses, you still get wet. When you are resolved from the beginning, you will not be perplexed, though you still get the same soaking. This understanding extends to everything" (Yamamoto, 2005).

Perception of physical, psychological, and spiritual pain may differ in various countries with different cultures and religions; nonetheless, we all aim for the same goal in palliative care.

Panic Attack

Michael James Coons
Department of Preventive Medicine, Feinberg School of Medicine, Northwestern University, Chicago, IL, USA

Synonyms

Panic disorder

Definition

Panic attacks are a state of sympathetic nervous system arousal that results in a discrete episode of intense fear or discomfort in the absence of objective danger. This fear is accompanied by a host of somatic and cognitive symptoms. Symptoms include tachycardia (i.e., racing heart), sweating, palpitations, trembling, dyspnea (i.e., shortness of breath), feelings of being smothered or feelings of choking, nausea, chest pain, abdominal distress, dizziness, light headedness, derealization or depersonalization, numbness or tingling in the face or extremities, chills or hot flushes, fear of "going crazy," fear of losing control, or fear of death from such an episode. Individuals must report experiencing at least 4 of the 13 possible somatic and cognitive symptoms. These aforementioned symptoms typically peak in intensity over a short period of time (i.e., 10 min or less). If individuals report experiencing excessive fear but manifest fewer than four symptoms, it is considered to be a limited-symptom panic attack. Panic attacks are classified into three main subtypes: cued panic attacks (i.e., panic attacks can occur in response to a specific situation or event), uncued panic attacks (i.e., panic attacks that occur "out of the blue" in the absence of a discernable trigger), or situationally predisposed panic attacks (i.e., panic attacks that occur immediately on exposure to or in anticipation of a specific situational cue or trigger). The experience of at least two *uncued* panic attacks is a prerequisite for the diagnosis of panic disorder. However, panic attacks can occur in the context of any other anxiety disorder (e.g., generalized anxiety disorder, social anxiety disorder) when cued by situational events or triggers (e.g., in response to excessive worry; during a social interaction). The possible consequences of such episodes make panic attacks of interest to behavioral medicine.

Panic Disorder

Michael James Coons
Department of Preventive Medicine, Feinberg School of Medicine, Northwestern University, Chicago, IL, USA

Synonyms

Panic attack

Definition

According to the Diagnostic and Statistical Manual for Mental Disorders, Fourth Edition (DSM-IV-TR), panic disorder (PD) is an anxiety disorder that is defined by the experience of recurrent (two or more) uncured panic attacks. Following these attacks and for a period of at least 1 month, individuals must report experiencing concern about either having additional attacks, concern about the potential implications of having panic attacks (e.g., death), or significantly change their behavior because of the experience of panic attacks (e.g., avoidance of certain situations). In this context, panic attacks cannot occur in response to the physiological effects of a substance (e.g., caffeine, marijuana), cannot be due to a general medical condition, and cannot be better accounted for by another mental disorder

(e.g., generalized anxiety disorder). PD can occur in isolation, or in the presence of agoraphobia (i.e., anxiety about particular places or situations in which individuals fear experiencing a panic attack). According to the DSM-IV-TR, PD occurs in approximately 1–2% of the general population. The onset of PD typically occurs between late adolescence and mid-30s. Researchers have shown that anxiety sensitivity (i.e., an individual difference variable involving the fear of anxiety-related somatic symptoms) is a robust predictor of the development of PD. However, PD (with or without agoraphobia) is diagnosed more commonly among women than among men.

Cognitive Behavioral Models

Theoretical models of PD suggest that among individuals who are predisposed to being fearful of somatic cues (i.e., having high levels of anxiety sensitivity), they catastrophically misinterpret physiological sensations when they occur (e.g., "my heart is racing, I *must* be having a heart attack"). Such distorted cognitions motivate a series of maladaptive behaviors (e.g., escaping the current situation to prevent the catastrophic outcome, avoiding situations because of the fear of experiencing a future panic attack, not leaving the house alone in the event of a panic attack). Over time and across situations, these escape-, avoidance-, and safety-seeking behaviors become negatively reinforced, resulting in a reliance on engaging in these behaviors to either prevent a panic attack from occurring, or in minimizing the potential (perceived) negative and catastrophic outcome(s). Together, these maladaptive cognitions and behaviors contribute to greater sympathetic arousal that results in a host of somatic symptoms (e.g., racing heart, dyspnea, nausea, shaking/trembling), which perpetuates the cycle of panic.

Assessment

Prior to commencing any pharmacological or psychological intervention, it is essential to establish a differential diagnosis to determine if PD is the most appropriate diagnosis. This can be accomplished through the administration of structured clinical interviews, the completion of various self-report instruments, and if necessary, a thorough medical evaluation. The Structured Clinical Interview for DSM-IV (SCID-IV) and the Anxiety Disorders Interview Schedule IV (ADIS-IV) are the two "gold standard" clinical interviews for the anxiety disorders. These interviews are modeled after diagnostic criteria from the DSM-IV and assess the presence of all anxiety disorders, along with a variety of potentially comorbid axis I conditions (e.g., mood disorders, substance use disorders, somatoform disorders, psychotic disorders, and adjustment disorders). In conjunction with structured clinical interviews, a variety of well-validated self-report instruments are available to assess the nature, extent, and risk for PD symptoms. These include the Anxiety Sensitivity Index, Revised (ASI-R), the Panic Disorder Severity Scale (PDSS), and the Agoraphobic Cognitions Questionnaire (ACQ). If there is potential for a patient's panic symptoms to be caused by an underlying medical condition (e.g., atrial fibrillation), a thorough medical evaluation is required before a diagnosis of PD can be established.

Treatment of PD

Efficacious treatments for PD include both pharmacological and psychological interventions. Both selective serotonin reuptake inhibitors (SSRIs) and benzodiazepines are used in the treatment of PD. However, it is recommended that benzodiazepines be prescribed using a scheduled dose, as opposed to an "as needed" basis (i.e., PRN). This helps to minimize the risk of the benzodiazepine use becoming a maladaptive safety behavior that may exacerbate PD-related cognitive distortions. Cognitive behavior therapy (CBT) remains as the front-line psychological intervention for PD. Treatment components include psychoeducation (around the fight-or-flight system, CBT model of panic), identification and restructuring of cognitive distortions, and graded exposure (cognitive, in vivo, and interoceptive). Recent technological advancements permit the augmentation of exposure-based interventions with virtual reality equipment.

Parallel Group Design

J. Rick Turner
Cardiovascular Safety, Quintiles, Durham, NC, USA

Synonyms

Independent treatments group design

Definition

A parallel group design is an experimental study design in which each subject is randomized to one of two or more distinct treatment/intervention groups. Those who are assigned to the same treatment are referred to as a treatment group.

While the treatments that these groups receive differ, all groups are treated as equally as possible in all other regards, and they complete the same procedures during the study. This parallel activity on the part of the groups of individuals is captured in the term "parallel group design."

The term controlled study is often heard in this context. One group will receive the treatment of interest and another group a control treatment, against which responses during and at the end of the treatment intervention are compared. Going one step further, the term concurrently controlled study makes clear that the different groups take part in their respective treatment arms at the same time. If all of the subjects in one treatment group completed their participation first, and then all of the other subjects completed their participation at some later time, it is quite possible that other factors could confound the results.

Parasympathetic Nervous System (PNS)

Michael Richter[1] and Rex A. Wright[2]
[1]Department of Psychology, University of Geneva, Geneva, Switzerland
[2]College of Arts and Sciences, Department of Psychology, University of North Texas, Denton, TX, USA

Definition

The parasympathetic nervous system (PNS) is one of two main branches or subsystems of the autonomic nervous system (ANS). It originates in

the brain stem and sacral spinal cord and commonly – but not always – yields peripheral adjustments that are complementary to those produced by its counterpart, the sympathetic nervous system (SNS).

Description

The parasympathetic nervous system is one of two main branches or subsystems of the autonomic nervous system, the physical system responsible for nonconsciously maintaining bodily homeostasis and coordinating bodily responses. Working with the second main branch, the sympathetic nervous system, the parasympathetic nervous system regulates a wide range of functions such as blood circulation, body temperature, respiration, and digestion. Parasympathetic activation commonly leads to adjustments on organs and glands that are complementary to those produced by sympathetic activation and suitable for low activity and bodily restoration ("rest and digest" as opposed to "fight and flight"). Examples of low activity and restorative adjustments are constriction of blood vessels in the lungs, increased gastric secretion, and decreased heart rate and contraction force. Although parasympathetic adjustments tend to complement sympathetic adjustments, they do not always. For example, both parasympathetic nervous system arousal and sympathetic nervous system arousal increase salivary flow, although to different degrees and yielding different compositions of saliva.

Basic functional units of the parasympathetic nervous system are preganglionic and postganglionic neurons. Preganglionic neurons have cell bodies in the brainstem or sacral spinal cord and axons that extend to cell bodies of postganglionic neurons. Postganglionic neurons have cell bodies that are clustered in so-called ganglia and relatively short axons that innervate target organs and glands.

The major neurotransmitter of the parasympathetic nervous system is acetylcholine. It is the neurotransmitter of all preganglionic and postganglionic neurons. Stimulation of the cholinergic receptors of the nicotinergic subtype located on the cell bodies of the postganglionic neurons by acetylcholine leads to an opening of nonspecific ion channels. This opening permits the transfer of potassium and sodium ions, which depolarizes the postganglionic cell and initiates an action potential in the postganglionic cells. Muscarinic cholinergic receptors are located on target organs and glands. Stimulation of muscarinic receptors by acetylcholine activates G-proteins, which trigger the effector response via a second-messenger pathway. Specific effects depend on the innervated visceral structure. For instance, activation of the muscarinic receptors of the heart muscle leads to reduced heart rate and heart contraction force. Stimulation of muscarinic receptors of the salivary glands increases salivary flow.

In working jointly with the sympathetic nervous system, the parasympathetic nervous system does not function in an all-or-none fashion, but rather activates to different degrees. Depending on the affected visceral structure and situation, it may be more or less active than the sympathetic nervous system. Shifts in the magnitude of sympathetic and parasympathetic influence can occur locally within a single visceral structure (e.g., the eye) or across visceral structures, with local shifts occurring to meet highly specialized demands (e.g., a change in ambient light) and global shifts adapting the body to large-scale environmental changes (e.g., the appearance of a substantial physical threat). Autonomic control is maintained by structures in the central nervous system that receive visceral information from an afferent (incoming) nervous system. A key central nervous system structure is the hypothalamus, which integrates autonomic, somatic, and endocrine responses that accompany different organism states.

Degenerative parkinsonism; Parkinsonism; Parkinson's disease; PD; Secondary parkinsonism

Definition

Parkinson's disease (PD) is the second most common neurodegenerative disorder and is characterized by motoric symptoms of resting tremor, rigidity, bradykinesia, and gait disturbance. The psychosocial aspects of PD involve the interaction of PD symptomatology, psychological development and function, personal relationships, and environmental factors.

Description

Parkinson's disease (PD) is a common neurodegenerative disorder that affects approximately between 500,000 and a million Americans of all races and ethnic groups, and 0.3% (5 million) of the world's population. Pathologically, PD is an inexorably progressive disorder of unknown cause in which neurons of the substantia nigra progressively degenerate resulting in greater degrees of brain dopamine deficiency. In addition, a number of other neuronal pathways degenerate including cholinergic, noradrenergic, and serotonergic pathways. Primary motor manifestations of PD include resting tremor, bradykinesia (e.g., slowed motor ability), rigidity, and gait disturbance. Important clinical features to establish the diagnosis of PD include

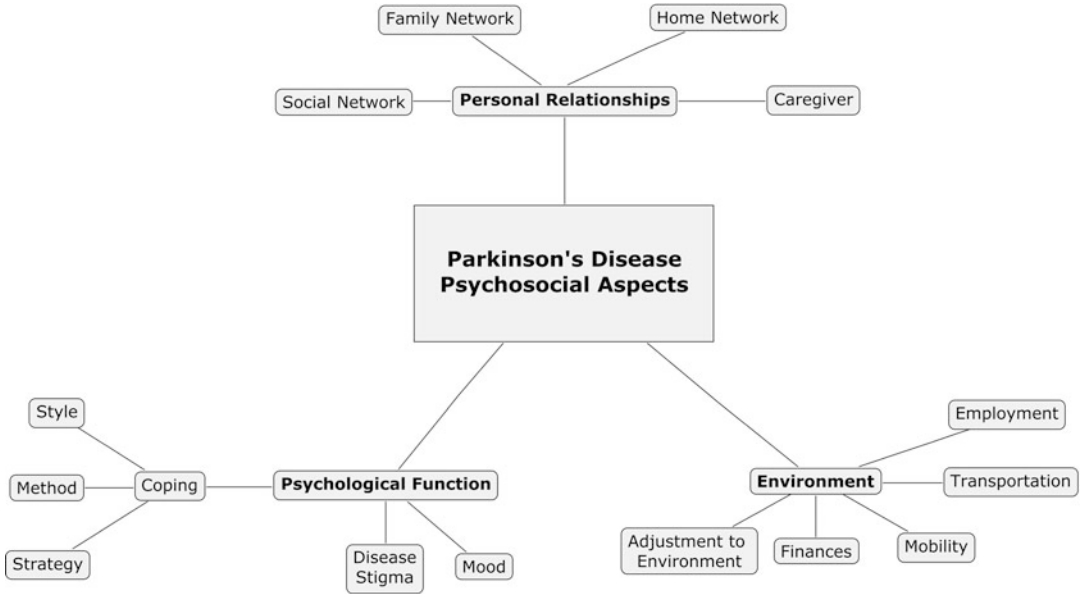
asymmetric symptom onset and responsiveness to levodopa, a commonly used medication to treat PD symptoms. Due to a combination of endogenous and exogenous factors, a significant proportion of patients with PD also suffer from comorbid medical and psychiatric illnesses. This can include pain, insomnia, autonomic dysfunction, as well as sensory and cognitive difficulties.

There has been a primary use of a biomedical approach to inform PD that has focused on the physical, neurological, and medical PD symptoms. A biopsychosocial approach may inform other domains, particularly psychosocial function. Psychosocial aspects of PD revolve around three broad domains including (1) personal relationships, (2) psychological function, and (3) environmental factors (see Fig. 1). These domains are all impacted by the progression and severity of PD symptomatology and age. As patients progress through different disease stages, psychosocial aspects will be relatively affected. There are approximately five stages of PD. In stage 1, the PD symptoms are minimal and may have some impact on activities of daily living, though by stage 2, the PD symptoms are more noticeable and begin to interfere with routine physical tasks. At stage 3, the PD symptoms may be more severe and impede most physical activities. At stages 4 and 5, the PD symptoms may be of such severity that the person is unable to live independently. Thus, greater PD disease severity is associated with greater adverse impact on psychosocial functions. For instance, late-stage PD decreases mobility and communication, thus limiting patients' ability to care for themselves and resulting in greater reliance upon others for activities of daily living. Decreased processing speed, medical problems, and other normal effects of aging exacerbated by PD factors limit self-care behaviors, which further impact psychosocial functioning.

Personal relationships are a tremendous resource for patients with PD. These relationships include many integrated networks of family and friends, and most importantly, caregivers. The size and quality of the social network as well as the subjective viewpoint of the patient all determine a social network's ability to assist patients with PD. A larger and higher quality network may be able to provide more resources than one that is small and of poor quality. The network's quality can be determined by its ability to provide resources for the PD patient in terms of physical and emotional support. Adequate relationship networks are essential to patient well-being, and patients should be encouraged to engage in activities that foster and enhance supportive relational networks. Importantly, should a professional caregiver be unavailable, family and friends may serve dual roles as caregivers, which can complicate the interpersonal relationship. The role of the caregiver may be minimal at the early stages of PD, but increases proportionately to the disease stage, as does stress and strain. Thus, it is important for caregivers to practice healthy stress management techniques.

The psychological functions domain includes mood and affect, personal view of self, and coping. There is a complex interaction between PD and psychological functions. For example, intact psychological functions before the onset of PD can help mitigate the onset of psychiatric illnesses such as depression and decreased self-worth. On the other hand, PD has been associated with an increase in depression and decrease quality of life. Regarding personal perception, patients may be burdened by disease stigma and see themselves as impaired, incapable to care for themselves, and less worthy than others. These negative personal perceptions can be changed with therapeutic management, which can then have positive impacts on overall health. Coping functions can be subdivided into coping style (active, passive), coping method (problem-solving, emotional focused), and coping strategies (cognitive, behavioral, cognitive-behavioral). Adaptive coping functions can help minimize the impact of PD symptoms, decrease poor health burden, and increase psychosocial function. Patients and caregivers should work together when implementing coping strategies in order to ensure that they are in sync and achieve maximal benefit.

The environmental domain includes areas that involve patients with PD to interact with others. This includes such areas as finances, employment and occupational performance, and



Parkinson's Disease: Psychosocial Aspects, Fig. 1 Figure 1 shows three global domains of psychosocial aspects relevant to persons with Parkinson's disease (PD) including psychological function, personal relationships, and the environment. These three domains, independently or collectively, may be impacted by the progression and severity of PD symptomatology

transportation and mobility. Physical PD symptoms (e.g., tremor, postural instability) can affect safety as well as employment and occupational performance. Patients may be unable to perform certain job duties due to PD symptoms or may be embarrassed by some symptoms such as tremors. This can impede work performance for those who are employed or limit others from seeking employment. Mobility and transportation difficulties can decrease self-reliance and increase dependency on others, which can then impact psychological functions. The adverse impact on environmental factors is related to the age of PD onset. Early PD onset tends to have a more marked adverse impact on multiple domains including employment, marital status, and quality of life. Some patients may view early PD onset as premature aging, with profound negative psychosocial consequences.

Parkinson's disease impacts not only motoric function but also psychosocial function. Given its progressive, degenerative nature, it can negatively affect psychosocial domains of personal relationships, psychological function, and environmental factors. These domains are interrelated and are further associated with PD disease severity, age, and age of illness onset. A biopsychosocial approach to therapeutic management will help to inform these domains.

Synonyms

Community-based participatory research

Definition

Participatory research is an approach to research that emphasizes equitable involvement and shared decision making of community members, organizational representatives, and researchers in all aspects of the research process, ranging from the choice of research question through the interpretation, dissemination, and application of results (Israel, Eng, Schulz, & Parker, 2005). While there has been longstanding recognition that meaningful, ongoing collaboration between communities and researchers is essential to the design and conduct of research that will ethically address community concerns and translate research findings into sustainable public health gains, there has been a resurgence of interest in the participatory approach to health research due to the confluence of two trends. First, researchers have faced the disconcerting fact that many promising findings published in the academic literature are never translated into behavior change by the target populations and therefore do not result in health improvement. Second, potential participants have grown tired of being viewed as the "subjects" of research, and some feel that there has been little benefit to their communities in return for their participation even while they recognize the need for information-gathering. This convergence has led to a restriking of the power balance between the observers and the observed, and the promotion of participatory research.

Passive Coping Strategies

Linda Carroll
Department of Public Health Sciences, University of Alberta, Edmonton, AB, Canada

Synonyms

Avoidance; Helplessness

Definition

Coping is the set of intentional, goal-directed efforts people engage in to minimize the physical, psychological, or social harm of an event or situation (Lazarus & Folkman, 1984; Lazarus, 1999). There are many different theoretical and empirical frameworks for understanding coping and many different ways of classifying coping strategies, but one such classification is "passive coping." Passive coping refers to feeling of helplessness to deal with the stressor and relying on others to resolve the stressful event or situation (Zeidner & Endler, 1996). Those engaging in passive coping relinquish to others the control of the stressful situation and of their reaction to that situation, or allow other areas of their lives to be adversely affected by the stressful event or situation (Field, McCabe, & Schneiderman, 1985). This reliance on external resources is contrasted with "active coping," in which the individual is relying upon their own resources to cope with the stressor. Passive coping is associated with depression and poor psychological adjustment, as well as a poor outcome.

Passive coping generally involves avoidance, withdrawal, and wishful thinking. Examples of passive coping strategies are such cognitions as "it's awful and I feel that it overwhelms me," "I pray to God it won't last long," and "I know someday someone will be here to help me and it will go away for awhile." Behavioral examples of passive coping strategies include talking (complaining) to others about the situation either to ventilate feelings, get sympathy or elicit their help, withdrawing from social and other activities, or relying on medication to cope with the situation. Catastrophization (e.g., thinking "it's terrible and I think it's never going to get better") is sometimes considered a passive coping strategy.

Pathophysiology

Michael Witthöft
Psychologisches Institut Abteilung Klinische Psychologie und Psychotherapie, Johannes Gutenberg Universität Mainz, Mainz, Germany

Definition

Pathophysiology (consisting of the Greek origin words "pathos" = suffering; "physis" = nature, origin; and "logos" = "the study of") refers to the study of abnormal changes in body functions that are the causes, consequences, or concomitants of disease processes. Studies of pathophysiology are concerned with the investigation of *biological* processes that are directly related to disease processes of physical, mental, or psychophysiological conditions and disorders (e.g., alterations in the endocrine system, in certain neurotransmitters, or inflammatory parameters related to the activity of the immune system). Thus, pathophysiological research aims at identifying biological markers and mechanisms for predicting and explaining disease processes in terms of *etiology* and *pathogenesis*. Pathophysiology is formally considered as a subdiscipline within physiology.

Description

The fundamental aim of the domain of pathophysiology is to unravel the altered biological (i.e., physical and chemical) processes in our organism that precede, accompany, or follow certain disorders or diseases. In this regard, pathophysiological research aims at identifying factors and mechanisms that are relevant for answering questions of *why* and *how* certain disorders and diseases develop (i.e., questions about *etiology* and *pathogenesis*). Pathophysiological mechanisms of mental, physical, and psychophysiological disorders are rather complex. Yet, many pathophysiological findings and models are incomplete, preliminary, and speculative. However, research into the biological mechanisms of conditions in behavioral medicine is growing rapidly.

Methods and Designs in Pathophysiology Research

Since *pathophysiology* is mainly concerned with indentifying objective, biological factors that are relevant for certain disease processes, *quantitative methods* and *experimental* research designs are typically used. Current examples of research methods used in *pathophysiological* research in behavioral medicine are brain imaging techniques (i.e., (functional) magnetic resonance or positron emission tomography) to explore altered patterns of brain morphology and neural activity associated with certain disorders. Another example of pathophysiological research represents studies that aim at quantifying the amount of stress hormones (e.g., corticosteroids) in the blood and saliva (either in a resting state or after acute stress induction). In addition, *electroencephalography* and *electrocardiography* are typical diagnostic tools in pathophysiology research. In addition to studies with human patients and control participants, animal models (e.g., mouse and rat models) are also routinely used to test predictions of *pathophysiological* hypotheses relevant for our understanding of complex medical, psychological, and psychophysiological conditions in humans (e.g., stroke, schizophrenia).

Examples of Pathophysiological Research

As examples of *pathophysiological* investigations and findings relevant to the field or *behavioral medicine*, three examples from the realm of *obesity*, *chronic pain*, and *stress-related disorders* will be outlined briefly.

Pathophysiology of Obesity: The Metabolic Syndrome

Obesity is associated with an increased risk to develop numerous chronic and life-threatening diseases (e.g., cardiovascular diseases, type-2 diabetes, stroke). Several *pathophysiological* factors have been identified that frequently co-occur with obesity and that are suspected to mediate between *obesity* and severe medical diseases. In this regard, the following physiological

abnormalities have been identified and termed "the metabolic syndrome" (Cornier et al., 2008): abdominal obesity, insulin resistance, dyslipidemia (i.e., abnormal amount of lipids in the blood), and hypertension. Among these four defining features, abdominal obesity and insulin resistance appear as the core factors in the *pathophysiology* of the *metabolic syndrome*. The *etiology* of the *metabolic syndrome* has to be considered as complex and multifactorial and is still widely unknown. As interventions aiming at treating and preventing the *metabolic syndrome*, lifestyle modifications and weight loss (e.g., via increased physical activity) are recommended.

Pathophysiology of Chronic Pain

Pain is considered as a highly adaptive sensation that effectively signals dangers in terms of threats to our body integrity and helps to avoid injuries. *Pain* is the result of a complex interplay between neurobiological and psychological processes, both in the peripheral and central nervous system. Although acute *pain* is highly adaptive, *chronic pain* typically lacks this adaptive purpose. Regarding chronic pain conditions, the mechanism of "central sensitization" (Woolf, 2011) has been proposed to account for the phenomenon of ongoing pain in the absence of sufficient "objective" *nociceptive* stimulation. Accordingly, changes in the excitability of spinal cord neurons are responsible for reductions in pain thresholds, and prolonged neuronal responses to certain stimuli explain why stimuli that are generally considered as non-noxious and non-painful become pain-eliciting stimuli in patients with *chronic pain*. The concept of *central sensitization* rests on the principle of *neural plasticity* of the nociceptive system and a cascade of molecular and biochemical processes has been observed to be involved in *central sensitization* (e.g., Latremoliere & Woolf, 2009).

Pathophysiology of Stress Related Disorders

Ongoing and severe stress represents a threat to one's mental and physical well-being. Regarding the *pathophysiology* of the stress response, a chronic state of uncontrollable, stressful life circumstances has been linked to alterations in the function of the hormonal stress system. Qualitatively different alterations are thereby observed in certain mental and psychophysiological disorders: In the *pathophysiology* of depressive disorders, the hormonal stress system (in terms o the *hypothalamic-pituitary-adrenocortical* system; *HPA*) has been observed to be hyperactive which is reflected in increased *cortisol* secretion of the adrenal glands (e.g., Müller & Holsboer, 2004). This *hypercortisolism* is the direct consequence of increased secretion of the corticotrophin releasing hormone (CRH) (from the paraventricular nucleus of the hypothalamus) and the release of the adrenocorticotropic hormone (ACTH) via stimulation of the anterior pituitary gland (Ehlert, Gaab, & Heinrichs, 2001). The *hypercortisolism* observed in depression is most likely attributable to dysfunctions in HPA-axis feedback mechanisms that are responsible for the downregulation of the cortisol release (via CRH and ACTH). It has to be acknowledged that the phenomenon of *hypercortisolism* only occurs in certain subtypes of depression (e.g., melancholic depression).

Interestingly, the opposite phenomenon of a reduced activity of the *HPA* system resulting in a state of *hypocortisolism* is observed in patients with atypical depression, and patients with complex stress-related disorders. Regarding the latter group of disorders, reduced levels of cortisol indicative of lower HPA-axis reactivity have been observed in patients with *posttraumatic stress disorder*, *chronic fatigue syndrome*, *chronic pain disorders*, *fibromyalgia*, *irritable bowel syndrome* and other *functional somatic syndromes* and *somatoform disorders*. Childhood traumas have also been linked to *hypocortisolism* as evidence for early life stress-induced dysregulation of the *HPA* axis (Heim et al., 2009). Moreover, *hypocortisolism* was detected in people with rheumatoid arthritis and asthma.

Patient Control

Yori Gidron
Faculty of Medicine and Pharmacy, Free University of Brussels (VUB), Jette, Belgium

Definition

This is a central issue in behavior medicine, since it relates to models of stress, to patient behaviors and outcomes, and has vast clinical implications. Patient control (PC) can reflect both subjective or perceived control, as well as objective control. The perceived control can be understood as one's subjective appraisal of the ability to influence outcomes in a situation. Perceived control reflects a secondary appraisal process in general stress models (Lazarus & Folkman, 1984; Taylor, 1995). In contrast, objective control reflects the externally determined and externally validated level of control over a situation. Thus, objective PC is accurate, while subjective PC refers to subjective levels of control, and thus, could also be inaccurate. Subjective PC is a crucial predictor of health behaviors in the theory of planned behavior, showing a relation to behavior either directly or via intentions. For example, subjective PC has been shown to be important in choice over food types (Lawrence & Barker, 2009), of relevance to overweight. Subjective PC is strongly related to the broader concept of self-efficacy, the belief that one can carry out a certain behavior despite the existence of barriers. Subjective PC could be affected by objective control, but also by past experiences with similar or different stressful situations. Overgeneralizing lack of control from an uncontrollable to a controllable situation reflects the core of "learned helplessness," which has vast implications for multiple outcomes including depression (Abramson et al., 1989) and possibly even acceleration of tumors (Palermo-Neto, de Oliveira Massoco, & Robespierre de Souza, 2003). In pain patients, subjective PC is positively correlated with engagement in activity, of clinical relevance to daily functioning (Chiros & O'Brien, 2011). Subjective PC can

also be an important moderating variable in the detrimental effect of various factors on health or well-being. For example, Tovbin, Jean, Schnieder, Granovsky, and Gidron (2003) found that low albumin was related to poorer quality of life in dialysis patients, but only in those with low, but not high, subjective control. Objective PC is important in "patient-controlled analgesia" (PCA), where patients control the amount and timing of receiving analgesics during treatment for pain. A meta-analysis of 55 studies found that PCA led to less pain and greater patient satisfaction than did conventional analgesic regiments given by a health professional (Hudcova, McNicol, Quah, Lau, & Carr, 2006). Importantly, the subjective and objective aspects of PC are interrelated: In patients receiving PCA, those with an external locus of control had more pain and less satisfaction with this treatment, while an internal locus of control (which also reflects greater perceived control) was predictive of lower pain and greater satisfaction from PCA (Johnson, Magnani, Chan, & Ferrante 1989). Taken together, PC is an important predictor of patient outcomes, and can be a moderator of the effects of other factors on health outcomes. It is thus of great importance to assess and consider PC in behavior medicine research and clinical practice.

Patient-Centered Care

Cassie Cunningham
College of Public Health, University of Iowa, Liberty, IA, USA

Definition

Patient-centered care is a term that is becoming widely used in medical practice. It is typically

described in the context of patient-practitioner communication. In contrast to provider-centered care, which places control and decision-making power almost solely in the hands of the health-care provider, is patient-centered. Patient-centered care promotes active participation on the part of the patient decisions regarding their health and health care. Moreover, patient-centered care requires practitioners to provide care concordant with the patient's values as well as account for the patient's desire for information provision and for shared decision-making responsibilities. Patient-centered care has been shown to be associated with increased patient satisfaction and adherence and may also enhance the relationship between the patient and the health-care provider.

Patient-Reported Outcome

Hiroe Kikuchi
Department of Psychosomatic Research, National Institute of Mental Health, National Center of Neurology and Psychiatry, Tokyo, Japan

Definition

Patient-reported outcomes (PROs) are responses to questions or statements about their perceptions or activities, such as symptoms, capabilities, or performance of roles or responsibilities (Revicki, Hays, Cella, & Sloan, 2008). These responses are typically measured by self-completed questionnaires and combined in some way to create summary scores that can be used to measure concepts such as physical, psychological, or social functioning and well-being, or symptom burden or severity. Symptoms can be rated based on frequency, severity, duration, degree of bother, or impact on patient activities. PROs are increasingly accompanying the traditional clinical ways of measuring health and the effects of treatment on the patient, both nationally and internationally, in order to make a more comprehensive evaluation. According to this context, The Patient-Reported Outcome Information System (PROMIS®) initiative, funded by National Institutes of Health (NIH), began in 2004 with six primary research sites and a statistical coordinating center in the USA. The aims of PROMIS® is to use measurement science to create a state-of-the-art assessment system for self-reported health and to provide clinicians and researchers access to a national resource for precise and efficient measurement of patient-reported symptoms, functioning, and health-related quality of life, appropriate for patients with a wide variety of chronic disease conditions (Cella et al., 2010). In 2010, a second round of PROMIS® funding was provided by the NIH, expanding the network to 13 researchers at 12 research sites. In addition, the US Food and Drug Administration (FDA) 2006 draft guidance on "Patient-Reported Outcome Measures: Use in Medical Product Development to Support Labeling Claims" has engendered wide discussion about PRO domains that should be endpoints in clinical trials (Cleeland, Sloan, & ASCPRO Organizing Group, 2010). In the guidance, reducing the severity and impact of symptoms is considered as a natural intervention endpoint for cancer, a condition associated with considerable symptom burden. Because symptoms are best described by patients who have them, PROs as measures of treatment effectiveness or the differences among treatments provide essential information about the efficacy and toxicity of a treatment and its effects on function. The FDA guidance provides a framework for addressing such issues as clinical significance, study design, and statistical methods. However, there are some problems to be solved. In the guidance, no set of recommended approaches for assessing specific symptoms by patient report in clinical trials exists, other than for pain. Recommendations

about the best approach for evaluating responsiveness and determining minimally important differences for PRO instruments are still needed (Revicki et al., 2008). With regard to PROMIS®, there is also criticism that PROMIS® appears to ignore the International Classification of Function (ICF) sponsored by the World Health Organization (WHO). ICF certainly does not represent the gold standard, but it is a system that, through the weight of WHO endorsement, will be used for a long time to come (Boers, 2010).

Pediatric Quality of Life Inventory (PedsQL)

Melissa A. Alderfer[1] and Meghan L. Marsac[2]
[1]Division of Oncology, The Children's Hospital of Philadelphia, Philadelphia, PA, USA
[2]The Center for Injury Prevention and Research, The Children's Hospital of Philadelphia, Philadelphia, PA, USA

Synonyms

PedsQL 4.0

Definition

The Pediatric Quality of Life Inventory or PedsQL™, now in its fourth version, is a series of assessment instruments designed to measure the health-related quality of life of children.

The authors of the measure conceptualize health-related quality of life as the physical, psychological, and social functioning of the child. The PedsQL 4.0 provides an opportunity for the assessment of both overall (generic) quality of life as well as disease-specific quality of life.

The PedsQL 4.0 Generic Core Scales are appropriate for assessing health-related quality of life in both healthy and chronically ill children. The four scales making up this generic battery include Physical Functioning (8 items), Emotional Functioning (5 items), Social Functioning (5 items), and School Functioning (5 items). From these four core scales, three standardized summary scores can be calculated: a Total Quality of Life Score, a Physical Health Summary Score (based on the physical functioning items), and a Psychosocial Health Summary Score (combining emotional, social, and school items). In addition to these generic core scales, condition-specific modules have been developed for children with arthritis, asthma, brain tumors, cancer, cardiac conditions, cerebral palsy, diabetes, end-stage renal disease, neuromuscular disorders, and rheumatological diseases.

On each of the PedsQL 4.0 scales, the respondent is asked to indicate how much of a problem each item has been in the past month with response options of: 0 = never; 1 = almost never; 2 = sometimes; 3 = often; and, 4 = almost always. Item scores are reverse coded, linearly converted to a 100-point scale, and averaged to form scale and summary scores with higher scores indicating better quality of life. Parent completed versions of the scales, reporting on their child's health-related quality of life, are available for toddlers (aged 2–4), young children (aged 5–7), children (aged 8–12), and adolescents (aged 13–18). Parallel, developmentally appropriate, child self-report versions of the scales are available for young children, children, and adolescents. Parent-report infant scales and self-report young-adult and adult scales are also available. The PedsQL 4.0 is available in many languages including Spanish, French, German, Italian, Hebrew, Portuguese, and Russian.

The psychometric properties of the PedsQL 4.0 are generally good. Adequate internal consistency has been demonstrated for the scales with most researchers reporting coefficient alphas greater than.70. As evidence of validity, scores on the scales have been shown to correlate with other measures of health-related quality of life and to functional indices of health such as the number of days the child was ill, the number of school days missed by the child, the number of work days missed by the parent, and objective measures of disease severity. The generic core scales have also been found to distinguish between children with chronic health conditions and those who are healthy.

Further information regarding the PedsQL™ 4.0 including access to the measures can be obtained at www.pedsql.org.

Penetrance

Rong Jiang
Department of Psychiatry and Behavioral Sciences, Duke University, Durham, NC, USA

Definition

Penetrance in genetics is the proportion of individuals carrying a particular gene variant (allele or genotype) that also possess an associated trait (phenotype). If penetrance of a disease allele is 100%, then all individuals carrying that allele will have the associated disease. Penetrance only considers whether individuals express the trait or not. This differs from expressivity, which characterizes qualitatively or quantitatively the extent of phenotypic variation given a particular genotype. Penetrance is age related (Bessett et al., 1998) and is affected by environmental and behavioral factors such as diet and smoking. It is also modified by other genes and epigenetic regulation.

Definition

Perceived benefit refers to the perception of the positive consequences that are caused by a specific action. In behavioral medicine, the term perceived benefit is frequently used to explain an individual's motives of performing a behavior and adopting an intervention or treatment. Researchers and theorists attempt to measure positive perceptions because they believe that a behavior is driven by an individual's cognition in terms of acceptability, motives, and attitudes toward such behavior, especially if positive.

In psychology, five models may explain the performance of health behavior related to the construct of perceived benefit. First, the Health Belief Model (Becker, 1974) describes that the perceived benefit is one of the four major predictors of health-related behavior. Second, the Transtheoretical Model (Prochaska & DiClemente, 1986) posits that the progress of change depends upon the decisional balance weighting between perceived benefits and barriers. Third, the Protection Motivation Theory (Rogers, 1983) puts forward that the intention to protect oneself depends upon four cognitions among which is the perceived efficacy (inlcuding benefits) of the recommended preventive behavior. Finally, the Theory of Reasoned Action (Fishbein & Ajzen, 1975) and its extension the Theory of Planned Behavior (Ajzen, 1985) both suggest that a person's behavior is driven by the persons' attitude about the behavior, which consists of beliefs about the consequences of performing the behavior multiplied by his or her valuation of these consequences.

In trauma literature, perceived benefits essentially mean the perceptions of positive psychological changes as a result of coping with a trauma or a highly stressful event (McMillen & Fisher, 1998). For example, after struggling with a highly stressful event, an individual may experience increases in personal strength, relatedness to others, and one's appreciation of life. In particular, McMiller and Fisher have developed the Perceived Benefit Scales (PBS) to assess several commonly reported positive by-products of adversity. On the PBS, respondents rate 30 positive by-product items on how similar they were to their own experiences by using a 5-point scale. The PBS has eight subscales: increased self-efficacy, increased faith in people, increased compassion, increased spirituality, increased community closeness, increased family closeness, lifestyle changes, and material gain. This concept is a form of cognitive coping strategy often associated with improved outcomes including participation in cancer screening tests.

Perceived behavioral control

Definition

Perceived behavioral control is the extent to which an individual perceives that they are in control of a particular behavior (Ajzen, 2002).

Description

Perceived behavioral control (PBC) was included in the Theory of Planned Behavior (TPB; Ajzen, 1991) in order to predict/explain behaviors that are not entirely under the volitional control of the individual. According to the TPB, PBC is determined by beliefs regarding factors that may act to facilitate or inhibit successful behavioral performance (Ajzen, 1991; Conner & Armitage, 1998). For example, a belief that exercising after work is associated with many barriers (i.e., cold weather, icy sidewalks, limited schedule) may lead to low perceived behavioral control over exercise, in turn leading to less frequent exercise during winter months. However, a belief that there are few barriers to exercising (i.e., favorable weather, few other time commitments) may result in greater perceived behavioral control over exercise, which in turn may lead to more frequent exercising during summer months. Importantly, control beliefs may concern factors external to the individual (e.g., weather conditions), or internal (e.g., innate ability; Conner & Armitage, 1998).

In the context of the TPB, PBC is thought to influence behavioral performance in two ways. First, PBC affects behavioral performance indirectly by influencing behavioral intentions to perform a particular behavior (Armitage & Connor, 2001). Those who perceive that they are in greater control of a given behavior may have stronger intentions to act compared to those who perceive less control over the behavior. That is, the influence of PBC on behavior is mediated through intentions.

PBC can also affect behavioral performance directly (Armitage & Connor, 2001). Given that perceptions of behavioral control may reflect actual behavioral control, PBC may influence behavioral performance as an immediate antecedent under conditions where there is little volitional control (Ajzen, 1991). For example, if an individual does not have access to a fitness facility or equipment, low PBC for engaging in resistance training would accurately reflect the individual's actual (low) control over the behavior.

Perceived Risk

Yori Gidron
Faculty of Medicine and Pharmacy, Free University of Brussels (VUB), Jette, Belgium

Definition

This term refers to an individual's subjective evaluation of his or her risk of an illness or an adverse outcome, often in relation to performing a certain risky behavior. This term maps onto the Health Belief Model (Rosenstock, 1966), which tries to model why people use health services or adhere to medically advocated healthy behaviors. Perceived risk, for example, can be in relation to having a myocardial infarction due to smoking or having skin cancer due to sun exposure or having an accident due to risk taking on the road. Relevant to perceived risk, Weinstein (1982) coined the terms "unrealistic optimism" and "unrealistic pessimism," where people are asked to estimate their risk of having a disease or an adverse outcome, compared to people of their age and sex. Answers are rated on a Likert scale ranging, for example, from −5 (far below others' risk) through 0 (same as others' risk) to +5 (far above others' risk). Levels of perceived risk could be related to prior exposure to a condition, one's knowledge of such a condition, exposure to one of a condition's risk factors, and to personality aspects. For example, in a recent review of 53 studies on risk perception among people at high risk for cancer, Tilburt et al. (2011) found that family cancer history, previous tests and treatments, younger age, believing in cancer's preventability and severity, monitoring coping style, distress, and the ability to process numbers all correlated with cancer risk perceptions. Concerning prediction, many studies have shown that perceived risk is related to various behavioral and health outcomes. For example, Mann, Allegrante, Natarajan, Halm, & Charlson (2007) found that level of perceived risk was one of several predictors of adherence to prescribed statins, which are used to treat hypercholesterolemia and prevent cardiac events. Knowing one's levels of perceived risk can help predicting his or her adherence to an advocated health behavior or to stopping an unhealthy behavior. Furthermore, perceived risk, if unrealistic, can be a target of brief cognitive restructuring, in the service of healthier behaviors, disease prevention, and treatment.

Perceived Stress

Anna C. Phillips
Sport & Exercise Sciences, University of Birmingham, Edgbaston, Birmingham, UK

Synonyms

Stress

Definition

Perceived stress is the feelings or thoughts that an individual has about how much stress they are under at a given point in time or over a given time period.

Perceived stress incorporates feelings about the uncontrollability and unpredictability of one's life, how often one has to deal with irritating hassles, how much change is occurring in one's life, and confidence in one's ability to

deal with problems or difficulties. It is not measuring the types or frequencies of stressful events which have happened to a person, but rather how an individual feels about the general stressfulness of their life and their ability to handle such stress. Individuals may suffer similar negative life events but appraise the impact or severity of these to different extents as a result of factors such as personality, coping resources, and support. In this way, perceived stress reflects the interaction between an individual and their environment which they appraise as threatening or overwhelming their resources in a way which will affect their well-being (Lazarus & Folkman, 1984). Perceived stress is commonly measured as the frequency of such feelings via a questionnaire such as the Perceived Stress Scale (Cohen, Kamarck, & Mermelstein, 1983). Perceived stress measures are often used to examine relationships between stress and health within behavioral medicine research.

Perceived Stress Scale (PSS)

Sherilynn F. Chan and Annette M. La Greca
Department of Psychology, University of Miami, Coral Gables, FL, USA

Definition

The Perceived Stress Scale (PSS) is a 14-item self-report measure designed to assess "the degree to which situations in one's life are appraised as stressful" (Cohen, Kamarck, & Mermelstein, 1983, p. 385). Specifically, items are designed to measure the extent to which one's life is perceived as "unpredictable, uncontrollable, and overloading" (Cohen et al., 1983, p. 387). The measure was intended for use with community samples of adolescents or adults with an educational level of junior high school or more. Sample items include the following: "In the last month. . .how often have you been upset because of something that happened unexpectedly?," ". . .how often have you felt that you were unable to control the important things in your life?," and ". . .how often have you felt confident about your ability to handle your personal problems?" (Cohen et al., 1983). Half of the questions are positively stated and reverse coded. Each item is rated on a 5-point scale (0 = Never, 1 = Almost Never, 2 = Sometimes, 3 = Fairly Often, 4 = Very Often) and summed to create a total score. Ten-item (PSS-10) and four-item (PSS-4) versions of this measure have also been developed (Cohen & Williamson, 1988; Cohen et al., 1983).

The PSS is one of the most widely used instruments used to measure stress perceptions; both the 14- and 10-item versions have good psychometric properties. In studies of adults, the PSS-14 has strong internal consistency ($\alpha = .84$ to .86) and good test-retest reliability ($r = .85$ over a 2-day period, $r = .55$ over a 6-week period; Cohen et al., 1983). In terms of concurrent validity, the PSS-14 is positively related to the number and perceived impact of life stressors ($r = .17$ to .35; Cohen et al., 1983). In terms of predictive validity, PSS scores predict depressive symptoms ($r = .65$ to .76), various health-related outcomes ($r = .52$ to .65), and social anxiety ($r = .37$ to .48) (Cohen et al., 1983). Factor analyses conducted with psychiatric inpatients revealed two factors: perceived distress and perceived coping (Hewitt, Flett, & Mosher, 1992; Martin, Kazarian, & Brieter, 1995).

Psychometric data also support the reliability and validity of the PSS-10 (Roberti, Harrington, & Storch, 2006), and an exploratory factor analysis revealed two factors: perceived helplessness and perceived self-efficacy (Roberti et al., 2006).

Overall, no significant gender differences have been found with either version of the PSS (Cohen et al., 1983; Roberti et al., 2006). The PSS-4 can be a useful measure when an abridged version is needed; however, its internal reliability ($\alpha = .72$) and test-retest reliability ($r = .55$) are lower than that for the longer versions (Cohen et al., 1983). The PSS-14 and PSS-10 have been translated into many different languages, including Hungarian, Turkish, Spanish, Portuguese, Japanese, and Thai, with good reliability and validity.

The PSS can be used to examine the role of appraised stress in physiological and behavioral disorders and can also be employed in research and clinical settings as an outcome variable (Cohen et al., 1983). Furthermore, it can be used as a screening device to identify individuals at risk for certain psychiatric disorders such as depression (Cohen et al., 1983) and may be a valuable tool for use within clinical settings to aid treatment planning and monitor treatment response (Roberti et al., 2006).

