Opening Quotations

Some of the unhealthful behaviors that make the greatest contribution to the current burden of disease are cigarette smoking, the abuse of alcohol and drugs, the overeating and underexercise that produce obesity, and Type A behavior. Unfortunately, these behaviors are stubbornly resistant to change and discouragingly subject to relapse. Thus, for behavioral scientists to promise to achieve too much too soon is to court disastrous disillusionment. But any contributions that behavioral scientists can make to reduce any of them will have highly significant implications for health.

As behavioral medicine researchers, we must become more directly involved in translating gains in the science of clinical and community (disease) prevention to gains in public policy. We have an unprecedented window of opportunity given the growing recognition at all levels of health care and government that clinical and community interventions that promote and support health behaviors will be essential for success in reducing the nation's most prevalent and costly heath problems and untenable health-care costs and disparities. This is the kind of opportunity that propelled the founders of our field 25 years ago, and we are better prepared than ever in our history to seize it.

Early Developments in the Field of Behavioral Medicine

At the editors' request, this Foreword provides a personal account of the early development of behavioral medicine. With many colleagues, I was fortunate to play a role in bringing together behavioral and biomedical sciences in such a way that the synergism resulting from this interaction resulted in ideas, conceptualizations, models, and ultimately interventions that were truly different from preexisting approaches to health and illness. As noted in the Preface, the contents of this encyclopedia bear witness to the manner in which behavioral medicine has matured during the past 30 years, illustrating current activities in the domains of basic research, clinical investigation and practice, and public health policy.

In 1963, I was a psychology intern in the Department of Medical Psychology at the University of Oregon Medical School (now called the Oregon Health Sciences Center). Under the guidance of Joseph Matarazzo, chair of the department, the relationship between medicine and psychology was undergoing an historic realignment. Joe had a fascinating and exciting perspective on the nature of such relationships and on psychology's potential to make those relationships mutually rewarding for both patients and practitioners. I consider myself fortunate to have been "in the right place at the right time" when a request came from the Division of Cardiothoracic Surgery for psychological and psychiatric consultation on a problem that was mystifying the surgeons.

Under the leadership of Albert Starr, surgeons were performing groundbreaking procedures known as "open heart surgery" on patients who had been incapacitated, typically for many years, by their heart conditions. These surgeries offered them the opportunity to reclaim their earlier lives as active members of society, and, in some cases, to take on roles that were denied to them since childhood. Paradoxically, following surgery, many patients, rather than expressing their gratitude for the opportunity to be "made whole again," become angry, depressed, and suicidal. With colleagues from the departments of psychology and psychiatry, we begin a search for the "underlying mental illness" that must have been uncovered by the stress of the surgery. However, rather than discovering the presence of psychiatric illness, it was found that the *absence of psychological strength* was a key factor associated with the behavioral anomalies. This finding led to the development of a program to psychologically evaluate a candidate's readiness to undergo surgery and to better prepare psychologically vulnerable candidates for the recovery experience.

My dissertation on psychological adjustment following open heart surgery led me to the Division of Psychosomatic Medicine in the Department of Psychiatry at the Johns Hopkins University School of Medicine, and to the application of psychodynamic theory to problems as diverse as diabetes, cardiovascular disease, cancer, and transgender surgery. In 1974, I accepted a position at the National Heart, Lung, and Blood Institute (NHLBI) of the National Institutes of Health (NIH) as chief of a unit that would eventually become the Behavioral Medicine Branch. The first year was *very* difficult since I was essentially the only behavioral scientist at NHLBI, and no one understood exactly what I was supposed to do and why I was there. However, I considered this to be a singular opportunity to bring the behavioral and biological sciences together, if only we could come up with a model, a theoretical framework that made sense to both groups and was scientifically viable.

Good problem-solving strategies break the overall problem down into more manageable pieces. The first was to address the lack of fundable studies in the NHLBI portfolio, which comprised a total of four regular research grants (R01s). The institute director commented to me that behavioral scientists must not be very good scientists as their applications were routinely disapproved or failed to make the funding payline. However, investigation revealed that the 25 "behavioral" applications submitted for the current round were scattered among 14 different study sections. Two issues became evident: (1) many of the behavioral applications were biologically weak and (2) the multidisciplinary expertise necessary to properly review applications that had both behavioral and biological endpoints was missing from the various study sections to which the applications had been assigned.

It became clear that two efforts were needed. First, it was necessary to make both biomedical and behavioral scientists aware of the need for a collaborative "biobehavioral" approach involving top-tier expertise in both areas when submitting grant applications. Second, it was necessary to campaign within the NIH for a study section that could provide relevant peer review for these biobehavioral applications. NIH agreed to convene an "ad hoc" temporary review group (the Behavioral Medicine Study Section) to assess whether there really was a need for such a group. Clearly there was, since 3 years later the study section was formally chartered as a standing study section.

Meanwhile, it became obvious that to develop and sustain meaningful research programs within the NIH would require organized, active, outside constituencies of scientists and clinicians who could provide peer review to all aspects of NIH program development and scientific leadership, i.e., partnerships with academic and professional societies that could provide advice and guidance were needed. With specific regard to biobehavioral research, the need for credible representation led us to Neal Miller, a behavioral scientist who was well known to, and highly respected by, the biomedically oriented Institute staff. Neal had performed landmark studies of learning and biofeedback. He was persuaded to serve as keynote speaker for the 1975 NHLBI Working Conference on Health Behavior. The 3 days of intensive deliberations between senior behavioral and biomedical scientists were

summarized and published as a proceedings to serve as the public blueprint for the Institute's future biobehavioral scientific agenda.

Along with the 1977 Yale Conference on Behavioral Medicine sponsored by NIH, this meeting set the stage for a 1978 organizational meeting hosted by David Hamburg, President of the Institute of Medicine of the National Academy of Sciences. The deliberations of this two-day gathering of highly respected biomedical and behavioral scientists gave birth to two organizations, the Society of Behavioral Medicine (SBM) and the Academy of Behavioral Medicine Research (ABMR). The founding leaderships of these organizations agreed to be complementary rather than competitive in mission and purpose, with SBM serving both scientific and professional interests of all persons interested in the field and ABMR being a small invitation-only group of distinguished senior scientists dedicated to identifying and promoting "gold standard" science in behavioral medicine. SBM created a newsletter that became the high-quality scientific and professional journal *Annals of Behavioral Medicine*, and ABMR published an annual volume, *Perspectives on Behavioral Medicine*, summarizing scientific presentations at their annual retreat meeting.

During this early developmental period, a potentially divisive issue arose among the cadre of behavioral medicine pioneers: Exactly what is meant by the term "behavioral medicine?" Agreement on a common definition of the field was clearly necessary. One contingent defined behavioral medicine primarily as "behavior modification with medical patients," while another contingent took a broader view which included the aforementioned aspect, but challenged both the behavioral and biomedical communities to join forces as "the interdisciplinary field concerned with the development and integration of behavioral and biomedical science knowledge and techniques relevant to the understanding of health and illness, and the application of this knowledge and these techniques to prevention, diagnosis, treatment and rehabilitation." The latter became the agreed-upon definition by both behavioral medicine organizations and survived intact for a decade until the founders of the International Society of Behavioral Medicine proposed in 1990 that "psychosocial" be added to "behavioral and biomedical" to better align the definition with the charters of the emerging European national and regional behavioral medicine organizations.

The underlying concepts of behavioral medicine are perhaps thousands of years old. Prior to the emergence of behavioral medicine in the mid to late 1970s, the most recent effort to capture mind-body interactions can be attributed to those engaged in research and practice of psychosomatic medicine. Primarily psychodynamically oriented psychiatrists, they began to take note of behavioral medicine, initially identifying the fledgling organizations with the first definition mentioned previously (behavior modification with medical patients) whereas their interests were principally focused upon how the principles of psychoanalysis could be applied to the treatment of somatic disorders. However, as the second definition gained traction among the rank and file of the behavioral medicine community, psychosomatic medicine scientists and practitioners were challenged to either resist or join forces with the newcomers. Over the next decade, it became clear that, while

psychoanalytic theory was intellectually provocative, it lacked the tools of modern day science to test its theories, and hence such theorizing remained in the realm of speculation. Behavioral medicine, on the other hand, took full advantage of the new monitoring instrumentation generated in large part by the U.S. space program's need for ambulatory monitoring of physiological processes via telemetry. Such instrumentation facilitated exploration in the laboratory and in real life of how variation in biological processes may be stimulated by behavioral inputs, as well as how biological processes may impact behavior. Over the next 20 years, the membership of the American Psychosomatic Society and the organization's flagship journal, *Psychosomatic Medicine*, shifted their emphasis to one indistinguishable from that of organized behavioral medicine.