Synonyms

Stress appraisals

Definition

The construals or appraisals of an event that result in the experience of stress. Major theoretical definitions of stress emphasize perception as an important component responsible for the experience of stress. According to Lazarus and Folkman (1984), events are perceived as stressful if they are perceived as (1) relevant to one's well-being and (2) having the potential for harm or loss. Primary appraisals of demand, difficulty, and/or uncertainty when weighed against secondary appraisals of coping resources and abilities may result in further perceptions of stress as a challenge to be met and overcome (resources outweigh demands) or as a threat to be endured (demands outweigh resources). These resultant perceptions can

influence the psychological and physiological responses to the stressor (Tomaka, Blascovich, Kelsey, & Leitten, 1993). Perceptions of a stressful event's duration (chronic vs. acute), severity, controllability, and predictability can also influence responses to the stressor. According to Hobfoll (1989), stress results from the perceived potential loss of resources. As a result, perceptions of current resources and the potential to gain resources are involved in perceiving an event as stressful.

Peripheral Arterial Disease (PAD)/ Vascular Disease

Leah Rosenberg
Department of Medicine, School of Medicine, Duke University, Durham, NC, USA

Synonyms

Complications of atherosclerosis; Intermittent claudication; Rest pain

Definition

Peripheral arterial disease is the mismatch of blood flow supply and demand in the distal arteries.

Description

Peripheral arterial disease (PAD) is a common manifestation of atherosclerosis and is often a complication of hypertension and/or diabetes. It is estimated that PAD affects more than eight million Americans. PAD, or the accumulation of atherosclerotic plaques leading to narrowing in noncardiac vasculature, can affect renal arteries, carotid arteries, or any other branch vessels from the aorta like the subclavian artery or iliacs. When patients with PAD become symptomatic, there is a mismatch between the metabolic supply and demand of a tissue. When an upper or lower extremity is involved, PAD may starve the affected muscle of oxygenated blood flow and causes discomfort or pain, usually exacerbated by increased activity of the affected limb. In the lower extremity, this mismatch generally presents as intermittent claudication, commonly referred to as "walking pain," where patients develop lower extremity discomfort while ambulating. While there are anatomical entrapment syndromes, deep venous thromboses, and other neurological entities that must be ruled out, PAD is a significant cause of morbidity and mortality (American Heart Association, 2011).

PAD may present before arteriosclerotic disease of the great vessels, or heart becomes clinically relevant. Signs of lower extremity PAD on physical exam include shiny, tight, and hairless skin on the lower leg. Other signs of PAD include ischemic nonhealing leg ulcers and gangrene. The limb temperature often feels cool to the touch and has decreased sensation on examination. Most patients do not perceive the rest pain of intermittent claudication. In fact, only approximately 10% of patients with measurable PAD present to physicians complaining of the typical activity-related symptoms of PAD. Early signs of PAD include erectile dysfunction, leg cramps, or muscle fatigue that exceeds the expected effects of normal exertion.

The ankle-brachial index (ABI) is an excellent screening test for PAD of the distal extremity, although direct arteriography is the gold standard. Measuring a patient's ABI is a relatively low-cost, noninvasive diagnostic test that uses the systolic blood pressure readings of the brachial, posterior tibial, and dorsalis pedis arteries. Each lower extremity is examined separately. The formula involves by dividing the maximal ankle pressure in each lower extremity by the higher of the two brachial artery pressures.

The symptoms of PAD may be modifiable through lipid management and behavioral change. While not life threatening, moderate-to-severe PAD and claudication can have a serious impact on a patient's quality of life. Treatment for PAD may be behavioral (i.e., physical activity, smoking cessation), medication-based (statins and antiplatelet agents), or interventional (angioplasty, stent implantation, or bypass surgery).

Perseverative Cognition

J. F. Brosschot[1], Bart Verkuil[1] and Julian F. Thayer[2]
[1]Clinical, Health and Neuro Psychology, Leiden University, Leiden, Netherlands
[2]Department of Psychology, The Ohio State University, Columbus, OH, USA

Synonyms

Intrusive thoughts; Repetitive thinking; Rumination; Worry

Definition

Perseverative cognition is defined as "the repeated or chronic activation of the cognitive representation of one or more psychological stressors" (Brosschot, Gerin, & Thayer, 2006). Stressful events, or stressors, can make people "linger on" mentally. Humans, unlike animals, can make mental representations of stressors, long before and long after these events occur or are believed to occur. This continued cognitive representation of stressful events, before or after their occurrence, and even regardless of their actual occurrence, is called perseverative cognition. It can take the form of worry, rumination, angry brooding, etc., but also, for example, as mind wandering about negative topics. Perseverative cognition appears to play a causal or sustaining role in several major psychopathologies (anxiety disorders, depression, post-traumatic disorder) (Watkins, 2008) – indeed, worry is the hallmark of general anxiety disorder – as well as in somatic disease, including subjective bodily complaints as well as cardiovascular disease (Verkuil, Brosschot, Gebhardt, & Thayer, 2010).

During perseverative cognition, physiological activity can be increased. The "perseverative cognition hypothesis" (Brosschot et al., 2006) holds that the health damage due to stress is actually caused ("mediated") by perseverative cognition, because the latter prolongs the physiological responses to stressors. It has been suggested that perseverative cognition may partly be unconscious, while it still has physiological effects (Brosschot, Verkuil, & Thayer, 2010). This possibility, or the more general possibility of unconscious stress having health impacts, has the potential to open a new area in stress research.

There are several ways to reduce perseverative cognition. The most direct way is "postponing" or "scheduling" worrying or rumination, that is, limiting it to small daily time periods to obtain control over it. More indirect interventions are mediation mindfulness and computer-based attentional training techniques (Verkuil et al., 2010).

Definition

Although definitions may vary across the theoretical and methodological approaches, the term *personality* generally refers to stable patterns in how people think, act, and feel that make them unique.

Description

The study of personality has been guided by two major themes: (a) the study of individual dimensions along which people differ (i.e., nomothetic approaches) and (b) the study of individuals as unique and integrated people (i.e., idiographic approaches). Diverse theoretical and methodological approaches that have guided research in these two major domains have also contributed to controversies that have waxed and waned throughout the history of this discipline. In addition, research focused on explicating the relative role of the person versus the situation, as well as biology versus environment has been central to this area of psychology; however, in recent years, the focus on such false dichotomies has yielded to more integrated theoretical perspectives on personality. Emerging personality research ranges from the study of genetics and biological systems to the influence of culture on personality development and expression. An overview of the prominent theoretical approaches to the study of personality is provided below, including psychoanalytic, trait, social-cognitive, and interpersonal approaches.

Psychoanalytic Approaches to the Study of Personality

Although less prominent in current personality research, it is important to describe the psychoanalytic perspective on the development and manifestation of personality. Specifically, psychoanalytic approaches assert that stable personality patterns develop in childhood. According to this perspective, early childhood experiences are important, because they shape how individuals relate to others as adults. As individuals develop into mature adults, mental

processes not only guide interpersonal interactions, but may also operate in parallel so that people can feel conflicted about the same person or situation. According to this perspective and start the sentence with Personality develops as individuals learn to relate to others by regulating tension associated with sexual and aggressive drives. Finally, psychoanalytic theory emphasizes the role of mental representations of the self, others, and relationships as a framework for how people interact with one another. Psychoanalytic approaches have emphasized that behavior arises from thoughts, feelings, and motives that are outside of awareness. This reliance on unconscious mental processes separates psychoanalytic approaches from other perspectives on personality development.

Early psychoanalytic writing placed motivation at the center of theories of personality. According to this perspective, human motives could be grouped into two broad classes: life instincts (that include self-preservation and sexual motives) and death instincts or aggressive motives. This dualistic approach to personality was criticized for being overly simplistic. Subsequent research efforts expanded upon these two instincts by creating a more extensive catalog of "needs" or motives. These attempts to reformulate the psychoanalytic concept of instincts and motives stimulated a great deal of empirical research. Despite stark criticism, research on unconscious motives on adult behavior has provided the foundation for several important developments in the study of personality. For example, empirical work on unconscious motives has stimulated the fields of cognitive information processing, including research on implicit psychological mechanisms that have made the study of the unconscious more scientifically acceptable.

An important criticism of the psychoanalytic approach to personality is that the operationalization of key theoretical constructs has proven difficult. Assessments of unconscious motives and thoughts through the traditional psychoanalytic methods of free association, the unpacking of defense mechanisms, the analysis of transference processes, and dream interpretation have generally failed to hold up to minimal standards of reliability and validity necessary for empirical investigation.

Among the many attempts to operationalize psychoanalytic constructs for empirical investigation of personality, the Thematic Apperception Test (TAT) is perhaps the most well known and widely used. The popularity of the TAT as a measure of unconscious motives greatly diminished due to early criticisms of low internal consistency, temporal reliability, and a lack of correlation with self-reported measures of motives.

Trait Approaches to the Study of Personality

Trait theories of personality have typically used three different strategies to study the number, nature, and organization of dimensions along which people differ. One trait approach uses statistical techniques, such as factor analysis, to identify underlying personality dimensions applicable to all people. Another approach is to construct typologies based on a priori theories that are applicable to subgroups of people. Finally, idiographic approaches to the study of personality reject the search for basic traits common to all people, and instead focus on patterns of behavior that are unique to an individual.

The *lexical hypothesis* has been central to trait approaches to personality. The *lexical hypothesis* states that most of the descriptors that distinguish one individual from another have become embedded in our natural language. If the *lexical hypothesis* is correct, the basic dimensions of personality can be discovered, because all important individual differences will be spoken and eventually encoded into trait descriptors. Early work guided by the *lexical hypothesis* provided some initial structure, but did not provide a framework for distinguishing, naming, and ordering individual differences in behavior and experience. Early taxonomic efforts paired down initial attempts to derive personality traits from large lists of terms, but were limited by data-analytic techniques that were not sophisticated enough to handle large and complex data sets. With statistical advancements, research focused on examining the factor structure of

personality descriptors in the lexicon grew considerably. Proponents of this approach debated about the number of factors sufficient to describe personality (with 16, 5, and 3 being the predominant models) and the applicability of applying a group of factors to all people. Critics of the trait approach argued that these individual difference factors lacked consistency across situations and were poor at actually predicting specific behavior.

Following a brief period of relative dormancy in the 1970s and 1980s, due in part to the above-stated criticisms, research on the trait structure of personality increased dramatically during the mid-1980s. By the early 1990s, many personality psychologists reached a general (though still not unanimous) consensus that the trait domains could be described most broadly by five orthogonal factors, or clusters of traits. This five-factor trait model has been typically measured with self-report questionnaires and includes the following factors: neuroticism – hostility, depression, and anxiety; extraversion – warm, active, and assertive; openness to experience – open to ideas, values, and fantasy; agreeableness – modest, straightforward, and altruistic; and conscientiousness–dutiful, self-disciplined, and ordered. Yet, some psychologists have maintained that three factors, not five, characterized as neuroticism, extraversion, and psychoticism – a dimension characterized by low agreeableness and low conscientiousness – account for a majority of the variance. Despite criticism regarding the underlying assumptions of factor-analytic techniques, the five-factor model approach to the study of personality has proven to be a useful model for predicting outcomes at the individual, interpersonal, and social levels of analysis.

Beyond factor-analytic approaches, some trait theorists propose that personality is based on bundles of trait-like characteristics that can be classified as types or typologies presumed to cover all people. Recent statistical advancements (e.g., multilevel modeling techniques) have greatly increased our understanding of individual differences by allowing for the examination of the trajectory and rate at which people change. These approaches tend to focus on limited subgroups by examining combinations of personality variables as well as other variables such as intelligence, conduct, and externalizing behavior. These statistical and methodological advances have allowed researchers to examine more variables and the ability to account for interactions among those variables when describing what constitutes personality. Whereas these approaches to the study of personality are innovative, they are not without flaw. Specifically, critics have noted that this approach dissembles people into component parts that results in "types" that account for a limited amount of the variance in whatever outcome is under investigation.

Finally, the idiographic approach to the study of personality rejects the search for underlying personality traits common to all people, and instead focuses on identifying central themes in an individual's life. The idiographic approach is also concerned with describing the patterning of traits within an individual and using that pattern to predict future behavior. Research advocating for an idiographic approach claims that factor-analytic approaches might not account for the full range of personality characteristics within a person.

Social-Cognitive Approaches to the Study of Personality

Personality psychology was greatly influenced by the cognitive revolution in psychology that occurred during the late 1950s and early 1960s. This early research rejected the construct of motivation and focused on the complexity of cognitive processes. Importantly, the cognitive revolution in psychology spurred interest in the importance of "the self," leading to the examination of constructs such as self-esteem, self-schema, self-monitoring, and self-regulation. Research on the self broadened the view of personality by considering not only conceptions of what constitutes "the self," but also the ways in which our self-concept reflects our perceptions of how others view and respond to us.

More broadly, the concept of self-identity has spawned research endeavors aimed at creating a

conceptual bridge between the self and the role that social variables such as gender, race, class, and nationality play in the development of personality. Recent theoretical models of self-identity emphasize a "life story" approach to the study of personality. According to this perspective, personality is constructed by an individual through self-defining life narratives. These life narratives are created with the intent of describing individuals as integrated, whole people.

During the late 1960s and early 1970s, critiques of personality psychology produced a major crisis within the field, and led to an in-depth examination of many of the fundamental theories and methods used by personality psychologists. This perspective placed emphasis on situations, claiming that the examination of broad dispositional personality variables was unnecessarily overemphasized.

This approach advocated the notion that it is difficult to demonstrate the consistency of individual difference factors from one situation to the next and that individual difference factors rarely predict specific behaviors. This assertion not only challenged the basic premise of personality psychology, but also generated a paradigmatic crisis, resulting in an ideological split between those who study individual difference factors and those who examine the effect of situations on people. Those psychologists who advocate for a situationist approach construe personality as an organized system of goals, motives, and expectancies that mediate psychological processes that occur across situations. Proponents of this approach maintain that this characterization of personality accounts for both stability within the person as well as adaptive behavior across situations.

The response to this critique was to improve measurement techniques and to conduct studies demonstrating the consistency of personality over time. Yet, other researchers responded by examining how moderator variables, such as gender, interact with situational factors and with traditional trait descriptors. Those who emphasize the importance of context or situation maintain that dispositional traits are manifest as affective and cognitive processes that become activated during a distinct situation. Over time, these situation-by-behavior profiles are thought to shape who we are as individuals, leading to "dispositional signatures" that distinguish us as unique individuals.

Interpersonal Approaches to the Study of Personality

From an interpersonal perspective, personality is considered to be expressed in interactions with other people. Interpersonal theories of personality development do not merely emphasize observable behavior between individuals. Instead, interpersonal theories extend beyond personality development to include personality structure, function, and even pathology. According this perspective, interpersonal interactions support the development and maintenance of personality as patterns of interpersonal interactions give rise to lasting concepts of the self and others.

There have been two distinct empirical traditions to describe interpersonal functioning – the individual differences approach and the dyadic approach. The individual differences approach focuses on the qualities of an individual that are assumed to give rise to behavior that is consistent over time. This perspective led to various formulations of a structural model of interpersonal traits, actions, and problems often referred to as the interpersonal circle or circumplex. Circumplex models of behavior are used to anchor descriptions of theoretical concepts. Circumplex models of personality maintain that individual differences can be described as combinations of the circle's two underlying dimensions of dominance/submission and warmth/hostility. Interpersonal qualities close to one another on the perimeter of the circle are conceptually and statistically similar, qualities 90° apart are conceptually independent, but related, whereas qualities located 180° apart on the circle are considered conceptual and statistical opposites. This model of interpersonal functioning is not typically tied to interactions with a specific person or context, but rather is most often used to describe qualities of an individual interacting with a generalized other person.

In contrast, the dyadic approach assumes that two people comprise a basic unit of analysis for understanding personality. Accordingly, the interpersonal learning of social behaviors and self-concept is based on a variety of interpersonal situations. Interpersonal learning occurs across situations when interactions with others shape, refine, and maintain lasting conceptions of the self and others in relation to the self. In addition, this perspective on personality emphasizes that interpersonal behavior does not occur at random; instead, reciprocal relational patterns between two or more people help to define an interpersonal field. Within this interpersonal field, behavior from one individual pulls for responses from another, creating a dynamic, transactional process that leads to a conceptualization of the self. Interpersonal theories also include aspects of other theories of personality, but uniquely contribute to personality psychology by combining structural models that describe behavior with an examination of interpersonal situations.

Emerging Approaches to the Study of Personality

In recent years, the study of personality has benefited from advances in molecular genetics and functional imaging techniques. Within the domain of molecular genetics, research has focused on identifying specific biological pathways that contribute to complex cognitive and emotional behaviors. Advancements in the field of behavioral genetics may increase our understanding of the biological underpinnings of how individual differences in personality emerge and how those individual differences confer risk or resilience for mental and physical health. Other approaches that apply molecular genetic techniques to the study of personality involve examining the association between a particular phenotype and a specific allele of a gene.

Functional neuroimaging techniques hold promise for understanding personality by examining brain activity among individuals with varying levels of individual difference factors. Emerging advances in neuroimaging techniques may also help to further refine our understanding of how people process emotional information, including social connections. Yet, examining a single variation in alleles or the functional contributions of one brain region will not hold much explanatory value for our understanding of individual differences in thought, behavior, and emotions. With advancing techniques, future research should involve the careful application of methods and concepts learned from decades of investigation in order to refine our understanding of personality.

Personality and Health: Implications for Behavioral Medicine

Theory and research examining the influence of personality on health and disease has been an influential force for the development of the fields of health psychology and behavioral medicine. Research in this domain has been concerned with understanding the effects of personality on both the development and trajectory of health and disease. Possible mechanisms linking personality and health include the psychophysiological effects of stress and the extent to which personality traits are related to specific behaviors that may either promote or compromise health. Of particular interest to behavioral medicine is research that examines how certain personality characteristics confer differential risk toward negative affective states and behavioral dysregulation that often accompanies the diagnosis of and adjustment to chronic illness. Evidence that personality is a powerful predictor of health and illness has not only contributed to the development of behavioral medicine and health psychology, but has also helped revitalize personality research by challenging the critique of personality traits as having limited predictive utility.

Pessimism

Ryan Garcia
University of Texas Southwestern Medical Center at Dallas, Dallas, TX, USA

Synonyms

Dispositional pessimism

Definition

Pessimism is a personality variable that reflects the generalized tendency for an individual to have negative expectations about the future. Its development emerged along with that of dispositional optimism from models of self-regulation and goal achievement. Originally, pessimism was construed to reflect low levels of optimism, but it has emerged as an independent construct as the field of research has developed and grown. It is associated with a coping style characterized by problem and emotion avoidance coping (Solberg Nes & Segerstrom, 2006). Research suggests a pessimistic orientation places one at increased risk for depression and anxiety. Pessimism has also been associated with several different adverse health outcomes across a variety of settings, ranging from HIV + populations to increased mortality rates in individuals with cancer. The following terms are related to pessimism: defensive pessimism, unrealistic pessimism, and self-handicapping; however, these terms are not identical to pessimism, and have different associations with other variables.

Pew Internet and American Life Project

Chad Barrett
Department of Psychology, University of Colorado Denver, Denver, CO, USA

Definition

The Pew Internet and American Life Project is part of the Pew Research Center and is a nonpartisan and nonprofit organization that conducts research in order to provide information on the issues, attitudes, and trends that influence America and the world. According to their website, The Pew Internet and American Life Project examines "the impact of the internet on families, communities, work and home, daily life, education, health care, and civic and political life" (Pew Internet and American Life Project website). Each year, The Pew Internet and American Life Project releases 15–20 reports of research that address "how Americans use the internet and how their online activities affect their lives" (Pew Internet and American Life Project website). Data collection methods typically involve nationwide random phone surveys, online surveys, and qualitative research. In addition, data collection efforts are often augmented by research conducted by government agencies, technology firms, academia, and by various other expert researchers. Pew Internet and American Life Project aims to provide authoritative reports while maintaining neutral positions on policy issues and abstaining from providing endorsements of specific technologies, industries, organizations, companies, and individuals.

Description

The website for the Pew Internet and American Life Project provides a brief summary of highlights from their research related to health and health care (Fox, 2011). Such highlights include the following findings from recent surveys. Seventy-eight percent of adults in the USA use the internet and 83% own a cell phone. Eighty percent of internet users, or 59% of all US adults, use the internet to search for health or medical information. Seventeen percent of cell phone owners, or 15% of all US adults, have used their cell phones to look up health or medical information. Fox notes that since young people, Latinos, and African Americans are more likely than other groups to access the internet through their cell phones, this finding is of particular interest for studies targeting trends in these groups. Internet users most commonly search for health and medical information related to specific diseases or conditions, treatments or procedures, and doctors or other health professionals.

Another line of research has been examining the trends in how the internet influences people's relationships with health and medical information and with each other. As summarized by Fox (2011), many people use the internet to search for health information from other people's personal health-related experiences or to connect with others with similar conditions. Thirty-four percent of internet users, 25% of adults in the USA, have read about another person's experience with health or medical related issues by visiting an online news group, a website, or a blog. Twenty-four percent of internet users, or 18% of adults in the USA, have read online reviews of particular drugs or medical treatments. Eighteen percent of internet users, or 13% of adults in the USA, have used the internet to

connect with other people who share similar health concerns. People with rare or chronic conditions are especially likely to attempt to connect with others through the internet. Twenty-seven percent of internet users, or 20% of adults in the USA, have used online applications to monitor their weight, diet, exercise routine, or some other health indicators or symptoms. Six percent of internet users, or 4% of adults in the USA, have visited one or more websites in order to post comments or questions concerning health or medical issues. Four percent of internet users, 3% of adults in the USA, have posted comments or discussions about their experiences with a particular drug or treatment.

In addition to such highlighted findings, the website of the Pew Internet and American Life Project provides links to relevant study reports. The Pew Internet and American Life Project collects a variety of data that could be relevant to the field of behavioral medicine. The Project's website provides access to various studies and raw data sets dating back to 2000.

Pharmaceutical Industry: Research and Development

J. Rick Turner
Cardiovascular Safety, Quintiles, Durham, NC, USA

Synonyms

Drug development; New drug development

Definition

Contemporary research and development within the pharmaceutical industry is best described employing a lifecycle perspective. Four components of this are: drug discovery and drug design; nonclinical development; clinical development; and postmarketing surveillance (Turner, 2010).

Description

Drug Discovery and Drug Design

Drug discovery can be thought of as the work done from the time of the identification of a therapeutic need in a particular disease area to the time the drug candidate deemed most likely to safely affect the desired therapeutic benefit is identified. This drug candidate may be a small molecule or a biological macromolecule such as a protein or nucleic acid. The traditional mode of drug discovery is a long iterative process in which each molecule more closely approximates the ideal drug candidate. The modern discipline of drug design is much quicker. Computer simulation modeling

examines the "docking" of the drug molecule with the drug receptor and identifies the most likely chemical structure that will best dock with the receptor. The science of molecular engineering is then used to create the molecule suggested by the computer simulation.

Nonclinical Development

Nonhuman animal research is currently necessary before regulatory permission will be given to test a new drug in humans. Since part of the overall nonhuman animal testing is done before the drug is first given to humans, the term "preclinical" has a certain appeal and is used by many authors in place of nonclinical. However, a significant amount of nonhuman animal testing is typically conducted after the first administration of the drug to humans. Some of the more lengthy, more complex, and more expensive nonhuman animal testing is typically not started until initial human testing reveals that the drug has a good safety profile in humans and therefore has a reasonable chance of being approved for marketing if it also proves to be effective in later clinical trials. In this entry, therefore, the term "nonclinical" has been adopted for research involving nonhuman animals.

While human pharmacological therapy is the ultimate goal, understanding nonclinical drug safety and efficacy is critical to subsequent rationally designed, ethical human trials. Nonclinical research gathers critical information concerning safety, drug dose, and route and frequency of administration. It involves in vitro, ex vivo, and in vivo testing. For example, when investigating the cardiac safety of noncardiac drugs (drugs for noncardiac indications are not supposed to influence the heart's activity, and if they do it is likely to be in a deleterious manner), the following progression of levels of testing occurs: subcellular (investigation of individual ion channels within cardiac cell muscles or cardiomyocytes); cellular; isolated cardiac tissue; isolated heart; anesthetized intact animal; and conscious animal.

Preapproval Clinical Development and Postmarketing Trials and Surveillance

Pharmaceutical clinical trials are often categorized into various phases, with any given trial being identified as belonging to one of them. These categories traditionally include Phase I, Phase II, Phase III, and Phase IV, described as follows:

- Phase I. Pharmacologically oriented studies that typically look for the best dose to employ. Comparison to other treatments is not typically built into the study design.
- Phase II. Trials that look for evidence of activity, efficacy, and safety at a fixed dose. Again, comparison to other treatments is not typically built into the study design.
- Phase III. Trials in which comparison with another treatment (e.g., placebo, an active control) is a fundamental component of the design. These trials are undertaken if Phase I and Phase II studies have provided preliminary evidence that the investigational drug is safe and effective.
- Phase IV. These are postmarketing trials, conducted once the drug has been approved and in therapeutic use. There are various sorts of Phase IV trials. Some can be quite similar in design and conduct to preapproval therapeutic confirmatory trials. Other kinds include open-label trials, when both investigators and subjects know what treatment subjects are receiving, and large simple trials.

However, while commonly employed, these designations are not always used consistently. Accordingly, two studies with the same aims may be classified into different phases, and two studies classified into the same phase may have different aims. This nomenclature, therefore, can be confusing, and alternate systems of categorization are arguably more informative. One such system is presented in Table 1. The four categories correspond closely to Phase I to Phase IV, respectfully, but are more descriptive.

Among the goals of clinical development are:

- Estimation of the investigational drug's safety and tolerance in healthy adults.

Pharmaceutical Industry: Research and Development, Table 1 Classifying clinical studies according to their objectives (Based on ICH E8: General considerations for clinical trials)

Objective of trials	Study examples
Human pharmacology • Assess tolerance • Describe or define pharmacokinetics (PK) and pharmacodynamics (PD) • Explore drug metabolism and drug interactions • Estimate (biological) activity	• Dose-tolerance studies • Single- and multiple-dose PK and/or PD studies • Drug interaction studies
Therapeutic exploratory • Explore use for the targeted indication • Estimate dosage for subsequent studies • Provide basis for confirmatory study design, endpoints, methodologies	• Earliest trials of relatively short duration in well-defined narrow populations with the disease or condition of clinical concern, using surrogate of pharmacological endpoints or clinical measures • Dose-response exploration studies
Therapeutic confirmatory • Demonstrate/confirm efficacy • Establish safety profile • Provide an adequate basis for assessing benefit/risk relationship to support licensing (market approval) • Establish dose-response relationship	• Adequate and well-controlled studies to establish efficacy • Randomized parallel dose-response studies • Clinical safety studies • Studies of mortality/morbidity outcomes • Large simple trials • Comparative studies
Therapeutic use • Refine understanding of benefit-risk relationship in general or special populations and/or environments • Identify less common adverse drug reactions • Refine dosing recommendations	• Comparative effectiveness studies • Studies of mortality/morbidity outcomes • Studies of additional endpoints • Large simple trials • Pharmacoeconomic studies

- Determination of a safe and effective dose range, safe dosing levels, and the preferred route of administration.
- Investigation of pharmacokinetics and pharmacodynamics following a single dose and a multiple-dose schedule.
- Establishment and validation of biochemical markers in accessible body fluids that may permit the assessment of the desired pharmacological activity.
- Identification of metabolic pathways.
- Evaluation of the drug's safety and efficacy in a relatively small group of subjects with the disease or condition of clinical concern (the targeted therapeutic indication).
- Selection and optimization of final formulations, doses, regimens, and efficacy endpoints for larger scale, multicenter studies. Efficacy endpoints should be able to be measured reliably and should quantitatively reflect clinically relevant changes in the disease or condition of clinical concern.
- Evaluation of the drug's comparative efficacy (measured against placebo or an active comparator) in larger scale, multicenter studies, and collection of additional safety data.

HPA axis stimulation tests; Pharmacological challenge tests

Definition

The Hypothalamic-Pituitary-Adrenal (HPA) axis is the major neuroendocrine stress system in humans. Appropriate functioning of this highly dynamic multilevel system and its feedback mechanisms are assumed to modulate psycho-physiological adaptation to all major and minor challenges in life. In line with this, profound HPA axis alterations have been found in psychiatric disorders (most prominently affective disorders), in chronic medical disorders (e.g., cardiovascular disease), and in unexplained medical symptoms (e.g., chronic fatigue, Nater et al., 2008). Furthermore, it has been suggested that restoration of glucocorticoid receptor functioning and thereby improvement of HPA axis integrity might mediate treatment outcome in some disorders (such as depression) (Holsboer, 2000).

In order to assess the functional integrity of the HPA axis and its feedback mechanisms, standard pharmacological challenge tests have been developed. Targeting different levels of the axis, these tests meet two main goals: (a) to stimulate the HPA axis in order to assess its top-down reactivity, and (b) to stimulate negative feedback mechanisms of the HPA axis in order to test its feedback sensitivity.

Description

In general, HPA axis functioning can be assessed with repeated measures of its unstimulated effector steroids, that is, corticotropin-releasing hormone (CRH), adrenocorticotropic hormone (ACTH), and cortisol.

CRH is best measured in the cerebrospinal fluid (CSF). Plasma levels do not seem to reflect hypothalamic CRH secretion because (1) in addition to the CNS, many tissues in the periphery (such as the placenta) produce CRH and (2) the relatively high concentrations of CRH from the hypothalamic-hypophyseal portal venous blood are bound by CRH-binding protein until they reach the peripheral veins (Cunnah, Jessop, Besser, & Rees, 1987).

ACTH can be assessed in blood. Because the analysis of ACTH concentrations from blood plasma is relatively expensive, the number of repeated measures is usually limited. With a short plasma half-life and episodic secretion, ACTH levels in plasma have shown wide fluctuations and should be assessed in combination with repeated cortisol measures in order to increase reliability.

Cortisol can be measured in plasma (unbound and bound cortisol fraction), in saliva (unbound cortisol fraction), and in urine (unbound fraction).

Note that single measures of CRH, ACTH, or cortisol do not give a valid picture of HPA axis integrity, and more information is obtained by repeated testing.

Besides psychological challenge tests of HPA axis activity (Dickerson & Kemeny, 2004), highly standardized pharmacological challenge tests have also been developed. Among others, the administration of Insulin, Naloxone, Fenfluramine, Alprazolam, synthetic CRH, synthetic ACTH, Metyrapone, and Dexamethasone have been used to provoke changes in HPA axis activity. In the following, the most widely used HPA axis challenge tests will be briefly characterized.

Note that all challenge tests need to be employed under standardized conditions in a clinical setting.

CRH Stimulation Test

CRH stimulates ACTH secretion. Accordingly, administration of CRH is used to assess information about HPA axis dysregulation occurring down from the level of the pituitary (ACTH and cortisol).

Following one or two blood draws in order to assess ACTH and cortisol baseline levels, an IV bolus of 1 μg/kg of body weight CRH is administered. Repeated blood sampling at min 15, 30, 60, 90, and 120 will show a rapid rise and subsequent gradual decline in ACTH and cortisol following CRH administration.

In healthy subjects, the cortisol response in plasma after 30–60 min following injection is higher than 10 μg/dL (276 nmol/L). Usually, the test is well tolerated, with transient facial flushing in about 20% of the participants, occasional shortness of breath, or rare tachycardia, and hypotension.

ACTH Stimulation Test

With the ACTH stimulation test, the acute adrenal response to ACTH can be assessed. Before and following administration of 0.25 mg synthetic human α1-24-ACTH (tetracosactrin, cosyntropin, or "Synacthen") intramuscularly or intravenously, cortisol levels are measured repeatedly (e.g., baseline, 30, 45, and 60 min after injection). Due to ACTH administration, plasma cortisol rapidly increases within 30 min to at least 18–20 μg/dL (496–552 nmol/L), with peak responses at 30–60 min. Interestingly, substantially lower doses of ACTH were associated with the same endocrine response as the above-described high dosage. Consequently, the so-called low-dose ACTH test (1 μg) is gaining greater importance in endocrine research (Dickstein et al., 1991). Possible adverse side effects of this test include bradycardia, tachycardia, hypertension, peripheral edema, and rash. These side effects should disappear within a few hours after testing.

Dexamethasone Suppression Test

The synthetic corticosteroid Dexamethasone (Dex) binds to glucocorticoid receptors and thereby mimics the effects of cortisol. Consequently, researchers employ the Dexamethasone Suppression Test (DST) in order to assess HPA axis feedback sensitivity with an expected reduction in cortisol secretion following the administration of Dex.

In the standard DST procedure, 1 mg Dex is administered orally at 11:00 p.m. The following morning (8:00 a.m.), cortisol levels are determined in blood, saliva, or urine and may be again measured at 4:00 p.m. In healthy subjects, the standard DST will minimize cortisol secretion with plasma cortisol levels less than 2 μg/dL (50 nmol/L) at both measure time points. In depressed patients, the DST is thought to show non-suppression of cortisol due to *reduced* feedback sensitivity. However, studies on this test in depression have not shown high sensitivity and specificity (APA Task Force on Laboratory Tests in Psychiatry, 1987), with only about 40–60% of patients demonstrating a failure to suppress cortisol in response to the standard DST (Yehuda, 2006). In disorders characterized by *increased* HPA axis feedback sensitivity (such as Posttraumatic Stress Disorder, PTSD), the low-dose DST (0.5 mg or 0.25 mg) is preferably used. Following this test, normal cortisol suppression results in values around 5 μg/dL. The low-dose DST has been widely used in PTSD research, with PTSD subjects having been exposed to traumas (e.g., childhood abuse, combat, or Holocaust exposure) showing hyperresponsiveness (= lower post-DST cortisol) in this test (Yehuda, 2006). No adverse side effects have been reported for the DST.

Dex-CRH Test

In order to more precisely characterize underlying mechanisms of non-suppression in the Dex test, the combined Dex-CRH test has been developed, and improved sensitivity of this test compared to the Dex test has been shown in depression (Heuser, Yassouridis, & Holsboer, 1994). With the Dex-CRH test, the oral administration of Dexamethasone (1.5 mg) at 11:00 p.m. is combined with the intravenous administration of 100 μg CRH the following day in the afternoon (between 2:00 p.m. and 3:00 p.m.). Blood

samples will be repeatedly collected before CRH administration, and again at 15, 30, 60, 90, and 120 min after administration.

In healthy individuals, ACTH and cortisol will be suppressed prior to CRH administration. After CRH injection, ACTH and cortisol levels are first increasing and then decreasing (Carroll et al., 1981). Patients suffering from current major depression, but also from other psychiatric and medical conditions, show increased sensitivity, with markedly elevated ACTH and cortisol levels following the Dex-CRH test (Ising et al., 2005). Particularly in depression, repeated Dex-CRH testing has been discussed as a surrogate marker for drug efficacy (Ising et al., 2007). Adverse side effects following the combined Dex-CRH test are identical to those following CRH administration alone.

Metyrapone Test

Metyrapone is a method for assessing ACTH secretory reserve via the interruption of the negative feedback on the HPA axis. The drug inhibits P450c11 (11β-hydroxylase), the enzyme that catalyzes the final step in cortisol biosynthesis. The inhibition of cortisol secretion interrupts negative feedback of the HPA axis, which results in a compensatory increase in ACTH. This increase in ACTH secretion then stimulates biosynthesis in the cortisol precursor steroid (11-deoxycortisol) in plasma.

The overnight metyrapone test is used in order to test whether altered cortisol secretion is a function of increased/decreased ACTH drive from the pituitary or a result of adrenal alterations. A quantity of 30 mg/kg of metyrapone is administered orally, preferably at midnight. Plasma 11-deoxycortisol is then determined the following morning at 8 a.m. In healthy subjects, 11-deoxycortisol levels in plasma rise to more than 7 μg/dL (0.2 μmol/L) and plasma ACTH levels rise to greater than 100 pg/mL (22 pmol/L) the following morning. The test has been used in PTSD research (for a review see Yehuda, 2006) as well as in depression research (Young, Ribeiro, & Ye, 2007). Possible adverse side effects include gastrointestinal symptoms, headaches, dizziness, hypotension, and allergic skin reactions.

Summary and Outlook

The investigation of neuroendocrine alterations in psychiatric and medical disorders has largely improved our knowledge of the pathophysiology of these disorders. The next steps will be to further improve the sensitivity, specificity, and thereby validity of HPA axis challenge tests. Note that so far, reliable results can only be obtained with repeated application of challenge tests and repeated HPA axis assessment. Confounding factors, such as eating disorders, restrictive dieting, diabetes, gender, and alcohol consumption have been discussed in the literature with mixed results (e.g., APA Task Force on Laboratory Tests in Psychiatry, 1987; Ising et al., 2005; Young, Ribeiro, & Ye, 2007). This is particularly relevant, as oftentimes these factors might be substantially altered in psychiatric and medical conditions.

A variety of CNS processes can trigger or dampen HPA activation. Among others, these mechanisms may include alterations in levels vasopressin, serotonin, endorphins, oxytocin, neuropeptide Y, substance P, and cytokines. So far, on the level of HPA axis dynamics alone, we are not able to trace back specifically involved CNS mechanisms; in other words, the specificity of HPA axis challenge tests cannot exceed the specificity of the HPA axis itself. Future studies should combine imaging data, administration of centrally active substances (e.g., intranasal administration of vasopressin and oxytocin), in combination with HPA axis challenge tests, thus providing further insights into the specificity of the involved mechanisms in healthy as well as in pathological endocrine functioning.

Phenotype

Jeanette McCarthy
Community and Family Medicine, Duke University Medical Center, Durham, NC, USA

Definition

The term phenotype refers to an organism's outward appearance and characteristics. This contrasts with the individual's genotype, the set of alleles that an offspring inherits from both parents. In the behavioral sciences, including Behavioral Medicine, the fundamental issue of heredity is the extent to which differences in genotype account for differences in phenotype, i.e., observed differences among individuals (Plomin, DeFries, McClearn, & Rutter, 1997).

In contrast to single-gene disorders such as Huntington's disease and phenylketonuria (PKU), complex dimensions, disorders, and conditions of clinical concern in Behavioral Medicine are influenced by heredity, but not by one gene alone. Multiple genes are typically involved, and so too are multiple environmental influences, and phenotypes are often the result of the combined effects of both genotype and environmental factors.

Definition

Physical activity (PA) is any body movement that leads to skeletal muscle contraction and noticeable increases in energy expenditure (US Department of Health and Human Services [USDHHS], 2008). Such activities can be walking, washing windows, or gardening.

Description

Introduction

There is strong evidence that there are greater physical, physiological, and possibly mental health benefits from a lifestyle that includes more occupational and leisure-time physical activity (PA) than a predominantly sedentary (inactive or underactive) lifestyle (USDHHS, 2008). These benefits include a risk reduction for type 2 diabetes, overweight/obesity, cardiovascular disease, stroke, high blood pressure, an adverse lipid profile, osteoporosis, sarcopenia, and loss of function and autonomy in older age. There is also a great interest in the benefits of PA for mitigating and possibly preventing cancer and its significant morbidity and mortality rates: the evidence is strongest for the prevention of colon and breast cancer. Regular PA can also help in weight loss (when combined with reduced calorie intake) and is associated with reduced depression and better cognitive functioning (among older adults) (USDHHS).

On the negative end, there is low risk of adverse events such as injuries, when generally healthy people engaged in moderate-intensity activity. However, when performing the same activity, people who are less fit are more likely to be injured than those who are fitter. The risk of cardiac events such as heart attacks during PA is rare. But there is a risk of such events when an individual suddenly becomes much more active than usual (e.g., shoveling snow). When both the benefits and risks of PA are considered, it is clear that the health benefits of PA far outweigh the risks of adverse events for a majority of people.

Given the overwhelming evidence for substantial benefits from PA, *physical inactivity* is a national public health problem. Recent data from the 2009 National Health Interview Survey (NHIS) indicates that 35% of US adults report engaging in regular leisure-time PA, 33% reported some leisure-time PA, and 33% report no participation in leisure-time PA (http://www.cdc.gov/nchs/fastats/exercise.htm.) NHIS data for 2005–2007 showed that 30.7% of US adults engaged in PA sufficient in frequency and duration to be classified as regular and 39.7% report

no leisure-time PA (Schoenborn & Adams, 2010). Men (61.9%) were more likely than women (58.9%) to engage in at least some leisure-time activity. The percentage of adults who engage in at least some leisure PA increased with education and with family income but decreased with increasing age. Married adults were more likely than those in other marital status groups to engage in at least some leisure-time PA. White adults (61.9%) and Asian adults (60.3%) were more likely than black adults (48.8%) to engage in at least some leisure-time PA. Finally, adults living in the US South (27.4%) were least likely to engage in regular leisure-time PA compared with adults living in any other region.

What Is Physical Activity?

Body movement for the purposes of health benefits can be defined by multiple constructs. Some of these constructs are similar but are still distinct. *PA* is any body movement that leads to skeletal muscle contraction and noticeable increases in energy expenditure (USDHHS, 2008). Such activities can be walking, washing windows, or gardening. To assess how much PA someone has to engage in for a specific health outcome, the term "dose response" is used (USDHHS). Dose response refers to the frequency, intensity, duration, and type of PA needed for a certain health outcome (i.e., fitness). Typically, PA is measured in kilocalorie (kcal), metabolic equivalent (MET), minutes, or MET-minutes per day or week (USDHHS). Such measurements occur through various assessment methods that will be addressed below.

A construct that can be seen as interchangeable with PA is exercise, but these terms are not identical. *Exercise*, a subset of PA, is planned, structured, and repetitive bodily movement (such as participating in an aerobics class) with the goal of improving or maintaining physical fitness (USDHHS, 2008). *Physical fitness* primarily consists of aerobic power or cardiorespiratory fitness measured by maximal and submaximal stress testing or a field test (USDHHS). PA is something an individual does which can help to achieve greater physical fitness. In addition to PA, various factors such as age, sex, health status, and genetics can also affect physical fitness. In *aerobic activity* or endurance activity, the body's large muscles move in a rhythmic manner for a sustained period of time as in brisk walking, biking, or swimming. *Resistance training* (or strength training) consists of repetitive movements geared toward greater skeletal muscle strength, power, endurance, and mass (USDHHS). *Flexibility training* refers to repetitive activities to improve the movement of joints through their full range of motion (USDHHS).

Assessment of Physical Activity

Reliable and valid measures of PA are essential to understand energy expenditure in various populations. There are three common ways to assess PA: (1) criterion methods, (2) objective measures, and (3) subjective/self-reports. The selection of any of these three methods can be based on feasibility, cost, the specific research or clinical setting, and type of population.

Criterion methods such as doubly labeled water and indirect calorimetry are the gold standards for measuring PA (Vanhees et al., 2005). Doubly labeled water (DWL) measures total energy expenditure and does not require individuals to log their daily activity because it uses the body's water to record metabolic rates. Thus, this technique is objective and requires little participant burden. Even with these advantages, various factors that lead to changes in energy expenditure such as PA, basal metabolic rate, and diet-induced energy expenditure cannot be teased apart from each other (Vanhees et al.). Another important criterion method is indirect calorimetry. Energy expenditure is measured by oxygen consumption and carbon dioxide production through collected respiratory gases or in a respiration chamber (Vanhees et al.). Both DWL and indirect calorimetry are expensive and have limited usability. They are less feasible in studies where participants have to monitor their daily PA in the community or home setting or over multiple assessments or over extended periods.

The objective measures of PA include fitness testing, accelerometers, and pedometers. As mentioned earlier, aerobic capacity is measured through fitness testing conducted on a treadmill,

stationary bike, or a field test. These tests yield levels of peak oxygen consumption (VO_2 peak) which is an index of cardiorespiratory capacity (Gelieber et al., 1997). These treadmill or bike tests must be overseen by a physician and are expensive but are used to assess fitness in clinical and research studies.

Accelerometers and pedometers are more commonly seen in the literature because they are relatively inexpensive ($10–$450 and above) and participants can be taught how to use them without extensive training. Accelerometers and pedometers are motion sensors but with different purposes. Accelerometers measure all body movement and physical activities and can yield the dose of PA (e.g., Fogelholm et al., 1998). Thus, accelerometers are significantly more expensive than pedometers due to their use of technology (Vanhees et al., 2005).

Pedometers are battery-operated step counters that are worn on the waist and measure steps when engaging in PA (Vanhees et al., 2005). They are efficient in monitoring steps but may produce inaccurate readings due to inadvertent body movements. Activities such as biking and other activities where the body torso is stationary are not suitable for pedometers as are water activities. The reliability and validity of pedometers have been addressed in the literature (e.g., Vanhees et al.). It is anticipated that the next generation of pedometers will yield information on the "dose" of PA (i.e., intensity, frequency, and duration).

The third category of assessments is the subjective, self-report measures which include diaries, interviews, and questionnaires (e.g., von Poppel, Chinapaw, Mokkink, van Mechelen & Terwee, 2010). These subjective methods are inexpensive and generally do not take significant time. The measures are commonly used when assessing PA of large numbers of individuals. As with all self-report measures, problems with recall, over-estimation, and interviewer skill limit the validity of these instruments.

Physical Activity Guidelines

There are various PA guidelines for public health benefits, weight loss, or weight management and for patients treated for diseases such as cancer (Schmitz et al., 2010; USDHHS, 2008). For the purposes of this chapter, PA guidelines for improving general health for adults will be discussed.

In the 1960s and 1970s, the PA literature provided information that many health benefits could be achieved through vigorous intensity or high levels of PA. Since then, a large research base led to the first public health and PA guidelines issued in 1995 by the American College of Sports Medicine (ACSM) and Centers for Disease Control and Prevention (CDC) (Pate et al., 1995). These guidelines recommended that "every US adult should accumulate 30 min or more of moderate-intensity PA on most, preferably all, days of the week." The guidelines were based on evidence that moderate-intensity PA accumulated in short bouts could lead to improved health outcomes.