During this time, biobehavioral scientific programs were beginning to develop within several institutes at NIH, and funding for biobehavioral research increased exponentially, albeit unevenly. An inter-institute Committee on Health and Behavior was formed, with Matilda White Riley from the National Institute on Aging as its first chair. This committee served in an advisory capacity to the individual institute directors as well as to the NIH director, becoming the precursor for the Office of Behavioral and Social Science Research, Office of the Director, NIH, which is now under the leadership of Robert Kaplan, past president of both SBM and ABMR.

Although research funding was increasing, another challenge became evident: Where were the *training* resources to support new entrants to the field? Typically, research training programs in the biological and biomedical sciences relied on NIH support; it became obvious that such resources needed to be developed to establish a pipeline for "biobehavioral" scientists-in-training to receive both individual and institutional support. Donald Cannon, chief of the training branch at NHLBI, the unit responsible for supporting both types of awards at NHLBI became interested in the issue, and met with senior behavioral medicine researchers who could apply for such awards based on their research programs and the resources of their institutions. Over the next 3 years, 12 institutional awards were made to support cardiovascular behavioral medicine training for both behavioral/social scientists and biomedical/biological scientists, further solidifying the scientific base for the field.

These developments within the United States were mirrored in other parts of the Western world, with emerging organizations in several European countries grappling with the relevance of the behavioral medicine concept to their perspectives on health and illness. In the mid-1980s, discussions at an SBM annual conference with international attendees resulted in an agreement to form an International Society of Behavioral Medicine (ISBM) dedicated to supporting the emergence of new as well as existing national and regional behavioral medicine organizations. Funds to support several planning meetings were provided by the Rockefeller family and the Duke University Behavioral Medicine Research Center, and the first International Congress of Behavioral Medicine took place in 1990 in Uppsala, Sweden. The International Society (members are national or regional societies rather than individuals) represented seven national and regional societies at this first

meeting. *International Journal of Behavioral Medicine* became the scientific outlet for behavioral medicine studies of international relevance. By 2012, 26 (and counting. . .) national/regional societies from every continent formed the membership of ISBM.

Finally, one important element of the behavioral medicine paradigm deserves mention, as it is illustrative of the basic conceptual infrastructure of biomedical and behavioral *integration*. Often, biomedical and behavioral scientists pose the question of treatment efficacy in terms of which is more effective, pharmacologic or behavioral treatments. Rather than "either/or," the behavioral medicine position is to determine how both treatments, perhaps in combination or in sequence, may provide a more effective treatment than either alone. Several examples come to mind, for example, smoking cessation, hypertension treatment, and cardiovascular disease prevention. Using a drug to lower blood pressure or cholesterol can provide a window of opportunity to use non-pharmacologic strategies to maintain lowered blood pressure/cholesterol, thereby reducing/eliminating reliance on the medication. Smoking cessation programs typically are more effective when both behavioral and pharmacologic treatments are combined to sustain cessation. Pharmacologic agents are typically more efficient at creating the desired effect but may have long-term side effects; behavioral treatments may be less efficient at creating change but may be more effective at sustaining conditions that have been achieved pharmacologically. The bottom line is straightforward: Rather than asking which approach is superior, use the strengths of both areas of science creatively to achieve a sustainable treatment effect that minimizes unwanted side effects and could not be attained by using either approach by itself.

In summary, I have tried to provide a few personal insights into the events leading to the formalization of behavioral medicine as a viable, vibrant perspective on the promotion of health and the prevention and treatment of disease and as the multidisciplinary inquiry into the underlying mechanisms involving brain, genes, behavior, and physiology/biology. I hope that this provides a useful historical "snapshot" as you immerse yourself in the impressive array of accomplishments chronicled in this encyclopedia.

The following Foreword by Neil Schneiderman presents a personal view of behavioral medicine's future.

A Personal View of Behavioral Medicine's Future

The field of behavioral medicine appears to have a bright, important future. That is because contemporary scholarship in behavioral medicine has been constructed upon a solid foundation consisting of basic biological and behavioral science, population-based studies, and randomized clinical trials (RCT). The edifice that is emerging derives its strength and form from its interdisciplinary structure. It derives its reach and potential for future growth from its selection of key building materials and tools including the study of etiology, pathogenesis, diagnosis, treatment, rehabilitation, prevention, health promotion and community health. Because behavioral medicine approaches to prevention, treatment, and health promotion involve important relationships among behavior, psychosocial processes, and the sociocultural context, the roof of this structure will both consist of and benefit from the support of informed patients and populations, thoughtful educated health-care providers and involved communities.

Let us begin with population-based studies. During the second half of the twentieth century, epidemiological studies described important associations between traditional risk factors on the one hand and morbidity and mortality on the other, but elucidated relatively few of the variables mediating these associations. In my own area of cardiovascular disease (CVD) research, considerable attention has now focused upon obesity, inflammation, insulin resistance, oxidative stress, and hemostatic mechanisms as potential mediators. In this respect, traditional large-scale multicenter population-based studies have done a better job of describing the association between traditional risk factors (abnormal lipids, hypertension, smoking, diabetes, age) and CVD and their putative mediators than they have in describing the associations between biobehavioral, psychosocial, and sociocultural risk factors and CVD, and their mediators. However, this is now beginning to be addressed in such National Institute of Health (NIH) multicenter studies as the Hispanic Community Health Study/Study of Latinos (HCHS/SOL), Coronary Risk Development in Young Adults (CARDIA), and Multi-Ethnic Study of Atherosclerosis (MESA). Some of these studies are employing such preclinical measures of disease as carotid intimal-medial wall thickness and plaque by ultrasonography and coronary artery calcium by computed tomography to examine the progression of disease processes relating risk factors and CVD.

The examination of preclinical markers of disease as mediators between biobehavioral, psychosocial, and sociocultural risk factors on the one hand and chronic diseases on the other has been facilitated by the availability of

commercial assays. These assays have permitted the study of biomarkers involved in preclinical disease processes including adhesion molecules, pro-inflammatory cytokines, and oxidative stress in both animal and human studies. We can expect that many further advances will be made in the development of commercially available research methods and that they will increase our understanding of relationships among biobehavioral, psychosocial, and sociocultural risk factors and the pathophysiology of CVD, cancer, and other chronic diseases.

Although a wide range of epidemiological studies have called attention to potentially modifiable risk factors, and most chronic disease risk factors are modifiable (Yusuf et al., 2004), it should be recognized that chronic disease outcomes are the result of the joint effects of risk genes, the environment, and behavior upon these risk factors. One can therefore expect that on the basis of genomic analyses, future studies will begin to identify the extent to which particular individuals are vulnerable to specific risk factors and diseases and may be candidates for targeted behavioral as well as pharmacological interventions. Thus, in the coming era of personalized or tailored medicine, we may expect that behavioral medicine research will play an important role both in understanding the antecedents of disease that interact with genomic predispositions and in selecting appropriate treatment interventions.

The future for behavioral medicine science playing an essential role in population-based observational studies appears to be inevitable. This will occur because both the fields of behavioral medicine and epidemiology have expanded their horizons based upon important scientific findings. Early epidemiological studies focused upon hygiene and infectious diseases. By the middle of the twentieth century, epidemiological studies were examining the prevalence of multiple risk factors (e.g., smoking, dyslipidemia, hypertension) and disease outcomes (e.g., coronary heart disease [CHD], stroke, cancers). However, more recent multicenter observational studies have increasingly identified behavioral, psychosocial, and sociocultural variables as potential risk factors for chronic diseases. Thus, future multicenter observational studies will likely include demographic (e.g., racial/ethnic background, sex, socioeconomic status, neighborhood environments), psychosocial (e.g., temperament and personality, marital and work stressors, social support), lifestyle (e.g., medication adherence, diet, sleep, physical activity, smoking), biomarkers (e.g., immune, inflammatory, hemostatic, imaging), and genomic factors that influence disease outcomes. An important trend that is likely to increase in the future is the development of consortia of population-based studies (e.g., Population of Architecture using Genomics and Epidemiology: PAGE) whose purpose is to investigate mature genetic variants associated with complex diseases in large diverse populations. Such consortium studies are each beginning to include well over 100,000 participants. Perhaps most importantly the constituent studies and the consortia will be able to follow participants over the course of many years, providing important incidence data that will allow us to examine the specific causal variables influencing the course of disease. This represents an important opportunity for behavioral medicine scientists.