Due to further advances in understanding the health benefits of PA, misunderstanding of the prior 1995 ACSM and CDC PA guidelines, and continued physical inactivity of many Americans, a new set of PA guidelines were issued in 2007 by the ACSM and American Heart Association (AHA) (Haskell et al., 2007). These 2007 guidelines were tailored for children, healthy adults between the ages of 18–65, and older adults over age 65. For healthy adults, the guidelines recommend moderate-intensity aerobic PA for at least 30 min on 5 days each week or vigorous-intensity aerobic activity for at least 20 min on 3 days each week (Haskell et al.). These guidelines also clarified that (a) 30 min of aerobic or endurance activity can be achieved in at least 10-min bouts, (b) resistance training should be performed at least twice a week, and (c) individuals who wish to engage in more activity to improve health or reduce risk of disease could surpass the minimum recommendations (Haskell et al.).

In 2008, the US Department of Human and Health Services (USDHHS) released PA guidelines for health benefits and recommended a minimum of 150 min of moderate-intensity PA, 75 min of vigorous-intensity PA, or 500–1,000 MET min of PA per week. A combination of moderate- and vigorous-intensity activity

could be used to achieve these recommendations. These guidelines did not provide an empirically supported dose response prescription that included frequency of PA (i.e., number of days a week) because of insufficient evidence. On the other hand, the guidelines did clarify that the upper limit of MET values for moderate activity is 5.9 and the lower limits of vigorous activity are 6 METs. In the past, 6 METs overlapped as the highest and lowest values for moderate and vigorous PA, respectively (USDHHS, 2008).

Finally, there are other PA guidelines such as those related to the number of steps per day needed to achieve health benefits. It is commonly known that 2,000 steps equal 1 mile. Current PA guidelines suggest that accumulating at least 10,000 steps and greater per day indicates that one is active, and accumulating at least 12,500 steps per day indicates that an individual is very active (e.g., Tudor-Locke & Bassett, 2004).

Theories and Interventions

To respond to the challenge of reducing sedentary behavior, numerous interventions have been developed and tested for specific patient populations (e.g., individuals with diabetes, cardiovascular disease, osteoarthritis, cancer), individuals with specific risk factors (high cholesterol, hypertension), and the general population at various phases of the lifespan (young children, school-aged, college-level, middle-aged, and older adults). The interventions have been offered at schools, work sites, and in communities. PA has also been targeted to reduce other risk behaviors (e.g., smoking, alcohol, and other drug addiction). More recently, PA has been emphasized as part of the initiatives to combat the obesity epidemic in the USA. The interventions have yielded varying degrees of success. The Task Force on Community Preventive Services (Kahn et al., 2002) concluded that there are six types of interventions that have been shown to increase PA and cardiorespiratory fitness: point-of-decision prompts, community-wide education, school physical education and community social support, individual health behavior, and enhanced access to places for PA combined with informational outreach activities. Interventions have been offered using various modalities (in-person, by telephone, web-based, and more recently, using mobile technology such as palmtop computers and mobile phones) with varying degrees of "reach" to modify sedentary behavior.

In developing interventions, there is growing interest in *community-based participatory research* especially to reach subgroups that are more challenging to reach but are characterized by sedentary lifestyles. This type of research addresses predictors of health at the community and individual levels and includes the community of interest in the whole research enterprise. Thus, the participants or community are commonly involved with all areas of research conceptualization, development, and data collection. Furthermore, culturally relevant strategies and theories and social marketing principles are integrated a priori in the study to enhance recruitment and retention efforts. Community-based participatory research is gaining popularity given the public health epidemic of obesity and physical inactivity in diverse populations (Yancey et al., 2004).

PA interventions have been based on theories of behavior change. One of the more commonly used theories is *Social Cognitive Theory* (SCT) (Bandura, 1986) which posits that behavior, environmental factors, and personal factors of the individual, such as cognitions, emotions, and physical characteristics, are mutually influential. Interventions based on SCT focus on the importance of individuals' ability to control their behavior and how changes in the individual or the environment can produce changes in behavior. Success in being able to initiate and maintain the behavior change is determined by an individual's ability to regulate his or her own behavior through personal strategies (e.g., setting PA goals, monitoring progress toward goals), as well as environmental approaches (e.g., using social support or environmental prompts).

The *Theory of Planned Behavior* (Tpb) (Ajzen, 1991) is another widely used theory that proposes that behavior is directly predicted by

intention, which in turn, is directly predicted by attitude, subjective norm, and perceived control. Perceived control is the belief that a behavior can be performed with ease or difficulty and it may directly predict the behavior, attitude is the personal evaluation of performing the behavior, and subjective norm is the perceived normative beliefs of relevant others regarding the behavior. Thus, according to the theory, individuals will intend, and be motivated to, perform a behavior such as PA when they view it favorably, believe that important others think they should be physically active, and believe that PA is under their control and can be carried out.

The *Transtheoretical Model* (TTM) of health behavior change (Prochaska & DiClemente, 1983) postulates that individuals move through a series of six stages of motivational readiness while making a behavior change (i.e., precontemplation, contemplation, preparation, action, maintenance, and termination), and this approach has been applied to PA (Marcus & Simkin, 1993). While progressing through these stages, the individual engages in ten different cognitive and behavioral processes of change that are important in the adoption and maintenance of a new behavior. For example, research suggests that cognitive processes of change (e.g., setting realistic goals) should be encouraged among those in precontemplation and contemplation, while behavioral processes (e.g., placing reminders to exercise at work or home) should be promoted among those in the more advanced stages of motivational readiness. TTM-based interventions attempt to tailor PA programs to a participant's motivational readiness to change and utilize the processes of change to encourage progression in motivational readiness for PA.

The *Self-Determination Theory* (SDT) posits that behaviors are regulated by motives that range on a continuum from highly controlled (extrinsically motivated) to fully autonomous (intrinsically motivated). Extrinsically motivated behaviors arise to avoid negative emotions, a threat or a demand. Extrinsic motivation is also involved when an individual performs a behavior that he or she feels is valuable (but not necessarily inherently enjoyable; Ryan & Deci, 2000). Intrinsically motivated behaviors are those that are done to provide the individual inherent enjoyment, satisfaction, or pleasure. It is thought that intrinsic motivation for behaviors such as PA leads to greater interest, more confidence, and longer persistence of the behavior.

The *Protection Motivation* Theory (Rogers, 1983) emphasizes threat and coping appraisal. Threat appraisal consists of perceived severity (estimated threat of disease) and perceived vulnerability (estimate of chance of developing the disease), and coping appraisal consists of response efficacy (expectancy that the recommended behavior, i.e., PA, can remove the threat) and self-efficacy (belief that one can carry out the recommended behavior successfully, i.e., adopt and maintain PA). Both threat and coping appraisal affect intention to be physically active and PA behavior.

Theories that focus on the individual (e.g., beliefs, attitudes) have led to the development of various interventions to promote PA. However, variables based on these theories do not explain more than a relatively small percentage of the variance in PA levels. *Ecological models* have become increasingly popular in acknowledging multiple levels of influence on PA: individual, social/cultural, organizational, community, physical environment, and policy. They are "macro" in the sense that they go beyond the individual-level choices and decisions to become active in an effort to reduce sedentary lifestyles (King, Stokols, Talen, Brassington & Killingsworth, 2002). Such models focus on the environmental variables, the related type of PA (e.g., transit vs. recreational), and the extent to which specific environmental conditions (e.g., built environment) can facilitate or constrain recreational activity, transit activities, or both. For example, availability of playgrounds, sidewalks, biking, or walking trails is likely to facilitate PA. Conversely, unsafe neighborhoods and lack of sidewalks are likely to hinder PA.

To achieve widespread adoption of physically active lifestyles, much needs to be done to determine what models will facilitate dissemination of PA interventions and which approaches will

help adapt interventions for culturally diverse subgroups. The costs and benefits of such interventions also require attention. Finally, sustaining PA over time will require change at the policy and legislative levels as has been the case with smoking cessation.

Conclusions

PA has an important role to play in the prevention and management of many chronic diseases. Although there has been improvement in the overall prevalence of regular PA in the USA, a large subgroup does not engage in regular PA. Efforts to promote PA have focused on individual-level factors and, to a lesser extent, factors at the community and population level. New technologies can help extend the reach of interventions. However, addressing the barriers to adopting and maintaining PA in the twenty-first century will require efforts at the individual, community, population, and policy levels.

Physical Activity Interventions

Rick LaCaille
Psychology Department, University of Minnesota Duluth, Duluth, MN, USA

Definition

Physical activity interventions primarily aim to encourage sedentary individuals or those at risk for chronic diseases to initiate and maintain healthy levels of activity. Secondary goals of interventions may include improved weight or disease management, enhanced psychological well-being and stress reduction, and better quality of life. There has been a recent concerted effort to examine changing multiple health behaviors (e.g., dietary, tobacco cessation) in combination with sedentary behaviors. Interventions are often evaluated in the context of a randomized clinical trial (efficacy trials) or quasi-experimental designs (effectiveness trials).

Description

Recently, the US government released its first formal set of recommendations on physical activity (PA), the *Physical Activity Guidelines for Americans* (United States Department of Health and Human Services [USDHHS], 2008), thereby establishing increasing PA as a significant health goal for the twenty-first century. In addition to making clear the health benefits of PA, these guidelines emphasize accumulating targeted doses of moderate to vigorous-intensity forms of PA across the week (rather than on a daily basis) as well as provide specific guidelines for particular groups of people (e.g., youth, adults, older adults, pregnant women, adults with disabilities). However, because of the many benefits of PA and relatively low rates of individuals who engage in routine leisure-time PA, public health professionals have for some time developed strategies and interventions to increase PA (Buckworth & Dishman, 2002). Typically, PA interventions target a goal of consistently achieving at least 30 min of moderate intensity activity on 5 or more days per week. However, some interventions have focused on increasing low-intensity PA, such as walking or stair usage, which may be engaged in more often and in various settings. Duration and intensity of PA interventions have varied greatly from brief, single contacts to multiple contacts extending over 2 years. Efforts to promote PA involvement have, in general, fallen into one or a combination of the following levels of intervening: Individual, group, and community context.

Individual level interventions attempt to promote the adoption and maintenance of active lifestyles by targeting attitudes, beliefs, and behaviors of particular individuals who are not meeting PA guidelines. The most common theoretical paradigms guiding these interventions include social learning theory/social cognitive theory, theory of planned behavior, health belief model, and transtheoretical model (e.g., Marcus & Forsyth, 2009). Interventions have employed several strategies and techniques either successively or concurrently, often in a home-based context, to affect behavioral initiation and/or maintenance of change. The following strategies have been commonly used in interventions: health education, health-risk appraisal, motivational interviewing, written exercise prescriptions, mastery experience/self-efficacy enhancements, goal setting, incentives, contingency contracts, self-monitoring, self-reinforcement, and stimulus control. Delivery of individual interventions has often been via face-to-face or telephone interactions and print materials, though text message/e-mail and web-based programs with expert system algorithms for interactive and tailored feedback have become increasingly popular and considered a viable mode that may be appealing to some individuals (Marcus et al., 2006; Vandelanotte, Spathonis, Eakin, & Owen, 2007).

In contrast to individual level programs, group-based interventions occur in the context of small group settings (e.g., structured classes) and utilize this social environment to encourage PA. Although group interventions often also make use of the theoretical paradigms and strategies discussed within individual approaches, the group structure (e.g., group norms) and processes (e.g., interactions

and communications) that facilitate group cohesion and support for changing sedentary behaviors are emphasized. Group-based specific strategies include developing a distinct group identity (along with group name/clothing), establishing shared goals, mentoring by more experienced members, and encouragement of "fitness friends" and additional support.

Community-level interventions emphasize prevention and risk reduction that affects large segments of a particular population or community. Such PA interventions may include a combination of site-based (e.g., schools, health care, work, church), mass media (e.g., print media campaigns), built environments (e.g., constructing multiuse paths and trails), or policy/legislative (e.g., time allotted for PA at worksite, insurance premium reductions for engaging in PA) strategies and target system changes rather than behavior change of individuals. Thus, a fundamental assumption of community-level PA interventions is that large numbers of individuals will be accessed that may not have been identified otherwise and that the systemic change will yield behavior change in many more individuals.

Numerous reviews and reviews of reviews of PA intervention studies have been conducted (e.g., Foster, Hillsdon, & Thorogood, 2005). Reviews focusing exclusively upon intervention modalities/settings and subpopulations are also available. Overall, the data have suggested that PA interventions (compared to no-intervention or minimal-intervention controls) have garnered modest gains (Muller-Riemenschneider, Reinhold, Nocon, & Willich, 2008), with behavior modification strategies yielding the largest effects. However, behavior modification approaches have been criticized for lacking sustained effects once the intervention is completed as well as potentially compromising more autonomous motivation to engage in PA. A recent meta-analytic review indicated that the strategy of self-monitoring accounted for the most behavioral change of intervention participants, whereas the delivery context (e.g., individual vs. group), number of sessions, target population, and setting were not significant in determining intervention effectiveness (Michie, Abraham, Whittington, McAteer, & Gupta, 2009). Data also suggest that interventions targeting lower intensity and more active leisure time (e.g., walking) appear more successful in affecting change in PA behavior than those advocating more vigorous intensities and structured activities (Williams, Matthews, Rutt, Napolitano, & Marcus, 2008). Although the findings are inconsistent on the effectiveness of worksite interventions for promoting PA, a recent review of randomized clinical trials indicated such interventions may achieve modest effects with promoting healthy weight among employees (Anderson et al., 2009). Worksite settings are thought to offer valuable opportunities for PA interventions because of the potential for high exposure and reach, with promising strategies that include an increased emphasis on social networks (e.g., "buddy system") and built environments (e.g., stairwell enhancements, bike racks) as well as communication change strategies (e.g., persuasive point-of-decision prompts for increased PA or stairwell use). Although environmental strategies that create or improve access to PA for leisure or transportation purposes appear promising, at present, solid empirical evidence for such interventions is lacking. Community-level interventions involving large-scale multicomponent strategies, as well as targeting a combination of health behaviors (e.g., dietary), have demonstrated some initial effectiveness for increasing the percentage of active people across a variety of communities and populations, provided materials and messages are culturally adapted to the needs of the particular community and/or populations (Zaza, Briss, & Harris, 2005). While school-based physical education programs also appear effective in increasing PA levels, generalizability outside of the school setting has been limited (Marcus et al., 2006; Zaza, Briss, & Harris, 2005). On balance, family-based PA intervention have yielded mixed results, whereas classroom-based health education and single-component mass media campaigns have not been found to be effective for increasing PA (Marcus et al.; Zaza, Briss, & Harris).

Unfortunately, maintenance of behavioral change beyond 3 months is not often reported in PA interventions. The data and reviews that are available suggest that determinants of PA initiation

and maintenance may be different. A recent review found that maintenance was more likely for PA interventions that involved more than six behavioral change strategies, occurred for more than 24 weeks, and included face-to-face contacts as well as follow-up prompts to reinforce intervention content (Fjeldsoe, Neuhaus, Winkler, & Eakin, 2011). Notably, assessment of long-term sustainability of PA improvements did not extend beyond 24 months post-intervention for any of the studies examined. Increased assessments of PA maintenance and intervention sustainability appear to be a much needed emphasis in future research. Although cost-effectiveness analyses are also underreported in the literature and in need of greater prioritization (Hagberg & Lindholm, 2006; Muller-Riemenschneider, Reinhold, & Willich, 2009), some data suggest that both behavioral and environmental focused PA interventions may be cost-effective with the latter appearing to have potentially greater cost-effectiveness. In a similar vein, determining the public health impact of PA interventions has become increasingly important and emphasized, with the RE-AIM (Reach, Efficacy, Adoption, Implementation, and Maintenance) framework (Glasgow et al., 2010) serving as a useful model for evaluating and comparing any given intervention across the various levels (i.e., individual to community). Finally, because poor fidelity and adherence to treatment protocols and theoretical frameworks has limited conclusions from the data, there has been a recent effort to systematically create a taxonomy of behavior change techniques to more clearly map intervention components reported in studies (Abraham & Michie, 2008).

Physical Activity, Psychosocial Aspects, Benefits

Rick LaCaille
Psychology Department, University of Minnesota Duluth, Duluth, MN, USA

Definition

Numerous aspects of psychological well-being related to physical activity have been examined using epidemiological, cross-sectional, and experimental research strategies, including depression, anxiety, mood/affect, self-perception, cognitive performance, and quality of life. Moreover, these aspects have been considered in terms of acute bouts of exercise and chronic exercise/physical activity as well as potential underlying mechanisms.

Description

It is well accepted that physical activity (PA) has important and far-reaching benefits for enhanced physical health and reduced risk of premature mortality. However, notable psychological benefits have also been documented in the literature (Buckworth & Dishman, 2002). Recently, increased attention has been drawn to examining the impact of PA on serious mental illnesses (e.g., schizophrenia, substance abuse/dependence, eating disorders) and a call to consider integrating PA programs into mental health services as a means to improve psychological well-being and reduce risk for comorbid physical health problems (Holley, Crone, Tyson, & Lovell, 2011; Richardson et al., 2005). Although additional randomized clinical trials are needed to evaluate PA interventions for treating psychological disorders, some data exist supporting the psychosocial benefits in terms of alleviating both primary and secondary symptoms of psychological disorders, including reduced cravings and body dissatisfaction and improved mood and social functioning.

Depression

The most cited and striking evidence in support of the beneficial associations between psychosocial functioning and physical activity comes from studies examining depression. Prospective epidemiological studies have found depression to be associated with low levels of PA, whereas maintaining a moderately active lifestyle has been related to lower risk of developing depression (Biddle, Fox, & Boutcher, 2000). These data are suggestive of both a dose–response relationship and protective effect of PA. Both narrative reviews and meta-analyses of exercise interventions have reported moderate-to-large effects for individuals with clinical depression with the reduction in depression appearing for both aerobic and non-aerobic forms of exercise (Clark & Williams, 2011; Stathopoulou, Powers, Berry, Smits, & Otto, 2006). Importantly, the effect was more pronounced for individuals diagnosed with moderate-to-severe levels of depression than mild-to-moderate levels. These post-intervention effects have been demonstrated in older populations (>60 years) as well, though long-term intervention outcomes and follow-up appear to be lacking with most of the trials (Blake, Mo, Malik, & Thomas, 2009). Some data also point to PA yielding effects comparable to antidepressant medications. The effects for exercise may appear less immediate than medications, but exercise seems to offer a reduced risk for relapse with depression (Barbour, Edenfield, & Blumenthal, 2007). A recent meta-analysis of PA interventions and depressive symptoms (i.e., nonclinical depression) has reinforced the previous findings of somewhat smaller moderate effects with less depressive symptomatology for both men and women; however, the effect was strengthened when aerobic forms of exercise were combined

with non-aerobic exercise (i.e., resistance, flexibility) (Conn, 2010a). Supervised low-intensity PA interventions were shown to yield larger effect sizes than moderate- or high-intensity exercise, suggesting that increased aerobic fitness is not a primary mechanism responsible for antidepressive effects of PA.

Anxiety

Another central area of inquiry regarding the salutary effects of PA has involved investigating anxiety reductions in both clinical and nonclinical samples. Reviews of intervention studies using individuals with elevated levels of anxiety or diagnosed anxiety disorders have generally reported small-to-medium effect sizes with somewhat better effects demonstrated with aerobic forms of exercise and longer intervention programs (Biddle, Fox, & Boutcher, 2000). Some comparative studies have shown PA to provide similar results to pharmacological and other therapeutic techniques (e.g., relaxation) in anxiety reductions and related symptoms. However, similar to the findings with depressive disorders, the impact of PA on anxiety reduction generally appears to be more delayed but stable. A recent meta-analysis of anxiety outcomes of PA interventions with nonclinical samples found similar benefits of PA on reduced anxiety levels, though observed slightly more modest effects than seen with clinical samples (Conn, 2010b). Although no differential effect was found for aerobic versus non-aerobic forms of PA, greater anxiety reduction was observed with moderate-to-high intensity levels of exercise. In addition to chronic exercise (i.e., PA interventions), studies focusing on single bouts of exercise have examined changes in state anxiety with similar size effects. Larger reductions in anxiety appear for within-group than between-group comparisons and aerobic forms of exercise (rather than non-aerobic/resistance forms) appear most beneficial with reducing state anxiety. Single-session bouts of exercise have also been found to provide beneficial attenuated physiological reactivity and improved recovery from psychosocial stressors (Buckworth & Dishman, 2002).

Affective Response

Although some researchers have used mood and affect interchangeably, there has been considerable attention in the PA/exercise literature directed toward providing clarification of these constructs (e.g., Ekkekakis & Petruzzello, 2000). Overall, moods are emotion-related expressions (e.g., anxious mood, depressed mood) that are considered more complex and multifaceted, lasting only brief moments to days, and may develop without an identifiable event. While affect is also considered an emotion-related expression, it is thought to be more basic and vary along the orthogonal dimensions of valence (unpleasant/avoidance vs. pleasant/approach) and level of activation (calm vs. aroused). Thus, an affective response may entail unpleasant and low activation (e.g., fatigue, boredom), unpleasant and high activation (e.g., tension, distress), pleasant and low activation (e.g., relaxation, tranquility), and pleasant and high activation (e.g., vigor, excitement). A meta-analysis examining changes in pleasant high activation affect observed medium-sized effects shortly after a bout of aerobic exercise with larger effects noted for lower-intensity exercise (Reed & Ones, 2006). Other studies have also indicated that exercise may result in reports of increased vigor, relaxation, and tranquility and decreased tension, irritability, and fatigue (Biddle, Fox, & Boutcher, 2000). Additionally, high-intensity (or even moderate-intensity) exercise may result in increased negative/unpleasant affect, though there appears to be a great deal of variability in affective responses among moderate-intensity PA. More recent efforts to clarify the relationship between affect and exercise intensity have investigated affective responses that occur while physically active. This line of research has indicated that the ventilatory/lactate threshold (i.e., near maximal level of intensity and transition from aerobic to anaerobic metabolic supplementation) appears to be the point at which pleasant affective responses diminish while exercising and that postexercise affect may reflect a rebound from this decline or a continuation of pleasant affect if this level of intensity is not exceeded (Ekkekakis & Acevedo, 2006).

Cognitive variables (e.g., attentional focus, self-efficacy, attributions) appear to influence affective responses with intensities below or near the threshold; however, physiological/interoceptive variables (e.g., muscular or respiratory cues) come to play a more dominant role in influencing the affective response as the threshold is approached or exceeded. An important implication of this line of investigation lies in the potential to improve adherence to a PA program for novice exercisers by developing self-monitoring skills and cognitive strategies (e.g., attentional dissociation/association) while exercising and self-selecting intensity to maximize reinforcing positive affective responses.

Self-Perception

A related and equally important area, though considerably less studied, is the relationship between self-perception and PA. Self-perception is conceptualized as a multifaceted construct within which lie several related subjective attitudes and beliefs about one's self (e.g., self-esteem, self-concept) that may be organized in hierarchical levels (e.g., global self-esteem, physical self-esteem domain, situation-specific efficacy). Overall, cross-sectional studies have shown that engaging in PA appears weakly associated with higher global self-esteem, though a moderate relationship between better physical self-esteem and body image exists beginning in adolescence and extending into adulthood (Ekelund, Heian, & Hagen, 2005; Fox, 2000; Spence, McGannon, & Poon, 2005). Reviews of PA interventions reinforce this pattern of improved self-perceptions with the greatest improvements occurring for individuals with lower self-esteem. Some data also suggest that females may benefit more from participation in an exercise program than their male counterparts in terms of increased body image, physical self-esteem, and self-efficacy for exercise (Hausenblas & Fallon, 2006). Although both aerobic forms of PA and weight/resistance training seem beneficial, the combination of the two appears to offer greater improvements in body image and physical self-esteem.

Cognitive Performance

A growing body of evidence supports the beneficial effect of PA on cognitive functioning in both children and adults (Clark & Williams, 2011; Etnier, Nowell, Landers, & Sibley, 2006). Although cross-sectional design studies have suggested moderate-sized effects favoring fitter participants, most randomized exercise interventions indicate a more modest effect on improved cognitive processes. Studies with older adults have provided somewhat mixed results, with improved cognitive performance being most pronounced with simple reaction time-/speed-based tasks in some studies and executive-control tasks (e.g., planning, response inhibition, task choice/switching) showing greater benefits from PA in other studies. Some evidence indicates that regular participation in moderate PA during midlife may confer a reduced risk of later cognitive impairment/dementia (Colcombe & Kramer, 2003). With regard to children, benefits associated with PA have been observed in several cognitive domains (e.g., verbal abilities, attention and concentration, executive functioning) as well as improved academic performance. For both children and adults, such improved cognitive processing has been seen with acute bouts of exercise and longer term PA programs (Biddle, Fox, & Boutcher, 2000). Generally, acute bouts of exercise have demonstrated larger effects when lasting 30–60 min; PA programs exceeding 6 months have shown greater improvements than briefer interventions. Although the emphasis within the literature is usually on aerobic forms of PA, combining aerobic and resistive/weight training forms of exercise has demonstrated somewhat larger cognitive performance gains.

Quality of Life

A final area of consideration with regard to PA benefits involves the emerging concept of perceived quality of life, sometimes referred to as health-related quality of life. Quality of life is a multifaceted construct often encompassing physical (e.g., physical functioning, bodily pain), mental (e.g., vitality), and social components (e.g., role limitations, social functioning) or overall satisfaction with life and psychological

well-being. In terms of PA, the construct has been predominantly examined with older populations and those managing a chronic health diagnosis with exercise appearing to have a positive impact for several of these conditions (e.g., cancer, diabetes). A meta-analysis of older adults without clinical disorders found small-to-medium effects for PA on various aspects of quality of life/well-being, with aerobic forms of exercise and moderate intensity providing the greatest benefits (Netz, Wu, Becker, & Tenenbaum, 2005). Another more recent review examined the quality of life outcomes in the general adult population and reported consistently moderate-to-strong positive effects of PA in cross-sectional studies (Bize, Johnson, & Plotnikoff, 2007). However, few randomized clinical exercise trials have examined quality of life in healthy samples which limits the potential strength of the conclusions and generalizability to the general population.

Compulsive Physical Activity

Although the emphasis within the literature on psychosocial aspects of PA has been overwhelming on the beneficial effects, reports suggest potentially deleterious effects for some individuals. For instance, some investigations have documented compulsive/obligatory patterns of exercise engagement that may pose an increased risk for overuse injuries or reduced psychological well-being (e.g., increased self-criticism and body dissatisfaction despite improved fitness or some weight loss success) (Biddle, Fox, & Boutcher, 2000). The diagnostic validity of "exercise addiction" has been questioned by some investigators, and the incidence of such patterns is thought to be rare, though excessive PA/exercise has been more frequently reported as a secondary feature of some preexisting clinical disorders (e.g., body/muscle dysmorphia). Notably, some data exist supporting the use of PA/exercise as an adjunctive treatment for eating disorders with improvements in reduced drive for thinness and binge eating (Stathopoulou, Powers, Berry, Smits, & Otto, 2006).

Conclusions and Summary

Despite the large literature that exists on the psychosocial benefits of PA, a clear understanding of the underlying mechanisms is less evident. Numerous mechanisms have been proposed in the literature, including psychological/cognitive (e.g., sense of mastery, autonomy and personal control, distraction) and physiological/biochemical changes (e.g., thermogenic, cerebral adaptations, monoamine and endorphin levels) (Buckworth & Dishman, 2002). In summary, PA appears to have a sizeable antidepressant effect, with several other psychosocial benefits documented such as reduced anxiety, improved body image and physical self-esteem, enhanced cognitive performance, and perceptions of greater quality of life. A person's affect while being active, as well as following a bout of exercise, may fluctuate as a product of the level of intensity with higher levels potentially resulting in a diminished positive and increased negative affective response. Helping beginning exercisers self-identify and regulate this potential affect-intensity relationship may prove useful in maximizing the reinforcing positive affective responses and improving longer-term adherence to a healthier physically active lifestyle. Although PA may be associated with some reductions in psychological well-being for select individuals engaging in compulsive behavioral patterns, on balance, it appears that the benefits of PA exceed the risks of misuse.

Physical Examination

Margaret Hammersla
University of Maryland School of Nursing, Baltimore, MD, USA

Synonyms

Health assessment; Physical exam

Definition

Physical examination, assessment, is the systematic process of collecting data about a patient or client using the techniques of inspection, palpation, percussion, and auscultation to guide a clinician in the process of diagnosis of pathological states as well as developing a plan of care (Fennessey & Wittmann-Price, 2011). Physical assessment is an ongoing process that enables the clinician to continuously evaluate a patient's signs and symptoms, to monitor effectiveness of treatment, and to make adjustments in the plan of care as required (Zambas, 2010). This physical assessment is conducted in a systematic manner that is comfortable to both the patient and clinician; typically this is done using a head-to-toe approach.

Physical assessment is done for one of two reasons. The first reason is to conduct a complete physical exam of the entire body in order to screen the patient for potential health problems that have not yet manifested symptoms (Bickley & Szilagy, 2008) and monitor chronic health concerns. This exam is traditionally categorized based on body system (e.g., cardiovascular, respiratory, gastrointestinal). Each body system has its own set of unique advanced assessment procedures that allow the clinician to make a judgment about physical function based on what he or she sees, hears, and feels.

The second reason is to investigate a patient's chief complaint or follow-up on a current health problem such as hypertension or diabetes (Stern, Cifu, & Altkorn, 2009). For this more focused exam the clinician makes a determination of what body systems and exam components need to be conducted based on the differential diagnosis and/or the pathophysiology of the current health problem. This more focused exam typically utilizes more advanced techniques to obtain a deeper understanding of the physical changes that may be occurring due to disease process (Bickley & Szilagy, 2008).

Physical assessment, along with health history, is the first and most vital step in diagnosing and planning care for patients. A skilled clinician will be able to utilize findings from the physical exam to both support and rule out diagnoses.

Definition

Physical fitness is one's ability to execute daily activities with optimal performance, endurance, and strength with the management of disease, fatigue, and stress and reduced sedentary behavior.

Description

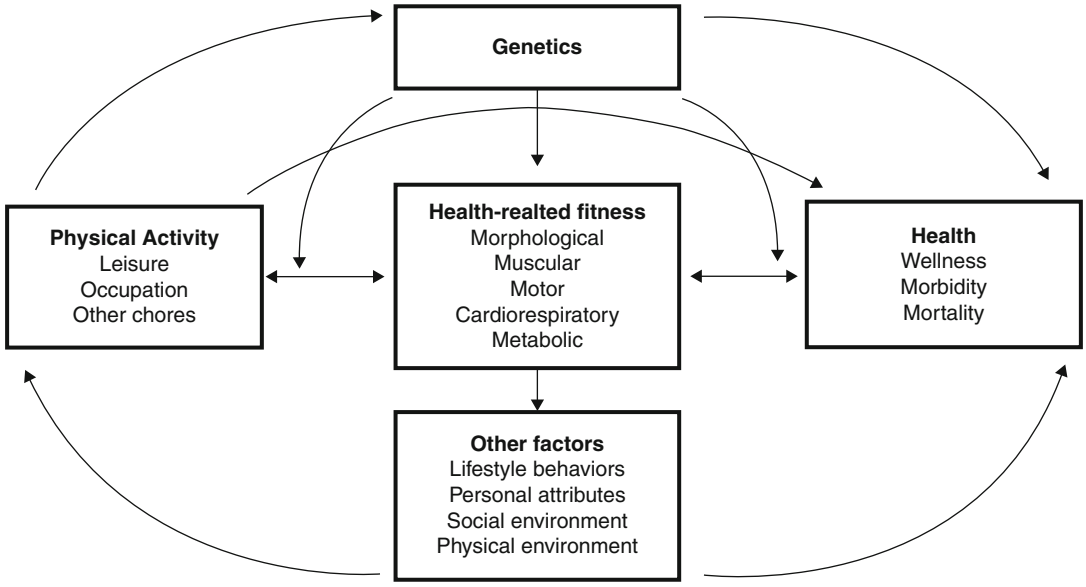
Physical fitness has multiple components and is conceptualized as either performance- or health-related. The specificity of performance-related fitness regarding one's athletic skill best relates to an individual's athletic performance. Conversely, health-related fitness is generalized to health status and is affected positively or negatively by one's habitual physical activity habits. Given the complexity of physical fitness and the epidemiological analysis taken presently, health-related fitness will be the focus of this discussion.

There are five major components of health-related fitness: morphological, muscular, motor, cardiorespiratory, and metabolic (see below), with muscular and cardiorespiratory fitness being the two primary facets assessed in research. As outlined in Fig. 1, a complex relationship exists among the five biological traits, physical activity level, and health outcome.

There are numerous methods to assess the different components of health-related physical fitness, ranging in feasibility and utility for a laboratory versus field-based testing. Morphology is typically assessed using body mass index (BMI, expressed as kg/m^2), a crude measure of body composition. More objective measures of body composition include skinfold technique, bioelectrical impedance, and dual-energy x-ray absorptiometry. Muscular strength can be evaluated by tensiometers, handgrip dynamometers, and strength gauges. Conversely, muscular endurance is measured by performing the maximum number of repetitions of common body movements, such as sit-ups or push-ups. Motor skills involve fine and gross motor skills and are most commonly assessed by a battery of tests that target balance, speed, control precision, reaction time, aim, and coordination. Cardiorespiratory fitness is the ability of the cardiovascular and respiratory systems to deliver oxygen to working muscles, in addition to the ability of those tissues to utilize that oxygen to produce energy. Peak VO_2, a reflection of cardiorespiratory fitness, is the highest rate of oxygen consumption by muscles during exercise and can be directly assessed by a maximal exercise test. Alternatively, peak VO_2 can be measured indirectly using a submaximal exercise test or timed distance run/walk protocol. Finally, to determine metabolic health, blood pressure and biochemical analyses of blood triglycerides and fasting plasma glucose are examined.

Natural differences exist in health-related physical fitness across the life span and by sex and ethnicity. The extent of the difference is dependent on the specific component of fitness. In general, level of physical fitness declines with age. Age-related decreases in peak VO_2 and muscular strength make even the simplest tasks physically demanding for the elderly compared to younger people. Sex differences in physical fitness are primarily attributed to differences in absolute muscle mass and morphology between males and females. Males generally tend to have higher levels of cardiorespiratory fitness and strength and decreased flexibility compared to females. Similarly, differences in cardiorespiratory fitness have been found between white and black individuals. On average, white males and females are found to have higher maximal VO_2 values compared to black males and females. It is important to keep in mind that depending on the population of interest, different approaches may be needed in order to appropriately assess physical fitness. For example, a maximal VO_2 exercise test may be appropriate for healthy adults or the fit elderly, whereas a different approach for assessing VO_2 in obese individuals or frail older persons may be required.

A multidisciplinary approach is necessary to achieve and maintain physical fitness. Specifically, meeting recommended physical activity and nutrition guidelines as well as acquiring



Physical Fitness, Fig. 1 Bouchard, Blair & Haskell (2006), p. 17

adequate rest are each important components to overall functional health. Not surprisingly, cardiovascular disease, diabetes, cancer, obesity, depression, osteoporosis, and premature death are associated with inadequate physical activity and hence poor physical fitness.

Health-Related Fitness Components and Traits

Morphological component	Body mass for height
	Body composition
	Subcutaneous fat distribution
	Abdominal visceral fat
	Bone density
	Flexibility
Cardiorespiratory component	Submaximal exercise capacity
	Maximal aerobic power
	Heart functions
	Lung functions
	Blood pressure
Muscular component	Power
	Strength
	Endurance
Motor component	Agility
	Balance
	Coordination
	Speed of movement
Metabolic component	Glucose tolerance
	Insulin sensitivity
	Lipid and lipoprotein metabolism
	Substrate oxidation characteristics

Physical Inactivity

Tyler Clark
School of Psychology, The University of Sydney, Sydney, NSW, Australia

Definition

Physical inactivity is the failure to meet the minimum recommended physical activity guidelines (i.e., 30-min moderate-intensity exercise on at least 5, although preferably all, days of the week or 75-min vigorous-intensity exercise to be undertaken in no less than 20-min increments thrice a week). Physical inactivity is one of the World Health Organization's (WHO) 12 leading risks to health. Physical inactivity is widespread and associated with increases in all causes of mortality and is an independent risk factor for chronic diseases.

Physical inactivity differs from sedentary behavior (e.g., sitting and not moving); physical inactivity refers to not meeting the aforementioned guidelines.

Description

Prevalence

The American Heart Association estimates that 60% of the world population does not meet recommended physical activity guidelines (American Heart Association, 2001). The American Centre for Disease Control (CDC) estimates 25% of adults are not active at all.

Risk Factors

Physical inactivity increases with age. While physical activity typically peaks in early adolescence, it then begins to decline, regardless of gender (World Health Organization, 2011a). Other demographic risk factors include low income and less education.

Behavioral correlates of physical inactivity include a reduction in leisure-time physical activity and the inclusion of more sedentary occupational and domestic activities (Healey, 2007).

Other environmental correlates of physical activity include population overcrowding, increased levels of crime, high-density traffic, low air quality, and a lack of parks, sidewalks, and sports/recreation facilities (WHO, 2011a).

Health Risks

Physical inactivity increases all cause mortality (World Health Organization, 2011b). The WHO estimates as many as two million deaths worldwide as attributable to physical inactivity. It is also an independent risk factor for chronic diseases such as ischemic heart disease, stroke, type 2 diabetes, breast cancer, colon cancer, and depression. Physical inactivity is also a leading cause of falls and fall-related injuries, particularly in older populations.

Physical inactivity has indirect health burdens as well, which include pain, disability, anxiety, and increased suffering due to medical conditions. These indirect burdens often lead to a reduction in an individual's quality of life, as well as shorter life expectancy, less workforce participation, decreased bone and functional health, and weight gain (Taylor, 2009).

Synonyms

Kinesiotherapy; Physiotherapy; Therapy, Physical

Definition

Physical therapy is a health service concerned with identifying and maximizing quality of life and movement potential within the spheres of promotion, prevention, intervention/treatment, habilitation, and rehabilitation. The spheres of practice are aimed at physical, psychological, emotional, and social well-being of a patient/client or population group. Physical therapy involves the interaction between physical therapists and patients/clients, other health professionals, families, caregivers, and communities in a process where movement potential is assessed, goals are agreed upon, and interventions carried out using knowledge and skills unique to physical therapists (World Confederation for Physical Therapy [WCPT], 2011a, b).

Description

Physical therapy is the service provided only by, or under the direction and supervision of physical therapists, to people and populations to develop, maintain, and restore maximum movement and

functional ability throughout the life span. Physical therapist practice includes the provision of services in circumstances where movement and function are threatened by the process of aging or by injury, diseases, disorders, or other conditions of health. Functional movement is central to physical therapist practice since it is at the core of what it means to be healthy. Physical therapists are guided in their practice by the professional behaviors of accountability, altruism, compassion/caring, cultural competence, ethical behavior, integrity, personal/professional development, professional duty, and social responsibility and advocacy. Physical therapist education consists of university-based education leading to entry-level qualifications that range internationally from bachelors, to masters or doctorate entry qualifications.

Physical therapist practice follows a patient/client management model that includes examination/assessment, evaluation, diagnosis, prognosis, plan of care, intervention/treatment, and reexamination (World Confederation for Physical Therapy, 2011a, b).

Examination by the physical therapist involves history taking, screening of the patient's/client's systems (cardiovascular/pulmonary, musculoskeletal, neuromuscular, and integumentary) and the use of specific tests and measures, the results of which are evaluated within a process of evidence-based clinical reasoning to determine the facilitators and barriers to optimal human functioning. The tests and measures used by physical therapists include any of the following: aerobic capacity/endurance; anthropometric characteristics; arousal, attention, and cognition; assistive and adaptive devices; balance; circulation (arterial, venous, lymphatic); cranial and peripheral nerve integrity; environmental, home, and work access and barriers/facilitators; ergonomics and body mechanics; gait and locomotion; integumentary integrity; joint integrity and mobility; motor function (motor control and motor learning); muscle performance; neuromotor development and sensory integration; orthotic, protective, and supportive devices; pain; posture; prosthetic requirements; range of motion; reflex integrity; self-care and home management; sensory and proprioceptive integrity; ventilation and respiration/gas exchange; and work, education, community, and leisure integration or reintegration.

Based upon the examination results, physical therapists evaluate the findings from the examination (history, systems review, tests and measures, environmental facilitators/barriers) to make clinical judgments regarding patients/clients. Physical therapists formulate the diagnosis that results in the identification of existing or potential impairments, activity limitations, and participation restrictions and then determine patient/client prognoses and identify the most appropriate intervention/treatment strategies to optimize patient/client functioning. The plan of care is developed that is consistent with legal, ethical, and professional obligations and administrative policies and procedures of the practice environment. Specific interventions/treatments are determined with measurable outcomes and goals associated with the plan of care and with the involvement of the person and their care providers, both professional and personal. Plans may include referral to other agencies and service delivery providers.

Physical therapists provide, whenever possible, evidence-based physical therapy interventions to achieve patient/client goals and outcomes. These interventions/treatments encompass three major areas: (1) coordination, communication, and documentation; (2) patient/client-related instruction; and (3) procedural interventions.

The procedural interventions include:

1. Therapeutic exercise (including aerobic capacity/endurance conditioning or reconditioning; balance, coordination, and agility training; body mechanics and postural stabilization; flexibility exercises; gait and locomotion training; neuromotor development training; relaxation; and strength, power, and endurance training for head, neck, limb, pelvic-floor, trunk, and ventilatory muscles)
2. Functional training in self-care and home management (including activities of daily living training; barrier accommodations or modifications; device and equipment use and training; functional training programs;

instrumental activities of daily living training; and injury prevention or reduction)
3. Functional training in work, community and leisure integration or reintegration (including barrier accommodations or modifications; device and equipment use and training; functional training programs; instrumental activities of daily living training; injury prevention or reduction; and leisure and play activities and training)
4. Manual therapy techniques (including acupressure; manual lymphatic drainage; manual traction; massage; mobilization/manipulation; and passive range of motion)
5. Prescription, application, and, as appropriate, fabrication of devices and equipment (including adaptive, assistive, orthotic, prosthetic, protective, and supportive devices)
6. Airway clearance techniques (including breathing strategies; manual/mechanical techniques; and positioning)
7. Integumentary repair and protection techniques (including selective and nonselective wound debridement; dressings; oxygen therapy; and topical agents)
8. Electrotherapeutic modalities (including biofeedback; electrotherapeutic delivery of medications; and electrical stimulation)
9. Physical agents (including athermal agents; cryotherapy; hydrotherapy; light agents; sound agents; and thermotherapy) and mechanical modalities (including acupuncture, dry needling; compression therapies; gravity-assisted compression devices; mechanical motion devices; and traction devices)

Interventions/treatments are aimed at prevention of impairments, activity limitations, participation restrictions, and injury. Interventions provided by physical therapists also include prevention, health promotion, and fitness for individuals of all ages and for groups and communities.

Reexamination by physical therapists occurs throughout the episode of service delivery to evaluate the effectiveness of interventions/treatments and outcomes and to adjust the plan of care in response to findings. Outcomes monitoring is part of building the evidence base for modifying the patient/client plan, as well as for the research underpinning professional physical therapy practice.

Physical therapy is an essential part of the health and community/welfare services delivery systems. Professional education prepares physical therapists to practice independently of other health service delivery providers as autonomous practitioners and also within interdisciplinary rehabilitation/habilitation programs. Physical therapists may act as first contact practitioners, and patients/clients may seek direct services without referral from another health care professional. Physical therapists provide consultation within their expertise and determine when patients/clients need to be referred to an other professional provider.

The professional names of physical therapy or physiotherapy, the titles physical therapist or physiotherapist and appropriate abbreviations (e.g., PT, FT, physio) as such or in any translation, are the sole preserve of persons who hold qualifications approved by national professional associations. Members of the public wishing to access the services of a physical therapist are entitled to know that recognized qualifications are held and that professional behavior is governed by ethical codes (World Confederation for Physical Therapy, 2007).

Physical therapists, guided by their own code of ethical principles, are concerned with the following purposes:

- Promoting the health and well-being of individuals and the general public/society, emphasizing the importance of physical activity and exercise
- Preventing impairments, activity limitations, participatory restrictions, and disabilities in individuals at risk of altered movement behaviors due to health or medically related factors, socioeconomic stressors, environmental factors, and lifestyle factors
- Providing interventions/treatments to restore integrity of body systems essential to movement, maximize function and recovery, minimize disability, and enhance the quality of life and inclusion, independent living and workability in individuals and groups of individuals with altered movement behaviors resulting

from impairments, activity limitations, participatory restrictions, and associated environmental factors (disabilities)
- Modifying environmental, home, and work access and barriers to ensure full participation in one's normal and expected societal roles

Physical therapists contribute to the development of local, national, and international health policies and public health strategies. Physical therapists may have roles in management, administration, supervision of personnel, education, research, and consultation to businesses, schools, government agencies, other organizations, or individuals.

Physical therapy services may be provided to individuals or populations and in a wide range of service settings, including but not limited to community-based rehabilitation programs; community settings including primary health care centers; individual homes; field settings (including in response to disasters); educational and research centers; fitness centers; health clubs; gymnasia and spas; hospices; hospitals; nursing homes; occupational health centers; outpatient clinics; physical therapist private offices and clinics; prisons; public settings (e.g., shopping centers) for health screening and promotion; rehabilitation centers; residential homes; schools including preschools and special schools; senior citizen centers; sports centers/clubs; and workplaces/companies.

Physiological Reactivity

Kristen Salomon
Department of Psychology, University of South Florida College of Arts & Sciences, Tampa, FL, USA

Synonyms

Stress reactivity; Stress responses

Definition

Physiological reactivity involves bodily changes in response to stressful stimuli or events.