Traditional observational studies have often reported findings using odds ratios, which provide estimates (with confidence interval) for the relationship between binary variables. Such studies have also permitted assessment of the effects of other variables on specific relationships using regression analyses. More recently, scientific interest in understanding the role of potential mediators of relationship between risk factors and disease outcomes has increasingly led to the use of analytic techniques such as structural equation modeling including path analysis, which until now have mostly been used in the social sciences. We can expect that a dramatic improvement in our understanding of the mediators between risk factors and disease outcomes will occur in the coming years.

The completion of the Human Genome Project in 2003 led to an increased interest in gene-environment interactions within the behavioral medicine research community. Such interactions occur when genetic factors affect measured phenotypes differentially, for example, when men with the E4 allele of the apolipoprotein E gene (APOE) were shown to have an increased smoking related risk for CHD events (Humphries et al., 2001). Other studies have shown that the interaction of the alpha 2ß-adrenergic receptor polymorphism with job strain is related to elevated blood pressure (Ohlin et al., 2007), and several other studies have related gene polymorphisms with cardiovascular reactivity to mental challenge. Most behavioral studies that have examined gene-environment interactions have been carried out on relatively small samples, but it appears inevitable that a large number of high-quality, well-powered, gene-environment studies of direct relevance to behavioral medicine will be initiated during the next few years.

In addition to the structural genomics exemplified in gene-environment interaction studies, functional genomic studies are also likely to become of increasing interest to behavioral medicine investigators. Briefly, functional genomics focuses on the basics of protein synthesis, which is how genes are "switched on" to provide messenger RNA (mRNA). Francis Crick, who along with James Watson discovered the structure of the DNA molecule, originally thought that each gene, consisting of a particular DNA sequence, codes for one specific mRNA molecule that in turn codes for a specific protein (Crick, 1970). Subsequently, it became evident that after being transcribed, most mRNA molecules undergo an editing process with some segments being spliced out. In this way, a gene can lead to more than one type of mRNA molecule and consequently more than one type of protein. Thus human cells, which each contain about 25,000 genes, are able to synthesize more than 100,000 different proteins.

Epigenetics refers to the altering of gene function without changes in the DNA sequence. This can occur either by methylation of the DNA itself or by remodeling of the chromatin structure in which the DNA is packaged. Because of these processes, in utero exposure to nutrition or social factors can cause permanent modification of gene expression patterns that may lead to increased risk of mental disorders, diabetes, cancer, or cardiovascular diseases (Jirtle & Skinner, 2007). As an example of how social exposure in early life can have long-duration epigenetic and phenotypic influences, Meaney and Szyf (2005) showed that neonatal rodents who received high

levels of postpartum nurturing revealed diminished cortisol responses to stressful experiences when they reached adulthood. Such studies are providing a strong basis for future epigenetic behavioral medicine research.

The important advances made by observational and mechanistic studies relevant to behavioral medicine research are paralleled by a few RCT that have provided evidence that behavioral interventions aimed at modifying lifestyle or psychosocial variables can help prevent morbidity and/or mortality in high-risk populations. Thus, for example, the Diabetes Prevention Program trial (Knowler et al., 2002) in the United States and the Finnish Diabetes Prevention Trial (Tuomilehto et al., 2001) each observed that lifestyle interventions targeting weight loss and an increase in physical activity can reduce the incidence of diabetes in prediabetic patients. Based upon the success of these trials, the NIH has sponsored Look AHEAD (Action for Health in Diabetes), an RCT that is scheduled to last for 11.5 years. This trial is specifically examining whether an intensive lifestyle intervention similar to that used in the Diabetes Prevention Program can prevent major CVD events in obese participants with type 2 diabetes. Whereas the diabetes prevention projects and the Look AHEAD trial are essential for establishing that lifestyle interventions can prevent type 2 diabetes and reduce CVD risk in diabetic patients, subsequent investigation will be needed for us to learn how such interventions can be applied to clinical practice.

Although psychosocial-behavioral RCT conducted upon patients following major adverse coronary events (e.g., myocardial infarction) have yielded both positive and null results, the three major trials that have reported positive results share important similarities that differentiate them from the studies reporting null results (Friedman et al., 1986; Gulliksson et al., 2011; Orth-Gomér et al., 2009). Thus, the participants in the three major RCT reporting positive results all received group-based cognitive behavior therapy that included, in addition to cognitive behavior therapy, relaxation training and attention to lifestyle problems. The interventions all included up to 20 sessions over a year or more and used therapists specifically trained to use behavior change techniques in order to conduct behavioral interventions with cardiac patients. Treatment began at least several months after the CHD event and patients were followed up for an average of 4.5–7.8 years. Although the trials yielding positive results each studied between 237 and 862 participants, the size of each study was insufficient to permit assessment of the efficacy of specific intervention components, the role of potential biological mediators or the applicability of the intervention to populations differing in terms of important demographic characteristics. Thus there is still a need to replicate and amplify the results of the previously successful trials in rigorous, large-scale, multicenter RCT that can identify the demographic, psychosocial, and lifestyle variables that influence specific behavioral and biological determinants of risk.

In the future, evidence-based medicine will play an ever-increasing role in clinical health care. The extent to which behavioral medicine can become a successful part of health-care delivery systems will in large part depend upon investigators in the field being able to master clinical translational

research, moving from efficacy to effectiveness with a high ratio of benefit to cost. Thus, for example, the Diabetes Prevention Program (Knowler et al., 2002) showed that in high-risk patients, a lifestyle intervention reduced the incidence of diabetes significantly better than a pharmacological intervention and that both interventions were superior to a placebo condition. However, the lifestyle intervention was labor intensive and required considerable effort to get participants to maintain improvement. In contrast, maintaining adherence to taking a pill once daily may pose a less daunting task. However, recent advances in web-based intervention research may level the playing field. Thus, automatic e-mail reminders, phone or e-mail based consultations with a health-care professional, interaction with web-based programs, and the instant availability of important specially tailored information on an interactive website can all help patient adherence. To the extent that weight loss programs that involve diet and exercise do more than only decrease the risk of type 2 diabetes but also improve other aspects of CVD risk, such programs are particularly valuable in terms of health promotion.

The RCT that decreased morbidity or mortality rate in CHD patients each required 20 or more group-based sessions (Friedman et al., 1986; Gulliksson et al., 2011; Orth-Gomér et al., 2009). When amortized over the length of the 4.5–7.8 year follow-up period, however, the cost compares favorably with that of most drugs also used in treatment. Participating in 20 or more sessions also poses a personal cost and some hardship for many people. However, the implementation of interactive web-based group sessions using both sound and video could obviate the need for most face-to-face meetings and allow interpersonal interactions to continue over long periods of time. It therefore seems apparent that the rapid advances taking place in science and practice during the internet era will prove helpful in making behavioral medicine an important ingredient of future health-care systems.

Future health-care systems could be strengthened by well-informed patients and by health-care providers who are grounded in behavioral medicine concepts as well as clinical medicine. Attention to the human and health-influencing aspects of neighborhoods (i.e., the built environment) are also important and dependent on informed public policy. Because Behavioral Medicine has been constructed based on the understanding of relationships among behavior, psychosocial processes, and sociocultural contexts, the field is well positioned to take a leadership role in informing future health-care policies. The field of behavioral medicine appears to have a bright, important future.