The classic features of physiological reactivity are increases in sympathetic nervous system and hypothalamic-pituitary-adrenal axis (HPA) activity, often referred to as the "fight-or-flight" response (Cannon, 1932). These responses include increases in heart rate, blood pressure, cardiac contractility, and cortisol. Changes in parasympathetic nervous system activity, immune function (Cacioppo, 1994), and non-HPA endocrine function (Taylor et al., 2000) can also occur. For reactivity to serve as a meaningful metric, stress responses must be compared to an unstressed resting state, or baseline, to control for wide individual differences in resting levels (Jennings et al., 1992). Physiological reactivity is most often assessed in response to acute stressors on the order of minutes (Steptoe & Vögele, 1991).

Pickering, Thomas G.

Eoin O'Brien
The Conway Institute, University College Dublin, Belfield, Dublin, Ireland

Biographical Information

Dr. Thomas George Pickering

Thomas George Pickering was born in the United Kingdom in 1940. He was educated at Bryanston School in Blandford, England, and went on to study medicine at Trinity College, Cambridge,

Editors' Note: Dr. Pickering passed away in 2009. The American Society of Hypertension has established the Thomas Pickering Memorial Lecture, the first of which was delivered at the Scientific Meeting in May 2012.

and the Middlesex Hospital Medical School, London, where he graduated in 1966.

Pickering's early postgraduate years were spent at the Middlesex and the Radcliffe Infirmary. He became a member of the Royal College of Physicians of London in 1968, becoming a fellow in 1980. He received a Ph.D. degree from Oxford University in 1970. In 1972, he went to New York to take up appointments as Associate Physician at the Rockefeller University Hospital and Assistant Professor at Cornell University. He spent 2 years as Assistant Professor at the Rockefeller University working with Neal Miller on biofeedback mechanisms. He was appointed Assistant Physician to the New York Hospital in 1974. He returned to theRadcliffe Infirmary in 1974 to work with Peter Sleight.

Pickering's earliest hypertension research at Oxford focused on baroreceptor function, the autonomic nervous system, and the emerging class of cardiovascular medications known as the adrenoreceptor blockers. Although he remained in Oxford from 1974 to 1976, the possibility of being able to work as both a practicing physician and a clinical investigator drew him back to New York City and Cornell University Medical College, where he spent more than 20 years in a productive career in cardiovascular behavioral medicine, clinical hypertension, and blood pressure measurement research. In 2000, he became Director of Behavioral Cardiovascular Health and the Hypertension Program at the Cardiovascular Institute of Mount Sinai Medical Center, and in 2003 he moved to Columbia University Medical College as Professor of Medicine and Director of the Behavioral Cardiovascular Health and Hypertension Program.

Major Accomplishments

Pickering practiced "translational research" long before the term became fashionable, translating his clinical observations in medical practice to research endeavors throughout his career. He made important observations on the relationship between renovascular disease and cardiovascular complications, and the impact of renal revascularization. He also observed that anxiety, perceived stress, job strain, and the medical care environment itself induced hypertension in some individuals who otherwise would not have been classified as hypertensive. He had a deep belief that psychosocial mechanisms played an important role in the pathogenesis of cardiovascular disorders.

Pickering's research interests also focused on new methods of blood pressure measurement, particularly the use of 24-h ambulatory monitoring and self monitoring. His identification of the importance of the circadian variability of blood pressure led to the study of the psychological influences of work and stress in hypertension and heart disease, a field in which he was regarded as the world authority. At a clinical level he studied the influence of sleep in hypertension and methods of improving adherence to medication in order to obtain better control of elevated blood pressure. Pickering also studied the application of non-pharmacological approaches to the management of hypertension, publishing prolifically in these areas. He published a total of almost 500 original research articles in a clear and concise manner. Several highly acknowledged experts acknowledge his leadership in coining the terms "white-coat hypertension" and "masked hypertension," conditions which he not only described, but did much to explain with well-designed studies. This work systematically investigated whether white-coat hypertension was benign, and whether masked hypertension enhanced risk.

Pickering served on many governmental and academic bodies including the American Society of Hypertension; the National Heart, Lung, and Blood Institute; the International Society of Hypertension; the American Heart Association; the US Cardiorenal Advisory Committee; the US Food and Drug Administration; and the Committee on Gulf War and Stress of the Institute of Medicine. As a senior editor of the Journal of Clinical Hypertension he wrote numerous editorials. In his later years he came to feel strongly that self-monitoring of blood pressure, as well as ambulatory blood pressure monitoring, should be covered by third-party insurance companies for patient hypertension care. In 2002, after 19 years

of lobbying, a scientific meeting of the Center for Medicare and Medicaid Services was established to develop a national policy for coverage of ambulatory blood pressure monitoring for patients with white-coat hypertension. At Pickering's suggestion, not only was evidence of the benefits of ambulatory monitoring presented at this meeting but the patients who had benefited gave testimony. The patients' stories had a substantial impact, and the meeting voted unanimously to approve national coverage for ambulatory monitoring.

Pituitary-Adrenal Axis

Jennifer Heaney
School of Sport and Exercise Sciences,
The University of Birmingham, Edgbaston,
Birmingham, UK

Synonyms

Hypothalamic-pituitary-adrenal axis

Definition

The pituitary-adrenal axis comprises the pituitary and adrenal glands. The main interactions that take place between these two endocrine glands are as part of the hypothalamic-pituitary-adrenal axis (HPA axis). Corticotrophin-releasing hormone (CRH) stimulates the secretion of adrenocorticotropic hormone (ACTH) from the anterior pituitary; this in turn stimulates the release of cortisol from the adrenal cortex (Martin, Reichlin, & Brown, 1997). More detail on the pituitary-adrenal axis and its function in the HPA axis can be found in Widmaier, Raff, and Strang (2004), O'Riordan, Malan, and Gould (1988), and Greenspan and Forsham (1983).

Placebo and Placebo Effect

Magne Arve Flaten[1] and Mustafa al'Absi[2]
[1]Department of Psychology, University of Tromsø, Tromsø, Norway
[2]University of Minnesota Medical School, University of Minnesota, 235 School of Medicine, Duluth, MN, USA

Synonyms

Conditioned response; Context effect; Expectancy effect

Definition

A placebo is any inert substance, procedure, apparatus, or similar, that alone has no effect in the body. The placebo effect is the psychological and/or physiological response to the placebo when it is administrated with a suggestion that the substance, procedure, apparatus, or similar will have an effect in the individual.

Description

Placebo comes from the Latin word "placere" which means "I shall please" and has been used in medicine to describe treatments that pleases the patient, but that has no specific effect on the symptom.

A placebo effect may occur when a substance, procedure, or other stimulus is administrated to a person, together with a suggestion that this will reduce or heal a symptom. The placebo effect may occur whether the substance or procedure is effective in reducing the symptom or not, as effective treatments may also induce placebo effects. Both the substance or procedure and the suggestion are necessary to produce a placebo effect. Administration of a pill without the suggestion, or the suggestion without the pill, will not generate a placebo effect. Thus, a placebo alone is not sufficient to generate a placebo effect, as it must be accompanied by a suggestion. The suggestion can be in the form of verbal information, e.g., "this capsule may contain a painkiller," that induces an expectation that the treatment will reduce the symptom. The expectation has been found to be correlated to the actual placebo response. Thus, it could be argued that the term "expectancy effect" should replace the vague and often misinterpreted term "placebo effect." Placebo effects may also be implicit and communicated through contextual factors. For example, a "pill" provided by a physician may have a stronger "placebo" effect than a pill provided by a nonmedical professional.

Placebo effects may also occur as a result of a conditioning process. For example, after the individual has been subject to effective treatment,

an association between treatment and its outcome may develop. The shape or color of tablets the patient has taken in the past to reduce pain or other problems may be associated with the drug effect, since the shape or color of the tablet (the conditioned stimulus) is reliably followed by reduction in the symptom (the unconditioned response). The features of the tablet can be associated with the effect of the drug in the central nervous system (the unconditioned stimulus) and come to elicit conditioned decreases in the symptom. Placebo effects induced by actual experience with the drug effect are stronger than placebo effects induced by verbal information alone (Flaten et al., 1999). For some symptoms, the conditioned stimulus exerts its effect by inducing an expectation, for other symptoms unconscious, automatic processes seem to be responsible for the placebo effect (Benedetti et al., 2003).

The placebo effect is observed as a reduction in a symptom in a group that receives placebo treatment with suggestion, compared to a natural history control group that receives no treatment and no suggestion. The natural history group controls for normal variations in the symptom due to normal healing processes or other changes that are not due to expectations of treatment effects. Response bias is serious problem, as subjects may feel obliged or may have a tendency to report on the symptom in accordance with the suggestion provided by the experimenter, without there being any improvement in the symptom, and studies must control for demand characteristics. Placebo analgesia, a reduction in pain due to expectations of having received a painkiller, is the most studied form of placebo effect. Pain is accompanied by changes in autonomic function, by well-defined changes in the event-related potential to painful stimulation, and by a cerebral response reliably involving the somatosensory cortex, the anterior cingulate cortex, and the insula. Placebo analgesia is accompanied by reduction in these correlates to the reported pain, indicating that the placebo effect is due to changes in the brain's response to the pain signal and not solely to a response bias, although this may contribute.

Multiple neurobiological pathways are thought to be involved in mediating effects of placebo, including those related to the endogenous opioid system and stress response systems. Placebo analgesia has been found to be reversible or partly reversible by the opioid antagonist naloxone. This is further evidence that the placebo effect is not due to a response bias, and indicates that expectations of pain relief activate the mid-brain descending pain inhibitory system. Wager et al. (2004) found that expectations of pain relief were associated with increased activity in the periaqueductal gray in the midbrain, a nucleus that controls pathways descending to the rostral ventral medulla and the dorsal horn. There, this pathway inhibits pain transmission, resulting in a reduced pain signal to the brain areas mentioned above, with a consequent reduction in pain sensation. Injections of opioids into the periaqueductal gray and the ventral medulla reduce pain, suggesting that endogenous opioids reduce pain via the same descending system. Eippert, Finsterbusch, Bingel, and Buchel (2009) furthermore showed that placebo analgesia involved dorsal horn activity, indicating that placebo analgesia is due to expectation of pain relief that in turn activates the descending endorphin-mediated pain inhibitory system.

In addition to pain, placebo effects are documented in, e.g., Parkinson's disease, depression, cardiac heart disease, sexual function, and airway resistance in asthmatic patients. This implies that there are several placebo effects with different underlying mechanisms. In Parkinson's disease, placebo treatment has been found to increase dopamine release in the basal ganglia, thereby improving motor function. Increased dopamine release has also been implicated in placebo analgesia. Most studies have found only a partial reversal of placebo analgesia by naloxone, whereas some studies have found no effect of naloxone on the placebo analgesic response. Thus, non-opioid mechanisms play a role in placebo analgesia. It has been hypothesized that placebo treatment leads to reduced anxiety or negative emotions, that could be a common factor across

placebo effects, and that different placebo treatments could activate additional disease-specific mechanisms.

Placebo effects can also be observed in the response to drugs of habitual use or abuse. Caffeine, e.g., increases arousal and decreases reaction time and fatigue, and habitual coffee drinkers who believe they receive caffeine but get a placebo, respond with caffeine-like reactions of increased alertness and faster reaction times, and increased dopamine release in areas associated with reinforcement. Subjects who believe they drink alcohol but receive placebo drinks report symptoms of intoxication and display deteriorated performance on cognitive and motor tasks. Likewise, subjects who believe they receive amphetamine but receive a placebo still report amphetamine-like effects.

Placebos are used as controls in randomized clinical trials, where the effect of the intervention is defined as the improvement over placebo. Since the participant does not know to which arm of the trial he or she has been randomized to, expectations of drug effects are the same in both arms, and expectations of receiving effective treatment are lower than in ordinary clinical practice or in experimental studies on the placebo effect. Thus, placebo effects are smaller or absent in clinical trials (Hróbjartsson & Gøtzscke, 2001). Drugs or other treatments may have noticeable subjective effects like drowsiness or nausea that may inform the participant that he or she has received active medication, thereby unblinding the trial for the participants in the active arm. To solve this problem active placebos are used, i.e., drugs that have similar subjective effects to the tested drug, but that have no effect on the symptom, instead of inactive placebos.

Plasminogen Activator Inhibitor (PAI-1)

Jonathan Newman
Columbia University, New York, NY, USA

Definition

The rupture of an atherosclerotic plaque is a recognized key event in acute ischemic syndromes, such as myocardial infarctions. The intravascular thrombotic response to a ruptured plaque is a complex cascade of thrombogenic (clot-forming) and thrombolytic (clot-dissolving) mechanisms. A key component of the thrombotic cascade is plasminogen activator inhibitor type 1 (PAI-1). PAI-1 inhibits the activation of plasminogen by tissue plasminogen activator (tPA) and urokinase (uPA) and, hence, inhibits clot lysis.

PAI-1 is a single-chain glycoprotein composed of nearly 380 amino acids. It is a member of

the serine proteases family and is synthesized by vascular endothelium and smooth muscle cells in both normal and atherosclerotic arteries. By synthesizing molecules like PAI-1, arterial smooth muscle cells can prevent bleeding from small vascular injuries; congenital deficiencies of PAI-1 are a rare cause of abnormal bleeding.

Associations between PAI-1 and incident or recurrent coronary heart disease (CHD) have been demonstrated, but not definitively proven. While circadian variation in PAI-1 levels (highest in the morning) may correlate to circadian patterns of myocardial infarction (highest in the morning), the relationship of PAI-1 to CHD, independent of other prothrombotic risk factors for coronary heart disease, such as diabetes or insulin resistance, has not been clearly shown. Additionally, individuals with specific genetic variations leading to increased PAI-1 production have not been clearly shown to have an increased risk of CHD. Lastly, while important in constitutive pathways of fibrinolysis, it is not clearly known whether the increased PAI-1 expression seen following plaque rupture and thrombosis is a causal pathway or an effect of the inciting event.

Polysomnogram

► Polysomnography

Polysomnography

Christopher Kline
Department of Psychiatry, School of Medicine, University of Pittsburgh, Pittsburgh, PA, USA

Synonyms

Polysomnogram; Sleep study

Definition

Polysomnography is the simultaneous recording of numerous physiological signals during attempted sleep, including activity of the brain, heart, eyes, and muscles. Polysomnography is considered the gold standard for the objective assessment of sleep and diagnosis of many clinical sleep disorders.

Description

Polysomnography (PSG), termed as such because of the multiple physiological signals that are recorded, has been employed for the characterization of sleep/wake status since the early 1900s. Measurement of the brain's electrical activity, or electroencephalography (EEG), is the primary physiological signal assessed during PSG. Concurrent measurement of eye movement (electrooculography, or EOG), submentalis muscle activity (electromyography, or EMG), and cardiac activity (electrocardiography, or ECG) are essential for the discrimination of specific stages of sleep. Besides the basic recording montage of EEG, EOG, EMG, and ECG, supplemental measures can be added to PSG for the assessment of respiratory and limb movement activity during sleep. See Fig. 1 for an example of a standard polysomnogram.

Polysomnography is most commonly performed in a sleep laboratory. However, due to digitization of sleep signals, portability of data collection units, and increased data storage capacities, full-scale polysomnography is now able to be performed in the home. Home-based PSG allows for a more ecological assessment of sleep, since patients often report altered sleep due to the artificial sleep laboratory environment (Edinger et al., 2001).

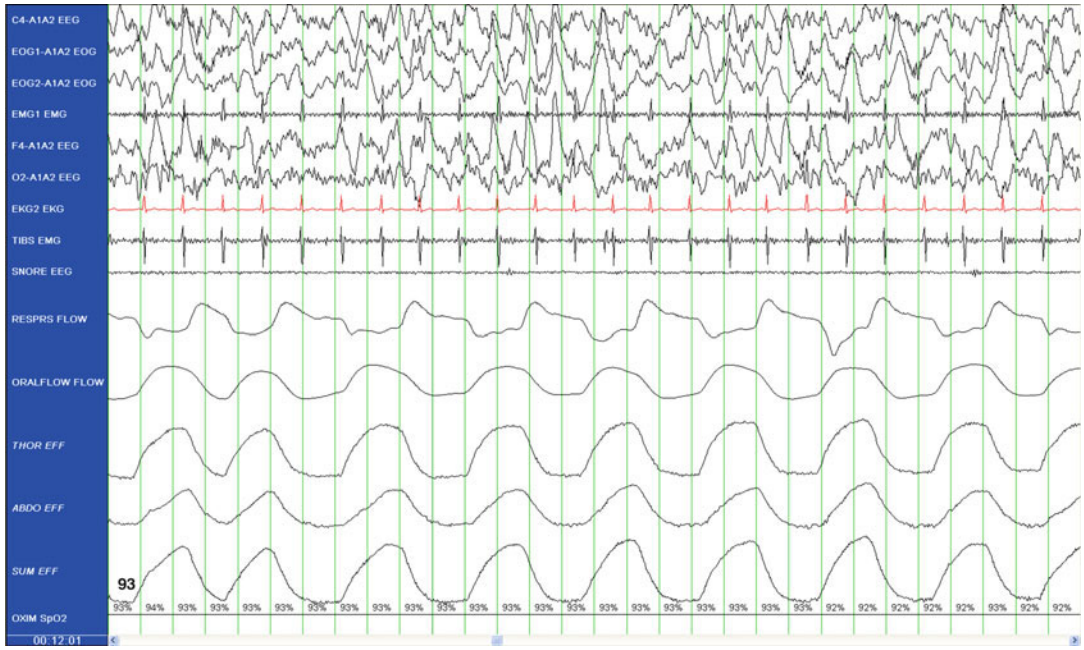
Indications

Polysomnography can be conducted for the objective assessment of sleep for any individual, regardless of whether a sleep disorder is suspected. However, PSG is indicated for the diagnosis of sleep-disordered breathing, narcolepsy, certain types of parasomnias (e.g., seizure disorders) and periodic limb movement disorder (Kushida et al., 2005).

Preparation

Prior to electrode placement, sites should be briefly cleaned with alcohol and an abrasive skin preparation to minimize impedance levels. Electrode cups are then filled with conducting paste and affixed to the proper site with medical tape or electrode paste backed by gauze. Alternatively, some sleep laboratories attach scalp electrodes with collodion glue. Electrode position for the electroencephalogram follows the International 10–20 system (Harner & Sannitt, 1974). A typical EEG montage for sleep includes bilateral electrodes in the occipital, central, and frontal regions, with bilateral mastoid process electrodes as reference electrodes (Iber, Ancoli-Israel, Chesson, & Quan, 2007).

For the electrooculogram, electrodes should be placed 1 cm lateral to and above the outer canthus of the right eye, and 1 cm lateral to and below the outer canthus of the left eye. For the electromyogram, electrodes are placed to assess the activity of the submentalis muscle of the chin; when limb movements need to be assessed, EMG activity of the anterior tibialis is measured with two electrodes on each leg.



Polysomnography, Fig. 1 A 30-s epoch of a standard clinical polysomnogram. Channels are listed on the left column. Electroencephalographic (C4-A1A2, F4-A1A2, O2-A1A2), electrooculographic (EOG1-A1A2, EOG2-A1A2), and electromyographic (EMG1) channels are shown here and are needed for the identification of sleep stages. Additional channels are included here for monitoring leg movements (TIBS; anterior tibialis EMG activity), cardiac activity (EKG2), snoring (SNORE), breathing patterns (RESPRS: nasal pressure; ORALFLOW: oronasal thermistor), respiratory effort (THOR EFF: thoracic effort; ABDO EFF: abdominal effort; SUM EFF: sum of thoracic and abdominal effort channels), and oxyhemoglobin saturation (OXIM SpO2)

A basic electrocardiogram lead, with torso electrodes corresponding to right arm and left leg placement, provides an assessment of cardiac activity. When sleep-disordered breathing is suspected, an oronasal thermal sensor and nasal cannula pressure transducer are used to detect airflow, respiratory effort is assessed with either esophageal manometry or (more commonly) inductance plethysmography belts around the thorax and abdomen, and measurement of oxyhemoglobin saturation is obtained with finger pulse oximetry. Sensors that measure snoring intensity and track body position through the night are commonly added to the recording montage.

Recording and Analysis

Following patient preparation, impedance checks and biocalibrations are performed to assure signal quality. Ideally, the electrode impedance for facial and scalp electrodes should not exceed 5 kΩ (Iber et al., 2007). Moreover, biocalibrations are a set of instructions delivered to the patient to verify signal quality. Recording system calibration is also undertaken before commencement of the sleep study.

With EEG, EOG, EMG, and ECG, changes in electrical potential are detected from electrodes at the skin surface, with the electrical potential at one site measured in relation to its referent electrode. Physiological signals are amplified, digitized, and then displayed for inspection and analysis. During digitization, signals are sampled at a specific rate (a minimum of 200 Hz is recommended for the recording of EOG, EEG, EMG, and ECG), with low- and high-frequency filter settings used to reduce signal artifact. For EOG, EEG, and EMG, signals are measured and displayed in microvolts, whereas ECG signals are displayed in millivolts.

Standardized scoring guidelines for sleep were first established in 1968 (Rechstschaffen & Kales, 1968) and updated in 2007 (Iber et al., 2007). Separate guidelines for scoring pediatric sleep were included in the 2007 update (Grigg-Damberger et al., 2007; Iber et al., 2007). Scoring of sleep stages occurs in 30-s epochs, with each epoch assigned a specific sleep stage that occupies the majority of the epoch.

Electroencephalographic activity is the primary characteristic that distinguishes sleep stages, with EOG and EMG being essential for the detection of rapid eye movement (REM) sleep. In adults, five distinct stages can be scored: wakefulness (W), stage 1 non-REM sleep (N1), stage 2 non-REM sleep (N2), stage 3 non-REM sleep (N3), and REM sleep (R). Stage W is characterized by a predominance of low-voltage, high-frequency EEG (most often alpha and beta frequency) and eye blinks, with elevated chin EMG activity. In stage N1 sleep, alpha EEG activity transitions to a slightly lower-frequency EEG (typically theta frequency), often accompanied by slow rolling eye movements, vertex sharp waves (sharply negative, transient waveforms distinguishable from background activity), and an attenuation of chin EMG from stage W. Stage N2 sleep is characterized by the presence of K complexes (high-amplitude biphasic waveforms typically $\geq$0.5 s in duration) or sleep spindles (rhythmic bursts of sigma-frequency EEG for $\geq$0.5 s) over a background of low-voltage, high-frequency EEG, along with a lack of EOG activity and further attenuation of chin EMG activity. Sleep is considered to be stage N3 sleep, also known as slow-wave sleep, when $\geq$20% of an epoch contains slow wave activity (delta EEG frequency with amplitude $>$75 μV). Finally, stage R sleep is characterized by low-amplitude, high-frequency EEG activity similar to wakefulness and N1 sleep, but with irregular rapid eye movements and minimal chin EMG activity (Iber et al., 2007).

The duration, percentage of total sleep time, and distribution of sleep stages across the night are typically retained for analysis. In addition, typical parameters measured from PSG-scored sleep include sleep onset latency (i.e., the length of time it takes to fall asleep), wakefulness after sleep onset (i.e., the amount of wakefulness that occurs after initially falling asleep), total sleep time (i.e., the total amount of sleep obtained), and sleep efficiency (i.e., the ratio of time spent asleep to the total duration of attempted sleep). In addition to these traditional measures of sleep, quantitative assessment of the sleep EEG is possible, in which the spectral content of the sleep EEG is decomposed to reveal the power of specific EEG frequency bands.

Additional guidelines are present when assessing respiratory events and periodic limb movements (Iber et al., 2007). An apnea is characterized by a $\geq$90% reduction in airflow for at least 10 s, whereas a hypopnea is defined by a $\geq$30% reduction in airflow for $\geq$10 s with a $\geq$4% decrease in oxyhemoglobin saturation. An apnea that is accompanied by inspiratory effort (as assessed by esophageal manometry or inductive plethysmography) is considered to be obstructive, whereas an apnea without inspiratory effort is classified as a central apnea. An apnea that is without inspiratory effort initially but resumes in the latter portion of the event is considered a mixed apnea. Significant leg movements during sleep are characterized by elevated tibialis anterior EMG activity that lasts for 0.5–10 s that is not immediately preceded or followed by a respiratory event.

Limitations

Despite its recognition as the gold standard for the objective assessment of sleep, there are many situations in which PSG might not be desirable and/or feasible. These include assessment of sleep across multiple nights, 24-h recording of sleep/wake activity, and assessment of a large cohort of patients. Under these conditions, the use of PSG may be excessive in cost, labor, or patient burden. Wrist actigraphy may be an acceptable alternative in these situations.

In addition, the "first night effect" is a well-documented phenomenon in which disturbed sleep is reported when assessed by PSG, presumably due to the discomfort and burden imposed by the numerous wires and electrodes and unfamiliar sleep environment (if conducted in the

laboratory). Although in some research studies this sleep disturbance has been shown to take multiple nights of PSG recording before resolution, most studies address the first night effect by conducting at least two consecutive nights of PSG recording and discarding the data from the first night in subsequent analyses.

Although considered an objective measure of sleep, the scoring of PSG is subject to human influence and therefore some degree of subjectivity. Although most sleep laboratories employ trained polysomnographic technicians to evaluate sleep studies, significant between-technician variation is possible. For that reason, quantitative EEG, an automated procedure in which the spectral content of the sleep EEG is analyzed across multiple frequency bandwidths, may provide unique information.

Population Health

Chris Zehr[1] and Peter A. Hall[2]
[1]Department of Health Studies and Gerontology, University of Waterloo, Waterloo, ON, Canada
[2]Faculty of Applied Health Sciences, University of Waterloo, Waterloo, ON, Canada

Definition

Population health is a general approach to assessing and managing health at the level of the whole population. Reduction of health-care inequities, prevention of illness, and contextual improvement are all central objectives of the population health approach.

Description

Population health is an approach that aims to improve the health of entire population with an emphasis on understanding and decreasing health inequities among groups of people within the population (Hertzman, Frank, & Evans, 1994). This approach deviates from a traditional biomedical approach that focuses treatment at an individual level and instead targets group-level phenomena through the implementation of broad-based and widely diffusible health interventions (Jeffery, 1989; Rose, 1985). Rather than focusing on treating illnesses after they emerge, population health interventions are characterized by a strong emphasis on primary prevention, or preventing illness before it develops. As such, modifiable risk factors for illness are a common focus of population health intervention such as smoking, obesity, high blood pressure, physical inactivity, and unhealthy diet as well as preventable disease such as heart disease, stroke, certain cancers, and diabetes (Wanless, 2003).

A defining feature of population health is an emphasis on upstream determinants of illness rather than proximal causes (Hawe, 2007; Link & Phelan, 1995). For example, it has been established that cigarette smoking is associated with myriad negative health consequences. A population health approach would seek to elucidate the conditions and factors upstream that put individuals at greater risk of smoking (e.g., low education levels, low income levels, peer group influence). By identifying upstream determinants of illness, population health interventions are developed that can target these more distal factors.

The population health approach considers health status as a product of a diverse range of factors that include, but are not limited to, individual behavior and life-style; biological and genetic factors; early development; the physical, social, and economic environment; and the health-care system itself (Evans & Stoddart, 1990; Kindig & Stoddart, 2003). Rather than viewing these influences as distinct and individual causes of illness and/or health, these and any other health-determining factors are viewed to interact with each other to determine health.

Population health research has highlighted social conditions as a particularly important determinant of health (Link & Phelan, 1995; Marmot, 2003). Socioeconomic status (SES), a measure of income and social position, has received a significant amount of attention. A robust association exists that suggests that those relatively higher on the socioeconomic gradient tend to experience better health and a longer life expectancy than those lower on the gradient (Hertzman et al., 1994; Lynch, Smith, Kaplan, & House, 2000). Due to the emphasis on minimizing inequities in health, a central focus of population has been to determine the nature of the SES-longevity relationship and how to mitigate it.

Because population health research seeks to impact the greatest number of people possible, interventions based on population health research are often implemented through policy, but also include media campaigns that serve to educate and make individuals aware of certain health-protective behaviors while warning of health-risk behaviors (Hawe, 2007). Population health interventions can also be delivered as programming in settings such as schools, churches, and workplaces. Moreover, when considering the diverse array of determinants of health, population health interventions have the potential to span different sectors not traditionally associated with health intervention (i.e., public transportation, education, agriculture, urban planning) to address a particular health issue.

A criticism of the population health approach is that while biomedical approaches to health care provide tailored treatment for individuals with specific health conditions, population health interventions generally work in a broad stroke manner targeting groups of individuals for whom intervention may not be necessary or beneficial. For example, using data from the Framingham Heart Study, Rose (1985) calculated that even a 10 mmHg lowering of the blood pressure distribution of a population could result in 30% reduction in mortality attributed to blood pressure. Though this may be potentially beneficial for the overall health of a population, this may provide little personal benefit to each individual. This has been termed the "prevention paradox" (Rose).

Despite this, Rose (1985) notes that population strategies can be powerful in their influence. Given that population health approaches are concerned with affecting large groups of people, they have the capacity to change social norms so that a health-risk behavior becomes less socially acceptable, or alternatively, that a health-protective behavior becomes more accepted.

Population Stratification

Abanish Singh
Duke University Medical Center, Durham, NC, USA

Definition

Often an apparently homogenous population group contains subgroups that are genetically distinct. These subgroups may have allele frequency differences due to systematic ancestry differences. Such population structure is known as population stratification.

Description

The mixture of groups of individuals with different allele frequency, i.e., heterogeneous genetic backgrounds, undermines the reliability of

association testing results. The assumption of population homogeneity in association studies may not always be true, and violation of the assumption can result in statistical errors. Genetically distinct population subgroups, possibly resulted from interbreeding of two different population groups, can exhibit disequilibrium between pairs of unlinked loci which may create confounding or spurious associations. Therefore, it becomes important to find and quantify genetically distinct subgroups within a population group. Various techniques including principal component analysis have been successfully used to quantify population stratification.

Population-Based Study

Roselind Lieb
Department of Psychology, Division of Clinical Psychology and Epidemiology, Basel, Switzerland

Definition

Population-based studies aim to answer research questions for defined populations. Answers should be generalizable to the whole population addressed in the study hypothesis, not only to the individuals included in the study. This point addresses the point of external validity of the findings. Therefore, the valid definition as well as the reliable and valid identification of populations in which research questions for specific populations can be studied is the most important issue in population-based studies.

Population-based studies may include a variety of study types. They may include case–control studies, cross-sectional studies, twin studies, or prospective and retrospective cohort studies. The important issue is the selection of the individuals that are included into the study – they should be representative of all individuals in the a priori defined specific population.

For example, in a population-based prospective cohort study, in which an association between a specific exposure and a specific outcome (i.e., the onset of a certain disease) is studied, all individuals sampled for the study should be representative for the addressed population. This means that the individuals under exposure and non-exposure should be identified within the same population. They should differ only on the exposition factor. Likewise, in a population-based case–control study, cases and controls should be also identified in the same population.

Otherwise, differences between cases and controls can be attributed to different population characteristics.

Positive Affect Negative Affect Scale (PANAS)

Vincent Tran
University of Texas, Southwestern Medical Center, Dallas, TX, USA

Synonyms

Positive and negative affect schedule

Definition

The Positive and Negative Affect Schedule (PANAS) (Watson, Clark, & Tellegen, 1988) is one of the most widely used scales to measure mood or emotion. This brief scale is comprised of 20 items, with 10 items measuring positive affect (e.g., excited, inspired) and 10 items measuring negative affect (e.g., upset, afraid). Each item is rated on a five-point Likert Scale, ranging from $1 =$ *Very Slightly or Not at all* to $5 =$ *Extremely,* to measure the extent to which the affect has been experienced in a specified time frame. The PANAS was designed to measure affect in various contexts such as at the present moment, the past day, week, or year, or in general (on average). Thus, the scale can be used to measure state affect, dispositional or trait affect, emotional fluctuations throughout a specific period of time, or emotional responses to events.

The PANAS is based on a two-dimensional conceptual model of mood, where the full range of affective experiences are reflected along two broad dimensions of positive mood (i.e., extent to which one is experiencing a positive mood such as feelings of joy, interest, and enthusiasm) and negative mood (i.e., extent to which one is generally experiencing a negative mood such as feelings of nervousness, sadness, and irritation). Importantly, the PANAS was developed to provide a brief scale that measures positive and negative affect as separate and largely uncorrelated constructs, such that one can experience both positive and negative emotions simultaneously. Both the positive and negative affect scales have good internal consistency, with Chronbach's alpha $\geq .84$ for each scale across multiple time frames. The scales also demonstrate good convergent and discriminant validity. The two-factor structure of the PANAS has been examined extensively and appears to be robust across different populations and temporal instructions.

Other versions of the PANAS have been developed. The PANAS-X is an extended version of the PANAS that may be used when more discrete measures of specific affective experiences are necessary. The PANAS-X includes 60 items that measure not only the two higher order scales (positive affect and negative affect), but also specific affects (joviality, self-assurance, attentiveness, fear, hostility, guilt, sadness, shyness, fatigue, serenity, and surprise). The I-PANAS-SF (International-PANAS-Short Form)

contains 10 items to measure positive and negative affect, and was developed to reduce redundancy or eliminate ambiguous meanings of some of the original PANAS terms. The PANAS-C is a child version of the PANAS; emotion terms were altered and instructions were simplified for use in childhood populations. Finally, the PANAS has also been translated into other languages, such as Japanese and Spanish.

Synonyms

Pleasant affect; Positive emotion

Definition

Positive affect can be described as the experience of a set of emotions reflecting pleasurable engagement with the environment. Positive affect reflects neither a lack of negative affect, nor the opposite of negative affect, but is a separate, independent dimension of emotion (Watson & Tellegen, 1985). It may be exhibited as either a trait-like variable, typically referred to as *positive affectivity*, or as a state-like variable (Watson, 2002). Research on positive affectivity has focused on associations with beneficial coping mechanisms, increased cognitive flexibility, and certain health benefits and improved outcomes.

Description

Watson and Tellegen (1985) presented a two-factor model of mood and affect, in which high levels of positive affect reflect enthusiastic, active, and alert mood states. They contrast this to negative affect, which includes aversive mood states, such as anger, guilt, nervousness, and fear. They suggest that a lack of positive affect reflects sadness and lethargy, whereas a lack of negative affect reflects calmness and serenity. Alternately, positive affect has been conceptualized as including positive emotions that reflect both high and low levels of energy and activation, including

joy, interest, contentment, and love (Fredrickson, 1998). Positive affectivity (i.e., the trait-like disposition to experience positive affect) has been found to relate to the personality variable of extraversion (Lucas & Fujita, 2000), which is one broad factor in the Five Factor Model of personality. This trait is most frequently measured via the Positive and Negative Affect Schedule (PANAS; Watson, Clark, & Tellegen, 1988). Lack of positive affect is considered central in the development and maintenance of depressive disorders (Watson et al., 1995); in fact, a highly effective treatment for depression utilizes behavioral activation to target anhedonia and induce positive experiences, which in turn increases positive affect (Jacobson et al., 1996).

Fredrickson's (1998) Broaden and Build Model of positive affect posits that positive emotion broadens individuals' awareness, encouraging creative, flexible, and exploratory thoughts and actions. She suggests that positive emotions serve an evolutionary function by expanding physical, intellectual, and social resources, enhancing overall well-being and health. Empirical research finds that individuals with induced positive, but not negative, affect experienced broader scope of attention and more a varied repertoire of potential action (Fredrickson & Branigan, 2005). Neuropsychological research has supported positive affect's beneficial influence on cognition. Specifically, positive affect enhances consolidation of long-term memory, working memory, and creative problem solving, potentially via an increase in brain dopamine levels (Ashby, Isen, & Turken, 1999).

The influence of positive affectivity on health and health processes has been extensively examined (see Pressman & Cohen, 2005). Positive affectivity is consistently and prospectively linked to lower reports of pain, fewer symptoms, and better self-rated heath. Positive affectivity is also associated with reduced morbidity from illness, including reduced risk of stroke incidence (Ostir, Markides, Peek, & Goodwin, 2001), and reduced risk of infection in healthy adults (Cohen, Doyle, Turner, Alper, & Skoner, 2003); however, less consistent evidence has been found in mortality and survival studies. Positive affectivity is thought to influence health either through a main effect model, in which positive affect directly affects physiological processes and/or coping behavior, or through a stress-buffering model, in which positive affectivity influences health by ameliorating potentially harmful influences of stressful life events on health.

The recent increase in research on positive affectivity can be associated with the rise of interest in Positive Psychology, which examines the science of positive human functioning (see Seligman & Csikszentmihalyi, 2000).

Definition

Positive psychology, the scientific study of positive phenomena from the neurobiology of positive emotions to application in the clinic and in everyday life, encompasses multiple efforts to understand and promote well-being and health (Aspinwall & Staudinger, 2003; Aspinwall & Tedeschi, 2010; Lopez & Snyder, 2009; Ryff & Singer, 1998; Seligman & Csikszentmihalyi, 2000). Key elements include (a) the identification of human strengths (qualities and processes that allow people to navigate adversity, pursue their goals, and make the most of life) and (b) empirical research directed toward understanding the diverse conditions that create and sustain such strengths. These processes have been investigated in a wide variety of domains, including education, social development, close relationships, aging, work, and health.

Description

Core Concerns of Positive Psychology and Health

Positive psychology is an active and growing field, with thousands of published articles in the

last decade, two major handbooks, a new *Encyclopedia of Positive Psychology*, a specialized journal (the *Journal of Positive Psychology*), and several edited volumes, journal special issues, and international conferences devoted to this topic. Within this voluminous literature, there are three main areas that examine the relationship of positive phenomena to physical health: (a) psychological adaptation to illness, (b) the impact of positive phenomena, such as positive mood, optimism, and hope, on physical health, and (c) interventions that use insights from this research to improve well-being in general and among people managing serious illness.

Understanding Psychological Adaptation to Illness

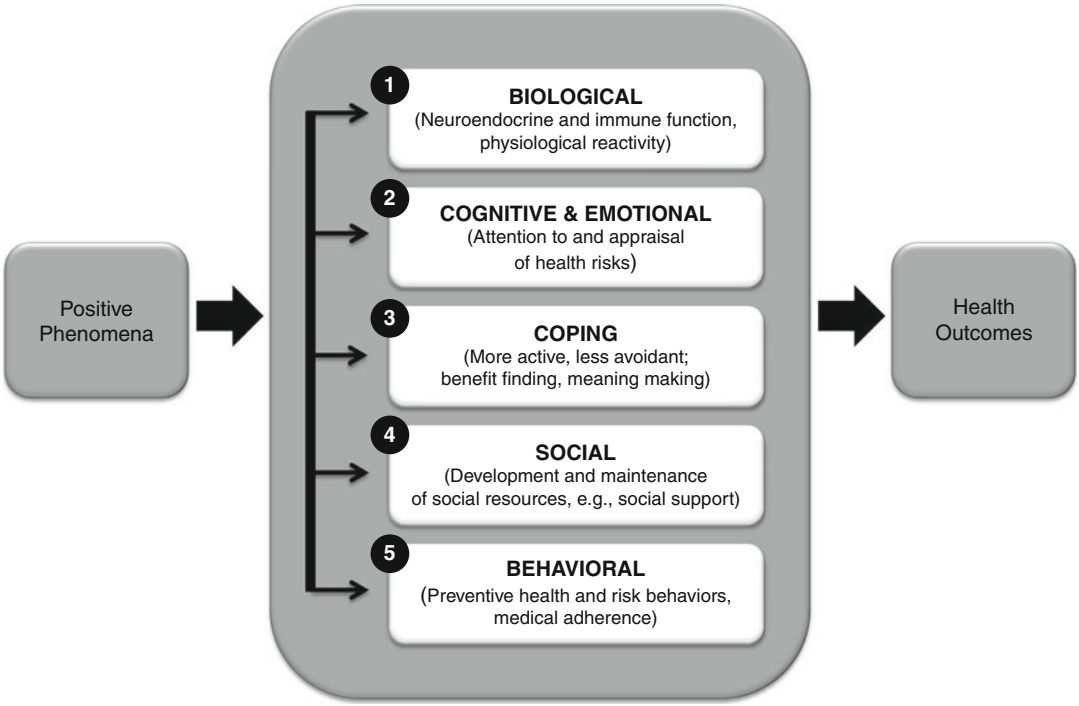
Multiple lines of research have examined the impact of negative life events, including serious illness, on people's beliefs about themselves, the benevolence of others, personal control, and views of the future. In general, research suggests that people who have experienced serious illness or other forms of adversity frequently report *both* positive and negative life changes. Frequently reported positive changes include a better sense of one's values and priorities, stronger social relationships, and an enhanced appreciation for life. Negative changes include fears for the future and feelings of personal vulnerability. Such changes are understood by many researchers to be the product of active efforts to manage and derive meaning and/or benefit from one's circumstances (Folkman, 2011; Taylor, 1983). Exciting developments in this line of research have related finding meaning and/or benefit to subsequent physical health outcomes, such as immune function (Park, Lechner, Antoni, & Stanton, 2009; Taylor, Kemeny, Reed, Bower, & Gruenewald, 2000).

As exciting as these findings are, it is important to understand their boundary conditions. In particular, not all events produce benefits or growth or do so for all people. Some particularly challenging events (severe interpersonal stressors, wartime experiences) seem to defy meaning-making coping. Further, large-scale longitudinal panel studies of life satisfaction following long-term unemployment and divorce suggest that people may not, on average, fully adjust to these events. Finally, there appear to be multiple "normal" responses to adversity. A recent advance in this area – made possible by rigorous prospective longitudinal studies of bereavement (Bonanno, 2004) – is the recognition that there may be multiple trajectories of mental health outcomes following adversity, with many respondents reporting stable good or even improving outcomes and a subset of respondents reporting either enduring preexisting distress or new elevations in distress. These different patterns of adjustment over time highlight the need to understand the antecedents and processes that account for them. The finding that there is considerable variation in response to adversity also suggests that global positive outcomes (e.g., "Cancer was the best thing that ever happened to me") may be true for some people, but may grossly misrepresent the experiences of others.

Understanding the Relation of Positive Phenomena to Physical Health

Although most research in positive psychology focuses on psychological well-being, there is increasing interest in the relation of such concepts as optimism, hope, positive affect, gratitude, benefit finding, and growth to physical health. Several recent meta-analyses suggest that positive phenomena show a reliable prospective beneficial relationship to multiple health outcomes, including longevity, in both healthy and ill samples (Diener & Chan, 2011; Howell, Kern, & Lyubomirsky, 2007; Pressman & Cohen, 2005; Rasmussen, Scheier, & Greenhouse, 2009). Importantly, this relationship is (a) not explained by the detrimental effects of either negative emotions or pessimistic expectations and (b) comparable in magnitude to that of these more widely studied negative phenomena. At present, the findings seem to be stronger for healthy samples than among people managing illness, and the strength of the findings varies by disease, with stronger and more encouraging findings for cardiovascular disease and HIV than for cancer mortality.

Researchers have examined multiple complementary pathways through which positive phenomena are related to health outcomes



Positive Psychology, Fig. 1 Five mutually interactive and complementary sets of pathways through which positive phenomena, such as positive mood and optimism, may influence human health

(Aspinwall & Tedeschi, 2010). Five sets of pathways are shown in Fig. 1. The first set of pathways involves direct relations to neuroendocrine and immune functions implicated in the etiology and progression of disease, as well as physiological reactivity to laboratory stressors. A second and third set of pathways involve the relation of positive phenomena to multiple aspects of attending to, appraising, and coping with health-risk information and the demands of serious illness, including the benefit-finding and meaning-making processes described earlier. A fourth set of pathways involves the relationship between positive phenomena and the development and maintenance of supportive social ties, especially during times of illness or other adversity. The fifth pathway represents the relationship of positive phenomena to the practice of preventive health behaviors, such as good nutrition, exercise, and sleep; the decreased practice of risk behaviors, such as substance abuse; and improved medical adherence.

Recent findings from the Women's Health Initiative illustrate the multiple pathways through which positive phenomena may influence health outcomes. In an 8-year prospective study of coronary heart disease in a sample of more than 97,000 US women, ages 50–79 (Tindle et al., 2009), dispositional optimism was found to prospectively predict decreased risk for coronary heart disease and all-cause mortality in the overall sample. Optimism also predicted lower cancer-related mortality for African-American women, but not Caucasian women. Compared to pessimists, optimists were less likely to have diabetes, hypertension, high cholesterol, or depressive symptoms; they were less likely to smoke, be sedentary, or be overweight; and they reported higher education and income, greater employment and health insurance, and greater religious attendance. However, the real kicker is that controlling for *all* of the above factors, optimism still predicted better health outcomes. These findings suggest that there is much that

remains to be understood about the relationship of positive beliefs to important health outcomes and that the multiple pathways outlined in Fig. 1 and described in the following sections may be implicated in such findings.