Preface

The establishment, advancement, and maturation of the field of behavioral medicine bears witness to interest among research scientists, clinicians, and policy makers in psychological, behavioral, and social influences on health and disease from the perspective of both the individual patient and global public health. It has become increasingly clear that such influences may negatively impact health and well-being and, equally importantly, that behavioral interventions may be protective and curative.

Neal Miller (1909–2002), an American psychologist and recipient of the National Medal of Science in 1964, is often credited as being the founder of behavioral medicine. He made significant contributions to our understanding of the relationship between reinforcement mechanisms and the control of autonomic behavior, and in pioneering the field of biofeedback, which is used successfully today to treat a variety of medical conditions. The original definition of behavioral medicine was developed at the Yale Conference on Behavioral Medicine and later published by Gary Schwartz and Stephen Weiss (1977):

> "Behavioral medicine" is the field concerned with the development of behavioral-science knowledge and techniques relevant to the understanding of physical health and illness, and the application of this knowledge and these techniques to diagnosis, prevention, treatment and rehabilitation.

While this definition remains the cornerstone of our interdisciplinary and integrative field, developments in many relevant subfields have advanced at rapid rates, and whole new specialties have arisen. This evolution was well exemplified by the publication in 2010 of the *Handbook of Behavioral Medicine* (Steptoe, 2010). Relevant knowledge and understanding of issues of interest in behavioral medicine is now contributed by the disciplines of and expertise from anthropology, behavioral and molecular genetics, behavioral science, biostatistics, clinical medicine, cultural studies, epidemiology, health economics, general medicine, genomics, psychiatry, psychology, physiology, public health and public health policy, and sociology, to name but a few. It was therefore considered an opportune and appropriate time to create the *Encyclopedia of Behavioral Medicine*, whose publication coincides with the 12th International Congress of Behavioral Medicine, held on August 29th to September 1st, 2012, in Budapest, with attendees representing multiple disciplines and many countries around the globe. The theme of

the meeting is "Behavioral Medicine: From Basic Science to Clinical Investigation and Public Health," the theme around which this *Encyclopedia* has been developed.

Accordingly, the *Encyclopedia* contains entries falling into three categories or domains that represent issues of interest: basic research, clinical investigation and practice, and public health and public health policy. The domain of basic research addresses the key questions of mechanisms of action, both in terms of how behavior can have a deleterious impact on health and how a change in behavior can be beneficial, either preventively or therapeutically. The domain of clinical investigation and practice translates this basic knowledge into clinical interventions on a patient-by-patient basis. Finally, the domain of public health and public health policy takes a broader view of how behavioral medicine research and interventions can impact the health of populations at the community, regional, national, and global levels. This includes addressing the system-wide/public education and advocacy/political activities that are needed to facilitate maximum benefits at the global level.

It can immediately be seen that behavioral medicine is indeed a multidisciplinary and interdisciplinary field. Researching mechanisms of action requires a detailed level of human biology, starting from the molecular genetic level and progressing from cellular to organ to whole-body study. A thorough understanding of environmental interactions with biological functioning is also necessary. The domains of basic research and clinical investigation and practice are linked by the increasingly important concept of translational medicine, that is, how to translate our mechanistic knowledge and understanding into successful clinical interventions most effectively and efficiently. The final challenge, likely the most challenging but ultimately providing the greatest benefit, is to address these interventions at the public health level.

Within these overarching categories, it is possible to group together various entries into categories of interest to individual readers or groups of readers pursuing their own research in cross-cutting areas. One example might be the impact of behavioral medicine research and interventions across the life span, that is, taking a life cycle approach. Entries in the *Encyclopedia* such as Children's Health Study, Elderly, End-of-Life Care, Geriatric Medicine, Life Span, Obesity in Children, and Successful Aging might be instructive in this case.

A second example might be looking at genetic predisposition to the deleterious impact of environmental factors and, equally of interest, to the therapeutic benefit of certain behavioral medicine interventions. Entries of interest here might be Family Studies (Genetics), Gene-Environment Interaction, Gene Expression, Genome-wide Association Study, and Twin Studies. While not always intuitively obvious, one of the most powerful ways to study the effects of environmental (behavioral) factors on a phenotype of interest (e.g., a given disease state or condition of clinical concern) is to study genetic influence on that phenotype (Plomin et al., 1997). Having done so, it is possible to remove from consideration the individual variation attributable to genetic influence and hence to focus on variation attributable to

environmental and gene-environment interaction influences. We are certain that readers will find many such groupings of entries relevant to their own interests and research.

Additional evidence of the growth of the discipline of behavioral medicine is provided by the fact that training in the field can be found in universities around the world, ensuring that the next generation of researchers and practitioners will be trained by current experts. Before going on to specialize in behavioral medicine research or clinical practice, individuals often receive their terminal degrees in disciplines such as medicine, public health, nursing, and psychology. Such diversity is a tremendous strength in this interdisciplinary field.

Like all such printed endeavors, the *Encyclopedia* proves a "snapshot in time" of its subject. Research during the past 30 years has provided the solid foundation from which future advances will be made, and it will be of great interest to all of us in behavioral medicine to follow its further development. We are grateful to Stephen Weiss for providing a Foreword entitled "Early Developments in the Field of Behavioral Medicine," which reviews important events in the discipline's evolution, and to Neil Schneiderman for providing a Foreword entitled "A Personal View of Behavioral Medicine's Future," which provides an insightful view of likely trajectories and benefits of our discipline. We hope that subsequent editions will provide additional snapshots in due course.

The conceptualization, writing, and publication of the *Encyclopedia of Behavioral Medicine* occurred over a 4-year period. The idea originated with our attentive and thoughtful Senior Editor from Springer, Janice Stern. Without Janice's forward thinking this *Encyclopedia* would not have materialized, and we are deeply grateful for her vision and support throughout its development. She first approached me (MDG) at the International Congress of Behavioral Medicine held in Tokyo, in August 2008. At the time it seemed to be a formidable task, to compile all of the terms that are used in the field of behavioral medicine into an A–Z compendium. My next meeting with Janice occurred in Montreal at a Society of Behavioral Medicine meeting during spring 2009. It was at that time my co-editor (JRT) had agreed to join forces with me in this effort. We then set about creating an advisory board, comprised of leading international experts in the field of behavioral medicine, and selecting our outstanding group of associate editors. They come from various parts of the world and permit this work to be truly an international collaboration. Without their hard work and dedication to this project we would not have the *Encyclopedia of Behavioral Medicine* in the form that you see it. They assisted in the selection of the terms that are included in the *Encyclopedia* and in the selection of the authors who developed each of the entries: our sincere thanks to all of you. We are indebted to the Springer Major Reference Works team including Anil Chandy, Tina Shelton, and Meetu Lall. This is the team that kept us organized, on task, and was instrumental in so many ways in bringing the *Encyclopedia* to fruition.

My journey in the interdisciplinary field of behavioral medicine has allowed me to delve into the fields of epidemiology, medicine, neuroscience, psychology, pharmacology, physiology, and public health. Throughout this entire journey, my mentor and teacher, Neil Schneiderman, has shaped my career. From my time as an undergraduate student, through graduate school, a postdoctoral fellowship, and on to becoming a faculty member, I have been fortunate to be by Neil's side. For this, first and foremost, I would like to acknowledge and dedicate this *Encyclopedia* to him.

To my wife Jill Turner, who has been by my side throughout the development of the *Encyclopedia*, I could not have done this without your patience and support.

MDG

I moved to the United States in 1987 to join Paul Obrist's group at the University of North Carolina at Chapel Hill. I met Neil Schneiderman shortly

thereafter, and he has been a great source of personal and professional support since that time. I am delighted that Marc has dedicated the *Encyclopedia* to him. I would like to acknowledge the scientific training I received at the University of Sheffield and the University of Birmingham. My doctoral work in cardiovascular psychophysiology and cardiovascular behavioral medicine was conducted in Birmingham under the supervision of Doug Carroll, with John Hewitt providing additional guidance in the fields of Statistics and behavioral genetics.

I would also like to thank my wife Karen for her support during the preparation of the *Encyclopedia*.

About the Editors

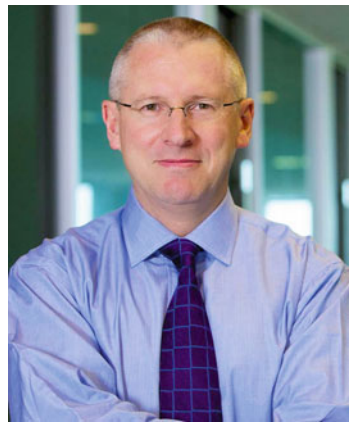
Marc D. Gellman is a Research Associate Professor of Psychology and the Associate Director of the Division of Health Psychology, Department of Psychology, University of Miami, Florida, USA. He is also Associate Director of the Behavioral Medicine Research Center and Associate Director of the Behavioral Medicine Training Program located at the Miller School of Medicine, University of Miami, where he holds a secondary appointment in the Department of Medicine. He has been a member of the faculty of the University of Miami since 1986. Dr. Gellman received all of his formal training (B.S., M.S., and Ph.D. degrees) from the University of Miami.

Since 1986, he has been continuously funded by the National Institutes of Health, primarily in the area of cardiovascular behavioral medicine. Dr. Gellman has published in a variety of journals including: *Psychosomatic Medicine*, *Health Psychology*, *Annals of Behavioral Medicine*, *Psychophysiology*, and others. Dr. Gellman currently serves on the editorial advisory board for the McGraw-Hill *Annual Editions: Drugs, Society, and Behavior*. He previously served on the editorial board of the Sage Publications scientific book series Behavioral Medicine and Health Psychology from 1997 to 2004, edited by J. Rick Turner, his co-editor for this *Encyclopedia*.

Dr. Gellman is a former board member of the International Society of Behavioral Medicine, serving as its secretary 2004–2008 and chair of the communications committee 2000–2004. From 2004 to 2006, he served as program co-chair for the International Congress of Behavioral Medicine. Dr. Gellman is a longtime board member of the Society of Behavioral

Medicine, serving in various capacities from 1996 to 2007. He continues to serve as a member of the Wisdom Council for the Society of Behavioral Medicine. Dr. Gellman is the recipient of the Distinguished Service Award from the Society of Behavioral Medicine and the Outstanding Service Award from the International Society of Behavioral Medicine. Dr. Gellman is a Fellow of the Society of Behavioral Medicine. He is also a member of the American Psychological Association, the American Psychosomatic Society, the Society of Behavioral Medicine, and the International Society of Behavioral Medicine.

In his spare time, he is an avid bicycle rider and enjoys "out of car experiences" with his wife Jill, touring numerous countries on their tandem bicycle. He is a wine aficionado, an enthusiast of rock, jazz, and reggae music, and occasionally lectures on the influence drugs have on culture, being inspired by his attendance at the historic Woodstock Music and Art Festival in 1969.



Rick Turner is Senior Scientific Director, Cardiovascular Safety, at Quintiles, a fully integrated biopharmaceutical services provider. He joined Quintiles after serving as the chairman of the Department of Clinical Research at the Campbell University School of Pharmacy. Prior to that, he was a principal clinical submissions scientist at GlaxoSmithKline, where he received awards for his work on the GlaxoSmithKline Clinical Trial Registry and in product development. He is also Senior Fellow, Center for Medicine in the Public Interest, and President and Chief Scientific Officer, Turner Medical Communications LLC.

Dr. Turner received his Ph.D. in psychophysiology and cardiovascular behavioral medicine from the University of Birmingham, United Kingdom, where he trained under Douglas Carroll. Following a postdoctoral fellowship there, he moved to the University of North Carolina at Chapel Hill to work in the laboratory of the late Paul Obrist and Kathleen Light. His work in the field of cardiovascular behavioral medicine led to 50 peer-reviewed publications and the receipt of two international research awards, the 1998 Distinguished

Scientific Award for an Early Career Contribution to Psychophysiology from the Society for Psychophysiological Research and the 1993 Early Career Award for Contributions to Psychosomatic Medicine from the American Psychosomatic Society. He is the author of the 1994 book *Cardiovascular Reactivity and Stress: Patterns of Physiological Response*, and was a coeditor of the book *Health and Behavior in Childhood and Adolescence*, which received a 2003 *American Journal of Nursing* Book of the Year Award. He became a Fellow of the Society of Behavioral Medicine in 1999.

Since entering the biopharmaceutical industry, Dr. Turner has published extensively in peer-reviewed and professional journals, and authored six books addressing methodological and statistical aspects of randomized, concurrently controlled clinical trials. He was a participant in the 2010 National Heart, Lung, and Blood Institute Clinical Trials Symposium, giving an invited presentation entitled "The Power of the Randomized, Concurrently Controlled Clinical Trial," and he travels extensively to provide clinical trial consulting services to biopharmaceutical companies worldwide and deliver presentations on drug safety topics at international scientific conferences.

Dr. Turner is particularly interested in the development of drugs for type 2 diabetes mellitus. He has testified before two U.S. Food and Drug Administration committees, the Endocrinologic and Metabolic Drugs Advisory Committee and the Drug Safety and Risk Management Advisory Committee, and is working with both biopharmaceutical companies and regulators to expedite the development of drugs for this disease. He is also an advocate of increasing adherence to drugs for all chronic diseases, including diabetes, by greater use of knowledge and strategies developed in the field of behavioral medicine.

Dr. Turner is on the editorial board of the peer-reviewed *Journal for Clinical Studies* and is editor-in-chief of the peer-reviewed *Drug Information Journal*.

Abrams, David B. (1951–)

David B. Abrams
Johns Hopkins Bloomberg School of Public Health, The Schroeder Institute for Tobacco Research and Policy Studies at Legacy, Washington, DC, USA

Biographical Information

David Abrams was born in Johannesburg, South Africa, on September 6, 1951. He married Marion Wachtenheim in 1981. He has three children, Tanya, Aaron, and Daniel, who passed away in 2008. He holds a B.Sc. (honors) degree in computer science and psychology from University of Witwatersrand, Johannesburg, South Africa (1974), during which time he studied under Alma Hannon (who also taught Joseph Wolpe, Arnie Lazarus, Terry Wilson, and Ray Rosen). Abrams completed his doctorate in clinical psychology under Terry Wilson at Rutgers University, earning

M.D. Gellman & J.R. Turner (eds.), *Encyclopedia of Behavioral Medicine*,
DOI 10.1007/978-1-4419-1005-9,

his Ph.D. in 1981, and his internship under David Barlow at Brown University in 1979. Joining the new Division of Behavioral Medicine at Miriam Hospital, founded by Michael Follick, Abrams was the first coordinator of the Behavioral Medicine Risk Factors Clinic.

Abrams is currently Professor, Department of Health, Behavior and Society at The Johns Hopkins Bloomberg School of Public Health and Executive Director of the Schroeder Institute for Tobacco Research and Policy Studies at Legacy®. From 2005 to 2008, he directed the Office of Behavioral and Social Sciences Research (OBSSR) at the National Institutes of Health (NIH). From 1978 to 2004, Abrams rose through the ranks at Alpert Medical School of Brown University, becoming Professor of Psychiatry and Human Behavior, Professor of Community Health, and founding Director of the Transdisciplinary Centers for Behavioral and Preventive Medicine. Abrams is a licensed clinical psychologist specializing in health psychology, tobacco use behavior, addictions, and lifestyle and contextual pathways to population health, conceptualized from a transdisciplinary "systems" framework.

In 1969, Abrams received the Old Parktonian university scholarship from Parktown Boys High School and the IBM undergraduate computer science award in 1973. He has published over 250 scholarly articles. He is the lead author of *The Tobacco Dependence Treatment Handbook: A Guide to Best Practices*, a recipient of a book of the year award. Abrams was a member of the Board of Scientific Advisors of the National Cancer Institute and served on several committees for the Institute of Medicine of the National Academies. He received the Joseph Cullen Memorial Award from the American Society for Preventive Oncology for lifetime contributions to tobacco control. He was President of the Society of Behavioral Medicine in 2003 and a recipient of their Distinguished Scientist, Distinguished Research Mentorship, and Service awards. Abrams is a fellow of the American Psychological Association, The American Academy of Behavioral Medicine Research, The American Academy of Health Behavior, and the Society of Behavioral Medicine. He received the Musiker-Meranda award for contributions to mental health from the Rhode Island Psychological Association and a distinguished alumnus award from Rutgers University.