1. *Biological pathways*. At present, more is known about the prospective relationship of positive phenomena to diverse health outcomes than about the specific pathways through which these outcomes are realized. Most studies have focused on cardiovascular, neuroendocrine, and immune function. Both experimental laboratory studies and field experiments link the induction of positive self-beliefs to reduce cardiovascular and neuroendocrine reactivity to evaluative stressors and to more rapid recovery from induced negative states among healthy young adults. Recent reviews link optimism to improved immune function, both among healthy people managing naturalistic stressors such as law school entry and among people managing HIV infection. These lines of research have also identified some potential short-term physiological costs associated either with optimists' active coping efforts or with the relatively intense positive affect inductions used to study physiological outcomes in laboratory settings (Pressman & Cohen, 2005). However, these authors also noted that these costs were not seen in naturalistic ambulatory studies where positive affect was associated with health-protective responses. Many researchers have attributed the health-protective findings of optimism and positive mood to reductions in perceived stress, highlighting the importance of such appraisals in understanding how positive phenomena are related to health outcomes.
2. *Attention to and appraisal of threatening health information*. In contrast to the idea that being happy or optimistic reduces awareness of negative realities (e.g., seeing one's world through "rose-colored glasses"), several experiments have demonstrated that induced positive affect or positive self-beliefs (e.g., through self-affirmation or success manipulations) promote constructive attention to negative information about health risks and personal weaknesses when the information is relevant to the self and said to be useful (Aspinwall & Tedeschi, 2010). Similar findings have been obtained for dispositional optimism. Interestingly, this greater attention to negative information does not appear to be in the service of downplaying its negativity or relevance to the self, but instead appears to be strongly responsive to its potential value in warding off or managing future negative events. The ability to adaptively confront, manage, and remember such information may have beneficial links to both coping and health behavior.
3. *Coping with serious illness*. A large literature suggests that positive affect and optimism promote constructive methods of coping with adversity, involving planning, information-seeking, suppression of competing activities, and seeking both instrumental and emotional social support (Aspinwall & Tedeschi, 2010). Notably, positive beliefs are consistently inversely associated with deleterious forms of avoidant coping, such as denial, mental and behavioral disengagement, and substance use. Researchers have argued that the tendency toward active, engaged forms of coping with adversity shown in pathway #3 and the ability to attend to negative information shown in pathway #2 may work together to promote a more informed understanding of actual or potential stressors. The term "upward spiral" has been used to characterize such processes.
4. *Development and maintenance of social resources*. Recent meta-analytic evidence suggests that positive affect plays a major role in the maintenance of satisfying social relationships (Lyubomirsky, King, & Diener, 2005). Specifically, people who report frequent positive affect also report a greater number of – and more satisfying – social relationships. Similarly, college students who reported greater optimism on arrival to college reported both greater initial friendship network size and greater increases in perceived social support over the course of their first semester, and

these social ties buffered distress at the end of the semester. Existing evidence suggests that there may be more at work in such findings than the idea that it is pleasant to be around people in a good mood. People in a good mood seem better able to understand the goals and priorities of their interaction partners, to express more gratitude, and to be more likely to help others than people in a neutral mood. These particular processes suggest that an important direction for future research and intervention might be to examine these processes among people managing illnesses and other demands such as caregiving that are known to tax social resources over time.

5. *Health behaviors and medical adherence*. An emerging literature suggests that positive beliefs and states are robust prospective predictors of better health behavior, including diet, exercise, and sleep, and lower practice of risk behaviors, such as substance abuse (Aspinwall & Tedeschi, 2010). These findings have been obtained both in healthy community samples, including large samples of older adults, and among people managing serious illnesses, such as HIV infection. In contrast, prospective studies link negative beliefs, such as pessimism and fatalism, to the practice of a wide range of health-risk behaviors, including substance abuse and high-risk sexual behavior. Understanding how positive beliefs like hope and optimism are related to the practice of inherently forward-looking behaviors, like preventive health behavior, remains an important research question. Researchers are also starting to examine how positive phenomena may be related to behavior change and medical adherence. Although it is well known that negative affect and interpersonal stressors contribute to relapse from behavior change efforts in multiple domains, the question of whether and how positive phenomena may have facilitative effects needs further investigation. With respect to medical adherence, randomized controlled trials of interventions in hospital settings demonstrate that increasing patients' optimism about the success of cardiac rehabilitation improves outcomes like angina symptoms and return to work.

Summary and Remaining Conceptual Questions. This section outlined five sets of pathways through which positive feelings and beliefs may influence physical health. These multiple pathways are complementary, rather than competing, and are likely to work in concert (Aspinwall & Tedeschi, 2010). Specifically, the ability to maintain attention to negative information about health risks may work in tandem with more active forms of coping that are more likely to elicit information about one's situation and support for managing it. Similarly, finding benefits and growth in one's experience and maintaining supportive social ties may each be related to subsequent health behaviors in important ways. Research that examines the interplay of these different pathways will likely yield not only a more complex account of the ways in which positive phenomena may be linked to human health but also an understanding of some of the cumulative benefits that may result.

Interventions to Promote Health and Well-Being

Interventions derived from the principles and pathways reviewed here have been employed to promote well-being in healthy samples, as well as psychosocial adjustment to chronic illness (Folkman, 2011; Park et al., 2009). For example, a burgeoning literature on the kinds of experiences that make people happy and the processes that contribute to hedonic adaptation both to positive and negative events have been usefully employed in interventions to improve daily positive affect, primarily in healthy samples. For people living with chronic illnesses like diabetes, various interventions ranging from writing about one's positive experiences to multiple-component programs have proved effective in enhancing positive affect, at least in laboratory settings. Experimental interventions to increase hope and gratitude have also been shown to improve reported pain tolerance and physical symptoms, respectively. Finally, although they were not conducted under the rubric of positive psychology, psychosocial interventions to provide social support and reduce stress among

people managing serious illness suggest that such interventions reliably reduce pain and anxiety and improve quality of life (Aspinwall & Tedeschi, 2010; Park et al., 2009). Understanding how the various pathways suggested here may be implicated in such effects – and used to enhance them – among people managing serious illness remains an important goal for future research.

Controversies with Respect to Both Theory and Application

The study of how positive phenomena – especially positive thinking – are related to health has generated both academic and cultural controversies (Aspinwall & Staudinger, 2003; Aspinwall & Tedeschi, 2010; Becker & Marecek, 2008; Lazarus, 2003). Researchers have questioned whether the focus on positive or optimal human functioning is new or sufficiently distinctive or developed to merit a special name as a new field; whether separating positive phenomena from negative phenomena is practicable, desirable, or meaningful (e.g., coping with adversity may inherently involve both); and whether the field focuses too much on the individual as the unit of analysis at the neglect of important social, cultural, economic, structural, and environmental determinants of health and well-being. With respect to positive psychology and health, critics have questioned (a) whether the field is too narrowly focused on individual positive feelings and self-beliefs as the primary outcomes of optimal human functioning; (b) whether the promotion of positive thinking among those managing serious illness may be trivial, distracting, and ultimately useless; and (c) whether positive thinking might actually be actively harmful if it impairs attention to negative aspects of experience or contributes to a culture of blame for individual misfortune.

Several critics (as well as the present authors) have traced the history of these ideas to the New Thought movement and subsequent popular efforts to promote health, well-being, and financial success through positive thinking (e.g., *The Power of Positive Thinking, The Secret*; see Aspinwall & Tedeschi, 2010, for discussion). With respect to the application of positive psychology to understanding health and illness, a primary concern – reflected more in critiques of the popular self-help literature on positive thinking than in scientific discourse on these issues – is the potential misuse of findings suggesting that positive emotions and beliefs may predict physical health and recovery from illness. Specifically, the demonstration that a positive attitude (e.g., optimism or hope) is linked to better health outcomes for some people in some situations may create, or be used to promote, unrealistic expectations about the ability to cure disease through positive thinking. Similarly, the demonstration that some people with serious illness report benefits and growth can be misconstrued to suggest that all people should do so, all of the time and regardless of circumstance. These pressures to maintain uniformly positive thoughts and feelings and to ascribe deteriorating health to failures of positive attitude have been described as "saccharine terrorism" and the "tyranny of optimism." While researchers have in general been quite careful not to mandate positive feelings among people dealing with adversity (and in fact have documented the presence of both positive and negative life changes and multiple trajectories of adjustment), various popular treatments have promoted the notion that an exclusive focus on positive thoughts and feelings will cure illness. Some critics aptly note that this approach is particularly prevalent – and pernicious – in popular treatments of cancer survivorship (Aspinwall & Tedeschi, 2010).

Conclusion

As scientific research on the relationship of positive phenomena to health proceeds, rigorous process-oriented research should dispel the notion that there is some kind of magic bullet to be found in positive thinking. Continued examination of the multiple biological, cognitive, emotional, social, and behavioral pathways linking positive phenomena to health is essential. Further, researchers interested in a balanced understanding of the link between positive phenomena and health outcomes should continue to design studies that are sensitive to both potential benefits and liabilities of

particular kinds of positive (and negative) thoughts and feelings in different situations (Aspinwall & Staudinger, 2003; Aspinwall & Tedeschi, 2010). Indeed, what the study of health and illness has to offer positive psychology is the opportunity to examine the multiple ways in which positive and negative phenomena may go hand in hand as people manage serious illness and its treatment.

Postpartum Depression

Michele L. Okun
Sleep Medicine Institute and Department of Psychiatry, School of Medicine, University of Pittsburgh, Pittsburgh, PA, USA

Synonyms

Major depressive disorder; Postpartum blues

Definition

Postpartum depression is moderate to severe depression in a woman after she has given birth. It may occur soon after delivery or up to a year later. Most of the time, it occurs within the first 3 months after delivery.

Description

Major depressive disorder with a postpartum onset (PPD) is a prevalent and serious disorder. Postpartum major depression (PPMD) is moderate to severe depression in a woman after she has given birth, clinically resembling major depression as described in DSM-IV. Feelings of anxiety, irritation, tearfulness, and restlessness are common in the week or two after pregnancy. These feelings are often called the postpartum blues or "baby blues." These symptoms almost remit without the need for treatment. Postpartum depression may occur when the baby blues do not fade away or when signs of depression start 1 or more months after childbirth. Up to 20% of women will have an initial major depressive episode within the first 3 month postpartum (Gavin et al., 2005), with the risk of suffering recurrent postpartum major depression (PPMD) at about 25% (Wisner, Perel, Peindl, & Hanusa, 2004). Women are at the highest risk during their lifetimes for depressive episodes during the childbearing years (O'Hara, Zekoski, Philipps, & Wright, 1990).

PPMD is considered a serious public health concern (Gaynes et al., 2005; Wisner, Chambers, & Sit, 2006). The maternal role, which is vital to the infant's safety, survival, and well-being (Logsdon, Wisner, & Pinto-Foltz, 2006), can be compromised by PPMD. Children of mothers with PPMD are at an increased risk of impaired mental and motor development, poor self-regulation, and behavior problems (Moehler, Brunner, Wiebel, Reck, & Resch, 2006). Postpartum depression and its consequences can persist from months to years after childbirth, with lingering limitations in physical and psychological functioning after recovery from depressive episodes (Burt & Stein, 2002; Marcus & Heringhausen, 2009; McCarter-Spaulding & Horowitz, 2007).

A myriad of factors contribute to the etiology of both incident and recurrent PPMD (Beck, 2001; Bloch, Daly, & Rubinow, 2003; Gaynes et al., 2005). Among the established risk factors, previous episodes of depression, family history of depression, and depressive symptomatology during pregnancy (O'Hara, Schlechte, Lewis, & Varner, 1991; O'Hara, Schlechte, Lewis, & Wright, 1991) are the strongest predictors for both incident and recurrent episodes. Demographic variables, including marital status, race, age, and socioeconomic status, have also been

implicated as risk factors (Beck, 2001; Ross, Campbell, Dennis, & Blackmore, 2006). Unfortunately, these recognized risk factors have proven inadequate at predicting which women will have a recurrent episode. Other risk factors that have been identified include the following: (1) age below 20 years; (2) currently abusing alcohol, taking illegal substances, or smoking (these also cause serious medical health risks for the baby); (3) having an unplanned pregnancy, or have mixed feelings about the pregnancy; (4) a stressful event during the pregnancy or delivery, including personal illness, death or illness of a loved one, a difficult or emergency delivery, premature delivery, or illness or birth defect in the baby; (5) little support from family, friends, or the significant other.

Disturbed sleep during late pregnancy represents another potential risk factor for PPMD. Several investigators report that disturbed sleep is a prodromal symptom of both first onset and recurrent depressive symptoms and/or episodes outside of the postpartum (Ford & Kamerow, 1989) as well as during the postpartum (Coble et al., 1994; Wolfson, Crowley, Anwer, & Bassett, 2003). Recently, Okun and colleagues showed that poor sleep quality in late pregnancy (Okun, Hanusa, Hall, & Wisner, 2009) as well as in the first 8 weeks postpartum (Okun et al., 2011) significantly contributed to recurrent PPMD. Wolfson and colleagues noted that women reporting more sleep disturbances in late pregnancy are more likely to have clinically significant depressive symptomatology at 2–4 weeks postpartum than those with few sleep disturbances (Wolfson et al., 2003). Coble and colleagues found that women with a history of depression had more sleep disturbances throughout pregnancy and into the postpartum than women without a history of depression (Coble et al., 1994). Taken together, these findings suggest that sleep disturbances in late pregnancy increase vulnerability to PPMD, particularly in women who are susceptible, such as those with a history of PPMD (Wisner, Parry, & Piontek, 2002).

There are two identified biological systems attributed to have an effect on the risk of developing PPMD. First are endocrine factors. Hormones such as progesterone, estradiol, prolactin, and cortisol peak during the last few weeks of pregnancy, followed by a drastic drop in their levels following delivery and into the early postpartum period (Abou-Saleh, Ghubash, Karim, Krymski, & Bhai, 1998). Dramatic drops in hormone concentrations, especially progesterone and the estrogens, likely contribute to postpartum depression (Abou-Saleh et al., 1998; Bloch et al., 2003); however, their specific role is unclear. Administration of estrogens to postpartum women appears to reduce depressive symptoms (Dennis, 2004). However, the dramatic reduction in concentrations of gonadal steroids after delivery does not lead to PPMD in all women (Bloch et al., 2003).

The second pathway involves alterations in the cytokine milieu (Bloch et al., 2003; Maes et al., 2000). The "cytokine hypothesis of depression" states that both the etiology and pathophysiology of depression are linked to dysregulation of inflammatory cytokines (Maes, 1994). Puerperal women may be particularly vulnerable because inflammatory cytokines increase significantly during the last trimester of pregnancy in preparation for delivery (Romero et al., 2006). Women who report increased depressive symptoms in the postpartum have corresponding higher levels of pro-inflammatory cytokines (Maes et al., 2000).

PPMD is a significant health concern. While there is no single test to diagnose PPMD, it is imperative for a woman to be evaluated if there is any indication that she has signs of depression or risk for depression. This will buttress not only her own mental and physical health, but the health of her baby.

Posttraumatic Growth

Vincent Tran
University of Texas, Southwestern Medical Center, Dallas, TX, USA

Synonyms

Adversarial growth; Benefit finding; PTG; Stress-related growth; Transformational coping

Definition

Posttraumatic growth is the experience of positive change after a traumatic or negative life

event. It is theorized to be the positive or adaptive outcome of a meaning-making process in which individuals are forced into a reevaluation process of their worldviews after experiencing a negative or life-changing event. Through this reevaluation process, some individuals may develop a more coherent understanding of themselves and the world. Common examples of growth after trauma include changes in life values, improved relationships with family and/or friends, growth in spiritual beliefs, and increased personal strength, empathy, or patience.

Description

The concept of growth from adversity is an ancient concept based in many religions and philosophical systems. However, it has been a formal focus of investigation in psychology only in the past few decades, coinciding with the development of psychometrically sound measures and the rise of positive psychology. The fields of health psychology and behavioral medicine, in particular, have latched onto the notion that one may experience positive change in response to adversity, including the adversity of coping with serious health threats and illnesses. For example, research on posttraumatic growth has been carried out in chronic illness populations such as patients with heart disease, cancer, rheumatoid arthritis, HIV/AIDS, and multiple sclerosis. It has also been studied in the context of veterans of war, victims of violence, bereavement, and family members/caregivers of those experiencing a negative life event.

Posttraumatic growth is conceptually very similar to benefit finding and stress-related growth, and these terms are often used interchangeably in the research literature. Multiple measures have been developed, which have facilitated the rigorous study of posttraumatic growth and related constructs. These scales include: benefit finding (Mohr et al., 1999; Tomich & Helgeson, 2004); Stress-Related Growth Scale (Park et al., 1996); and the Posttraumatic Growth Inventory (Tedeschi & Calhoun, 1996). Posttraumatic growth is differentiated from concepts such as resilience and hardiness, in which one may cope or adjust well in response to stress rather than experience positive transformation and an *improvement* in functioning, quality of life, or worldview. Posttraumatic growth is also conceptually differentiated from optimism because it reflects a change in experience rather than a dispositional trait, although the two constructs have been shown to be correlated.

Posttraumatic growth has been associated with adaptive coping processes including heightened problem-focused coping, social-support seeking, acceptance and positive reinterpretation, optimism, religion, cognitive processing, and positive affect. It has often been associated with better illness adjustment and health outcomes, less depression, and more positive well-being in chronic illness populations. Although the prevalence of posttraumatic growth varies widely from study to study, numerous studies suggest a majority of research participants endorse some type of growth from a negative or traumatic event.

Although research suggests that posttraumatic growth is associated with improved functioning and quality of life, there have been conflicting reports. Some studies report nonsignificant or even negative correlations between posttraumatic growth and well-being. These inconsistencies have driven researchers to more rigorously test proposed theories of posttraumatic growth and better clarify the processes by which posttraumatic growth occurs. More meticulous study has led to investigation of non-transformational change, mediators, moderators, and study of curvilinear associations between posttraumatic growth and well-being. Further elaboration on the theory of posttraumatic growth has led to studies on whether posttraumatic growth is the outcome of a series of life changes that have occurred or whether it is a cognitive process of reevaluation and understanding that unfolds over time. Researchers are also investigating whether posttraumatic growth reflects genuine changes in one's life (veridical growth) or whether it reflects perceptions of change or growth (non-veridical growth). Some have suggested that non-veridical growth may even reflect a maladaptive, defensive denial process,

although others claim that perceptions of growth that do not reflect true life changes may promote well-being in response to a traumatic event.

Posttraumatic Stress Disorder

Cortney J. Taylor, Whitney M. Herge and Annette M. La Greca
Department of Psychology, University of Miami, Coral Gables, FL, USA

Definition

By age 16 years, approximately two thirds of youth report having experienced at least one traumatic event (Costello, Erkanli, Fairbank, & Angold, 2002; Copeland, Keeler, Angold, & Costello, 2007). This is distressing in that exposure to a traumatic event can lead to the development of posttraumatic stress disorder (PTSD), which is a debilitating condition that is associated with several poor mental and physical health outcomes. As such, it is imperative to understand the development and course of PTSD, including its prevalence, comorbid conditions, assessment, treatment, and prognosis.

Diagnostic Criteria

PTSD is an anxiety disorder. Criteria for diagnosis include (a) exposure to a traumatic event that resulted in actual or threatened death or serious injury, or a threat to the physical integrity of the self or others, and also that the person's response involved intense fear, helplessness, or horror (American Psychiatric Association [APA], 2000, DSM-IV-TR, p. 467).

Further, an individual must meet criteria for three symptom clusters, each with more than 1 month duration: (b) one symptom of *reexperiencing* (e.g., recurrent distressing dreams of the event), (c) three or more symptoms of *avoidance* of stimuli associated with the trauma and *numbing* (e.g., efforts to avoid thoughts, feelings, or conversations associated with the trauma), and (d) two symptoms of increased *arousal* (e.g., difficulty falling or staying asleep). These symptoms must cause clinically significant distress or impaired functioning in the individual and cannot be accounted for by another disorder.

Proposed changes for DSM-V involve further explanation and expansion of the criteria. For example, criterion (a) may be expanded to include one or more of (1) experiencing the event, (2) witnessing the event, (3) learning the event occurred to someone close, or (4) experiencing repeated or extreme exposure to aversive details of the event. Also, the remaining criteria may be expanded to include the following: (b) one or more symptoms of *intrusion*, (c) one or more symptoms of *avoidance* of stimuli, (d) three or more *negative alterations in cognitions or mood* associated with the traumatic event, and (e) three or more symptoms of *alterations in arousal or reactivity* associated with the traumatic event (APA, 2010).

Further, there are differences in symptom presentation between children and adults who experience PTSD, which may be considered in DSM-V (APA, 2010). For example, within category B regarding intrusion, the DSM-V notes that children may have repetitive play reflecting the traumatic event, or trauma-specific reenactment during play, whereas adults may have recurrent, involuntary, or intrusive memories of the event. The DSM-V also specifies a different number of symptoms required to meet criteria for children than for adults. For example, adults are required to exhibit three or more symptoms, while children are only required to have two or more symptoms for both criterion D which are negative alterations in cognition and mood and criterion E alterations in arousal and reactivity, respectively.

Prevalence

Prevalence rates for PTSD vary greatly depending on the severity and type of traumatic event, as well as demographic factors. Prevalence rates of PTSD in youth range from 0.5% in typical community samples to 90% among sexually abused children (La Greca et al., 2012); the lifetime prevalence rate in adults is approximately 8% (APA, 2000, DSM-IV-TR, p. 466). Also, rates of PTSD are typically highest with events that involve violence, such as sexual abuse, terrorism, war, or the violent death of a loved one (Copeland et al., 2007). Women are twice as likely as men to evidence PTSD at some point in their lives (Foa, Keane, Friedman, & Cohen, 2008). The role of ethnicity is still unclear and evidence is mixed; some studies support an ethnic difference in rates of PTSD, while others suggest there are moderating factors such as differences in levels of exposure or socioeconomic status (Hamblen, 2007). Individuals from lower SES backgrounds have higher rates of PTSD than those with higher SES, and this may be due to the greater exposure to domestic violence or community violence among low SES individuals, which is associated with higher levels of PTSD.

Course of Disorder Over Time

Individuals who experience PTSD symptoms less than 1 month from the traumatic event may meet criteria for a diagnosis of acute stress disorder; if symptoms persist for more than 1 month, then the diagnosis is changed to PTSD. Individuals who present with PTSD for less than 3 months duration are considered to have the PTSD; if symptoms persist for more than 3 months, the diagnosis is *chronic* PTSD. Child physical or sexual abuse is often associated with a more chronic course of PTSD from childhood through adulthood. Finally, individuals who initially present with subsyndromal PTSD, but meet the full criteria at 6 months or more posttrauma, are considered to have *delayed-onset* PTSD. Some resilient individuals present with only a few symptoms of traumatic stress that never reach clinical thresholds and remit over time.

Common Comorbidities

PTSD is frequently comorbid with several other psychological disorders, including grief/bereavement, depression, anxiety, substance use and abuse, and health problems (Bonanno et al., 2010). Further, in children, PTSD is also commonly associated with behavioral concerns, such as acting out and disruptive behaviors (Cohen, Berliner, & Mannarino, 2010).

It is unclear whether PTSD plays a casual role in the development of additional comorbid conditions, or whether preexisting psychological conditions predispose a person to develop PTSD following a trauma (Perrin, Smith, & Yule, 2000). It is also possible that a broader underlying factor leads to the development of both PTSD and other conditions, which would account for the high rate of comorbidity (Perrin et al., 2000). Additional research is necessary to better understand the directionality of these comorbid relationships, which would also advance the conceptualization and treatment of PTSD.

Measures

There are several measures used in the assessment and diagnosis of PTSD in children and adults. The type of measure chosen depends on many factors, including the availability of a trained clinician, the individual's time and presenting condition(s), and the cost of the measure.

Clinician-administered interviews are the most thorough tools available and include (1) the Structured Clinical Interview for DSM-IV Axis I Disorders, used with adolescents and adults (SCID-I; First, Spitzer, Gibbon, & Williams, 1996); (2) the Kiddie-Schedule for Affective Disorders and Schizophrenia, used with children and adolescents (K-SADS-PL; Kaufman et al., 1997); and (3) the Diagnostic Interview for Children and Adolescents, used with children and adolescents (DICA-IV; Reich, Welner, & Herjanic, & MHS Staff, 1997). Each of these interviews includes a PTSD-specific module for assessing the presence of a traumatic event and any resulting symptoms required for diagnosis (APA, 2000). Although clinician-administered interviews are the most thorough diagnostic tool, they are also the most time consuming as well as the most expensive option.

Self-report measures of PTSD include the PTSD Checklist (PCL; Weathers et al., 1993) for adults, the Posttraumatic Stress Disorder Reaction Index (Steinberg, Brymer, Decker, & Pynoos, 2004), and the Trauma Symptom Checklist for Children (Briere, 1996). To assess a person's subjective response to trauma and/or stressful events more broadly, the Impact of Events Scale – Revised (IES-R; Weiss & Marmar, 1996) is often used with adolescents and adults. Although these measures are easy to administer and do not require a trained clinician, these measures provide significantly less detail and may require follow-up inquiry.

Treatment and Prognosis

Several treatment options are available for individuals with PTSD. Trauma-focused cognitive behavioral therapy (TFCBT) for children and adults and eye movement desensitization and reprocessing (EMDR) with adults have been indicated as effective treatments for individuals with PTSD (Foa et al., 2008; Bisson & Andrew, 2007). Another treatment option, sometimes utilized in conjunction with psychotherapy, is medication. Specifically, SSRIs and SNRIs are seen as first-line medication treatments for PTSD (Foa, et al., 2008).

Typically, PTSD symptoms decline drastically over the first-year posttrauma (Bonanno et al., 2010), while any further declines are more gradual (e.g., La Greca et al., 2010; Shaw et al., 1996). The prognosis for individuals with PTSD varies greatly depending on whether the individual has any comorbid conditions, their level of social support, and whether they have received treatment. Individuals with comorbid conditions, poor social support, and/or do not seek treatment will have a poorer prognosis than those who do not have these concerns. For individuals who do receive treatment, some evidence a decrease in symptoms after only four sessions of CBT, while others may require a longer course of treatment (Foa et al., 2008).

Definition

Prayer in all of its variations can be defined by two fundamental principles: (1) prayer is a form of communication and (2) the exchange of communication takes place between the self and the transcendent, immanent, and numinous forces that represent human notions of the sacred. Defining prayer in this way broadens William James' classic conceptualization of prayer as "every kind of inward communion or conversation with the power recognized as divine" to include not only that which comes from God but everything that is imbued with the power of sacredness.

Description

Throughout history, humankind has manifested a yearning to communicate with the sacred through prayer. Expressed in vastly different cultures and religious traditions, prayer constitutes a universal phenomenon that plays a crucial role in humanity's religious experience. In fact, for many individuals, prayer is their primary religious practice.

Prayer, in the theocentric Judaic, Christian, and Islamic religious traditions, represents a way to express thanks to God, participate in God's will, and move closer to God. From a theocentric perspective, prayer is, simply put, communication with God. Prayer, however, is not limited to God-centered religions; it also features prominently in the practices of nontheistic religious traditions such as Zen and Theravada Buddhism, Jainism, and Taoism as well as animistic and pantheistic belief systems such as Shinto and the indigenous religions that feature the worship of nontheistic spiritual entities. Secular individuals without religious affiliations or theistic beliefs also pray regularly in a variety of ways.

Types of Prayer

Scholars have devised a number of classification schemes in an attempt to impose some order on the extraordinarily diverse modes of prayer expression. Traditional descriptive typologies have focused on the reasons people pray as well as on the content of prayers. Gill (1994) classified prayers according to their intent: petition, invocation, thanksgiving, dedication, supplication, intercession, confession, penitence, and benediction prayers. Heiler (1932) proposed a rich typology to capture the "astonishing multiplicity" of the forms of prayer: primitive; ritual; Hellenistic; philosophical; personal; mystical; prophetic; the prayers of great religious personalities; the prayers of great men, poets, and artists; prayer in public worship; and prayer as a law of duty and good works.

More recently, researchers have developed typologies by asking people what they pray about, when they pray, why they pray, and to whom or what they pray. Ladd and Spilka (2002) proposed a threefold scheme which distinguishes among recipients of prayer. Inward prayer is directed toward one's inner self, outward prayer represents a connection with another human, and upward prayer signifies sacred communication with the divine. Poloma and Pendleton (1991) classified prayer in terms of four concise categories. Petitionary prayer involves requests to fulfill one's own spiritual or material needs or those of others by asking for guidance, forgiveness, and physical well-being. Meditative prayer involves thinking about the

divine, communicating with the sacred, or merely being in the presence of the sacred. Ritual prayer involves silent or verbal recitation of specific religious texts or mantras from memory or by reading scripture. Colloquial prayer, which takes the form of a conversation between individuals and their God or divine figure, may blend aspects of petitionary and meditative prayer. Poloma and Gallup (1991) found that while Americans most widely practice colloquial prayer, meditative prayer was associated with a closer relationship with God and higher levels of well-being.

Most prayer typologies have been created out of research involving individuals from predominantly Western cultures in which prayer is typically experienced in the context of organized, theistic religion. However, Banzinger, Janssen and Scheepers (2008) found that the prayer experiences of individuals from the Netherlands, a highly secularized society, also could be categorized using a typology similar to Poloma and Pendleton's scheme. While Banzinger et al. argued for the creation of a secular prayer type, their findings support the notion that some types of prayer experiences may be common to both secular and nonsecular individuals.

Prayer and Well-Being

The way that people communicate with the sacred can influence their physical and psychological health. Studies have linked prayer to better medical outcomes among patients dealing with cardiovascular disease, cancer, migraines, chronic pain post surgical recovery, and HIV.

Research studies have also shown that people who pray more frequently report a greater sense of well-being. More specifically, prayer has been associated with higher levels of overall mental health, lower levels of depression and anxiety, higher levels of self-esteem, and more positive mood among individuals with post-traumatic stress disorder ("PTSD"). How well prayer works may depend at least in part on how people perceive God. Bradshaw, Ellison and Flannelly (2008) found that frequency of prayer was positively correlated with higher rates of psychopathology among individuals who perceived God as remote or not loving. In contrast, among individuals who viewed God as close and loving, more prayer was tied to lower psychopathology. Other factors may also affect the relationship between prayer and well-being, including the content and intent of prayers, an individual's level of spiritual maturity, and the availability of additional coping resources.

Although studies have consistently demonstrated significant correlations between prayer and well-being, researchers have not yet identified the underlying psychological mechanisms that account for this relationship. Prayer may affect well-being indirectly by strengthening the relationships between individuals, God, and their faith community which may buffer the negative impact of stressors on health and well-being. Prayer may also manifest its effects through other psychological factors, such as increasing feelings of gratitude. Researchers have shown that greater frequency of prayer is associated with increased feelings of gratitude which are, in turn, correlated with lower rates of depression as well as higher levels of optimism and fewer negative health symptoms.

Prayer for one's own health and for the health of others represent the two most frequently used alternative health treatments in the United States. The proportion of Americans who pray to alleviate health problems increased from 43% in 2002 to 49% in 2007. This number may grow even further as the number of individuals who live with chronic physical or psychological illnesses rises. Many individuals who pray have also expressed a desire to integrate prayer practices into their medical treatment. In one study, 79% of critical care providers were asked by patients or their families to pray for them. In another survey, 48% of American patients indicated that they would like their doctor to pray for them. Over 90% of these patients felt that their doctor's prayers on their behalf had enhanced their health and aided in their recovery.

Some clinicians have begun to respond to the promising research findings and to the desires of many of their patients by considering how to incorporate prayer into specific treatments. Seventy-three percent of critical care nurses surveyed by Tracy et al. (2005) prayed while treating clients,

and 81% of these nurses had recommended the use of prayer to their patients. Pargament, Smith, Koenig, and Perez (1998) suggested that positive forms of religious coping such as seeking spiritual support through prayer could be successfully integrated into psychotherapy. The appropriateness of integrating spiritual practices such as prayer into treatment, however, remains a highly divisive topic within the health-care community.

Depression; Pregnancy complications

Definition

For most women, pregnancy is viewed as a natural and joyful event. In more than 80% of pregnancies, the delivery process is unremarkable, with no physiological or psychological complications. Indeed, the most notable changes associated with pregnancy often occur in social and partner relations, as well as changes to one's lifestyle. For instance, sleep deprivation and disturbance are the most frequently reported pregnancy-related disturbances. Pregnancy-related sleep disturbances, in turn, impact numerous facets of life including mood, cognition, social functioning, and memory (Harding, 1975).

For a small percentage of women, pregnancy and delivery are complicated by a variety of adverse outcomes. Preeclampsia, intrauterine growth restriction (IUGR), or preterm delivery can significantly affect the psychological health of women. Psychosocial aspects of pregnancy outcomes range along a continuum and are multidimensional. Psychosocial functioning in association with pregnancy complications may be a function of coping strategies, social support, and the overall emotional health of the mother and father. Sociodemographic factors, including parental age, socioeconomic status, and relationship quality also influence parental response to pregnancy complications. In the wake of adverse outcomes, parents may feel guilt, depression, anger, resentment, or withdrawal. Parents of infants transferred to the neonatal intensive care unit (NICU) may experience additional psychological burden, sometimes altering relationship dynamics (Zager, 2009) or mother-child bonding. Links between psychosocial factors and adverse pregnancy outcomes are currently underrecognized by health-care providers, which suggest that systematic prospective research is needed to more convincingly establish the significance of psychosocial factors and their potential for prevention.

Prehypertension

Jonathan Newman
Columbia University, New York, NY, USA

Description

In 2003, the seventh report of the Joint National Committee guidelines (JNC 7) proposed a classification for normal blood pressure (BP) and prehypertension based on the average of two more properly measured readings:

Normal blood pressure: systolic $<$ 120 mmHg and diastolic $<$ 80 mmHg

Prehypertension: systolic 120–139 mmHg or diastolic 80–89 mmHg

Compared to individuals with normal BP, prehypertensive individuals have a greater number of traditional cardiovascular disease (CVD) risk factors and have a greater risk of developing CVD independent of other CVD risk factors than individuals with BP $<$ 120/80. Prehypertensive individuals also have a greater risk of developing hypertension than normotensive individuals. Therefore, prehypertension can be conceptualized as an intermediate phenotype at elevated risk of developing traditional risk factors for CVD (such as hypertension) and at independent risk of developing CVD itself.

However, the ideal surveillance and management strategies for patients with prehypertension have not been well defined. Due to the associations between prehypertension and the development of overt hypertension and CVD, in 2007, the United States Preventive Services Task Force (USPSTF) recommended yearly BP screening for prehypertensive individuals and every other year screening for those with normotension. It remains unclear, however, how much of the excess CVD risk associated with prehypertension is due to the BP itself and how much is related to associated CVD risk factors: some analyses have shown that the excess CVD risk associated with prehypertension is attenuated after controlling for concomitant CVD risk factors. A more concrete problem with the diagnosis of prehypertension, however, may be the number of people affected: a recent analysis of the US population found that 39% of adults were normotensive, 31% prehypertensive, and 29% hypertensive. This suggests only a minority of Americans have normal blood pressure and raises the question of whether prehypertension should be defined as a "disease" state.

While there is limited evidence to suggest that treatment of prehypertension may prevent the development of hypertension, JNC 7 recommends careful follow-up for the development of hypertension or signs of end-organ damage (e.g., renal dysfunction or left-ventricular hypertrophy). Without the presence of CVD or other CVD risk factors (such as diabetes), prehypertension is generally treated with nonpharmacologic therapies such as weight loss, sodium restriction, dietary modification, and exercise.

Prevalence

Linda Carroll
Department of Public Health Sciences, University of Alberta, Edmonton, AB, Canada

Synonyms

Prevalence number; Prevalence rate

Definition

Prevalence is a measure of frequency of an illness, disease, or health conditions. Unlike incidence, which reflects new occurrences or changes in health states, prevalence is concerned with already existing health conditions, regardless of whether that health condition is of recent onset or is long-standing. Thus, prevalence of a particular condition refers to the proportion of the population which has that condition at a specified time. It is usually presented as x cases per 1,000 (or 10,000 or 100,000) people in the population. There are two types of prevalence: point prevalence (the type of prevalence most commonly reported) and period prevalence. Consider the example of the common cold. The "point prevalence" of the common cold in New York City means the proportion of people in New York City with a cold at a given point in time, i.e., the number of New York City residents with a cold on a specific day divided by the total number of New York City residents on that day. It is like a "prevalence snapshot." A 1-month "period prevalence" means the proportion of people in New York City who have had a cold at any point within the past month. It is analogous to time-lapse photography, reflecting the health state that has existed over a set period of time. A variation is lifetime prevalence or the proportion of people who have had the condition at any point during their lifetime.

Prevalence is usually measured in surveys or cross-sectional studies and reflects the burden of disease, rather than risk (incidence) of disease, which must be measured in longitudinal studies. Because prevalence is a measure of existing health conditions, it is affected by both incidence of that health state (the rate at which new cases develop) and the duration of that health state. A health condition might have a short duration because it is rapidly fatal, for example, rabies or Ebola, or because recovery is rapid, such as the case in the "24-h flu." Prevalence of a particular health condition can increase because there is an increase in incidence (e.g., during an influenza epidemic) or because people with that health condition are living longer with that condition (e.g., treatments may have extended the lives of those who suffer from that health condition). Alternatively, more effective treatments may shorten the recovery time.

Because prevalence is affected by recovery or death, it is an unreliable estimate of disease risk. This can be illustrated in the following example. The Framingham Heart Study reported equal prevalence of coronary heart disease in men and women. This could lead to the mistaken conclusion that men and women are at equal risk of developing coronary heart disease. However, the follow-up studies demonstrated that men were at greater risk of developing coronary heart disease and also had a higher fatality rate; while women were less likely to develop heart disease, but when they did, it was also less likely to be fatal. Thus, the prevalence in men and women was roughly equal because a lower risk was coupled with a longer duration of disease in women.

Levels of prevention

Definition

The natural history of disease is the course from onset to resolution (Last, 2000). The goal of epidemiology is to identify and understand causal factors of disease, disability, and injury so that effective interventions can be implemented to prevent the occurrence of adverse processes before they begin or progress (Stanhope & Lancaster, 2008). The definitions used in public health distinguish between primary prevention, secondary prevention, and tertiary prevention (Commission on Chronic Illness, 1957).

Description

The term "primary prevention" refers to intervention measures to prevent the occurrence (incidence) of new disease, disability, or injury (Leavell & Clark, 1965). This intervention must be implemented prepathogenesis and directed at individuals or groups at risk. Primary prevention efforts include health promotion and specific protection and are generally aimed at populations, not individuals (see Fig. 1). The application of primary prevention extends beyond medical problems and includes the prevention of other concerns that impact health and well-being, such as violence to environmental degradation. Education and public policy are major strategies for primary prevention.

Two other levels of prevention are termed secondary and tertiary prevention. Secondary prevention is a set of measures used for early detection and prompt intervention to control a problem or disease (prevalence) and minimize the consequences. Secondary prevention encompasses interventions that increase the probability that a person with a condition will have it diagnosed at a stage that treatment is likely to result in cure or reduction in the severity of a condition. Health screening is a major strategy of secondary prevention. Tertiary prevention focuses on the reduction of further complications of an existing disease, disability, or injury, through treatment and rehabilitation.

A landmark report published by the Institute of Medicine entitled: *Reducing Risks for Mental Disorders* (IOM, 1994) evaluated the body of research on the prevention of mental disorders. This report offered new definitions of prevention and provided recommendations on federal policies and programs. Levels of prevention across the natural disease history (Fig. 1) were defined as "prevention, treatment, and rehabilitation." Prevention, according to the IOM report (1994), is similar to the concept of primary prevention and refers to interventions to delay or avoid the initial onset of a disorder. Further, prevention has three types: universal, selective, and indicated, to reduce new cases. Universal efforts are directed to the entire population; selective prevention is for those at significant risk of a disorder due to biological, social, or psychological risk factors; and indicated prevention is for those with a mild disorder that has the potential to become more severe if not addressed in a timely manner.

Treatment refers to the identification of individuals with a disorder and providing treatment for those disorders, which includes interventions to reduce the likelihood of future co-occurring disorders. Maintenance refers to interventions that are oriented to reduce relapse and recurrence and to provide rehabilitation. Maintenance incorporates what public health defines as some forms of secondary and all forms of tertiary prevention.

THE NATURAL HISTORY OF ANY DISEASE OF MAN

LEVELS of APPLICATION of PREVENTIVE MEASURES				

Prevention: Primary, Secondary, Tertiary, Fig. 1 Levels of application of preventive measures in the natural history of disease

The concepts of risk and protective factors, risk reduction, and enhancement of protective factors (also referred to as fostering resilience) are central to most evidence-based prevention programs. Risk factors are those characteristics, variables, or hazards, that if present for a given individual, make it more likely that this individual, rather than someone selected at random from the general population, will develop a disorder. Protective factors improve a person's response to an environmental hazard resulting in an adaptive outcome.

The Agency for Health Research and Quality (AHRQ) provides ongoing administrative, research, technical, and dissemination support to the US Preventive Services Task Force (USPSTF). http://www.USPreventiveServicesTaskForce.org. The USPSTF is an independent panel of non-federal experts in prevention and evidence-based medicine, and is composed of an interdisciplinary mix of primary care providers (physicians, nurses, and health behavior specialists). The USPSTF conducts scientific evidence reviews of a broad range of clinical preventive health care services (such as screening, counseling, and preventive medications) and develops recommendations for primary care clinicians and health systems. These recommendations are published in the form of "Recommendation Statements."

Preventive Care

Shannon Idzik
University of Maryland School of Nursing and the University of Maryland Medical Center Emergency Department, Baltimore, MD, USA

Definition

Preventive care is the branch of health care that strives to prevent mental and physical illnesses. Many members of the health care team must partner together to achieve proper preventive care. Preventive care is divided into three levels of care: primary prevention, secondary prevention, and tertiary prevention.

Primary preventive care is the prevention of disease in a susceptible population through health promotion, education, and protective efforts. Ensuring adequate nutrition, advising patients about skin protection from ultraviolet radiation, educating about seat belt use, promoting safe home and work environments, prescribing oral fluoride supplementation in children with fluoride-deficient water, and administrating immunizations are all examples of primary preventive care.

Secondary preventive care is the prevention of disease through screening and early detection. Early recognition of disease through health care screening allows treatment to occur early in the course of the disease and may decrease complications. Examples of screening procedures that lead to the prevention of disease include fecal occult blood testing for detecting colon cancer, Pap smear for detecting early cervical cancer, routine mammography for early breast cancer, blood pressure and blood cholesterol measurement, oral examinations for early dental caries, and use of screening tools for depression.

Tertiary preventive care is the prevention of disease progression and disease sequelae after a chronic or irreversible disease diagnosis has been made. Limiting disability and promoting rehabilitation is important in tertiary prevention. Examples of tertiary prevention efforts include prescribing anticlotting agents such as aspirin in

patients who have cardiovascular disease, physical rehabilitation in patients who have suffered a stroke, and endodontic therapy in patients with severe dental decay.

Definition

Preventive Medicine Research Institute (PMRI) is a nonprofit research institute located in Sausalito, California, and founded by Dr. Dean Ornish. The mission of PMRI is to conduct scientific research examining the effects of diet and lifestyle choices on health outcomes.

Description

PMRI is a nonprofit research institute that is involved with scientific research studying the effects of diet and lifestyle choices on health and diseases. PMRI was founded by Dr. Dean Ornish, a leading researcher and physician advocating this type of prevention. The mission of PMRI is to conduct scientific research examining the effects of diet and lifestyle choices on health outcomes. In addition to research, another emphasis of PMRI is to educate health professionals and the lay public about the importance of preventive medicine and the benefits of lifestyle changes including diet, exercise, and stress management.

Primary Care

Shannon Idzik
University of Maryland School of Nursing and the University of Maryland Medical Center Emergency Department, Baltimore, MD, USA

Definition

Primary care is a component of integrated health care in which comprehensive and accessible care

is provided to a defined population. It is not disease- or organ-specific, but rather examines a person's overall state of health and well-being. Primary care is often the first point of contact into a health system for persons with a health concern including those with acute and chronic physical, mental, and social health issues. Primary care is a longitudinal and continuous approach to health maintenance including health promotion, disease prevention, health education, and counseling and includes diagnosis, treatment, and management of acute and chronic conditions. Primary care focuses on the provision of primary, secondary, and tertiary prevention measures, such as screenings, immunizations, and prevention of disease progression or sequelae. In primary care, the patient is seen as a partner in their health and health decisions. The primary care provider partners with the patient to coordinate other health services which includes a collaboration with and referral to other members of the health care team. Continuity in primary care is essential to develop and establish a patient-provider relationship. Primary care is not setting-specific and can be provided across a continuum of health settings such as the patient's private residence, provider office, hospital, or long-term care facility.

Primary Care Physicians

Steven Gambert
Department of Medicine, School of Medicine, University of Maryland, Baltimore, MD, USA

Synonyms

Family physician; General internist; PCP; PMD; Primary care provider; Primary medical doctor

Definition

A primary care physician is the physician who provides primary care, the physician selected to be the first doctor contacted for any medical condition. The physician acts as the patient's "gatekeeper," providing ongoing medical care, preventive services, medical counseling, and referrals to specialists as needed. Examples of physicians who may be considered to be primary care physicians include family medicine physicians, internal medicine physicians, OB/GYN physicians, pediatricians, and at times emergency medicine physicians. The number of primary care physicians has been declining in recent years with more physicians seeking careers as subspecialists or pursuing specialty care with financial rewards and increasing demands on time being major reasons for this change (Bodenheimer, 2006).

Primary Care Providers

Shannon Idzik
University of Maryland School of Nursing and the University of Maryland Medical Center Emergency Department, Baltimore, MD, USA

Synonyms

Family physician; General internist; Primary care provider; Primary medical doctor

Definition

Primary care provider is a generalist clinician who provides integrated accessible health care to a defined population. Nurse practitioners, physicians, and physicians' assistants who provide primary care are specially trained to provide primary care services. The primary care provider develops a sustained relationship with the patient and oversees all aspects of the patient's health. The primary care provider partners with the patient to coordinate other health services which includes a collaboration with and referral to other members of the health care team. Primary care providers are advocates for the patient throughout the entire health care system.

Principle of Equipoise

J. Rick Turner
Cardiovascular Safety, Quintiles, Durham, NC, USA

Synonyms

Clinical equipoise; Equipoise

Definition

Clinical equipoise exists when all of the available evidence about a new intervention/treatment does not show that it is more beneficial than an alternative and, equally, does not show that it is less beneficial than the alternative. For example, to be able to conduct a clinical trial that involves administering an investigational treatment that may confer therapeutic benefit to subjects for whom such benefit is desirable to some individuals, and to administer a control intervention treatment that is not capable of conferring therapeutic benefit to others, there cannot be any evidence that suggests that the investigational intervention shows greater efficacy than the control treatment or that it leads to greater side effects than the control treatment.

When individuals agree to participate in a clinical study, they do so with the understanding that all of the treatments are assumed to be of equal value. By the end of the trial, there may be compelling evidence that the investigational intervention is acceptably safe and statistically significantly more effective than the control intervention, but the study must be started with a good faith belief that the two treatments are of equal merit.