Major Accomplishments

Abrams is recognized for strategic and scientific contributions to disease prevention, particularly in tobacco control, addictions, and related risk factors. An integrative, "systems thinking" framework permeates his work. His accomplishments fall into two broad dimensions, reflecting the development of strategic research structures, frameworks, and organizations, and his personal research contributions.

He began his focus on strategic research frameworks in basic human physiology and human laboratory studies and in how basic science can inform clinical applications in behavior therapy. He then extended research to dissemination-implementation topics, focusing on worksites, the harnessing new informatics technologies, and the use of policy levers for large-scale impact on population health. John and Sonja McKinlay influenced his public health perspective on frameworks for making a cost-efficient (reach x effectiveness/cost) impact on populations. At Brown University, Abrams envisioned one of the early Transdisciplinary Centers for Behavioral and Preventive Medicine. He advocated for a Center with the organizational structure and function to foster the development of complex systems frameworks and simulation models to improve science-informed policy. He forged partnerships to integrate biopsychosocial and population sciences across disciplines, departments, and institutions.

In 1988, Abrams founded the Centers for Behavioral and Preventive Medicine, bridging basic, clinical, and public health sciences; medical school and campus departments; the Brown-affiliated teaching hospitals; and local institutions (University of Rhode Island; R.I. Dept. of Health). Abrams was instrumental in forging ties to obtain National Institutes of Health (NIH) grants and program project awards, the first of

which was founded in 1989 to establish one of the first National Cancer Institute (NCI) Cancer Prevention Research Units (CPRU). Abrams jointly codirected the CPRU for over a decade with James Prochaska and Wayne Velicer, University of Rhode Island. Regional collaborators were also added from Yale, Brandeis, Tufts, Boston, and Harvard Universities. Abrams was a member of the Robert Wood Johnson's Tobacco Etiology Research Network (TERN), where working with Richard Clayton, Dennis Prager, and the TERN team influenced his own research and vision for transdisciplinary science.

Over the years at Brown University, Abrams nurtured the Centers' faculty and the infrastructure that supported over 30 faculty and many trainees. The Centers evolved in the 2000s to house programs in the leading risk factors and major chronic diseases, including physical activity (Bess Marcus, Director); weight control, obesity, and diabetes (Rena Wing, Director); nicotine dependence and tobacco control (Ray Niaura, Director); and crosscutting programs in cancer, cardiovascular diseases, stress management, underserved populations, comorbidities across psychiatric, alcohol and substance abuse disorders, and HIV-AIDS. Teaching programs ranged from undergraduate and graduate classes to a health psychology internship and postdoctoral and early career fellowships supported by NIH training grant awards. From his arrival at Brown University in 1977 as a psychology intern to his departure in 2004 to become director of OBSSR at NIH, Abrams left a legacy and a culture of support, individual excellence and creativity, and a passion for transdisciplinary team collaboration to address complex problems in health behavior.

In 2005, Abrams was appointed Director of the Office of Behavioral and Social Sciences Research (OBSSR) and Associate Director of the National Institutes of Health (NIH). He was responsible for being the chief spokesperson for the NIH and the nation on matters of behavioral and social sciences and for advising the NIH Director, congress, and other government leaders on matters relating to the role human behavior plays in health and illness. He was responsible for strategic planning of behavioral and social sciences across all 27 of the NIH Institutes and Centers. Abrams spearheaded a new strategic prospectus for OBSSR with Alan Best, John McKinlay, and other consultants. He emphasized that the basic and applied sciences of behavior and behavior change are the bridge between biology and society. The social science scientific disciplines are as much a key to improving population health as are the biomedical and natural science disciplines. Abrams stressed the need for more collaborative interdisciplinary science, integrative thinking, and a robust systems science perspective to address complex pathways to disease prevention and health promotion.

Abrams added a communications office to the mission of OBSSR to showcase the achievements of the behavioral and social sciences across NIH. Returning to his undergraduate roots in computer sciences, he also embraced the use of new informatics, communications, computational, engineering, and mathematical modeling sciences as critical tools for the twenty-first-century transformation of the behavioral social and population sciences. Thus while at OBSSR, Abrams created a transdisciplinary vision for integrating "genomics" and "populomics" via epigenetics (the biological embedding of early experience) over the lifespan and across generations. The OBSSR strategic plan helped make visible and credible the investments in, and rigorous scientific contributions of, the behavioral, social, and population sciences to the NIH mission to improve the nation's health.

At Rutgers from 1974 to 1978, Abrams' early personal line of research interests blossomed under Terry Wilson's able mentorship, focusing on basic science of the cognitive-behavioral and physiological mechanisms in tobacco, alcohol use, and mood states (e.g., the role of stress and expectancy in alcohol and tobacco relapse risk). His masters thesis examined the reactivity of self-monitoring during smoking cessation, and in his doctoral dissertation and related studies, Abrams investigated pharmacological and expectancy effects of alcohol on physiological arousal, stress, and tension reduction theory (under Terry Wilson, Ray Rosen, and Peter Nathan). Moving

to Brown University, Abrams developed ideas (with Ovide Pomerleau) on use of standardized cue exposure and stress reactivity paradigms to elucidate basic mechanisms in nicotine dependence, craving, and relapse and thereby link human laboratory work to clinical treatment. Abrams also collaborated with Peter Monti to develop a parallel line of work in cue reactivity in alcohol use. Human laboratory research on cue reactivity and treatment implications has continued for over a decade with Ray Niaura and others taking a lead role, funded by the National Heart Lung and Blood Institute under Steve Weiss and Sally Shumaker.

Abrams branched out to work on self-help interventions to reach populations on a larger scale (dissemination/implementation and policy research) with grants from the National Cancer Institute under Tom Glynn. He developed and evaluated treatment programs at the worksite in a "systems" conceptual framework (with Lois Biener, Laura Linnan, Mike Follick, and Karen Emmons) to examine multilevel interactions of individual and cluster influences on behavior change in worksites. Abrams researched environmental and policy variables regarding secondhand smoke exposure with Karen Emmons and Bess Marcus. He conducted randomized controlled clinical trials of combined pharmacotherapy and behavior therapy treatment for smoking cessation with Michael Goldstein. In collaboration with Michael Follick, Abrams used randomized trials to evaluate worksite obesity treatments. They developed then evaluated an early form of the concept of harnessing intergroup competition and within-group cooperation to motivate weight loss among teams formed at worksites. Abrams research was consolidated when he became one of the principal investigators in a multicenter cooperative trial of cancer control at the workplace – the Working Well Project, funded by the NCI from 1989 to 1999.

Abrams also continued to collaborate on work in the addictions with interest in the comorbidity of alcohol-tobacco interactions with Damaris Rohsenow and in evaluating the physical activity to prevent weight gain in tobacco cessation treatment for women with Bess Marcus. Abrams helped develop the theme for a National Institutes of Alcoholism and Alcohol Abuse (NIAAA) conference on the need for a strategic research plan to examine alcohol-tobacco interactions from cells to society. He authored several chapters in the 1995 NIAAA conference monograph (No. 30) on Alcohol and Tobacco: from Basic Science to Policy.

In 1999, Abrams became a principal investigator of one of the seven NCI Transdisciplinary Tobacco Use Research Centers (TTURCs). He directed the TTURC with Ray Niaura and Steve Buka until appointed Director of OBSSR at NIH in 2005. This TTURC focused on phenotypes of tobacco use and related comorbidities to inform the intergenerational transmission of nicotine dependence and the tailoring of treatments. The TTURC followed up on the three generations of participants derived from the New England Cohort (originally with Lewis Lipsitt at Brown's psychology department) of the National Collaborative Perinatal Project, begun in 1959. Abrams continues to publish findings from the TTURC project with his colleagues, including a recent 2011 paper with Suzanne Colby on a lifetime measure of tobacco use patterns and trajectories, on generalizing from clinical trials to community samples with Amanda Graham, and on comorbidity of personality and alcohol and substance use disorders with Chris Kahler.

Abrams participated in a Robert Wood Johnson Foundation round table on consumer demand led by Tracy Orleans. He worked with David Levy on a series of computer simulation models to demonstrate the potential impact of putting what is known about evidence-based treatments and policies into widespread practice. These models informed Abrams membership in and contributions to the Institute of Medicine of the National Academies books "Bridging the Evidence Gap in Obesity Prevention (2010) and Ending the Tobacco Problem: A Blueprint for the Nation (2007)."

In 2008, Abrams became the Executive Director of the newly established Steven Schroeder

National Institute for Tobacco Research and Policy Studies at Legacy and Professor at Johns Hopkins Bloomberg School of Public Health. There, he continues to promote the need for efficient delivery of population level interventions and policies, with Donna Vallone, Cheryl Healton, and Legacy colleagues. Abrams continues collaborating with Amanda Graham and Nate Cobb on NCI-funded trials to evaluate Internet smoking cessation treatments and to examine social networks and social media phenomena for making an impact on populations. Together with Ray Niaura, Andrea Villanti, Jennifer Pearson, Mitch Zeller, Tom Kirchner, David Levy, and others, he is also developing and implementing strategic frameworks and studies whereby research can be strategically positioned to inform the Food and Drug Administration's 2009 congressional mandate to regulate tobacco products to reduce their population harms.

Absolute Risk

J. Rick Turner
Cardiovascular Safety, Quintiles, Durham, NC, USA

Definition

Absolute risk is best defined in conjunction with relative risk. For this example, we can define risk as the likelihood of an adverse consequence in two behavioral medicine interventions, Treatment A and Treatment B. Imagine that the risk is 1 in 10 for Treatment A and 2 in 10 for Treatment B. In this case, a relative risk statement can be made, saying that the probability of the event occurring following Treatment B is twice the probability of the event occurring following Treatment A. However, the same relative risk statement can be made for probabilities of 1 in 1,000,000 and 2 in 1,000,000. However, the absolute risks are vastly different: 1 and 2 in 10; and 1 and 2 in a million.

Description

Imagine that an intervention with beneficial therapeutic properties increased your risk of an adverse consequence (an event) from 1 in 10 to 2 in 10. It is possible that some individuals may consider that the risk is too great, and that they are not prepared to take this risk. Now imagine a different intervention with similarly beneficial properties that increases the risk of an event from 1 in a million to 2 in a million. In contrast to the first scenario, some individuals may feel that, while the relative risk has also doubled, the absolute risk has changed extremely slightly. Therefore, the expression of a risk in different ways, absolute and relative, can influence decisions made upon risk information.

Literature on risk reduction well exemplifies this. Statements of relative risk reduction can look considerably more impressive than statements of absolute risk reduction even though they are based on identical data. Consider that a decrease in risk from 6% to 3% is a 50% relative risk reduction. However, expressed in absolute terms, it is a 3% reduction. The same 50% relative risk reduction would be associated with a decrease in risk from 60% to 30%, but the absolute reduction of 30% would be much more important from a public health perspective. It is therefore very useful to patients and their physicians that risk information be provided in both absolute and relative terms.

Gordon-Lubitz (2003) commented as follows:

> Identical risk information may be presented in different ways, resulting in "framing bias." Perceptions of risk are particularly susceptible to framing effects. For example, patients are much more likely to favor radiation treatment over surgery when radiation is presented as having a 90% survival rate than when it is presented as having a 10% mortality rate. Although both numbers describe identical risks, the latter is perceived as more dangerous. Another common framing effect involves absolute and relative risks. For example, if a medication reduces an adverse outcome from 25% to 20%, then the absolute risk reduction is 5% and the relative risk reduction is 25%. Although the absolute and relative risk estimates are derived from the same data, patients are more strongly persuaded by the larger changes in relative risk.

Abstinence

Linda C. Baumann and Alyssa Karel
School of Nursing, University of Wisconsin-Madison, Madison, WI, USA

Definition

Abstinence is defined as the restraint from indulging in bodily activities that are experienced as giving pleasure. In medical settings this usually refers to drugs, alcohol, and most often sexual activity. Depending on the perspective, abstinence from sex can mean that all sexual activities are avoided, but it can also mean that only sexual intercourse is avoided. Abstinence is also considered a form of contraception; in fact it is the only form of contraception that prevents pregnancy with a 0% failure rate. Abstinence also prevents the spread of sexually transmitted infections.

In recent years the issue between abstinence-only sex education and comprehensive, or abstinence plus sex education has been widely debated. An abstinence-only sex education program focuses on promoting abstinence from sex until marriage due to the possibility of pregnancy and the spread of sexually transmitted infections. Morality is also discussed as a driving factor to remain abstinent. This approach avoids topics such as contraception or condom use and abortion, and rarely acknowledges that many teenagers are sexually active outside of marriage. An abstinence plus sex education program also promotes abstinence, but in addition also provides adolescents with discussion and information about contraception use, abortion, sexually transmitted infections including HIV.

Research on abstinence-only programs shows little evidence that this type of program has much positive impact on teenage behavior and may even put them at risk of being uninformed when it comes to matters of sexual activity. Research on comprehensive sex education programs show that these programs do not increase sexual activity among teens or increase the number of sexual partners, which has been a major concern of advocates of abstinence-only sex education. Research also shows that a comprehensive education program can reduce sexual behaviors that put teens at risk for pregnancy and acquiring sexually transmitted infections and therefore better prepares them to safely deal with the issue of sexual activity and the associated health risks.

As with abstinence and sex education, there is controversy over the effectiveness of many programs that promote abstinence with regards to drugs and alcohol. Drug Abuse Resistance Education (DARE) is one of the most widely implemented programs that teaches abstinence from alcohol, drugs, and violence. DARE reaches kids in over 75% of the United States school districts and is in over 43 countries worldwide. Research evidence, however, raises questions about the effectiveness of the program. In a 2001 report of the US Surgeon General, DARE was categorized as a program that "does not work."

AVE

Definition

The abstinence violation effect (AVE) refers to the negative cognitive (i.e., internal, stable, uncontrollable attributions; cognitive dissonance) and affective responses (i.e., guilt, shame) experienced by an individual after a return to substance use following a period of self-imposed abstinence from substances (Curry, Marlatt, & Gordon, 1987).

Description

AVE in the Context of the Relapse Process

The AVE was introduced into the substance abuse literature within the context of the "relapse process" (Marlatt & Gordon, 1985, p. 37). Relapse has been variously defined, depending on theoretical orientation, treatment goals, cultural context, and target substance (Miller, 1996; White, 2007). It is, however, most commonly used to refer to a resumption of substance-use behavior after a period of abstinence from substances (Miller, 1996). The term *relapse* may be used to describe a prolonged return to substance use, whereas *lapse* may be used to describe discrete, circumscribed "slips" during sustained abstinence (Marlatt & Gordon, 1985, p. 32).

As originally described by Marlatt and Gordon (1985), the relapse process typically begins when a person who has achieved abstinence encounters a situation that puts them at high risk for relapse (i.e., a high-risk situation). If the person is able to cope effectively with the high-risk situation, they may experience increased self-efficacy (i.e., confidence to avoid a lapse). If, on the other hand, they are unable to cope with the high-risk situation, they may experience decreased self-efficacy. If this decreased self-efficacy is paired with positive outcome expectancies for substance use, a person may have a heightened risk for a lapse. If a lapse occurs, it may be experienced as a "violation" of self-imposed abstinence, which gave rise to the term, AVE. The AVE may, in turn, precipitate a relapse if the person turns to substances repeatedly to cope with the resulting negative cognitive and affective reactions of the AVE.

AVE: Cognitive and Affective Responses to a Lapse

The AVE is characterized by a lapse paired with a specific constellation of negative cognitive and affective reactions. The role of cognitions stems from attributional theory (Weiner, 1974): a person might attribute their lapse to factors that are internal, global, and uncontrollable. For example, people may believe the lapse occurred due to their own, irreparable character defects or chronic disease determinants. The associated affective component stems from dissonance between the lapse and one's perceived self-image as an abstainer, which together with the attributions, can lead to feelings of guilt, shame, and hopelessness (Marlatt & Gordon, 1985). People who experience the AVE are more likely to progress from a lapse to a relapse (Miller, Westerberg, Harris, & Tonigan, 1996), and several studies have demonstrated the role of the AVE in predicting relapse among drinkers (Collins & Lapp, 1991), smokers (Curry et al., 1987), dieters (Mooney, Burling, Hartman, & Brenner-Liss, 1992), and marijuana users (Stephens, Curtin, Simpson, & Roffman, 1994).