Treating subjects in clinical studies (trials) in an ethical manner is of paramount importance. Clinical equipoise is a cornerstone of such ethical conduct. Other fundamental ethical principles include respect for persons, beneficence, and justice (see Turner, 2010).

Derenzo and Moss (2006) commented as follows:

> Each study component has an ethical aspect. The ethical aspects of a clinical trial cannot be separated from the scientific objectives. Segregation of ethical issues from the full range of study design components demonstrates a flaw in understanding the fundamental nature of research involving human subjects. Compartmentalization of ethical issues is inconsistent with a well-run trial. Ethical and scientific considerations are intertwined.

Probability

J. Rick Turner
Cardiovascular Safety, Quintiles, Durham, NC, USA

Definition

In situations where certainty is not possible, it can be helpful to assess how likely it is that something will occur. Quantification of this likelihood is particularly helpful in statistical analysis. The concept of probability is used in everyday language, but more loosely than in statistics. The statement "I'll probably be there on Saturday" involves a probabilistic statement, but there is no precise degree of quantification. If you know the individual making this statement, past experience may lead you to an informed judgment concerning the relative meaning of probably, but this is still a subjective judgment, not a quantitative statement.

In statistics, a probability is a numerical quantity between zero (represented here as 0.00) and one (1.00) that expresses the likely occurrence of a future event. Past events cannot be associated with a probability of occurrence, since it is known in absolute terms whether they occurred or not. A probability of zero denotes that the event will not (cannot) occur. A probability of one denotes certainty that the event will occur. Any numerical value between zero and one expresses a relative likelihood of an event occurring. Additionally, the decimal expression of a probability value can be multiplied by 100 to create a percentage statement of likelihood. A probability of 0.50 would thus be expressed as a 50% chance that an event would occur. Similarly, and more relevantly to inferential hypothesis testing, probabilities of 0.05 and 0.01 would be expressed as a 5% chance and a 1% chance, respectively, that an event would occur.

Problem Solving

Seth A. Margolis[1], Patricia Osborne[1] and Jeffrey S. Gonzalez[1,2]
[1]Clinical Psychology, Health Emphasis, Ferkauf Graduate School of Psychology, Yeshiva University, Bronx, NY, USA
[2]Diabetes Research Center, Albert Einstein College of Medicine, Yeshiva University, Bronx, NY, USA

Synonyms

Problem-solving skills training (PSST); Problem-solving therapy – primary care (PST-PC); Problem-solving therapy – SO (PST-SO); Social problem-solving therapy (SPST)

Definition

Problem-solving therapy (PST) is a brief, empirically supported, cognitive-behavioral intervention aimed at training clients to identify, evaluate, and resolve everyday problems through the methodical application of problem-solving skills. In addition to teaching specific coping skills, PST emphasizes the importance of maintaining a positive *problem-solving orientation* and a rational *problem-solving style* (D'Zurilla & Nezu, 2010).

An individual's *problem-solving orientation* encompasses how one perceives problems, to what/whom they attribute these problems, how they appraise problematic situations, and the degree to which they view their problems as under their control. A major goal of PST is to help clients view problems as solvable challenges instead of insurmountable impasses.

A person's *problem-solving style* addresses the characteristic way in which he or she attempts to manage problems in living. PST advocates a rational approach. This form of problem solving is taught through the use of four essential skills: defining the problem in precise and objective terms (i.e., problem definition and formulation), brainstorming potential solutions (i.e., generation of alternatives), weighing the pros and cons of each alternative and creating a plan of action (i.e., decision making), and implementing the most appropriate solution and evaluating the outcome (i.e., implementation and verification). In combination, these skills are meant to help individuals manage their problems in an organized and systematic manner.

Problem solving serves a critical function in the successful management of chronic medical conditions. PST has, therefore, been adapted for individuals affected by cancer, obesity, diabetes, cardiovascular disease, traumatic brain injury, stroke, as well as older adults, caregivers, and to promote treatment adherence.

PST has been successfully delivered in individual, group, and family formats by psychologists, psychiatrists, social workers, nurses, and graduate-level trainees. Most forms of PST are manual based and all make use of homework assignments. PST therapists tend to balance directive and collaborative treatment styles.

PST interventions have been implemented in primary care settings (Catalan et al., 1991; Mynors-Wallis & Gath, 1997; Oxman, Hegel, Hull, & Dietrich, 2008; Areán et al., 2010), via telephone and in the home (Grant, Elliott, Weaver, Bartolucci, & Ginger, 2002), within community clinics and online (Wade, Wolfe, Brown, & Pestian, 2005; Wade, Walz, Carey, & William, 2008).

Even though PST has been provided as both a stand-alone treatment and as a component of multifaceted interventions, more research is

needed to adequately compare the two. Although some studies have addressed PST's applicability to minority groups (Sahler et al., 2005) and different age ranges (Areán et al., 2010), supplementary research is needed in these areas. Finally, given the evidence that PST can be a successful intervention for behavioral medicine settings, it would behoove future investigators to attempt to extend findings to other chronic health conditions.

Problem-Focused Coping

Linda Carroll
Department of Public Health Sciences, University of Alberta, Edmonton, AB, Canada

Synonyms

Active coping

Definition

Coping refers to the intentional efforts we engage in to minimize the physical, psychological, or social harm of an event or situation. There are many different frameworks for understanding coping and many different ways of classifying coping strategies, but one such classification is problem-focused coping vs. emotion-focused coping. Problem-focused coping is that kind of coping aimed at resolving the stressful situation or event or altering the source of the stress. Coping strategies that can be considered to be problem-focused include (but are not limited to) taking control of the stress (e.g., problem solving or removing the source of the stress), seeking information or assistance in handling the situation, and removing oneself from the stressful situation.

Problem-focused coping is distinguished from emotion-focused coping, which is aimed at managing the emotions associated with the situation, rather than changing the situation itself. For example, when anxious about an upcoming exam, use of problem-focused coping strategies might involve checking with the teacher about material one is unsure of, or increasing the time spent studying, or even deciding not to take the exam (although removing oneself from the stressor might have other negative consequences in this particular example). In contrast, emotion-focused coping strategies might involve self-talk to increase one's confidence in one's test taking ability or using relaxation techniques to decrease fear and anxiety. Problem-focused coping works best when the source of the stress is potentially under an individual's control; however, when the source of the stress is beyond the individual's control, such strategies are not usually helpful. Examples are dealing with bereavement. In situations like this, problem-focused coping is less likely to be helpful than emotion-focused coping, for example, processing one's feelings or releasing one's feelings. Problem- and emotion-focused coping are not mutually exclusive, and individuals frequently use both problem- and emotion-focused coping strategies to deal with stress. For example, when feeling threatened, initial use of emotion-focused coping to gain control over the fear can facilitate the subsequent use of problem-focused coping. Problem- and emotion-focused coping are the two subscales that comprise the Ways of Coping Checklist.

Promotoras

Amelie Ramirez[1] and Barbara Turner[2]
[1]Department of Epidemiology & Biostatistics, The University of Texas Health Science Center at San Antonio, San Antonio, TX, USA
[2]The University of Texas Health Science Center at San Antonio, San Antonio, TX, USA

Synonyms

Community health advisors; Community health representatives; Community health workers (CHW); Health navigators; Lay health advisors; Lay health advocates; Outreach educators; Peer coaches; Peer health educators; Peer health promoters

Definition

Promotoras (or *promotoras de salud*) are female community health workers who provide a variety of services in their role as liaison between underserved Hispanics and traditional health care services. Their male counterparts are *promotores*, although it is less common to have men serve in this role. These terms translate to "promoters" of health, in this case among Hispanics who have historically experienced challenges accessing health care services and deficiencies in outcomes of care. These individuals are either volunteers or employees of the local health care system or other entities administering community interventions. They typically live in the community or neighborhood that they serve and thus can better communicate and relate to their clients because of their shared community experiences.

Description

Essentially, the *promotora* concept is a form of community-based peer support: nonprofessionals helping others with various health needs. These needs include: culturally appropriate education, informal advice and counsel, social support and encouragement, interpretation and translation, advocacy for health needs, disease management and prevention, health care system navigation, and community resource guidance. Depending upon the community health priorities and the specific goals and objectives of particular programs, *promotoras* may provide one or a combination of these services.

Historically, *promotoras* are part of a long tradition of lay health workers who serve critical health care and disease prevention roles in cultures around the world. For example, in eighteenth century Russia, *feldshers* began providing medical assistance in urban hospitals and the army. In China, during the 1960s, farmworkers were trained as "barefoot doctors" to give first aid, immunizations, and health education in rural areas. In Haiti, village health workers known as *accompagnateurs* attended individuals suffering from tuberculosis and HIV/AIDS. In Africa, health care workers provide the main form of health care delivery and especially have served as the linchpin for HIV prevention and treatment. Origins of the *promotoras* can also be found in Latin American countries, where laymen and laywomen were trained by church groups and other organizations to give community health assistance.

Efforts to establish formal community health worker programs in this country can be traced back over a half-century. Such outreach was subsequently included in the federal Migrant Health Act of 1962 and the Economic Opportunity Act of 1964, mandating utilization of

community health aides in many neighborhoods and migrant worker camps (Hill, Bone, & Butz, 1996). The Affordable Care Act of 2010 provided a more recent endorsement of the concept, specifying community health workers as an integral component of the nation's health care workforce (Affordable Care Act of 2010). With the rise in health care costs in recent times and increased awareness of the scope and cost of health disparities in this country, the peer-support approach has gained increasing support as a viable and potentially cost-effective means of helping fill gaps in the health care system. However, the evidence so far is conflicting and comes from less than optimally designed studies.

In the USA today, the nomenclature for peer health promotion personnel is diverse, including: community health workers (CHW), community health advisors, lay health advisors, lay health advocates, peer coaches, outreach educators, health navigators, peer health promoters, peer health educators, community health representatives, and, in Hispanic communities, *promotoras*. Often, some of these terms, including CHW and *promotoras*, are used interchangeably or in combination.

Surveys have found that these community health workers operate in all 50 states (U.S. Department of Health and Human Services Health Resources and Services Administration, 2007). Programs utilizing *promotoras* have flourished especially in states with large Hispanic populations such as California and along the USA-Mexico border. In 2009, Hispanics represented 16% of the US population (U.S. Census Bureau News, 2010) and this proportion is expected to rise dramatically in the coming decades. With the growing number of Hispanics, the peer-assistance concept has been incorporated into health programs and interventions across the country. This model has been evaluated in large cities, mid-size and smaller communities, as well as agricultural areas (working with farmworkers and their families), with favorable results in many studies.

Promotora involvement has been found to be useful in a broad range of needs, such as management of diabetes and other health conditions prevalent among Hispanics, screening for cancer and other diseases, and access to health care overall. They also can focus on addressing specific needs such as prenatal care, or healthy lifestyle behaviors in general (e.g., proper diet and exercise). In addition to working with diabetes and cancer patients, survivors, and at-risk individuals, *promotoras*/CHW have been involved in interventions targeting cardiovascular disease, HIV/AIDS, high blood pressure, asthma, mental illness, and other diseases.

Firsthand knowledge of the local Hispanic community and the personal and institutional barriers that residents of the community face in attaining adequate health care uniquely prepares *promotoras* for their liaison role. As Spanish speakers and residents of the neighborhoods they serve, *promotoras* offer assistance to reduce or remove linguistic and cultural barriers for segments of the population that have historically been difficult to reach for local health care agencies and services. At the same time, *promotoras* can provide assistance to professional health care personnel by educating providers and their staff about sociocultural factors that influence the health knowledge, beliefs, and attitudes, as well as the values and behaviors, of their Hispanic patients.

Among the strengths of the *promotora*/CHW models employed in various community health programs is the broad diversity of services peer health workers have been able to deliver. For example, as liaisons between health providers and underserved Hispanics, *promotoras* sometimes serve as interpreters as well as health system navigators, assisting in identification of benefits that clients are eligible to receive, and helping them complete necessary applications and forms. As case managers, *promotoras* typically facilitate contacts of health care providers with community members by maintaining accurate contact information and a record of interactions. As community organizers, *promotoras* have been called upon to motivate and encourage members of the community to participate actively in efforts to improve neighborhood living conditions. And as health educators, *promotoras* distribute and explain print and

other informative materials aimed at promoting screening, preventing disease, discouraging smoking, managing chronic diseases, and other health promotion purposes. In addition, interventions have utilized *promotoras* in various other roles, including as group presentation leaders; role models; and guides to community social, transportation, childcare, and other services and resources.

Promotoras are typically respected and trusted members of the community they serve. Due to their familiarity with their community and neighborhood, *promotora*s can move freely within the community and engage with various sectors. They provide their services in convenient locations, including homes, schools, churches, clinics, hospitals, community centers, job sites, and other locales. In many programs, they also participate in community events, such as health fairs.

In the past, *promotoras* and other community health workers have typically been trained on the job. With the increased utilization of peer-support models over the years, concerns about the quality of this training and the need for more standard certification of these workers have been increasingly raised. However, as of 2010, only a handful of states had taken steps to address these issues. In 1999, Texas was the first state to legislate voluntary training and certification for *promotoras* and community health workers (Nichols, Berrios, & Samar, 2005). In Minnesota, select community colleges offer a standardized curriculum for community health worker certification, with completion required for a worker to be eligible as a Medicaid provider (Rosenthal et al., 2010). In numerous states, certificates are being awarded, typically by community colleges and other programs, for completion of a course of community health worker studies. Proponents of required certification or credentialing note potential benefits, including offering assurance that workers possess basic competencies and promoting perceived legitimacy within health/human services fields. Others, however, contend that requiring certification may have a detrimental effect on the number of peer health workers from poor, minority neighborhoods and communities that most need to be served (Family Strengthening Policy Center, 2006).

From the substantial experience with *promotora*/CHW program implementation and research, the evidence is growing that peer support offers unique benefits to improve health care delivery and outcomes. This is particularly relevant, given rapidly expanding lower-socio economic status (SES) racial/ethnic segments of the population (particularly Hispanics), growing numbers of patients with chronic diseases, and spiraling health care costs. Systematic reviews of the benefit of peer support currently find that the evidence lacks sufficient rigor. Consequently, much more research needs to be conducted to define roles and scope of activities, determine effectiveness, develop consistent and adequate training, provide fair compensation, and, via certification and/or similar means, define a universally accepted and respected niche for *promotoras* among the nation's health care workforce.

Definition

Prostate Anatomy

The prostate is a walnut-sized gland that functions in the male reproductive system. It is positioned in front of the rectum and directly below the bladder, which stores urine. The prostate also encircles the proximal urethra, the canal which carries urine from the bladder and through the penis.

Three distinct zones of glandular tissue make up the prostate: the peripheral zone, central zone, and transition zone. Additionally, there is an area of fibromuscular tissue on the anterior surface. Each anatomic zone is uniquely affected by different disease processes. The majority of

prostate cancers develop in the peripheral zone, the largest zone by volume, while benign prostatic hyperplasia originates in the transition zone.

Description

Prostate Function

The prostate produces the thick, milky-white alkaline fluid that forms part of semen. The fluid provides nourishment to sperm and, along with fluid from the bulbourethral (Cowper's) glands, helps to neutralize the acidity of the urine residue in the male urethra and of the female vaginal canal, increasing the life span of sperm. During ejaculation, contraction of smooth muscles moves the fluid from the prostate into the urethral tract where it mixes with the sperm produced by the testicles and additional fluid from the bulbourethral glands and seminal vesicles. The resulting mixture, semen, passes from the urethra and out through the penis.

Common Disorders of the Prostate

There are three common conditions of the prostate: prostatitis, benign prostatic hyperplasia, and prostate cancer. Generally, older men are more susceptible to prostate disease. However, prostatitis can affect men at any age. Prostatitis is a benign infection of prostatic tissue, usually caused by bacteria. Inflammation can result in urine retention in the bladder, resulting in bladder distention (i.e., enlargement) and exposing the bladder to additional risk for infection. Additionally, prostatitis can trigger several urinary problems (e.g., pain or burning upon urination, urgency, and trouble voiding). Benign prostatic hyperplasia, or BPH, is another common prostatic condition caused by the noncancerous enlargement of the prostate gland in aging men. As the prostate enlarges, it compresses the urethra and irritates the bladder. Obstruction of the urethra, as well as gradually diminishing bladder function, results in the symptoms of BPH including dribbling after urination or a need to urinate often, especially at night. Some men also experience urinary incontinence, the involuntary discharge of urine. BPH symptoms can severely affect a man's, as well as his partner's, quality of life and can be further compounded by psychological factors (e.g., depression and anxiety) associated with BPH symptoms. Prostate cancer is the most common malignancy and the second most common cause of cancer death among men in the United States. Response to treatment is best when the disease is caught early. However, prostate cancer is generally asymptomatic when the disease is localized to the prostate. Screening for prostate cancer includes serum prostate-specific antigen (PSA) testing and digital rectal examination. There are many treatment options available to men diagnosed with prostate cancer (e.g., active surveillance, radiotherapy, and surgery). However, there is currently no consensus regarding the optimal treatment.

Definition

Prostate-specific antigen (PSA) is a protein produced by cells of the prostate gland. PSA functions in male fertility, and most of it gets expelled from the body in semen. However, low levels circulate in the blood. Elevated serum PSA levels often indicate the presence of prostate cancer and other prostate disorders.

Description

Measuring PSA

The PSA screening test measures the total level of PSA circulating in the blood serum. PSA levels above 4 ng per milliliter are considered above normal. However, total PSA does not offer a definitive diagnosis for cancer or other prostate disease. Therefore, additional measures of PSA have been integrated to depict a more comprehensive profile of prostate disease characteristics. For example, PSA velocity measures the rate of increase in PSA over time. Generally, larger PSA velocity is associated with prostate cancer. Free PSA is the percentage of circulating PSA that is not bound to other proteins. On average, men with a low percentage of free PSA are more likely to have cancer. PSA density is the PSA level divided by prostate volume. The likelihood of cancer is increased when PSA density is high.

PSA Testing and Current Guidelines

PSA testing has become increasingly popular because it allows detection of prostate cancer at early stages, before palpable detection during digital rectal examination. However, PSA testing also presents a high rate of false-positive and false-negative results, which has generated substantial controversy with regard to whether or not PSA screening is effective at reducing cancer deaths. Two large, randomized clinical trials are currently evaluating the efficacy of PSA screening. Preliminary findings indicate modest reductions in cancer deaths in the screening group but also note over-detection and potential overtreatment of clinically insignificant cancers in the same group. Accounting for these complex issues, the American Cancer Society (ACS) has revised its recommendations regarding routine PSA screening. The revised guidelines now recommend that doctors initiate comprehensive discussions with patients about their options for screening and that men use decision-making tools to make an informed choice about testing. The ACS suggests these guidelines are appropriate for patients over age 50 who are in good health with greater than 10 years of life expectancy. For men at higher risk (e.g., African American men and men with a positive family history), ACS guidelines suggest that discussions about screening begin earlier. The ACS does not endorse screening for men with several comorbid conditions or for men with less than 10 years of life expectancy. In response to the preliminary findings from the previously mentioned studies, the American Urological Association (AUA) also revised its screening recommendations, which

suggest extending screening to younger men. The AUA advises that PSA screening should be offered to well-informed men aged 40 years or older who have a life expectancy of at least 10 years. Additionally, AUA guidelines emphasize a shift away from using a single PSA threshold to determine whether to proceed to additional diagnostics. Instead, the combination of many factors (e.g., PSA profile over time, family history, race, age) should be considered.

Protection of Human Subjects

Marianne Shaughnessy
School of Nursing, University of Maryland, Baltimore, MD, USA

Synonyms

Human subjects protections

Definition

The organized oversight of research to ensure the rights and well-being of participants.

Description

The protection of human subjects in clinical research evolved in response to conditions surrounding medical research that were deemed unacceptable in the early to mid-twentieth century. In December 1946, an American military tribunal opened criminal proceedings against 23 German physicians who conducted medical experiments on thousands of concentration camp prisoners without their consent. Most of the subjects of these experiments died or were permanently disabled as a result. The Nuremberg Code of 1948 resulted, stating that "voluntary consent of a human subject is absolutely essential" and that "the benefits of research must outweigh the risks" (NIH). In 1964, the World Medical Association published recommendations for research involving human subjects, and the Declaration of Helsinki governs international research ethics and defines rules for "research combined with clinical care" and

"non-therapeutic research." This declaration was revised in 1975, 1983, 1989, and 1996 and remains the basis for Good Clinical practices used today (WMA).

In the United States, the Tuskeegee Syphilis Study (1932–1972) described the natural history of syphilis in 600 low-income African American males, 400 of whom were infected. Over 40 years, researchers provided medical examinations, but infected subjects were never told of their disease nor offered treatment, even after a known cure became available in 1947. Many of the subjects died from syphilis-related causes during the study. The study was stopped in 1973 by the U.S. Department of Health, Education and Welfare after its existence was publicized (CDC). The publicity generated by the Nuremberg trials, the Tuskeegee study, and other studies created a mistrust of medical researchers and a demand for a standards and guidelines for the ethical conduct of research. On July 12, 1974, the National Research Act (Pub. L. 93–348) was signed into law, creating the National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research. This commission generated the Belmont Report in 1976, a summary of the ethical principles identified by the Commission that should be used to guide human subjects research. These principles include (1) respect for persons, (2) beneficence, and (3) justice. The application of these general principles is further described in specific guidance for obtaining informed consent, complete assessment of risks, and benefits and selection of research subjects.

Medical research is conducted in a variety of academic and corporate settings, but all human subjects research studies should be evaluated by an Institutional Review Board or similar research oversight committee prior to initiation. This is a requirement for all federally funded research in the United States. These oversight boards are responsible for the review of each proposed study to ensure that the principles of the Belmont Report are applied and that the rights of potential and actual participants are respected. The Association for the Accreditation of Human Research Protection Programs (AAHRPP) reviews the processes established by these research oversight bodies and grants accreditation for such programs that meet general requirements and demonstrate processes geared toward continual improvement of research and the protection of human subjects.

Proteomics

J. Rick Turner
Cardiovascular Safety, Quintiles, Durham, NC, USA

Definition

Proteomics is the study of all of a genome's putative proteins and involves the systematic analysis of proteins to determine their identity, quantity, and function (Soloviev, Barry, & Terrett, 2004).

Description

The Human Genome Project and related work have focused considerable attention on sequencing aspects of genomic research. However, as Holmes, Ramkissoon, & Giddings (2005) noted, "The eventual goal of these projects is actually to determine how the genome builds life through proteins. DNA has been the focus of attention because the tools for studying it are more advanced and because it is at the heart of the cell, carrying all the information – the blueprint – for life. However, a blueprint without a builder is not very useful, and the proteins are the primary builders within the cell."

It is of interest to characterize the complement of expressed proteins from a single genome. Monitoring the expression and properties of a large number of proteins provides important information about the physiological state of a cell and, by extension, an organism. Cells can express very large numbers of different proteins, and the "expression profile" (the number of proteins expressed and the expression level of each of them) can vary in different cell types. Given that each cell contains all genomic material and hence information, this differential expression of proteins explains why cells perform different functions (Soloviev et al., 2004).

The 20,000–25,000 genes in the human genome actually generate many more than the commensurate number of proteins, with estimates as high as one million appearing in the literature (Augen, 2005). This huge number results from the observation that multiple, distinct proteins can result from a single gene. Consider the following steps in the journey from the genome to the proteome (Holmes et al., 2005):

- DNA replication results in many gene forms.
- Ribonucleic acid (RNA) transcription leads to pre-messenger RNA.
- RNA maturation results in mature messenger RNA.
- Protein translation results in an immature protein.
- Protein maturation results in a mature protein in the proteome (posttranslational modifications are possible here).

The tremendous diversity of proteins in the proteome is facilitated by multiple possible means of protein expression. At each stage of the multistep process just described, alternate mechanisms produce variants of the "standard" protein, resulting in a proteome that is far greater than the genome that generates it. Posttranslational modifications play a considerable part in this creation of diversity. These modifications include, for example, the process of glycosylation in which proteins are glycosylated and hence become glycoproteins, which act as receptors and enzymes.

Nobel Laureate James Watson commented as follows with regard to the fields of proteomics and transcriptomics (Watson, 2004): "In the wake of the Human Genome Project, two new postgenomic fields have duly emerged, both of them burdened with unimaginative names incorporating the '-omic' of their ancestor: proteomics and transcriptomics. Proteomics is the study of the proteins encoded by genes. Transcriptomics is devoted to determining where and when genes are expressed – that is, which genes are transcriptionally active in a given cell."

Psychiatric Diagnosis

Toru Okuyama
Division of Psycho-oncology and Palliative Care, Nagoya City University Hospital, Nagoya, Aichi, Japan

Synonyms

Diagnostic criteria; Psychiatric disorder

Definition

Psychiatric diagnosis defines a psychiatric disorder which causes subjective distress and disability and can be conceptualized based on symptomatology, epidemiology, and pathophysiology. The primary purpose of the psychiatric diagnosis is to distinguish a certain condition from non-disease conditions or other disease conditions and to make health providers communicate better with each other by using shared concepts and languages. Psychiatric diagnosis facilitates researches by maintaining the internal validity of each psychiatric disease and is important for examining the external validity of findings when applying research evidences into individual patients.

Description

The top two most important and frequently used psychiatric diagnoses classification systems are the International Classification of Disease (ICD) by World Health Organization (WHO) and the Diagnostic and Statistical Manual of Mental Disorders (DSM) edited by the American Psychiatric Association.

The ICD is the international standard diagnostic classification of physical and psychiatric diseases and other health conditions, defined by WHO. It has been developed for the purpose of international use since the beginning, and WHO Member States compile national mortality and morbidity statistics based on this diagnostic system. The tenth revision was published in 1992. The classification of mental and behavioral disorders is included in Chap. F. ICD-10 consists of Clinical Descriptions and Diagnostic Guidelines and Diagnostic Criteria for Research. The former provides clinical descriptions detailing the principal signs and symptoms of each disorder. The latter is intended to help those researching specific disorders to maximize the homogeneity of study groups.

The latest version of DSM is the fourth edition text revision published in 2000 (DSM-IV-TR), in which several important features are included. First, it adopts the descriptive approach: the diagnoses criteria are defined based on the symptomatology, rather than the underlying causes. Secondly, clearly defined diagnostic criteria are provided for each specific disorder. These criteria include lists of features that must be present for diagnoses to be made. Thirdly, DSM-IV-TR is

a multidimensional evaluation system (Axis I: clinical disorders and other conditions that may be a focus of clinical attention, Axis II: personality disorders and mental retardation, Axis III: any physical disorder or general medical condition, Axis IV: the psychosocial and environmental problems that contribute significantly to the development or exacerbation of the current disorder, Axis V: a global assessment of functioning). The codes and terms used in the DSM-IV are designed to correspond with the codes used in the ICD-10.

It is also important how to apply these diagnostic criteria into each actual patient, in order to maximize the reliability of psychiatric diagnosis. Structured interviews were developed for this purpose. In structured interviews, the procedures for interviews including how to ask about the presence or absence of certain symptom and how to categorize patients' responses are strictly defined so that high inter-rater reliability of the diagnosis can be achieved. Since currently there are no gold standard objective diagnostic tests for psychiatric diagnosis, structured interviews are considered to be gold standard.

A clinical diagnosis includes the whole process of diagnostic formulation in addition to a psychiatric diagnosis based on the diagnostic criteria. A diagnostic formulation is an attempt to understand each patient comprehensively and individually by describing what has been influencing the feeling and behavior of the patient and what relationship might exist between the patient's life situation/background and the psychiatric illness.

Psychiatric Disorder

▶ Psychiatric Diagnosis
▶ Psychological Disorder
▶ Psychiatric Illness

Psychiatric Illness

Maxine Holmqvist
Clinical Health Psychology, University of Manitoba, Winnipeg, MB, Canada

Synonyms

Mental illness; Psychiatric disorder; Psychological disorder

Definition

A condition or syndrome with distinctive cognitive, affective, and/or behavioral symptoms, arising from underlying psychobiological dysfunction and causing significant distress, impairment, or an increased risk of death, pain, disability, or an important loss of freedom (American Psychiatric Association [APA], 2000).

Description

Psychiatry is a branch of medicine that focuses on the diagnosis and treatment of mental illness. It did not emerge as an independent discipline until the late 1800s; however, the roots of psychiatric assessment and treatment extend back to the ancient

Greeks and Egyptians (for a comprehensive overview of the history of psychiatry, see Wallace & Gach, 2008). Psychiatric illnesses are currently diagnosed with reference to either the Diagnostic and Statistical Manual of Mental Disorders, 4th edition (DSM-IV; APA, 2000) or the International Classification of Disease, 10th revision (ICD-10; for more information on these systems, see *Psychological Disorders*, this volume). Psychiatric diagnoses are descriptive, and with few exceptions, they convey very little about etiology. McHugh and Slavney (1998) identify different perspectives that psychiatrists use to conceptualize cases and plan interventions. Disease reasoning presupposes that a patients' condition is the result of changes or defects in brain functioning. In contrast to this, behavioral reasoning presupposes that a patient's condition is the result of dysfunctional behavior. These two perspectives suggest different interventions; where the presumed cause is pathology of the brain, it follows that the appropriate treatment would likely involve medical intervention (e.g., pharmaceutical drugs, surgery, transcranial magnetic stimulation), while a behavioral disorder would respond best to behavioral treatment (e.g., attention to antecedents and consequences, behavior modification, exposure therapy). The use of the word "illness" in the term "psychiatric illness" implies that disease reasoning is being used; an illness is something a patient *has* rather than something that they are *doing* (McHugh & Slavney, 1998). Therefore, this term may be more commonly used to refer to psychoses and disorders with known biological pathophysiology (e.g., Huntington's disease) and less commonly used to refer to conditions where symptoms are primarily behavioral or appear more voluntary (e.g., gambling, anorexia nervosa).

Regardless of their presumed origin, psychiatric illnesses such as depression and post-traumatic stress disorder are risk factors for the onset of complex medical conditions like coronary heart disease. Furthermore, psychiatric illnesses may develop as a consequence of disease processes, and can be significant independent predictors of poor prognosis in several conditions, including heart disease and end-stage renal disease.

Psychoeducation

Shin-ichi Suzuki[1] and Asuka Tanoue[2]
[1]Faculty of Human Sciences, Graduate School of Human sciences, Waseda University, Tokorozawa-shi, Saitama, Japan
[2]Advanced Research Center for Human Science, Waseda University, Tokorozawa, Saitama, Japan

Definition

Psychoeducation is a method of providing patients/clients and their families a theoretical and practical

approach to understanding and coping with the consequences of their psychological disorders/problems or physical illnesses/responses.

The main goals of psychoeducation are the enhancement of adherence; improvement of illness management or stress control skills, such as early recognition of episode recurrence and development of strategies for effective coping with symptoms; improvement of social and occupational functions; and quality of life.

The role of psychoeducation encompasses not only imparting knowledge and information regarding treatment/psychological support through media such as leaflets or information web sites or feedback to individuals based on test results, but it is also characterized by active cooperation such as intervention exercises with patients and their families.

Psychoeducation may be conducted in a group including individuals with similar problems (e.g., chronic diseases such as diabetes, HIV/AIDS, and PTSD) and individual therapy sessions. Group therapy is also expected to foster support among patients/clients. Thus, the psychoeducational approach has a lot in common with general psychosocial support for schizophrenia, mood disorders, eating disorders, and drug addiction, but it can also be applied to further the field of education.

Particularly, in the context of a medical setting, the therapists will try to explain the normal reactions of symptoms related to each psychological disorder or physical illness at the beginning. This will prevent any misinformation from being circulated among the patients and expand their understanding of the intervention, and it will lead to an improvement in the interactions of patients/clients in the treatment. Evidence from systematic reviews has reinforced the effect of these treatments stating that psychoeducational interventions for unipolar depression are effective, can prevent the worsening of depression, and be used as a preventive instrument (e.g., Cuijpers, 1997).

As mentioned above, psychoeducation is a treatment that is routinely practiced in a number of fields, and it will continue to be considered essential in terms of the treatment and prevention of relapses.

Psychological Disorder

Maxine Holmqvist
Clinical Health Psychology, University of Manitoba, Winnipeg, MB, Canada

Synonyms

Behavioral disorder; Emotional disorder; Mental disorder; Psychiatric disorder; Psychiatric illness

Definition

A distinctive pattern of cognitive, and/or behavioral symptoms in an individual, arising from underlying psychobiological dysfunction and causing significant distress, impairment, or an increased risk of death, pain, disability, or an important loss of freedom (American Psychiatric Association, 2000). Psychological disorders do not include culturally sanctioned responses to life events (e.g., feeling sad after a significant loss).

Description

The term "psychological disorder" is often used interchangeably with similar terms, including "mental disorder" and "psychiatric illness." It may be a preferable term to "mental disorder," which evokes a mind/body dualism that is inconsistent with modern theories that emphasize the biopsychosocial origins of disease (Fulford, Thornton, & Graham 2006). The term "psychological disorder" is broad, encompassing both disorders that manifest primarily with dysfunctional behaviors (e.g., anorexia nervosa, alcohol dependence) and disorders that manifest primarily with involuntary symptoms (e.g., schizophrenia, depression; McHugh & Slavney, 1998). In contrast, the term "psychiatric illness" more typically refers to the latter category, assuming that these disorders are more rooted in brain dysfunction (see *Psychiatric Illness*, this volume). To date, genetic studies have not supported this distinction (e.g., Bienvenu, Davydow, & Kendler 2011).

Historical Background

Psychological disorders are cultural constructs, created through a variety of social processes, including debate, voting, and expert consensus (Raskin & Lewandowski, 2000). Classifying psychological symptoms into disorders allows service providers to communicate with one another and for evidence-based knowledge to be accumulated and shared. It can enhance treatment planning and is critical for health care management (e.g., allowing governments to monitor the incidence and prevalence of various conditions in the population and allocate resources appropriately). While modern classification systems are empirically informed, current diagnostic categories are heavily influenced by historical forces (Kendler, 2009). Today, the two most common classification systems for psychological disorders are the Diagnostic and Statistical Manual of Mental Disorders, 4th edition (DSM-IV), and the International Statistical Classification of Diseases and Related Health Problems, 10th revision (ICD-10). Both the DSM-IV and the ICD-10 are categorical systems that enable the user to record the presence or absence of a condition or disease according to certain standardized rules; in contrast to this, dimensional systems of classification are quantitative and are more likely to utilize psychometric measures and statistical procedures. In addition to more closely mirroring theoretical models of psychological pathology that characterize symptoms on a continuum with normal functioning (see "▶ Psychological Pathology", this volume), these systems can be helpful in providing additional information that is likely to be important clinically. The importance of dimensional assessment to treatment planning and monitoring in particular has also been highlighted, and several proposed dimensional assessments are being evaluated for feasibility during the upcoming DSM-V field trials (Stein et al. 2010).

The Diagnostic and Statistical Manual of Mental Disorders (DSM)

The DSM is published by the American Psychiatric Association (APA). Its aim is to provide common language and standard criteria for the classification of mental disorders, and it is the primary system used in North America. There have been five revisions since the DSM was first published in 1952 (APA, 2000). The current edition is the 4th edition, text revision (DSM-IV-TR); the fifth edition (DSM-V) is due to be published in May 2013 (American Psychiatric Association, 2011). The DSM describes how qualified individuals can assign diagnoses based on predetermined criteria. Diagnoses are recorded using a multiaxial system, with different disorder subtypes coded on different axes. While efforts have been made to keep the diagnostic codes in the DSM consistent with the ICD, this has not always been possible due to the differing revision cycles. Primary goals for the DSM-V include improving diagnostic validity and reliability and enhancing clinical utility.

International Statistical Classification of Diseases and Related Health Problems (ICD)

The ICD originated in the 1850s, when medical statisticians identified the need for a standard nomenclature to record cause of death and other

important health statistics. Originally published as the International List of Causes of Death by the International Statistical Institute in 1893, responsibility for the ICD was taken over by the World Health Organization (WHO) when it was created in 1948 (World Health Organization, 2007). Currently, the ICD is the international standard diagnostic classification system for epidemiological reporting and research among WHO member states (e.g., monitoring the incidence and prevalence of diseases in a population, recording national mortality and morbidity statistics); it also aims to provide useful information for health management and clinical purposes. The scope of the ICD has increased with each revision and update. In the early 1960s, a series of meetings were held with the aim of improving the diagnosis and classification of mental health disorders. The current edition, the ICD-10, was completed in 2007 and contains a comprehensive listing of "mental and behavioral disorders," which are coded on axis V (F00-F99).

As with psychiatric illnesses, psychological disorders can often predict the risk of developing complex medical conditions (e.g. heart disease); the reverse is also true. Furthermore, psychological disorders have prognostic value in some illnesses, including cancer, heart disease and renal failure.

Definition

Thoughts, feelings, and attitudes that influence behavior

Description

Behavioral medicine incorporates not only the effect of individual's actions on their health but also how psychological factors affect the physical body. This is a progression from traditional biomedicine, which conceptualizes the mind and the body as separate entities. Behavioral medicine has started to break down this artificial boundary, illuminating the close relationship between mind and body, and therefore the role that psychological factors play in disease.

A key psychological factor is stress, which is known to affect many systems of the body. This summary will focus on the immune system, a system once thought to be independent of psychological factors. Research investigating the effect of stress on vaccinations generally indicates that chronic psychological stress impacts on the immune response. In a study conducted by Cohen and colleagues, 394 healthy individuals completed a questionnaire to assess degree of psychological stress and were then given nasal drops containing a respiratory virus (Cohen, Tyrrell, & Smith, 1991). The rates of respiratory infection increased in a dose-response manner with increases in psychological stress. This relationship was not altered when the researchers controlled for variables that might affect this relationship (e.g., the infectious status of subjects in close vicinity to each other). The level of psychological stress reported by the individuals prior to exposure to the virus was therefore directly related to the level of infection. This relationship has been consistently duplicated; for example, Phillips and colleagues found that the stress of bereavement in the year prior to influenza vaccination was associated with a poorer antibody response (Phillips et al., 2006).

However, it is too simplistic to conclude that stress suppresses the immune system. Different types of psychological stress have different effects on the immune system. It is therefore important to differentiate between acute, short-term stress and long-term chronic stress. It has generally been found that long-term stress suppresses the immune system (Bauer et al., 2000), whereas acute stress potentiates it (Herbert et al., 1994).

It is important to note though that the effect of psychologically stressful events varies between individuals based on how they evaluate the event and their coping strategies (Lazarus & Folkman, 1984). Pettingale and colleagues investigated the effect of coping strategy on recovery from cancer (Pettingale, Morris, Greer, & Haybittle, 1985). Fifty-seven women who had recently undergone mastectomy were interviewed 4 months after their operation. They were categorized in to four groups dependent on coping strategy: stoic acceptance, denial, fighting spirit, and helplessness/hopelessness. They found that coping strategy was related to 10-year disease-free survival; those women who adopted denial or fighting spirit coping strategies tended to survive longer.

The level of chronic stress and coping styles may interact to affect the immune system. Stowell and colleagues found that under conditions of high chronic stress, people who had active coping styles had higher proliferation of leukocytes to stimulation by mitogens than people who had avoidance coping mechanisms (Stowell, Kiecolt-glaser, & Glaser, 2001). However, they also found that when experiencing low levels of chronic stress, people that used avoidance mechanisms to cope had higher proliferation levels of leukocytes than those that used more active mechanisms to cope. The relationships between certain coping methods and immune function may therefore depend on perceived stress levels.

Immune response may also be affected by personality traits such as neuroticism (Phillips, Carroll, Burns, & Drayson, 2005), internalization in adolescents (Morag, Morag, Reichenberg, Lerer, & Yirmiya, 1999), and trait negative affect (Marsland, Cohen, Rabin, & Manuck, 2001). More widely, it has been suggested that a constellation of personality traits such as high levels of anxiety, neuroticism, depression, anger, and hostility may be linked with a range of

diseases (Friedman & Booth-Kewley, 1987). However, prospective studies are required to confirm that these traits contribute to the etiology and progression of disease.

Schnurr and colleagues investigated the effect of posttraumatic stress disorder (PTSD) in 605 veterans of World War II and the Korean conflict (Schnurr & Avion, 2000). They controlled for age, smoking, alcohol use, and body weight at study entry. They found that PTSD symptoms were associated with increased onset of arterial lower gastrointestinal dermatologic and musculoskeletal disorders. The authors state that it is premature to draw firm conclusions from their study about the relationship of PTSD to these disorders. However, their findings were very similar to those reported by Boscarino and colleagues in their study of Vietnam War veterans (Boscarino, 1997)

Less dramatically, it has also been found that daily hassles affect the physical body. In a study of 48 undergraduate students, levels of daily hassles correlated with the General Health Questionnaire somatic symptoms scale (Sheffield, McVey, & Carroll, 1996). Daily hassles have also been linked with fluctuations in blood pressure. Steptoe and colleagues (1996) recorded the blood pressure (BP) hourly from 49 male firefighters on work and nonwork days (Steptoe, Roy, & Evans, 1996). They found that systolic BP readings accompanied by feelings of anger and stress were significantly greater than those without negative moods in both work and nonwork settings. They concluded that the raised systolic BP during working hours observed was affected both by physical activity and concurrent mood and that stress and anger were particularly influential.

Abnormal psychology; Psychopathology

Definition

The scientific study of psychological disorders and their causes.

Description

Psychological pathology is the study of the causes, components, course, and consequences of psychological disorders. These are characterized by *abnormality* and *dysfunction*.

Abnormality

Psychological disorders are defined by diagnostic criteria, like those outlined in the Diagnostic and Statistical Manual of Mental Disorders (DSM; American Psychiatric Association [APA], 2000) or the International Statistical Classification of Diseases and Related Health Conditions (ICD; World Health Organization, 2007). These criteria are composed of "marker symptoms," or thoughts, feelings, and/or behaviors identified as abnormal for a variety of reasons (e.g., because they cause distress, disadvantage, or disability or are highly inflexible or irrational; Stein et al., 2010). Symptoms can be understood as qualitatively different from normal or as extreme variants of common traits. Some symptoms are abnormal because they deviate significantly from a statistical mean. The notion of deviance from the mean is the underlying rationale for many commonly used psychometric tests, but is perhaps most clearly illustrated using the concept of intelligence. It is assumed that intelligence is normally distributed in the population; thus, individuals whose scores on a standardized test of intelligence fall below a specific cutoff may be diagnosed with mental retardation. It is important to note that even in this circumstance, meeting this cutoff is not sufficient for a diagnosis; there must be additional evidence of dysfunction (e.g., deficits in self-care and academic performance; APA, 2000). Thus, a trait or behavior is not necessarily "pathological" simply because it is highly unusual – high intelligence may be equally rare, but is not usually debilitating. Similarly, some characteristics that are presumed to be dysfunctional may be quite common (e.g., depressive thoughts, binge drinking). Importantly, abnormality can only be defined in reference to a given population; thus, the boundaries between normal and abnormal will shift over time and across cultures.

Dysfunction

Symptoms that cause significant impairment in important life domains may also be considered "pathological." Accordingly, dysfunction is often assessed with reference to the consequences of the symptom or disorder. Increasingly, psychological research is providing evidence of dysfunction by showing that certain psychological traits or behavioral patterns (e.g., perfectionism, type "A" personality, avoidance of feared stimuli) are reliably associated with undesirable physiological, social, and occupational outcomes (e.g., procrastination, chronic hypertension, strengthening of a phobic response). Dysfunction is also sometimes assessed in evolutionary terms, with symptoms referred to as "maladaptive," suggesting that they deviate from functioning that would have led to survival and reproductive success in the past.

Scientific psychology

Definition

The term *psychological science* refers to the accumulated body of psychological knowledge (i.e., pertaining to brain, behavior, social, or mental processes) that has been generated through the systematic application of the scientific method. The term *psychological science* may also refer to the process of conducting psychological research through the use of the scientific method.

The scientific approach to studying social, mental, and behavioral phenomena has existed for the full history of the field of psychology. Though some have questioned the applicability of scientific methods to researching mental phenomena for at least as long as its existence, psychological science has always been at the core of psychology as a field, and scientific rigor has been an aspiration even within the applied subdisciplines of psychology, including clinical and health psychology. Psychology as a discipline has more strict adherence to the scientific method than most social sciences, and so the nature of accumulated knowledge within psychology in the first century of its existence would be largely considered scientific in nature.

Commitment to the scientific method in psychological research is traceable back to William James (1842–1910) in North America and Wilhelm Wundt (1832–1920) in Europe, though its roots likely extend even earlier than these two individuals. Notably, both James and Wundt were trained initially as physicians, highlighting the long-standing interconnectedness of psychological science and health science from the time that psychology emerged as a legitimate area of scientific inquiry. Psychological knowledge aims to be scientifically based by following basic scientific criteria of empiricism, replicability of a method, and the testing of generalizable hypotheses and models which eventually explain psychological phenomena.

In 1989, the inaugural issue of *Psychological Science* was published by the Association for Psychological Science (formerly named the American Psychological Society). This flagship journal was intended to be a showcase for leading psychological research conducted with rigorous adherence to the scientific method. The prominence of *Psychological Science* has grown steadily from its inception to present, and it is currently among the highest ranking empirical journals in the field of psychology (Association for Psychological Science, 2012).

Synonyms

Distress; Strain; Stress; Stressor

Definition

H. Selye (1936) defined stress as "non-specific responses that be resulted from a variety of different kinds of stimuli." However, Selye's stress theory has only focused on physiological stress, and psychological factors have not been considered. Research on life stress examined the relationship between diseases and life events. Many studies were conducted for clarifying the psychological factors related to stress, and the results revealed that psychological factors play a significant role in the occurrence of physiological and psychological stress responses. Lazarus and Folkman (1984) proposed that stress occurs when people perceived that the demands from external situations were beyond their coping capacity. Today, the definition "stress is the process of interaction from resolution requests from the environment (known as the *transactional* model)" is widely accepted.

From the perspective of psychological stress research, the ambiguous elements related to stress have distinguished two aspects of stress. One is called "stressors," which cause stress (e.g., interpersonal problem, hard work, noise, and trauma). Another is called "stress responses," which are nonspecific physical and mental changes induced by stressors (e.g., frustration, depression, anxiety, and stomachache). Psychological stress responses that caused by various daily experiences are emotional, cognitive, and behavioral changes; their degrees have also become main factors affecting physical and mental health. However, as mentioned in the definition of Lazarus and Folkman (1984), psychological stressors are related to one's cognition and coping process rather than induced stress responses directly. Therefore, an effective approach for reducing psychological stress responses should include not only the removal of stressors but also enhancing the cognitive and behavioral coping capability.

Synonyms

Mental health professional; Psychological researcher; Psychological scientist

Definition

A psychologist is a professional who has earned a doctoral degree in psychology at a regionally accredited university or professional school. Some psychologists are primarily involved in conducting research and contributing to the scientific body of knowledge in psychology, while others use this scientific knowledge in applied settings. Psychologists work in several different work sectors, including clinical practice settings, academic and research settings, and consultation to apply psychological principles in private or public industries. Major settings in which psychologists work include universities and medical schools, private practice, clinics and counseling centers, industry and government, hospitals, and school districts. In recent decades, psychologists have increasingly focused their work on health-related research and with patients in medical settings. This is evidenced in the rapid growth of the membership in the Health Psychology Division of the American Psychological Association (Division 38), and in the fact that psychologists comprise 73% of the interdisciplinary membership of the Society of Behavioral Medicine.

Although psychologists often enjoy a variety of professional roles, some psychologists (e.g., clinical and counseling psychologists) are primarily involved in the practice of psychology. Applied psychologists focus on the identification, assessment, treatment, and/or consultation related to psychological issues impacting human behavior in applied settings. Interventions may include individual, group, or family psychotherapy, as well as consultation with community and private organizations. In order to regulate the practice of psychology and to ensure mental and behavioral health services are provided by qualified professionals, psychologists must obtain a professional license. Each state has its own requirements for licensure; in addition to the doctoral degree, states commonly require additional postdoctoral training and passing scores on national and state licensure exams.

Other psychologists primarily conduct basic or applied research and/or teach in academic or university settings. Psychological science uses statistical and empirical methods of measurement to understand mental processes and behavior, which can be at the social, cognitive, biological, and/or emotional level. Major specialty areas studied in psychology include clinical, counseling, educational, experimental, industrial/organizational, developmental, social, personality, physiological, and quantitative psychology. The American Psychological Association, an organization representing psychologists in the United States,

has 54 divisions and interest groups, demonstrating the range and variety of subdisciplines or specialty interest areas of psychologists. The Association for Psychological Science is an organization dedicated to promoting scientifically oriented psychologists and psychology as a scientific discipline.

Psychometrics

Definition

Psychometrics is the construction and validation of measurement instruments and assessing if these instruments are reliable and valid forms of measurement. In behavioral medicine, psychometrics is usually concerned with measuring individual's knowledge, ability, personality, and types of behaviors. Measurement usually takes place in the form of a questionnaire, and questionnaires must be evaluated extensively before being able to state that they have excellent psychometric properties, meaning a scale is both reliable and valid.

Description

A reliable scale consistently measures the same construct. This can occur across testing sessions, individuals, and settings. A valid measure measures what it says it is going to measure. If something is valid, it is always reliable. However, something can be reliable without being valid.

For example (see Fig. 1), if someone has five darts and is told to hit the bull's eye every time, their ideal aim is to be both reliable (consistent) and valid (accurate) with their throws. In part 1, the throws are neither reliable nor valid because their efforts are scattered across the board. In part 2, the throws were reliable, hitting the same spot every time. However, they did not hit the targeted spot of the bull's eye so they were not valid. Part 3 shows the perfect example of being both reliable and valid. The throws hit the spot they intended to hit and did so consistently. This same concept is applied to questionnaire measurements.

If a researcher is trying to create a new scale to measure depression, they want to make sure the scale reliably measures depression in someone with depression. For example, if the same individual filled out the questionnaire three times in the same day, they would produce the same score each time. The researcher also wants to make sure the scale is valid, which means that the scale is actually measuring depressive symptoms and not some other mood or behavior.

Psychometric theory

Definition

Psychometric theory is a well-recognized approach for developing psychological measurement and standardized education tests (Kim-O & Embretson, 2010). It can be divided into two categories: classical test theory (CTT) and item response theory (IRT). CTT was pioneered a century ago by Spearman, while IRT developed in the 1950s and 1960s.

Kim-O and Embretson (2010) provided a thorough discussion of IRT and why it has become the preferred approach. In the CTT model, estimates of examinees' true test scores are often linear transformations of the raw test score, and are related to relevant normative populations by the transformation. Alternative test forms can be used to estimate true scores if the forms are parallel tests with the same expected true scores and error distributions. Psychometric indices for items in CTT are related to the properties of the test scores, particularly reliability and variance. In other words, item difficulty is defined as the proportion of persons passing or endorsing an item, while item discrimination is defined as the correlation of the item with the total test score.

The CTT approach, however, has several limitations. An examinee's true score depends on the difficulty level of a test, i.e., it is test-dependent: Scores will not be comparable between easy and hard tests. Second, the item characteristics

depend on the ability of examinees, i.e., they are sample-dependent. Item difficulty, for example, will vary substantially if the true score distributions vary between populations. Third, one of the key assumptions, that two true test scores and two error variances are identical in the two tests (the parallel test assumption), is never fully met in practice. Therefore, it becomes difficult to compare examinees who take different tests, and to contrast items whose characteristic indices are computed using different groups of examinees.

In contrast, in the IRT approach the examinee's true score is not test-dependent, the item parameters are not sample-dependent, and the parallel test assumption is not needed. See Kim-O and Embretson (2010) for further discussion of this approach.

Psychometric theory is used extensively in behavioral medicine research. As two examples, Kiernan, Moore, and Schoffman (2011) assessed the psychometric properties, initial levels, and predictive validity of a measure of perceived social support and sabotage from friends and family for healthy eating and physical activity. Second, Lo et al. (2011) introduced the Death and Dying Distress Scale (DADDS), a new, brief measure developed to assess death-related anxiety in advanced cancer and other palliative populations. Their paper described its preliminary psychometrics based on a sample of 33 patients with advanced or metastatic cancer. Additional examples are provided in the "References and Readings" section of this entry.

[2]Brandeis University, Waltham, MA, USA

Synonyms

Behavioral endocrinology

Definition

Psychoneuroendocrinology (PNE) is an interdisciplinary field of research integrating psychology, endocrinology, and neuroscience to study the interactions between mind, brain, and hormonal function (Dantzer, 2010).

More specifically, PNE focuses on the way psychological factors influence neuroendocrine functions and, conversely, the way hormones influence higher brain functions. As such, PNE is not only interested in hormone synthesis, release, transport, breakdown, and feedback control but in

the interaction of hormones with their target tissues (e.g., the immune system), including the molecular mechanisms of their action.

PNE research is often concerned with health implications associated with even subtle chronic changes in hormonal patterns. While sex is one of the biggest factors influencing the body's neuroendocrine state, other factors of interest include health effects of age-related changes and changes observed in the context of diseases such as the metabolic syndrome or mood and anxiety disorders. By far, the most intensely studied area, however, is PNE of stress, which aims at describing and understanding neuroendocrine changes associated with acute as well as chronic physiological and especially psychological stress and how stress-related changes in turn impact behavior, cognition, affect, and health (for a review, see Dantzer, 2010).

Behavioral immunology

Definition

Psychoneuroimmunology (PNI) is the study of the functional relationships between central nervous system, behavior, and immune system.

These relationships have been documented to be multidirectional. For example, while behavior can influence immune processes through changes in nervous system signals, immune signals have been shown to alter the function of the central nervous system, thereby influencing behavior. Further, all systems exert regulatory control over each other, forming a complex communication network.

PNI research aims at describing this network and thus to contribute to the understanding of the behavioral and biological mechanisms underlying the links between psychosocial factors and health as well as disease development and progression. Psychosocial factors studied in PNI thereby range from negative psychological states such as depression and anxiety, to social support, interpersonal relationships, and personality factors. Disease-related processes investigated include cancer, susceptibility to infection, wound healing, HIV/AIDS, autoimmune diseases, and cardiovascular diseases. One important PNI branch focuses on how stress and stress-related neuroendocrine processes (see ▶ Psychoneuroendocrinology) affect health as well as disease development and progression.

As such, PNI is truly interdisciplinary, integrating not only knowledge from immunology, neuroscience, and psychology, but also from areas such as psychiatry, endocrinology, physiology, and pharmacology.

Stress response

Definition

Psychophysiologic reactivity refers to cardiovascular and biological responses to situations that are perceived as stressful, threatening, and/or physically harmful. Reactivity is defined as the response with respect to resting values. Some of the stressors that are commonly used in laboratory-based psychophysiological studies are designed to replicate real life, such as problem solving and public speaking tasks (Kamarck & Lovallo, 2003). It is, however, often advantageous to use novel stressors, such as the Stroop word-color conflict task and mirror tracing, in order to remove the potential confounding influences of education and work experience. Psychophysiologic stress testing allows individual differences in responses to standardized stress to be evaluated and related to psychosocial factors and health outcomes (Chida & Hamer, 2008). Behaviorally evoked psychophysiological responses are a relatively stable individual trait, consistent across time and stressor type. The magnitude or pattern of an individual's stress response is largely augmented by the immediate actions of the autonomic nervous system and delayed response of the hypothalamic-pituitary-adrenal axis, which releases various hormones (i.e., catecholamines, cortisol, etc.) into the circulation. These systems drive specific responses that include an increase in blood pressure and heart rate, changes in cardiac sympatho-vagal balance, skeletal muscle vasodilatation, the release of hemostatic and inflammatory markers, and activation of various immune cells. Although psychophysiologic reactivity is beneficial for maximizing performance, excessive and enduring responses are also relevant to health and well-being and are thought to contribute to underlying disease pathology.

Psychophysiologic Recovery

Mark Hamer
Epidemiology and Public Health, Division of Population Health, University College London, London, UK

Synonyms

Relaxation; Return to baseline; Rumination

Definition

Psychophysiologic recovery is defined as the rate at which a cardiovascular or biological variable returns to resting levels following a stressor. It is not uncommon to observe prolonged elevation in blood pressure following induction of mental stress, and this might last for up to an hour or so following the cessation of the stressor. This has also been observed in naturalistic settings, for example, in teachers, blood pressure has been shown to remain elevated throughout the evening following a stressful working day at school. A slower rate of psychophysiologic recovery has been linked to several risk factors and poorer health outcomes (Brosschot, 2010). One difficulty with isolating the predictive value of recovery is that those taking the longest time to return to baseline are likely to be those who showed the greatest reactivity. Nevertheless, recent evidence suggests that poor recovery and heightened reactivity are in fact independent predictors of health outcomes. The mechanisms underlying poorer psychophysiologic recovery are incompletely understood, although various psychological factors such as rumination and coping strategies have been implicated.

Psychophysiological

Definition

How does mental and emotional life tie in with the workings of the body? Psychophysiology is the branch of psychology that studies the behavior of the individual in a biological context. It is an attempt to chart the mutual interactions between psychological processes and the workings of the body, giving equal emphasis to both.

Description

A fundamental principle of psychophysiology is that thoughts and feelings cannot exist apart from the body. It follows that a full understanding of psychological processes depends on understanding the biological context from which they proceed. Due to its emphasis on integrating our understanding of mental and physiological processes, psychophysiology has contributed to research methods and theory building in behavioral medicine and to the neurosciences of cognition and emotion. Psychophysiology does this by providing a theoretical basis and a set of measurement methods that help to disentangle relationships between psychology and biology and between our thoughts and emotional experience in relation to good and poor health. From this perspective, psychophysiologists bring a physiological emphasis to the study of behavior and mental processes, and one expression of this emphasis is the contributions psychophysiology has made is to the understanding of emotions and their impact on good and poor health. Although it is accepted in psychophysiology that thoughts and feelings do not exist without the brain and the body, it is necessary to emphasize that the thoughts and feelings of interest are not equivalent to or directly reducible to these physiological processes.

The emphasis of psychophysiology, like that of behavioral medicine itself, is primarily on the whole person. However, it is necessary to measure the functions of specific systems, such as the cardiovascular system, endocrine system, or immune system in the course of psychophysiological investigations. This calls for a methodology that allows emotional experience to be studied simultaneously with physiological functioning in ways that are unobtrusive and minimally invasive. This ensures that the person being studied is behaving in a normal manner, as in everyday life, and is not reacting unduly to the apparatus or laboratory setting. Psychophysiological principles have been used to study responses to stress in the laboratory, responses to stressors in daily life, and individual differences in such responses.

Behavioral medicine is both a science and an approach to clinical practice. These two parts are concerned with the influence of behavioral factors on health and disease. Behavioral medicine holds that states of health can be influenced by overt behaviors, such as dietary habits, and by covert behaviors, such as emotional states and stress responses. This perspective leads behavioral medicine researchers to ask questions about the ways that emotional states and stress responses can affect health through their influence on physiology. The goal is to bring to light how our behaviors and our ways of perceiving and reacting to the world may affect our well-being for better or worse. Such research addresses questions in several major areas, including (1) how the body responds during positive and negative emotion states, (2) how a given person may differ from one time to the next in stress

reactivity, (3) the ways in which persons differ from one another in their stress responses, and (4) on the positive side, to establish the effects of behavior on good health and longevity. To carry out such research, behavioral medicine draws in part on the theory and methods developed in the field of psychophysiology.

In laboratory studies, persons are often exposed to stressors to determine how they react to such challenges both emotionally and physiologically. The results are thought to indicate how emotionally relevant events and behavioral stressors can affect physiology in daily life and therefore whether they may contribute to disease. As one example, a commonly used stressor is public speaking. This challenges the subject to make up a short speech and deliver it without notes and to do so in a fluent and convincing manner. Public speaking is stressful because most persons wish to avoid the embarrassment of doing poorly and to be seen as masterful and competent by observers in the laboratory. Using this method, the social world can be modeled in a small way in the laboratory, and the participant's disposition is invoked to produce a stress response. During public speaking, this process of social evaluation, along with the resulting fear and anxiety, produces substantial increases in heart rate and blood pressure and stress hormones, including catecholamines and cortisol. The person's mood states usually are assessed at rest before the task begins and again at the end using paper-and-pencil measures or brief interviews. Similarly, autonomic reactions are often measured at rest and during stress using automated blood pressure monitors and impedance cardiographs, and endocrine responses may be observed using saliva or blood sampling. In this manner, the person's psychological, cardiovascular, and endocrine reactions may be measured to provide a picture of how physiological reactions are set off by psychologically meaningful events.

This research strategy can then be extended to compare different kinds of people for potential differences in their physiological reactivity to stress. One common example is for the researcher to identify young, healthy individuals who have a family history of high blood pressure and also to find those with no such history. These family history groups can then be compared in the laboratory for differences their stress responses, perhaps using the public speaking stressor or some other method. This allows potential differences in stress reactivity to be assessed in relation to a family history of this prevalent cardiovascular disease. It is then possible to follow such persons for a period of years to establish which persons become hypertensive and which retain a normal blood pressure. Do persons from the family history group have a greater likelihood of becoming hypertensive in middle age? Are persons with greater reactions to stress more likely to become hypertensive, regardless of family history? Such studies therefore allow potential interactions between family history and stress reactivity to be studied. If persons with a family history of hypertension who are also highly reactive to social stress are much more likely to become hypertensive, then we would conclude that the family history created a biologically based risk factor that was enhanced by an elevated level of stress responsivity. In contrast, should risk of hypertension be increased equally by high reactivity in persons with and without a family history of hypertension, we would conclude that family history and reactivity tendencies contribute to hypertension risk in an additive manner.

Although the laboratory provides a well-controlled environment with an extensive range of measurement techniques, ambulatory methods have been used with increasing frequency outside the laboratory to document how challenges in persons' daily lives can affect cardiovascular, endocrine, or immune systems. Such methods measure the person's responses to naturalistic stressors, such as work stress, or challenges in the home, such as family conflict or the stress of caring for a chronically ill spouse. Such studies rely on small, lightweight monitors that can be worn comfortably as persons go about their daily routines. These monitors can make reliable measurements in a wide range of circumstances. Such systems are able to track heart rate, blood pressure, and physical activity. In addition, the person usually reports on their subjective state using brief paper diaries or personal digital assistants.

As in laboratory studies, this ambulatory method may be used to estimate the interaction of stress responses and disease risk. Persons with and without a family history of hypertension may be compared as they go about their daily lives. As in the laboratory, persons with the largest or most prolonged reactions to stress at home or at work are suspected of having greater risk of future disease, and again, they may be followed up for actual occurrence of hypertension in future years. Ambulatory systems currently in use include traditional Holter electrocardiographs, blood pressure monitors, and impedance cardiographs. The success of these systems has led several commercial companies to develop reliable products for research and clinical use.

Although some research focuses on family history, other work seeks to connect psychological dispositions, such as hopelessness, depression, or hostile style to disease risk. Studies using this strategy may compare highly hostile persons with nonhostile individuals with a specific hostility provoking interaction, such as harassing comments during work on a difficult task. By measuring physiological reactions to such specific challenges in persons with different psychological characteristics, a clearer picture may be developed of the psychological and physiological interplay that is suspected of contributing to disease.

While much of this research focuses on negative emotion states, stress responses, and risk of disease, there is a growing interest in positive emotional states and in studying persons who tend frequently to experience the positive emotions of joy and happiness. As in the above examples such persons can be selected for their emotion traits using a combination of self-report techniques and in laboratory tests of brain function. Persons high in typical positive affect can then be compared to those with less positive affective states in their resistance to the effects of stress and in their long-term states of health.

The research examples listed above all depend on testing persons while they are relaxed and resting, as well as when they are under stress or perhaps in a pleasurable mood. For these reasons, it is desirable to use measurement methods that do not cause discomfort or distress. Behavioral medicine research has therefore relied on methods of psychophysiological measurement that are noninvasive or minimally invasive and cause the volunteer no discomfort. The examples above focused on the cardiovascular system which can be studied using methods such as the electrocardiogram, blood pressure monitoring, and impedance cardiography to measure pumping action of the heart and constriction of the blood vessels, and, occasionally, fluid output to assess kidney function. Stress research often uses additional methods to track responses of the endocrine system, involving collection of urine, blood, or saliva for measurement of stress hormones and other substances associated with stress and pain responses. Still, other studies examine the immune system here using minimally invasive techniques in the collection of blood for later measurement of the numbers of immune system cells and their biological activity. Closely related to these physiological measurements is the need to classify persons as to personality and temperament characteristics to establish relationships between acute stress responses or chronic allostatic responses in the lab or in daily life. These considerations call for use of interviews or paper-and-pencil measures of personality and mood states. Finally, the application of such psychophysiological techniques calls for appropriate selection of tasks and ways to analyze the data.

Psychosocial adaptation; Rehabilitation psychology; Response to disability

Definition

Chronic illness and disability profoundly impacts the lives of many individuals. For example, approximately one in five Americans has physical, sensory, psychiatric, or cognitive impairments that affect their daily activities. Psychosocial adaptation entails the integration of illness or disability into the individual's life, identity, self-concept, and body image. Psychosocial adaptation is defined as the process in which a person with a disability moves from a state of disablement to a state of enablement and is characterized by the transformation from negative to positive well-being (Livneh & Antonak, 2005). Observed across disability groups, psychosocial adaptation occurs as the individual moves toward a state of optimal person-environment congruence. The final stage of psychosocial adaptation, known as adjustment, represents maximum congruence between the individual's subjective experience and his or her external environment.

Description

Introduction

Psychosocial adjustment to chronic illness and disability (CID) is a long-term, dynamic process influenced by intrinsic and extrinsic variables within a specific context (Chan, Cardoso, & Chronister, 2009; Livneh & Antonak, 2005). There are several terms used to describe the adjustment to disability process. Specifically, *adjustment, adaptation*, and *acceptance* of disability are concepts commonly used to describe the process and outcome of coping with CID. *Adaptation* has been defined as the dynamic process a person with CID experiences in order to achieve the final state of optimal person-environment congruence known as *adjustment* (Smedema, Bakken-Gillen, & Dalton, 2009). The term *acceptance* was coined by Beatrice Wright (1983) who defined *disability acceptance* as an outcome in which the disability is incorporated as part of the individual's self-concept and is accepted as non-devaluing.

Today, *response to disability* is a widely accepted terminology considered to most accurately describe the adjustment process, because it fully conveys response to disability as a subjective experience that is not necessarily negative. Furthermore, response to disability involves a dynamic process as opposed to a one-time event (Smart, 2009). The response to disability process reaches beyond psychological aspects of adjustment to include a complex and dynamic interaction of a wide variety of psychological, societal, environmental, and personal factors. This entry will provide readers with a review of the prominent psychological, social, environmental, and personal factors that interact to influence the individual process.

Psychological Factors

Somatopsychology. Psychological aspects of CID have been most broadly explored in the context of *somatopsychology*, the study of the physique's influence on behavior and how that relationship is mediated by the effectiveness of the body as a tool for actions. The emphasis of somatopsychology is on the meaning of disability that is unique to the individual, as well as the value the disability holds for other individuals in a person's life (Smedema et al., 2009). The theory considers self-concept, body image, and coping to be psychological schemas and functions crucial to successful adaptation. Specifically, *self-concept* and *body image* represent mental schemas by which humans perceive and identify themselves. An individual with CID must alter one's body image and self-concept to incorporate the physical changes into one's daily life. Therefore, reorganization of these mental schemas is critical to successful adaptation (Livneh & Antonak, 2005).

Coping. *Coping* strategies also affect the response to disability process. Coping requires the individual draw on some personal or environmental resource to reduce the negative impact of a stressor (Chronister, Johnson, & Lin, 2009), including both adaptive and maladaptive strategies. In the context of disability adjustment, coping generally refers to cognitions, emotions, or behaviors that mediate the relationship between disability-related stressors (i.e., nature, type, duration, prognosis, perception, and severity) and the response to disability. Coping strategies associated with response to disability can be divided into three psychological categories: cognitive, behavioral, and affective (Smart, 2009). *Cognitive* response refers to how an individual chooses to think about or view the disability. *Behavioral* response refers to actions taken to manage the disability, including compliance to treatment recommendations, seeking social support, returning to work, and using self-advocacy strategies to manage the impact of stigma and prejudice. *Affective* response refers to how the individual feels about the disability and how he or she manages the emotions associated with the disability (Smart, 2009). A positive coping strategy within the context of disability may include having a realistic view of the disability and awareness of limitations without exaggerating them. Conversely, a negative coping strategy may involve substance use or self-blame. The coping strategies employed strongly influence the response to disability. For example, healthy coping strategies, such as seeking out social support or redefining life goals, may improve body image and quality of life while decreasing social isolation and feelings of helplessness.

Based upon the disability acceptance theory (Wright, 1983), Wright developed a cognitive restructuring framework known as the *coping* versus *succumbing* model. In this model, a person said to be *succumbing* to disability overemphasizes negative effects of impairment and neglects the challenge for change and meaningful adaptation. Conversely, a person said to be *coping* with disability is able to focus on personal assets and is oriented to activities that are within the individual's physical capabilities (Smedema et al., 2009). Wright (1983) proposed four primary value changes that reflect the *coping* perspective including (a) *Enlargement of the scope of values*, which requires the individual recognize that values beyond those presumed lost can be achieved despite limitations of CID; (b) *Subordination of the physique* occurs when

the individual changes the cognitive belief that physical is a true representation of one's worth, desirability, or competency; (c) *Containment of disability effects* occurs when the individual recognizes disability as limited to the impact of the actual impairment, rather than being globally debilitating; and (d) *Transformation from comparative status to asset values*, which occurs when the individual avoids comparing oneself to a nondisabled standard and focuses attention on his or her assets (Smart, 2009). The four primary value changes challenge each of the previously held beliefs, resulting in acceptance of disability (Wright, 1983). Conversely, signs of the *succumbing* perspective include (a) denial or acting as if the disability does not exist; (b) idolizing normal standards or applying old values to the new situation; (c) failure to modify previous aspirations within the context new situations; (d) eclipsing behavioral possibilities and limiting one's opportunity to learn new skills to address the new situations more effectively; and (e) overcompensation of perceived deficiencies in one area by exaggerated striving in another area (Wright, 1983).

Stage model. The response to disability process has also been conceptualized as a sequence of psychological stages, similar to those experienced during grief (Smedema et al., 2009). Stage models typically describe the process of adjustment as a linear series of psychological stages, requiring the completion of previous stages before the final stage of adjustment. Many stage models have been proposed to describe stages of adjustment. Livneh and Antonak (2005) concluded that the numerous stage models may be described within these five broad categories: (a) initial impact, which includes shock and anxiety; (b) defense mobilization, which includes bargaining and denial; (c) initial realization, which includes mourning, depression, and internalized anger; (d) retaliation, which includes externalized anger or aggression; and (e) reintegration or reorganization, which includes acknowledgment, acceptance, and final adjustment. The stage models provide a structure for understanding and predicting the course and outcome of an individual's response process (Smart, 2009). Nonetheless, the applicability of the stage theory to persons with CID has been criticized for the following three reasons: (a) "stages" are not universally experienced; (b) a state of final adjustment (e.g., resolution, acceptance, assimilation) is not always achieved; and (c) psychological recovery does not follow an orderly sequence of reaction phases (Livneh & Antonak, 2005). Finally, the existence of a universal, progressive, phase-like, orderly sequence of predetermined psychosocial reactions to disability has not been adequately supported by empirical research (Livneh & Antonak).

Ecological model. The most contemporary approach to conceptualizing and understanding the response to disability process is the *ecological* approach. Considered atheoretical, this approach incorporates components of somatopsychology and stage theory, while emphasizing the interaction of personal *and* contextual variables (social/environmental and personal factors) on psychosocial adaptation (Smedema et al., 2009). This approach also adopts a comprehensive and holistic approach to outcome measurement beyond that of acceptance or adjustment to CID, encompassing a person's overarching quality of life (Livneh & Antonak, 2005). As such, understanding response to disability beyond the psychological processes described above is critical in developing a full perspective of an individual's response to disability. Below is a review of key contextual variables important to consider in the response process.

Societal Factors

Societal definitions of disability. The manner in which society defines CID influences the adjustment to process. Definitions of disability help to identify the location of the problem and who is held responsible for the solution (Smart, 2009). Four of the most popular models of disability include the (a) biomedical model; (b) environmental model; (c) functional model; and (d) sociopolitical model. The biomedical model has the longest history. This model defines disability as pathology located within the individual and represents a deviation from the norm.

Therefore, treatment is focused solely on "fixing" the individual. The environmental model suggests that the individual's environment may cause, define, or exaggerate the disability. For example, if a person with paraplegia does not have a wheelchair, then the impairment is worsened. The functional model posits that the functions of the individual influence the definition of the disability. For example, an individual who is physically active would be much more affected by mobility impairments. Finally, the sociopolitical model, also known as the Minority Group Model or the Independent Living Model, proposes that disability is not a personal attribute, but caused by society, and thus society should bear the responsibility for dealing with disability (Smart, 2009). *Self-advocacy* is a critical component of the sociopolitical model of disability. Self-advocacy is rooted in the American ideals of autonomy and self-determination. In contrast to consequences of the medical model, including dependency, marginality, and social exclusion, self-advocacy refers to persons with disabilities taking control of their own lives, speaking up for themselves, being in control of their own resources, and having the right to make life decisions without undue influence or control from others.

The World Health Organization International Classification of Functioning, Disability and Health (WHO, 2001) is a contemporary, biopsychosocial approach to defining disability that considers the biomedical, environmental, functional, and social models in its explanation of disability. This model conceptualizes disability along five major domains: (a) body functions and structures; (b) activities; (c) participation; (d) personal factors; and (e) environmental factors (Chan, Gelman, Ditchman, Kim, & Chiu, 2009). The ICF recognizes disability as an interaction between all of these factors and cannot be defined apart from the individual's context.

Societal attitudes. Negative attitudes toward persons with disabilities are well documented in the literature (Chan, Livneh, Pruett, Wang, & Zheng, 2009). Negative attitudes or unfavorable evaluative statements related to a person, object, or event are considered *invisible barriers* that arise from the environment and impact the response process by limiting opportunities, access, and help-seeking behaviors, as well as reducing overall quality of life (Chan, Livneh et al., 2009). Related concepts include *prejudice, discrimination*, and *stigma*. *Prejudice* is a negative generalization toward a group of people and the assumption that an individual belonging to that group has the characteristics based on the generalization. For example, "all persons with CID are intellectually inferior." *Discrimination* is the action carried out based upon prejudice. For example, an employer who does not hire a person with CID because he or she believes persons with CID are "unsafe." Finally, *stigma* is a term that encompasses the problems associated with stereotyping, prejudice, and discrimination; it is the chain of events resulting from negative attitudes and beliefs, resulting in discrimination. Persons with disabilities often have limited access to work, housing, and other community resources because of stigmatizing attitudes that have led to discriminatory behavior (Chan, Livneh et al.).

Commonly cited sources of negative attitudes and stereotypical views regarding persons with CID include the *safety threat*, the *ambiguity of disability*, the *salience of the disability, spread or overgeneralization*, *moral accountability for the cause and management of the disability*, *inferred emotional consequences of the disability*, and the *fear of acquiring a disability* (Smart, 2009). Cook (1998) indicated that the general public also exhibits a "hierarchy of preferences" for specific groups of persons with CID; for example, people hold more favorable attitudes toward persons with physical disabilities than individuals with mental disabilities and persons tend to have more positive attitudes toward persons with intellectual disabilities than those with psychiatric disabilities.

Environmental Factors

A large majority of persons with CID live at or below the poverty level (Smart, 2009). Although most persons with CID report they want to work (Louis Harris Associate Inc. Polls, 1994), and despite protections afforded by the Americans with Disabilities Act, persons with CID have

greater difficulty finding or maintaining work, and unemployment and underemployment rates of persons with disabilities are high (Smart, 2009). This is due in part to prejudice and discrimination, worksite inaccessibility, and financial disincentives built into many disability benefits programs (e.g., SSI/SSDI). Other environmental factors that influence the response process include limited mobility and access to transportation, architectural barriers, frequency and duration of hospitalizations, lack of institutional support (medical services, educational programs and technological supports; political and religious groups), poor living conditions, limited availability of job opportunities, and inadequate accessibility of worksites (Livneh & Antonak, 2005).

Personal Factors

Age and developmental status. Age and developmental stage, such as those identified by Erikson (1968), interact with CID to influence the response process. For example, the process of adaptation differs significantly between individuals born with CID and those who acquire CID later in life. Developmentally speaking, for an *infant* with a congenital disability, the primary task of establishing trust in the world through the relationship with mother or primary caregiver may be compromised if the infant is hospitalized for long periods and is cared for by multiple health professionals (Smart, 2009), whereas during *early adulthood*, the tasks of establishing a family and beginning a career are important and may be impacted by CID. For *older adults*, the resulting impact of CID on independence and functioning is variable, ranging from minimal impact to substantial lifestyle change. While functional loss and disability may be a normal part of aging for some, social isolation, dependence, restricted activities and participation, and the loss of loved ones surrounding the individual can impact quality of life. Indeed, with disability, older adults face multiple life transitions in later years of life.

Gender. Gender is important to consider in the response process. Patterson, DeLaGarza, and Schaller (2005) suggest that men and women respond differently to various CIDs. For example, in the area of spinal cord injury, men experience greater difficulties related to sexual functioning than women, resulting in feelings of loss of "manhood" or "masculinity." With respect HIV/AIDS, women are more socially isolated than men because of cultural backgrounds commonly associated with females with HIV/AIDS, and because rates of transmission are lower and occur through a different mode. Furthermore, a woman with HIV/AIDS experiences issues related to pregnancy, including potential transmission from mother to infant. Women and men also respond differently following myocardial infarction, such that men return to work sooner and are more likely to participate in physical activity to cope with stressors related to the condition.

Culture. *Culture* involves the beliefs, customs, practices, social behaviors, and set of attitudes of a particular nation or group of people (Chronister & Johnson, 2009), and *worldview* is the framework of ideas and beliefs through which an individual interprets the world and interacts with it according to their philosophy, values, emotions, and ethics. Culture and worldview inform how disability is defined and experienced, and both aspects contribute to the response to disability process. For example, in contrast to the explanation of disability perpetuated by the medical model, some cultures perceive the origin of disability to be of the metaphysical-spiritual realm. For other cultures, disability is a condition that should not be altered, because it is considered to be predetermined by fate and not amenable to adaptive intervention. For example, the deaf culture rejects the notion that group members have a disability and identify as individuals with a different communication modality that live in a hearing world. Furthermore, the number of persons from culturally diverse backgrounds in the USA with CID is disproportionate, and these individuals are often at risk for experiencing multiple negative experiences or "double" discrimination and stigmatization, barriers that are likely to influence response to CID (Chronister & Johnson, 2009).

Disability. Disability characteristics are also important to consider in the adjustment process and vary significantly across and within

conditions. According to Smart (2009), there are ten disability factors that influence response to disability including time of onset (congenital, acquired), type of onset (insidious versus acute), course of disability (direction, pace of movement, degree of predictability), functions impaired (meaning of functioning, degree of intrusiveness, residual functioning and assistive technology), severity of the disability (number of disabilities experienced and areas of functioning affected, treatment necessary, and degree of stigma directed at the individual), visibility of the disability, degree of disfigurement, and prognosis (what is expected for the future).

Sexual orientation/identity. Sexual orientation is an important factor to consider in the response to disability process. Persons with CID that are identified with sexual orientations, such as lesbian, gay, bisexual, transgender, queer, questioning, intersex, and asexual (LGBTQQIA), are vulnerable to stereotypes, bigotry, abuse, bullying, and violence. They are subject to a complex array of prejudices by the mainstream population, including double prejudice for equal rights, higher rates of marginalization and discrimination, confusion in navigating identity development, and the prevailing view that persons with disability are asexual or unsuitable sexual partners (Miville, Romero, & Corpus, 2009).

Conclusion

Response to CID involves a complex and dynamic interaction of psychological, social, environmental, and personal variables. Somatopsychology and stage models provide a foundation for understanding the psychological processes of disability adjustment. The ecological approach builds upon this work to facilitate a broader conceptualization of psychosocial adjustment to address the importance of additional personal and contextual variables. Indeed, response to CID is a unique, personal experience that must be considered within the individual's context, including the sociocultural influences that contribute to how society defines and responds to CID. Contemporary definitions of disability conceptualize disability from a biopsychosocial perspective (i.e., WHO ICF model), recognizing body functioning and contextual factors as critical to disability determination and intervention planning. This framework, coupled with the ecological approach to adjustment to disability, replaces traditional approaches to yield a more holistic picture of adaptation.

Definition

Psychosocial characteristics is a term used to describe the influences of social factors on an individual's mental health and behavior.

Description

A psychosocial approach to human behavior involves the relation between intrapersonal psychological and environmental aspects. Psychosocial characteristics is commonly described as an individual's psychological development in relation to his/her social and cultural

environment. "Psychosocial" means "pertaining to the influence of social factors on an individual's mind or behavior, and to the interrelation of behavioral and social factors" (Oxford English Dictionary, 2012). Psychosocial factors, at least in the context of health research, can be defined as the mediation of the effects of social structural factors on individual health, conditioned and modified by the social structures contexts in which they exist (Martikainen, Bartley, & Lahelma, 2002). These statements raise the question of what the relevant broader social structural forces are, and how such forces might influence health through their effects on individual features.

Individual psychological and social aspects are related to individual's social conditions, mental and emotional health. For example, the main factors that influence children's mental health are the social and psychological environment (Halpen & Figueiras, 2004).

Environmental factors play an important role in the etiology of emotional problems in childhood. The cumulative risk effects from a "vulnerable environment," e.g., negligence, poverty, drug abuse, are more important in determining emotional problems in children than the presence of one single stressor, regardless of its magnitude. According to Barylnik (2003), the analysis of the characteristics of a juvenile delinquent's sample showed a high rate of psychiatric disorder and social phobia, alcoholism, organic brain dysfunctions, low intelligence quotients, and behavior problems.

The term "psychosocial" is widely used for determining an individual's health outcome. Psychological and social factors expressed as thoughts, expressive emotions, and behaviors are significant for human functioning and the occurrence of disease. Mentally healthy people tend to react in positive ways to negative situations, compared to emotional unstable people, who react negatively to similar situations. Hence, irrational thoughts may be a sign of bad psychosocial health. Therefore, for psychosocial instable people it is preferable to have special social bonds with and social support from other people. On the other hand, prejudice from others is often a result of poor psychosocial health that causes poor social relations.

Hence it is understood that health is better understood in terms of a combination of biological, psychological, and social factors rather than only in biological terms (Santrock, 2007). This is in contrast to the traditional and reductionist biomedical model of medicine which suggests that every disease process can be explained in terms of an underlying deviation from normal function such as a pathogen, genetic or developmental abnormality or injury (Engel, 1977).

The World Health Organization's (WHO, 2001) definition of health is "a state of complete physical mental and social well-being, and not merely the absence of disease and infirmity." This WHO definition has been criticized because cause and effect is mixed. The concept of "psychosocial health," in some cases, may combine traditional medical definitions of disease and infirmity with measures that reflect individual responses to disease and even in some cases indicators of the social context itself. However, such measures have merit in recognizing individuals' experiences and quality of life, meaning an important outcome of individual's psychosocial condition (Martikainen et al., 2002).

Psychological factors; Psychosocial variables

Definition

Social factors include general factors at the level of human society concerned with social structure and social processes that impinge on the individual. Psychological factors include individual-level processes and meanings that influence mental states. Sometimes, these words are combined as "psychosocial." This is shorthand term for the combination of psychological and social, but it also implies that the effect of social processes are sometimes mediated through psychological understanding (Stansfeld & Rasul, 2007).

Description

The relationship between psychological factors and the physical body can be influenced by social factors, the effects of which are mediated through psychological understanding. Examples of psychosocial factors include social support, loneliness, marriage status, social disruption, bereavement, work environment, social status, and social integration. To illustrate that the role psychosocial factors can play in physical disease, this entry will focus on the relationship between social support and mortality.

In 1979, Berkman and Syme conducted a prospective study to investigate the relationship between social support and mortality (Berkman & Syme, 1979). The study included 6,928 adults from the general population of Alameda County, California. They recorded four sources of social contact: marriage, contacts with close friends and relatives, church membership, and informal and formal group associations; mortality was followed-up 9 years later. They found that respondents with each type of social tie had lower mortality rates than respondents lacking such connections. From these four variables, they then constructed a Social Network Index, which weighted intimate contacts more heavily than more superficial ones. Using this index, they found a consistent pattern of increased mortality rates with each decrease in social connection. Men who were the most isolated had an age-adjusted mortality rate 2.3 times higher than men with the most connections. This relationship was independent of self reported physical health status, year of death, socioeconomic status, and such health behaviors as smoking, alcohol ingestion, physical inactivity, obesity, and low utilization of preventive health services or health practices.

The effects of level of social support on mortality rates were investigated by Rosengren and colleages (Rosengren, Orth-Gomer, Wedel, & Wilhelmsen, 1993). They invited half of all men in Gothenburg who were born in 1933 (then 50 years old) to have a health examination and complete a measures of emotional support and social integration. Seventy-six percent responded. These men were then followed-up after 7 years, and mortality ascertained. Their data indicated that emotional support may attenuate the impact of adverse life events, possibly by strengthening the psychobiological resistance to stress.

Frasure-Smith and colleagues found in their study of 887 post-myocardial infarction (MI)

patients that depression, but not social support, was directly related to mortality (Frasure-Smith et al., 2000). However, very high levels of support protected patients from the negative prognostic consequences of depression. They found that three different measures of social support independently improved depression: higher scores on a measure of perceived social support, a greater number of close friends and relatives, and living with other people. They suggest that clinicians should ascertain patient's views of their social support in their assessments of post-MI depression.

Differences in health status between people with differing levels of social integration cannot simply be attributed to differences in health behaviors between the two groups. In two parallel studies, Cacioppo and colleagues investigated four mechanisms by which loneliness (a discrepancy between their desired and actual relationships) may negatively impact on morbidity and mortality (Cacioppo et al., 2002): (1) poorer health behaviors than nonlonely individuals, (2) altered cardiovascular activation, (3) elevated levels of hypothalamic pituitary adrenocortical activation, and (4) poorer sleep quality. Participants were 89 undergraduate students, and in a second study, 25 older adults (age range 53–78 years). They found that the health behaviors of lonely and nonlonely participants were similar. However, cardiovascular function differed between these groups in both the younger and older participants. They speculated that the differences they found in the hemodynamic function observed in the younger subjects may contribute to elevated blood pressure in lonely older adults. They also found that younger and older lonely adults suffered lower quality sleep, possibly leading to diminished health and well-being.

The plethora of research in this area, measuring different aspects of social relationships, led to uncertainty as to which aspect increased the risk of mortality. A recent meta-analytic review of 148 studies has revealed that stronger social relationships increased the likelihood of survival by 50% (Holt-Lunstad, Smith, & Layton, 2010). They found that complex measures of social integration were better predictors of mortality than binary indicators of residential status (e.g., living alone or with others). This is partly because living in a negative social relationship can increase risk of mortality. However, they also caution against assuming causation, due to the difficulty of conducting randomized controlled trials to investigate this topic. They conclude that the data they present makes a compelling case for social relationship factors to be viewed as an important risk factor alongside factors such as smoking, diet, and exercise.

Definition

Psychosocial factors are influences that affect a person psychologically or socially. There are multidimensional constructs encompassing several domains such as mood status (anxiety, depression, distress, and positive affect), cognitive behavioral responses (satisfaction, self-efficacy, self-esteem, and locus of control), and social factors (socioeconomic status, education, employment, religion, ethnicity, family, physical attributes, locality, relationships with others, changes in personal roles, and status).

Description

Psychosocial Factors in Everyday Life

Psychosocial factors and influences differ across individuals and may contribute to the development or aggravation of mental and physical disorders. Previous studies have indicated that depression, social isolation, and behavioral escape-avoidance coping were associated with the risk of mortality for cancer patients (Falagas et al., 2007) and patients with cardiac disease (Rozanski, Blumenthal, & Kaplan, 1999). A serious loss (bereavement, divorce, and disability), relationship problems, work stress, family crisis, financial setback, or any unwelcome life change can trigger depressive disorders (Meltzer, Gill, & Petticrew, 1995). Furthermore, those disorders may negatively impact some psychosocial factors. For example, depressive disorders substantially reduce a person's ability to work effectively and personal and family income and increase the probability of unemployment (Ormel et al., 1999).

Psychosocial Factors in Natural and Technological Disasters

Repeated disasters in Japan such as the Great Hanshin Earthquake and the Great East Japan Earthquake showed us the importance of these psychosocial factors in life events. Furthermore, the Great East Japan Earthquake caused not only death and destruction but also secondary disasters such as the Fukushima nuclear accident. The severity of these natural and technological disasters (e.g., the extent of death and destruction, the length of exposure, evacuation, proximity to the epicenter, and contradictory media reports about the health effects of radiation) are likely to have an adverse impact on victims' mental health (Bromet, Havenaar, & Guey, 2011).

In contrast, positive psychosocial factors in life events such as connectedness to others, the spirit of patience, politeness, and mutual aid may contribute to prevent an aggravation of the situation and change things for the better. In The Great Hanshin Earthquake and The Great East Japan Earthquake, Japanese people have handled their grief and loss and overcome numerous difficulties with mutual cooperation and the spirit of patience. These psychosocial factors provide us the energy to recover from severe life events.

Psychological and social effects

Definition

Psychosocial impact is defined as the effect caused by environmental and/or biological factors on individual's social and/or psychological aspects.

Several psychiatric disorders may affect psychological and social aspects of individual's lives. Examples are (a) obsessive-compulsive disorder (OCD), whereas these patients might present social marital disabilities, problems related to occupations and low income (Vikas, Avasthi, & Sharan, 2011), (b) people with cancer, who experienced negative psychological effect such as bad feelings and fears, as well as moderate to high levels of anxiety and psychological distress (Primo et al., 2000), (c) traumatic events such disasters, urban violence, and expose of terrorism may also impact on present psychosocial status (Eisenman et al., 2009). Natural disasters, like flooding, have been reported to cause a wide range of psychosocial impacts, leading the victims to present psychiatric symptoms (Paranjothy et al., 2011). For example, after the tsunami in Southern Thailand and Hurricane Katrina in the USA caused high levels of posttraumatic stress disorder (PTSD) among the victims. The prevalence of mental health disorders has been significantly higher among individuals who experienced floodwater in their houses compared to individuals who did not face this type of personal experience (Paranjothyet al., 2011). Individuals who are victims of these environmental phenomena might need more substantial and sometimes sustained intervention (de Zulueta, 2007).

Psychosocial Predictors

Joanna Long and Jennifer Cumming
School of Sport and Exercise Sciences, University of Birmingham, Edgbaston, Birmingham, UK

Synonyms

Health behavior predictors; Psychological predictors

Definition

Psychosocial variables which act as predictors either of other psychosocial variables or behaviors, cognitions, risk, severity, mortality, or a number of other factors which may relate to behavioral medicine research, such as health outcomes.

Description

Psychosocial variables encompass both the social and psychological aspects of someone's life and cover a broad range of both positive and negative factors often measured in behavioral medicine research. Social factors include quality of life, health behaviors (alcohol consumption, smoking status, drug use), physical activity level, and socioeconomic status, whereas personal factors include depressive symptoms, perceived stress levels, anxiety, and mood (see ▶ Psychosocial Variables). Psychosocial variables often interrelate and can be used to predict behavioral and/or health outcomes. These variables also act as risk factors for mental health and chronic conditions, such as rheumatoid arthritis, HIV, gastrointestinal disorders, and Parkinson's disease, among many others. For these reasons, psychosocial predictors are important to assess when investigating cofactors of disease and targeting interventions within a population.

Within cross-sectional research, psychosocial predictors may correlate with other psychosocial variables or the behavior and health outcomes investigated. Examples of cross-sectional studies using psychosocial predictors within behavioral medicine research includes Ng and Jeffery (2003) who found an inverse relationship between perceived stress and exercise, and Blair and Church (2004) who investigated the link between physical activity status with obesity and health behaviors, such as smoking and diet. Although this design provides immediate research, it is limited to a particular time point for assessing relationships that may vary over time. Alternatively, longitudinal designs are used to study

psychosocial predictors in a group of individuals over a period of time, perhaps for many years. This may permit researchers to predict future behaviors, risk, and health outcomes in research. For example, Leserman et al. (1999) investigated the relationship between perceived stress and AIDS diagnosis in HIV patients over 5.5 years. Also, Whooley et al. (2008) investigated the relationship between depressive symptoms and health behaviors such as physical activity levels, smoking status, and alcohol consumption with risk of cardiovascular events over 5 years in patients with existing coronary heart disease. Taking assessments at multiple time points permits researchers to examine whether changes in psychosocial factors relate to long-term disease or condition changes. Compared to cross-sectional research, a longitudinal study also provides a more accurate idea of the direction of the predictor's relationship. However, cross-sectional and longitudinal studies cannot infer causation or show the direction of the relationship.

Psychosocial Variables

Joanna Long and Jennifer Cumming
School of Sport and Exercise Sciences, University of Birmingham, Edgbaston, Birmingham, UK

Synonyms

Health behavior variables; Psychological variables

Definition

Variables encompassing psychological and social factors.

Description

The term "psychosocial" has a broad meaning when considering health research and social epidemiology. It is formed from two words: psychological and social. Psychological factors can be positive, such as happiness, affect, and vitality, or negative, such as anxiety, perceived stress, and depressive symptoms. These can also be split to distinguish between trait and state aspects. Personality traits, depressive factors, well-being, quality of life, and the impact of

significant life events and trauma are less likely to fluctuate on a day to day basis (i.e., more trait-like or stable variables), whereas anxiety, perceived stress, mood, affect, happiness, and vitality are more unstable (i.e., more state-like). Furthermore, cognitive, behavioral, and affective facets within psychosocial factors can be identified. For example, someone may think about taking up smoking, and subsequently begin smoking, which in turn may lower perceived stress levels.

Social factors involve the relationship a person has with their environment, such as their age, sex, ethnicity, level and perception of social support, socioeconomic status, neighborhood factors, family history, and health behaviors. The environment can also promote or hinder whether individuals engage in positive or negative health behavior. For example, certain behavioral factors, such as the likelihood of exercise participation, smoking, alcohol intake, and drug abuse may be influenced by the physical environment. If an individual lives within a community that is safe and accessible, for example, they may be more likely to engage in high levels of outdoor physical activity, such as walking around the neighborhood.

Psychosocial variables therefore encompass a large range of factors relating to an individual's psychological state and social environment and potentially have either positive and negative consequences for health and behavioral outcomes (see ▶ Psychosocial Predictors). These variables are also important to consider when investigating either the risk, or progression, of an illness or disease. For example, high perceived stress levels, anxiety, and depression may accelerate progression of HIV or coronary heart disease (Barefoot et al., 1996; Leserman, 2008). Similarly, understanding of these variables allows researchers to examine developmental processes, such as healthy aging or the effects of a long-term intervention within the population.

There are two main ways of measuring psychosocial variables. Administering questionnaires is the most common method used in research. For example, the Perceived Stress Scale (PSS) (Cohen et al., 1983) assesses the degree to which situations in one's life are perceived as stressful, whereas the Centre for Epidemiological Studies Depression Scale (CES-D) (Kohout et al., 1993) measures current level of depressive symptomatology. The items making up the questionnaire are often summed together to create an overall score for the variable being measured (e.g., depression) and can be compared to norms generated for clinical and general populations. For example, the CES-D questionnaire has a range between 0 and 30, with a score of 10 or more indicating possible clinical depression. It is important that the questionnaires used are reliable, valid, and specific to the population which is being studied. Alternatively, researchers may choose to use structured or semi-structured interviews to assess psychosocial variables. A structured interview involves asking respondents a predetermined and limited number of questions about a specific topic, whereas a semi-structured interview is more flexible and allows new questions to be brought up or emerging topics to be explored. Interviews provide a qualitative aspect to the research, which is often used to complement the quantitative data provided by questionnaires when taking a mixed-methods approach.

Psychosocial Work Environment

Karen Jacobs[1], Miranda Hellman[2], Jacqueline Markowitz[2] and Ellen Wuest[2]
[1]Occupational Therapy, College of Health and Rehabilitation Science, Sargent Collage, Boston University, Boston, MA, USA
[2]Boston University, Allston, MA, USA

Synonyms

Mental strain; Physical illness; Psychological and social conditions people experience in the workplace; Stress and occupational health

Definition

Psychosocial work environment pertains to interpersonal and social interactions that influence behavior and development in the workplace. Research has been conducted to determine the effects of the psychosocial work environment on stress levels and overall health. One study in particular found that low levels of support and control at work leads to increased rates of sickness absence (North, Syme, Feeney, Shipley, & Marmot, 1996). In other words, a positive and supportive psychosocial work environment is beneficial to employees in an occupational organization.

Psychosomatic

Makiko Ito
Department of Stress Science and Psychosomatic Medicine, Graduate School of Medicine, The University of Tokyo, Bunkyo-ku, Tokyo, Japan

Definition

Psychosomatic is defined as one involving or depending on both the mind and the body as mutually dependent entities.

The term has been used to refer to the following:

1. Physical disorders, those caused or aggravated by psychological factors and, less often, to mental disorders caused or aggravated by physical factors
2. The branch of medicine concerned with the mind-body relations
3. The field of study, one sometimes designated "psychosomatics," concerned with the relationship between mind and body

Description

It is said that the foundation for psychosomatic movement was laid 2,500 years ago in ancient Greece.

In the fifth century BC, Hippocratic principles emphasized what we consider to be some of the basic tenets of psychosomatic medicine: concern about the relationship between the physician and

the patient and about importance of the environment and of the adaptive factors in health and disease.

Francis Bacon advocated investigation of the mental faculties and of the interaction of body and mind by case studies and by study of the relationships between the individual and society. A passage written by Bacon in 1605 is the first explicit scientific statement about psychosomatic medicine in English.

Psychiatry and psychosomatic medicine owe an immense debt to Johann Reli, who was the first use the word psychiatry.

Another pioneer in German psychiatry was Johann Heinroth, who was the first to use the word psychosomatic in 1818. He insisted that the mind in health and disease was essential to the treatment of illness.

The significance of Freud's dynamic principles of psychological causality and of the unconscious is enhanced.

In the 1920s and 1930s, psychosomatic concepts were supported by two major advances in physiology as well as by psychoanalytic findings. Pavlov's discovery of the conditioned reflex furnished a tool for measuring emotional correlates of stress, and Cannon's work on adrenaline, the endocrine glands, and on the autonomic nervous system stimulated the development of research in psychophysiology.

Resurgent interest in psychosomatic medicine in the 1920s and the 1930s started with clinical work, initially case histories that described psychosomatic phenomena. Within a few years, Alexander and Dunbar proposed theories of psychosomatic illness.

In 1950s, Hans Selye advocated a concept that an external stressor had an influence on physical health, which is called "general adaptation syndrome." The theory of Selye contributed to mind and body medical advance greatly.

George L. Engel proposed that health is affected by a biological factor, a psychological factor, and the social support.

After that, including a famous Framingham study, a way of thinking that an unhealthy habit and action had an influence on health directly came to attract attention worldwide. Health and a complicated biological, psychological, and sociological health model about the disease came to be recognized in the medicine, and a field called the behavior medicine was born in this way. The current psychosomatic medicine regards this behavior medicine as the one of the important theoretical bases, but aims at the promotion of the medical care of all people while not only it but also psychology takes in various study.

▶ Psychosomatic Disorder

Psychosomatic Disorder

Tetusya Ando
Department of Psychosomatic Research, National Institute of Mental Health, National Center of Neurology and Psychiatry, Kodaira-shi, Tokyo, Japan

Synonyms

Psychophysiologic disorders; Psychosomatic diseases; Psychosomatic illness

Definition

1. Somatic diseases or disorders characterized by objective organic changes and/or functional changes that could be induced, progressed, aggravated, or exacerbated by psychological, social, and/or behavioral factors.
2. Physical illness or symptom believed to be caused by psychological factors.

Description

The term "psychosomatic" carries two connotations having an ancient tradition in Western thinking and medicine: psychogenesis of disease and holism. Psychogenesis is an etiologic hypothesis about the role of psychological factors in human disease. The core notion of holism is that mind and body is inseparable and mutually dependent aspects of man, and it implies a view of the human being as a whole.

The idea of psychogenesis resulted in the concept of psychosomatic disorder, a physical illness or symptoms believed to be caused by psychological factors. Notion of psychogenesis has been criticized because it is incompatible with current multifactorial view of diseases, and the term "psychosomatic disorder" is misleading since it implies a special class of disorders of psychogenic etiology and absence of psychosomatic interface in other diseases.

Holistic concept resulted in multifactorial model of illness called "biopsychosocial" model by Engel. In this model, illness is a result of interacting mechanisms at the cellular, tissue, organic, interpersonal, and environmental level. Biopsychosocial approach to illness and health covers the psychosomatic medicine, behavioral science, social science, neuroscience, stress physiology and epidemiology, psychoneuroendocrinology/immunology, psycho-oncology, and so on.

Psychosomatic medicine has focused on the study of the interaction of psychosocial and biological factors in health and disease. Psychosocial factors may induce, sustain, or modify the course of virtually all kind of diseases including infections and cancer, though their relative weight may vary from disease to disease and from patient to patient suffering from the same disease. Japanese Society of Psychosomatic Medicine defined psychosomatic disorders as somatic diseases "characterized by objective organic changes and/or functional changes that could be induced, progressed, aggravated, or exacerbated by psychological, social, and/or behavioral factors."

Psychosocial factors possibly affecting individual vulnerability, onset, course, and outcome of diseases are early and recent life events, chronic stress, personality variables, coping ability, social support, psychological state such as depression, anxiety, anger, hostility, irritability, psychological well-being, and abnormal illness behavior. Mechanisms through which psychosocial factors could influence health and disease are mediated by central and autonomic nervous systems, neuroendocrine systems, and immune systems. Psychosocial stressors may also affect health and disease through changes in health-related habits and behaviors, such as smoking, eating, drinking, exercise, and drug use. Psychological factors may also play role in adjustment to disease, attitude to medical care, doctor-patient relationship, adherence to treatment, impairment in social functioning, and quality of life of patients.

For example, high levels of stress, low levels of social support or social isolation, low socioeconomic status, personality factors, and negative emotions such as anger or hostility, depression, and anxiety are associated with increased cardiovascular disease morbidity and mortality. These psychosocial factors have been associated with enhanced sympathetic nervous system activation, impaired parasympathetic activity, increased circulating levels of catecholamines and corticosteroid, enhanced blood coagulation and fibrinolysis, endothelial dysfunction, coronary vasospasm, and various inflammatory markers. Lifestyle modification (e.g., smoking cessation, diet, exercise) improves cardiovascular health. Psychological interventions, such as relaxation, stress management, cognitive, and behavior therapies may improve psychological distress and psychological functioning in cardiovascular patients.

As a summary, the term "psychosomatic disorders" is misleading and discouraged to be used at least in the sense of psychogenic disease. Holistic concept, another major connotation of "psychosomatic," resulted in biopsychosocial model of illness. Irrespective of whether the term "psychosomatic disorder" is used or not, it is important to perform research and medical practice of a disease from a multifactorial perspective.

Psychosurgery

Douglas Carroll
School of Sport and Exercise Sciences, University of Birmingham, Edgbaston, Birmingham, UK

Synonyms

Psychiatric surgery

Definition

Psychosurgery is brain surgery conducted explicitly to amend aspects of human behavior. As such, it can be distinguished from neurosurgery, where the aim is to address some specific and identifiable brain pathology such as a tumor. Although there are noticeable gray areas such as brain surgery for intractable pain or to halt the spread of epileptic seizures from one brain hemisphere to the other, the above distinction is important in differentiating between the primarily behavioral aims of psychosurgery and the primary aims of treating physical pathology that characterize neurosurgery.

Description

The first psychosurgical operation was undertaken on November 12, 1935 by Egas Moniz at the Neurological Institute of the University of Lisbon, Portugal. Moniz's surgery was conducted on severely disturbed psychiatric patients who had proved resistant to other forms of treatment. He called his operation the prefrontal leucotomy; a wire garrote inserted via a cannula or "leucotome" was used to severe connections between the prefrontal cortex and more posterior parts of the brain. In 1949, Moniz was awarded the Nobel Prize in Medicine "for his discovery of the therapeutic value of prefrontal leucotomy in certain psychoses." Moniz's activities in the field of psychosurgery were curtailed, though, when he was shot by one of his psychosurgical patients; the bullet lodged in his spine and he retired, a hemiplegic, in 1944.

However, Moniz's initiative was enthusiastically transported to the USA and UK, where the operation was re-branded: the frontal lobotomy was born. As indicated, the target patient group were psychiatric patients suffering from severe and intransigent psychoses. The Second World War through up a great number of such patients; the late 1940s and early 1950s were to prove the heyday of the frontal lobotomy. It has been estimated that between 40,000 and 50,000 operations were conducted in the USA during

that period with a further 12,000 undertaken in the UK. From its outset, psychosurgery was subject to fierce controversy. Its opponents regarded it as a grievous, unjustified, and irreversible assault on the human personality. Its proponents, on the other hand, confidently testified that it was a valid and efficacious treatment for many seemingly intractable psychiatric disorders. Sober and objective assessment was difficult since the vast majority of psychosurgical data stem from uncontrolled observations where even the minimal attributes of good experimental design are absent: control groups, independent evaluation of treatment effects, lengthy follow-ups, etc. Accordingly, claims of efficacy based on data of such dubious scientific status can command little confidence.

By the late 1950s, psychosurgery was on the wane; the newly introduced major tranquilizers offered a seemingly easier and decidedly less contentious way of managing the behavior of severely disturbed psychiatric patients. Nevertheless, just as it seemed safe to go back into mental hospital, psychosurgery began to re-brand itself once more. By the late 1960s and early 1970s, psychosurgery was enjoying a modest renaissance. This time around, the operations were technically more sophisticated. The main differences, though, were the neural and behavioral targets. No longer was the prefrontal cortex the focus but rather structures that lay deep within the brain: components of the limbic system such as the amygdala, which is implicated in emotion and motivation. No longer was severe psychosis the sole or even main target; instead, the focus had shifted to vaguer and more diagnostically problematic behaviors such as aggression and hyperactivity. Deviance had replaced psychiatric disturbance. As before, the battle between opponents and proponents was enjoined, and as before, the available data did not afford anything like a proper scientific assessment. Again, its day in the sun was short-lived; psychosurgery had all but disappeared by the 1980s. This time, though, it was regulation and legislation that did the trick.

Puberty

Adriana Carrillo and Carley Gomez-Meade
Department of Pediatrics, Miller School of Medicine, University of Miami, Miami, FL, USA

Synonyms

Menarche; Sexual maturation

Definition

Puberty is the transition from being sexually immature to sexual maturity and attainment of

reproductive capacity. Complex interactions of hypothalamic-pituitary hormones and neuroendocrine factors take place to initiate puberty. Recent research indicates kisspeptin and its receptor GPR54 to play a key part in the initiation of puberty. Kisspeptin and GPR54 increase at the onset of puberty. Kisspeptin neurons innervate and stimulate hypothalamic gonadotropin releasing hormone (GNRH) neurons. In addition, kisspeptin neurons express estrogen and androgen receptors which may be important for the onset and tempo of puberty. The onset of puberty is also marked by increasing pulse and frequency of GNRH from the hypothalamus. GNRH then stimulates the pituitary to secrete gonadotropins (luteinizing hormone (LH) and follicle stimulating hormone (FSH)) which directly stimulates the ovaries or testes to produce sex steroids. The increase of sex steroids induces the physical changes of puberty. The progressive physical changes during puberty are described by the Tanner staging system. Both boys and girls have five stages. The first Tanner stage (Tanner stage I) is prepubertal or sexual immaturity and the fifth Tanner stage describes a sexually mature adult. Tanner stage II marks the beginning of sexual maturation (Lifshitz, 2007; Oakley, Clifton, & Steiner, 2009).

Puberty begins earlier in girls than boys. The normal range for the onset of puberty in females is 8–13 years of age. The first sign of puberty in girls is breast development at an average age of 10.4 years in Caucasian girls. African American girls begin puberty earlier at a mean age of 9.5 years. Tanner stages follow progress through puberty with changing contour of the breast. The development of pubic hair is not under the same control as the ovaries. Adrenarche is a result of increased adrenal androgens and occurs before breast development in 10% of girls. Pubic hair is also described by Tanner stages. Puberty is also marked by an increase in percent body fat, maturation of the vaginal mucosa, and uterine and endometrial growth. Accelerated growth begins early in puberty for girls with peak growth velocity during Tanner stage II– III. The average age of menarche for Caucasian girls is 12.5 years and 12 years for African American girls. Menarche is associated with a deceleration in growth and typically occurs during Tanner stage IV. Menarche occurs approximately 2 years after Tanner stage II breast development in normally maturing girls. Early menstrual cycles may be anovulatory and irregular with subsequent ovulation and development of regular cycles. Adult contour breast and adult pubic hair distribution marks Tanner stage V and the completion of puberty.

The normal age range for the onset of puberty in boys is 9–14 years. The average age for the development of Tanner stage II for Caucasian males is 12 years and 11.2 years for African American males. The first sign of puberty in boys is increased testicular volume. Puberty progresses with continued testicular enlargement and penile enlargement as described by the Tanner stages. Mid-puberty axillary hair and androgen sensitive hair on the face, chest and back begins. Also in mid-puberty, males have peak linear growth, voice change, and acne. There is a progressive increase in total bone mineral content and lean body mass and a decline in body fat. Spermarche is attained at Tanner stage III. Peak growth velocity occurs during Tanner stage IV in males. Puberty is complete at Tanner stage V with adult genitalia and adult distribution of pubic hair.

Deviations from normal in the onset of puberty and progression through puberty may represent normal variation or pathological disease. Normal variations include premature adrenarche, gynecomastia during male puberty, and premature thelarche in females. Precocious puberty or delayed puberty may represent abnormal pubertal development. It is important to recognize abnormal variations in puberty that may require intervention.

Premature adrenarche is the early development of pubic hair, typically after 6 years of age for males and females. It is more common in females and is usually benign. Females with a history of premature adrenarche have an increased risk of polycystic ovarian syndrome and insulin resistance. A bone age radiograph can be used to determine effects of sex steroids on skeletal maturation. The bone age in

premature adrenarche is normal. In addition, gonadotropin hormones are normal and there is no breast development in females or testicular enlargement in males.

Gynecomastia is usually a self-limiting development of palpable breast tissue in 40% of males during puberty. It usually begins in early puberty and resolves within 2 years. It is typically minimal and does not require treatment. Some conditions are associated with excessive or prolonged gynecomastia including Klinefelter syndrome and other causes of decreased testosterone production. Other pathological causes of gynecomastia are some testicular tumors, liver failure, ketaconazole, spirinolactone, marijuana, and other medications.

In females, early benign breast development is called premature thelarche. It is usually present at birth and increases in size over the first 2 years of life. It may also occur around 6 years of age. It is nonprogressive and is not associated with accelerated growth, elevated pubertal hormones, or other changes associated with puberty. As with premature adrenarche, this is not associated with accelerated growth, normal bone age, or elevated pubertal hormones.

Precocious puberty is the abnormal development of secondary sexual characteristics before 7 years of age in Caucasian females, 6 years of age in African American females, and before 9 years of age in males. Precocious puberty in females is most commonly idiopathic premature activation of the hypothalamic-pituitary-gonadal axis, termed idiopathic central precocious puberty. Other causes of central precocious puberty include abnormalities of the central nervous system (CNS) such as brain tumors, intracranial irradiation, infections, or congenital malformations. CNS pathology is more common in males than in females. Outside of the CNS, estrogen or testosterone production may occur independent of gonadotropin secretion from the pituitary gland. In females, estrogen from ovarian cysts, ovarian tumors, or exogenous estrogen exposure may stimulate the onset of puberty. Rarely, genetic mutations can stimulate ovarian estrogen production. McCune Albright syndrome is due to an activating mutation of a signaling protein that results in café au lait spots, fibrous dysplasia, and precocious puberty in females. In males, androgen production stimulating penile growth and pubic hair can come from adrenal or testicular tumors. Congenital adrenal hyperplasia is due to a genetic mutation that leads to the overproduction of adrenal androgens that causes precocious puberty in males and virilization in females. Virilization in females includes clitoromegaly, hirsutism, and acne.

If puberty does not occur spontaneously prior to 14 years in males and 13 years in females it is considered delayed. In addition, puberty in males should be completed within 4.5 years after its onset. If a female has not menstruated by 16 years of age or 5 years after the onset of puberty it is termed primary amenorrhea. The most common reason for delayed puberty is constitutional delay of growth and puberty. Constitutional delay is characterized by a decline in growth velocity during early childhood followed by a normal growth velocity with a delayed bone age. Puberty occurs late and final height is normal. There is typically a family history of late puberty.

Pathologic causes of delayed puberty can be divided into those due to failure of the hypothalamus or pituitary to secrete gonadotropins and those due to failure of gonads to respond to gonadotropins. Delayed puberty with low gonadotropins can be secondary to chronic disease, genetic syndromes, gene mutations, or CNS pathology. Syndromes that are associated with low gonadotropins are Prader-Willi, Lawrence Moon, and Kallman syndromes. Anorexia, malnutrition, HIV, Crohn's disease and hemoglobinopathies are some of the chronic conditions that may cause delayed puberty. Endocrine disorders associated with delayed puberty are hypothyroidism and hyperprolactinemia. Tumors, radiation, infection, or congenital malformation can affect the production and secretion of gonadotropins.

Delayed puberty due to gonadal failure is most commonly due to sex chromosome abnormalities. Klinefelter syndrome males carry two X chromosomes and one Y chromosome. Klinefelter syndrome is characterized by testicular failure, disproportionate long limbs, poor

musculature, and gynecomastia. In females, Turner syndrome is due to loss of genetic material from one X chromosome. Females with turners have ovarian failure, short stature, and a spectrum of other dysmorphisms. Gonadal failure can also be due to gonadal dysgenesis or direct damage to the gonads such as trauma, medication, radiation or infection (Lifshitz, 2007; Sperling, 2008).

Public Health

Marc D. Gellman
Behavioral Medicine Research Center,
Department of Psychology, University of Miami,
Miami, FL, USA

Definition

Public health refers to those activities by which a society attempts to increase life expectancy, decrease morbidity, and help improve health-related quality of life.

Description

There has often been a widespread misconception that public health is limited to "health care for low-income families." The Centers for Disease Control and Prevention created a list of the ten Great Public Health Achievements in the twentieth century that remind us of how far we have come, how we got here, and exactly what public health is: the active protection of a nation's health and safety, credible information to enhance health decisions, and partnerships with local minorities and organizations to promote good health. The choices of topics for this list were based on the opportunity for prevention and the impact on death, illness, and disability: they are not ranked by order of importance. The list includes the following: vaccination, motor-vehicle safety, safer workplaces, control of infectious diseases, decline in deaths from coronary heart disease (CHD) and stroke, safer and healthier foods, healthier mothers and babies, family planning, fluoridation of drinking water, and last but not least, the recognition of tobacco use as a health hazard.

During this period, the health and life expectancy of persons residing in the United States improved dramatically. Since 1900, the average lifespan of persons in the United States has lengthened by greater than 30 years, of which 25 years of this gain are attributable to advances in public health. The unprecedented increase in longevity seen during the first half of the twentieth century was also seen in other countries, primarily in economically advanced countries. The decrease in mortality rate was largely due to a decline in infectious diseases related to vaccination, decreased exposure to infection because of improved hygiene, improved nutrition, and the development of antibiotics to cope with bacterial infections. However, as infectious diseases declined as the leading cause of mortality in economically advanced countries, they were eclipsed by chronic diseases. By the middle of the twentieth century, CHD, cancer, and stroke accounted for more than 60% of the death rate in the United States.

Public health efforts to eradicate infectious diseases have been successful in an increase in longevity in economically developed and even many less developed countries. Similarly, improvements in healthy lifestyle have led to decreases in morbidity and increases in longevity in these countries during the second half of the twentieth century. At the same time, the HIV/AIDS pandemic in sub-Saharan Africa has led to an even steeper decline in life expectancy. The growing spread of HIV/AIDS across the Asian continent is of considerable concern.

At this point, early in the twenty-first century, the major causes of death in the United States

included (1) heart disease, (2) cancer, (3) stroke, (4) unintentional injuries, (5) chronic obstructive pulmonary disorder, (6) pneumonia and influenza, (7) diabetes, (8) suicide, (9) liver disease, (10) HIV/AIDS, and (11) homicide. Behavioral psychosocial, and sociocultural factors associated with lifestyle contribute to virtually all of these causes of mortality. Even in the case of infectious disease such as pneumonia, risk factors can be related to disruptions of natural pulmonary host mechanisms related to lifestyle factors such as smoking and alcohol abuse. Similarly, infection from HIV is primarily spread through high-risk sexual practices and the sharing of contaminated drug paraphernalia.

As scientists attempted to find specific causal agents in the pathogenesis of cancer and CVD throughout most of the twentieth century, a new approach emerged. Unable to find single causes of diseases, attention shifted to the role of environment and host in the pathogenesis of chronic diseases. Whereas single cause-and-effect models proved successful in studying the genesis of infectious diseases, an understanding of the basis of chronic diseases turned to models based on the presence of risk factors. The identification of risk factors makes prediction of chronic diseases more likely, but individual risk factors cannot be identified as necessary and sufficient causes for many diseases. In this respect, interactions among agent, host, and the environment have now taken center stage.

At the beginning of the risk-factor revolution, it was widely believed that the causes of chronic diseases such as CHD could be explained in terms of a few biological (e.g., high cholesterol, high blood pressure) and lifestyle (e.g., smoking) risk factors; this turned out not to be the case. Other variables contributing to CHD turned out to include physical inactivity, excess consumption of alcohol, and obesity. Still other factors under investigation include individual difference variables such as depression and hostility and sociocultural variables including low socioeconomic status, ethnic minority status, lack of social support, and occupational stress.

To achieve public health objectives, it is sometimes useful to deal with unyielding problems at multiple levels. Although behavioral interventions administered at the individual level tend to produce successful weight loss in the short term, few people maintain their weight loss over the long term. In order for individual-based interventions to succeed on a population basis, such interventions should take place in a sociocultural environment that is conducive to healthful eating and exercise. Improving the availability of healthy food choices, providing economic incentives for healthy eating by selective taxation, ensuring through the schools that children and adolescents get adequate exercise, enhancing accessibility of physical activity for the general public by providing bicycle paths and highway lanes, and initiating mass media campaigns supporting a healthy lifestyle could be useful for maintaining weight loss.

The recent successes in tobacco control in the United States provide a heartening example of how multilevel approaches to a major public health problem can lead to a decline in disease. In this case, the improvements have occurred in cardiovascular disease (CVD), some cancers including lung and esophageal cancer, and respiratory diseases. At the interpersonal level, smoking cessation interventions, sometimes in conjunction with pharmacologic treatment, have been effective. At the organizational level, smoking cessation support groups, school campaigns against smoking, restrictions on smoking in restaurants and work sites, and reductions in health insurance premiums for nonsmokers have been established. Finally, at the societal level, laws against juvenile smoking, taxation of cigarettes, and governmental sponsored antismoking campaigns have all been realized. These measures have led to a marked improvement in the nation's health. Unfortunately, the export of tobacco products outside of the USA to other countries remains a threat to improvements in global public health.

A distinction is sometimes made between clinical or high-risk approaches to disease treatment and prevention versus population-based strategies. Although there is some value in differentiating between these approaches, they should be seen as complementary because neither strategy

is effective for all behaviors or all target groups. Thus, an important public health task is to identify which risk behaviors are open to individual-based versus population-based interventions and how to make these interventions synergistic with one another. Application of the social and behavioral sciences to improve health and combat disease occurs at multiple levels and requires putting into practice different skills both within and across levels. Genetic counseling for those at familial risk of disease, family counseling to reduce substance abuse, and interfamilial violence and group counseling to help those living with HIV/AIDS are examples of interpersonal interventions at the individual level. At the organizational level, interpersonal interventions such as blood pressure screenings and smoking cessation programs, the provision of physical fitness facilities, and media communication have been used in schools, work sites, and community centers. Finally, societal-type interventions involving media and policy actions can occur at the community, state, or federal level. Seat-belt laws, public service announcements about drunk driving, and taxation of cigarettes are examples of interventions at this level.

An important cornerstone of public health is prevention. Primary prevention refers to measures taken to reduce the incidence of disease. In the case of CVD, for example, people may be encouraged to quit smoking, decrease intake of dietary fat, and increase physical activity before diseases become evident. In contrast, secondary prevention involves reducing the prevalence of disease by shortening its duration. Mortality from certain cancers, for example, prostate cancer, is decreased by early detection of the cancers when they are still treatable. Still another form of prevention is tertiary prevention. This involves reducing the complications associated with chronic diseases reducing the complications associated with chronic diseases and minimizing disability and suffering. Medication adherence training in HIV/AIDS patients is a form of tertiary prevention.

Widespread social disorganization and the growing disparity in income within and between nations also pose a global threat to public health. Because public health is a global matter that is closely tied to international policies, hope for future improvements in public health will largely depend on global improvements in public policy.

Pulmonary Disorders, COPD: Psychosocial Aspects

Akihisa Mitani
Department of Respiratory Medicine, Mitsui Memorial Hospital, Chiyoda-ku, Tokyo, Japan

Synonyms

Chronic obstructive pulmonary disease

Definition

Patients with COPD often suffer from anxiety and depression. These psychological distresses cause low quality of life, social isolation, increased hospitalization rates, and might increase mortality. Treatments include pharmacotherapy, psychotherapy, and pulmonary rehabilitation.

Description

Patients pulmonary disorders are more likely to be of lower self-esteem and downgrade the significance of life in their depression, and chronic obstructive pulmonary disease (COPD) is no exception. However, in spite of the high prevalence of the disease, psychosocial aspects of COPD and other pulmonary diseases have not been fully investigated, compared to cancers or cardiovascular diseases (Hill & Geist, 2008; Hynninen & Breitve, 2005; Kaptein & Scharloo, 2008; Kaptein & Scharloo, 2009; Maurer & Rebbapragada, 2008; von Leupoldt & Dahme, 2007).

(COPD) is a disease characterized by airflow obstruction. The respiratory symptoms are dyspnea, chronic cough, and sputum production. The treatments of COPD include medications focusing on bronchodilators, pulmonary rehabilitation, and oxygen administration.

Psychiatric disorders often appear in patients with COPD. Among them, anxiety and depression are most frequent, but the accurate prevalence is hard to say. In previous reports, the prevalence of anxiety ranges between 10% and 100% and the prevalence of depression, between 10% and 80%. However, it is an indisputable fact that anxiety and depression are often underdiagnosed and/or undertreated. Other disorders include panic disorder, hypochondriasis, and hysteria.

Variables, such as physical disability, smoking, long-term oxygen therapy (LTOT), low body mass index, and severe dyspnea, are associated with anxiety and depression.

As for anxiety, major presumed underlying mechanisms are smoking and dyspnea. Smoking is the most important environmental risk factor for the development of COPD. Adolescents with high levels of anxiety tend to have smoking habits, and smokers with a history of an anxiety-related disorder also experience more symptoms of nicotine withdrawal on cessation of smoking, resulting in tendency to nicotine addiction. Therefore, patients with COPD caused by smoking are likely to show higher levels of anxiety than the general population. Dyspnea is the most common symptom of COPD. The severity of dyspnea changes in response to air temperature or exercise and notably increases during acute exacerbations. For the patients, such episodes of increased dyspnea during exacerbations are associated with anxious feelings, although dyspnea at rest or on exertion does not correlate so much with anxiety. Furthermore, anxiety, in turn, increases the sensation of dyspnea. These bidirectional relationships between dyspnea and anxiety contribute to the increased prevalence of

anxiety-related disorders in COPD (Kaptein & Scharloo, 2008).

Depression in COPD could be caused by various factors such as low body mass index. However, some of them are confounders, making the analysis difficult. The lack of social support for elderly people, their past medical history, and their low socioeconomic status are mixed as risk factors for depression. The use of systemic corticosteroids for treatment, although the long-term use of it is not a standard medication, might cause depression. In addition, there is a relationship between smoking and depression, but little is known about it. Cigarette smoking might prompt a feeling of relaxation for some patients, and smoking cessation could be associated with an increased rate of depression. Chronic hypoxemia and LTOT are also closely related to symptoms of depression, although the underlying mechanisms remain unclear. It is true that LTOT improves survival and exercise capacity, but it may, at the same time, reduce social interactions because the use of oxygen therapy makes the patients lose in several areas of their lives.

Psychological stress typically plays a considerable role in the life of COPD patients because of the interaction of somatic and psychological factors. The emotional response to chronic pulmonary disorders results in further inactivity and social isolation. The patient may feel useless and lose interest in future project. In addition, COPD patients with psychological disorder tend to feel fatigue and short of breath more than patients without such a distress, although psychological distress has not been proved to worsen objective measures of functional exercise capacity. Inadequate perception of dyspnea contributes to a progressive avoidance of activities, resulting in a vicious circle where a physical deconditioning leads to more dyspnea.

As a result, anxiety in COPD patients lowers quality of life and increases hospitalization rates and the economic burden. Intensities of anxiety are correlated with measures of social isolation, suggesting that COPD patients with anxiety have impaired social interactions. The impact of anxiety on the physical disability and mortality of COPD patients is less clear. Depression also causes low quality of life, decreased adherence to treatment, increased frequency of hospital admissions, and prolonged length of stay, resulting in higher medical cost. In addition, depression negatively affects physical function in COPD patients, and the mortality rate among depressed patients is increased. Furthermore, depressed patients tend to make a preference for "do not resuscitate" decisions.

Treatments of psychological distress in COPD patients consist of pharmacotherapy, psychotherapy, and pulmonary rehabilitation.

In pharmacological therapy, antidepressants are commonly used, although evidence for their use in COPD patients is inadequate. Still, they might benefit COPD patients with symptom of anxiety and depression. Selective serotonin reuptake inhibitors (SSRIs) are regarded as first-line therapy. Tricyclic antidepressants and low-dose benzodiazepines could be effective. Administration of benzodiazepines to COPD patients with hypercapnia demands extreme caution because of their respiratory depressant effect; needless to add, each drug has its own side effects and must be used carefully.

Many psychological aspects are relevant to a variety of treatments of COPD. One of the most recent focuses within behavioral treatment on COPD is on self-management. Self-management education is likely to be associated with a reduction in hospital admissions without any detrimental effects in other parameters. Other methods, such as relaxation and biofeedback training, also might have some good effect, although many questions are still not answered.

COPD patients with respiratory symptom should receive comprehensive pulmonary rehabilitation with or without psychological distress. There is growing evidence that it does improve depressive symptoms. However, there remain some questions to be solved. Further research should focus on finding effective and acceptable maintenance strategies. It also remains to be solved whether pulmonary rehabilitation is as effective in COPD patients with severe anxiety and depression. Above all, it is not clear which elements confer psychosocial benefits for COPD patients. Only improvements in exercise capacity

may be associated with improvements in anxiety and depression, or it would be better to add a specific psychological component to pulmonary rehabilitation. At present, it is considered reasonable that a comprehensive pulmonary rehabilitation programs should include at least disease education or psychosocial components as the most effective formats.

Lung function

Definition

Pulmonary function testing (PFT) is a process for assessing functional status of the lungs, for obstructive and restrictive lung disease screening, and for evaluating treatment response (e.g., medications, chest physical therapy). Spirometry, using a spirometer, is the most common of the pulmonary function tests and measures the amount (volume) and the speed (flow) of air that can be inhaled and exhaled. It is designed to measure changes in lung volume and can only measure lung volume compartments that exchange gas with the atmosphere. Graphical measurement of gas movement (in and out of the chest) is referred to as a spirograph, and the tracing is called a spirogram. Spirogram tracings typically include both predicted and observed values to aid in clinical diagnostic evaluation.

The spirometry procedure is highly dependent on individual effort and cooperation and to ensure reproducibility, is generally repeated three times. Typically, individuals are asked to take the deepest breath they can and then exhale into the sensor as hard as possible, for as long as possible (preferably at least 6 s). It is sometimes directly followed by a rapid inhalation (inspiration) to evaluate for upper airway obstruction. The most common parameters measured in spirometry are vital capacity (VC); forced vital capacity (FVC); forced expiratory volume (FEV) at timed intervals of 0.5, 1.0 (FEV1), 2.0, and 3.0 s; forced expiratory flow 25–75% (FEF 25–75); and maximal voluntary ventilation (MVV). Airflow patency is estimated by measuring the flow of air an individual can exhale as hard and as fast as possible. Reduced airflow or obstruction can be a result of narrowed airways (e.g., asthma, bronchial inflammation, emphysema, tumor external compression). Airflow restriction is a decrease in lung volumes and is a measure of both FVC and residual volume. There are a variety of causes of restrictive lung disorders and include pneumonia, scoliosis, kyphosis, pleural effusion, obesity, tumors, and neuromuscular diseases.

As a person ages, the natural elasticity of the lungs decreases, and this translates into smaller

lung volumes and capacities. Males typically have larger lung volumes and capacities than females. Subsequently, PFT interpretation should be based on results of a normal person of the same age and gender. Body height and size also have an impact of PFT results. As an individual ages, their body mass may increase as a result of increased body fat to lean body mass ratio changes. For example, if an individual becomes obese, the abdominal mass prevents the diaphragm from descending as far as it could, and PFT observed (measured) results will be less than predicted (from preestablished normal data tables). Ethnicity may also impact PFT results, and interpretation of observed data should be compared to normal data of similar ethnic groups. Results are usually given in both raw data (liters per second) and percent predicted (i.e., the test result as a percent of the predicted values for the patients of similar characteristics). Generally, results nearest to 100% of the predicted value are the most normal, and results over 80% are often considered normal.

Qualitative Research Methods

J. Rick Turner
Cardiovascular Safety, Quintiles, Durham, NC, USA

Definition

Qualitative research methods collect and analyze qualitative data, which are often expressed in words rather than numbers. Qualitative data can be distinguished from quantitative data, which are expressed in numbers (e.g., a systolic blood pressure of 120 millimeters of mercury [mmHg]).

One example of a qualitative characteristic is skin coloration (at least as traditionally described). While normal skin colors vary from pinkish white to black, medical conditions and diseases can cause alterations of an individual's skin color. Anemia can lead to a white color (in those not normally so white). Various inflammations can lead to a red color (e.g., a severe rash), and cyanosis resulting from cardiac failure or lung failure leads to a blue color. Such assessments are not recorded and reported in numbers but in descriptive text.

Some researchers regard categorical data as qualitative data, even though numerical representations do occur when presenting the data. Consider the variables sex and blood group. Each of us falls into a mutually exclusive category for each one, e.g., male or female, and O, A, B, and AB. None of us falls into more than one category in each case. Additionally, there is no order to the categories: blood group B neither comes before or after blood group O. In a group of individuals of interest, data could be presented as counts of the number of individuals falling into each category in each case, thereby using numbers.

There are categories that can be ordered. For example, ordered categories of a pain that is experienced would be mild, moderate, and severe. Again, for a group of individuals of interest (perhaps subjects undergoing mindful meditation therapy or another behavioral intervention for pain), it is possible to describe how many individuals reported a pain falling in each of the categories.

Health-related quality of life

Definition

Quality of life (QoL) is a term used to refer to an individual's total well-being. There is disagreement between scientists, sociologists, and clinicians about the conceptualization of QoL, and hence, a clear definition is lacking (Hunt, 1997). However, current definitions can be categorized into three types (Farquhar, 1995): (1) global definitions, such as happiness/unhappiness; (2) definitions that break down QoL into a series of components or dimensions; and (3) focused definitions, which are often pragmatic approaches in which QoL is seen as synonymous with domains of the field of interest to the researchers (e.g., functional status is sometimes used as a measure of QoL by health researchers).

The first type of definitions has been researched since Aristotle, and still no consensus has been reached on how to define happiness and how to measure it (Fayers & Machin, 2000). The second and third types of definitions have underlying assumptions for which consensus exists about the domains encompassed by QoL. These latter two types of definitions provide a more practical approach for research purposes.

Across all definitions, considerable agreement exists that QoL is conceptualized as a multidimensional construct incorporating primarily the person's evaluation of his/her own life. The World Health Organization (WHO) defines QoL as the individuals' perception of their position in life in the context of the culture and value systems in which they live and in relation to their goals, expectations, standards, and concerns. It is a broad-ranging concept affected in a complex way by the person's physical health, psychological state, level of independence, social relationships, personal beliefs, and their relationship to salient features of their environment (World Health Organization, 1995).

The impact of health and illness on a person's QoL is referred to as health-related quality of life (HRQoL). QoL and HRQoL are often used interchangeably.

Quality of Life: Measurement

Maartje de Wit
Medical Psychology, VU University Medical Center, Amsterdam, North Holland, The Netherlands

Definition

Subjective assessment of the various aspects of quality of life.

Description

Quality of Life (QoL) is considered an important outcome variable in health-care practice and research. Consideration of QoL provides health-care providers, researchers, and policy makers insight into how variables of interest (e.g., chronic disease, medication use, living environment) impact a person's subjective well-being, which is instrumental to improving health-care practice systems.

QoL measures may be of potential value in comparing outcomes in clinical trials, evaluating interventions, commissioning programs of care, assessing the outcomes of new treatments, and in audit work. Further on, measuring health-related QoL (HRQoL) can facilitate discussion between patients and professionals in health care and stimulate the dialogue between medical outcomes and patients' subjective views (de Wit et al., 2008; Detmar, Muller, Schornagel, Wever, & Aaronson, 2002; Pouwer, Snoek, van der Ploeg, Ader, & Heine, 2001).

Measurement of QoL

Despite a clear definition of QoL, there is general agreement that health-related QoL (HRQoL) encompasses physical, cognitive, affective, psychological, social well-being, health perception, and disease- and treatment-related symptoms. Overall QoL expands upon this and incorporates non-medical-related aspects of a person's life such as the influence of work, spirituality, and other life circumstances (Koot, 2001).

QoL can include both objective and subjective perspectives in each domain (Testa & Simonson, 1996). The objective assessment of QoL focuses on what the individual can do, and is important in defining the degree of health. The subjective assessment of QoL includes the meaning to the individual; essentially it involves the translation or appraisal of the more objective measurement of health status into the experience of QoL. Differences in appraisal account for the fact that individuals with the same objective health status can report very different subjective QoL (Fayers & Machin, 2000).

Generic and Disease Specific Instruments

There are a wide variety of instruments available to obtain information on QoL. These instruments can be divided into generic and disease-specific instruments. Generic measures attempt to measure all important domains of QoL. Generic measures are most useful when comparisons or decisions have to be made for large groups of patients with disparate conditions and backgrounds (Fayers & Machin, 2000). For example, it gives the opportunity to compare the QoL of people with diabetes with their healthy peers or to people with asthma.

Disease-specific measures include domains that are designed to be valid only for a specified condition. Therefore they maximize content validity and support greater sensitivity and

specificity (Guyatt, Feeny, & Patrick, 1993), and may be particularly informative for disease management at the individual patient level. Advances in the development of QoL questionnaires for children resulted in generic questionnaires with complementary disease-specific modules (Bullinger, 2005; Ravens-Sieberer et al., 2008; Varni, Burwinkle, & Seid, 2005; Varni, Seid, & Rode, 1999). This measurement approach enables researchers and professionals to compare children with a specific disease to their healthy peers and also examine the impact of the disease at the same time.

QoL Measurement in Children

The development and validation of instruments for children have evolved over the past 30 years. Traditionally, parents have been the ones reporting on their child's HRQoL, because the child was seen as an unreliable respondent. When the child is very young or ill, the child may indeed be unable to complete questionnaires. However, relying on the parent as informant may result in incomplete assessment to the extent that the child's subjective experience and perceptions of HRQoL may be overlooked (Eiser & Morse, 2001a). Especially as the child grows older and develops his/her own life, the HRQoL reports of parents become less informative. It has been shown that parents and children agree more on objective domains of HRQoL (i.e., physical functioning) than on subjective domains, like emotional and social functioning (Eiser & Morse, 2001a; Janse, Sinnema, Uiterwaal, Kimpen, & Gemke, 2008).

As children and parents do not necessarily share similar views about the impact of illness, children are more directly involved in decisions about their own care and treatment as they mature. However, assessment of QoL in children poses unique problems (Eiser & Morse, 2001a). Children do not share adult views about the cause, aetiology, and treatment of illness. They may interpret questions differently, and adopt a different time perspective. In addition, their abilitiy to use rating scales, understand the language, and generally complete lengthy questionnaires of the type used in adult work, may be compromised by age and cognitive development. These considerations have guided the development of QoL questionnaires especially for children (Eiser & Morse, 2001a; Solans et al., 2008).

Choosing an Instrument

Because of the broad, multidimensional nature of QoL, it is advised that researchers who want to measure QoL define what they mean by "quality of life," or explain which domains of quality of life they want to measure using a specific instrument. For example, the terms "health-related QoL" (HRQoL), "functional status," and "health status" are often used interchangeably. However, although health or functional status can be part of HRQoL, it does not take the patient's perspective into account.

The Patient-Reported Outcome and Quality Of Life Instrument Database (PROQOLID) (www.proqolid.org, Mapi Research Institute, 2001–2011) provides an outline of available instruments to measure patient-reported outcomes or QoL. It should be noted, however, that identification of an instrument in this database does not necessarily mean it is valid and reliable in view of the question at hand. Thus, instruments should be selected with care (Bradley, 2001; Eiser & Morse, 2001b; Fayers & Machin, 2000; Koot & Wallander, 2001; Solans et al., 2008).