In contrast, if people attribute the lapse to external, unstable (i.e., changeable), and controllable causes, they may not interpret the lapse as a threat to their self-image and may instead view it as a unique occurrence that can be avoided in the future. This attributional style may diffuse the

person's affective response to the lapse and reduces the likelihood of a progression from lapse to relapse (Laws, 1995; Marlatt & Gordon, 1985; Walton, Castro, & Barrington, 1994). Averting the AVE may have lasting effects: as the situation is less affectively charged, the individual might be open to exploring the determinants of the lapse and to experimenting with alternative coping strategies in the future. This may, in turn, lead to increased self-efficacy and more effective coping across various high-risk situations (Marlatt & Gordon, 1985).

Preventing the AVE Response

Clinicians may help clients interrupt the relapse process at various points and ultimately avoid the AVE. First, clinicians can help clients identify and apply effective behavioral and cognitive strategies in high-risk situations to avoid the initial lapse altogether. If a lapse occurs, clinicians should be empathetic and nonjudgmental in their approach (Miller & Rollnick, 2002) and should help clients reframe the lapse as the product of multiple factors (versus only internal factors), as being controllable (versus uncontrollable), and as situation-specific (versus global; Larimer, Palmer, & Marlatt, 1999). A step-by-step exploration may help clients learn how to interrupt the relapse process at various points to avoid future lapses, the AVE and/or relapses (Larimer et al., 1999). Further, the clinician may elicit and positively reinforce clients' existing coping skills to support the clients' self-efficacy and may teach clients additional behavioral and cognitive coping strategies for application in future high-risk situations, as necessary (Witkiewitz & Marlatt, 2007). Finally, clinicians should assess whether clients are coping adequately with the negative affective component of the AVE, which may otherwise precipitate future lapses or relapses.

Definition

The National Research Council defines elder mistreatment as "intentional actions that cause harm or create a serious risk of harm (whether or not harm is intended) to a vulnerable elder by a caregiver or other person who stands in a trust relationship to the elder or failure by a caregiver to satisfy the elder's basic needs or to protect the elder from harm" (Bonnie & Wallace, 2003, p. 40).

Description

EM may occur in the community setting (domestic EM) or in institutional settings, such as nursing homes and adult family homes. In the United States, data about EM among community-dwelling, vulnerable older adults suggest that victimization will rise from 1.25 million in 2010 to 2.2 million in 2030 based on the aging demographics of America. Further, it is estimated that for every case of EM that is reported, more than five cases go unreported (Tatara, 1997). This means that there will be over 6.6 million unreported cases by 2020 and over 11.7 million unreported cases by 2030, leading to extraordinary suffering and disability among vulnerable older adults.

Elder mistreatment is the outcome of actions which include neglect, physical, sexual, and emotional/psychological abuse; financial and material exploitation; and abandonment. When domestic violence (DV) occurs in situations in which the older adult is vulnerable, domestic violence in later life (DVLL) is a form of elder mistreatment. While self-neglect in community-dwelling older adults, resident-on-resident aggression in long-term care settings and "stranger crimes" (e.g., sweetheart scams; assaults by strangers) are serious issues, they are considered separately from elder mistreatment. Older adults who self-neglect are not necessarily vulnerable adults and there is no caregiving dyad involving a "trusted other" (Bonnie & Wallace, 2003; Dong et al., 2009). Resident-on-resident aggression involves vulnerable adults, but they are not in a caregiving dyad with each other, as they rely on professional staff for care (Lachs, Bachman, Williams, & O'Leary, 2007). Stranger crimes also do not necessarily involve vulnerable older adults or trusted others with a duty of care (Bonnie & Wallace, 2003).

Neglect of community-dwelling vulnerable older adults by trusted others is the most prevalent type of domestic EM, with over 70–80% of cases in that category. Recent estimates of domestic EM place the prevalence since reaching age 60 years and past-year prevalence of psychological mistreatment at 13.5% and 4.6%; physical mistreatment at 1.8% and 1.6%; and sexual mistreatment at 0.3% and 0.6%, respectively. The estimated past-year prevalence of financial mistreatment by family members is 5.2% (Acierno et al., 2010). The prevalence of EM in institutional settings is unknown, but the problem is thought to be widespread and serious (Hawes, 2003). For example, from January 1999 to January 2001, there were 5,283 nursing home citations for almost 9,000 abuse violations (Minority Staff SID, 2001). Regardless of the type(s) of elder mistreatment experienced by vulnerable older adults, EM imposes serious consequences for the health and safety of its victims, including a three-times higher adjusted risk of death for community-dwelling older adults (Lachs, Williams, O'Brien, Pillemer, & Charlson, 1998).

Domestic elder mistreatment is a form of family violence in that the vast majority (90%) of abusers are family members. Adult children are the more prevalent (47%) perpetrators of domestic EM, followed by spouses/partners (19%) and other family members (Tatara, 1997). Perpetrators of institutional EM include staff and family or friends who visit (Hawes, 2003).

EM risk involves characteristics of both the vulnerable older adult and the caregiver. Risk factors in community-dwelling older adults include older age (>70), low social support, and the number of self-care deficits that lead to dependence on others for care (Acierno et al., 2010). Characteristics of adult children who are likely to mistreat their vulnerable parents include dependence of the adult child on the parent for housing and financial support; substance abuse; mental illness; and poor social integration. If the abuser is a spouse or partner, abuse may be the continuation of existing domestic violence into later life; new behavior in the caregiving spouse/partner; or a new relationship in which there is partner violence (Bonnie & Wallace, 2003).

EM risk in institutional settings may be related to characteristics of staff caregivers. For example, psychological abuse of residents was related to higher caregiver work stress (role strain, demand, and work overload) and lower caregiver educational level (Wang, Lin, Tseng, & Chang, 2009). Risk for all mistreatment types is related to the degree to which residents are dependent on staff for care (Cohen, Halevy-Levin, Gagin, Priltuzky, & Friedman, 2010; Post et al., 2010).

Action steps for prevention and early intervention of elder mistreatment include appropriate assessment and screening policies with clear clinical practice protocols for staff to follow; protocols to guide staff in reporting cases to proper authorities; mechanisms for participating in complaint investigations to ensure that accusations of mistreatment are verified and handled appropriately; educational programs, consultation and follow-up protocols for healthcare professionals; and research and public policy actions to address the issue.

Acculturation

Definition

Definition and Theoretical Background

Acculturation is the process by which migrants to a new culture develop relationships with the new culture and maintain their original culture (Berry & Sam, 1997). Acculturation has been classically defined as the changes that develop when groups of individuals come into contact with a different culture (Redfield, Linton, & Herskovits, 1936). This process was initially conceptualized as unidimensional, in which retention of the original culture and acquisition of the new host culture were cast at opposing ends of a single continuum (Schwartz, Unger, Zamboanga, & Szapocznik, 2010). According to this unidimensional model, migrants were expected to acquire the values, practices, and beliefs of their new homelands and discard those from their cultural heritage. Acculturation is now more often conceptualized as complex and multidimensional, meaning that both cultures change under the influence of each other and acculturation is influenced by a number of contextual factors (Berry & Sam, 1997; Sam & Berry, 2006).

According to Berry and Sam (1997), acculturation involves four strategies: assimilation, separation, integration, and marginalization. Assimilation means immersion in the new culture and breaking from the original culture; separation refers to the nondominant group distancing themselves from the new, dominant culture and holding onto original cultural practices and beliefs; integration is when individuals maintain both their original cultural identity while taking part in the new culture's practices; marginalization refers to what occurs when individuals leave behind their original cultural identity but do not take part in the new culture.

Some researchers feel that definitions of acculturation need to move beyond behavioral indicators and include other factors such as language use, values, and attitudes (Thomson & Hoffman-Goetz, 2009). Investigators stress the importance of emigration and immigration contexts as modifiers of the acculturation experience (Thomson & Hoffman-Goetz, 2009).

Description

Measuring Acculturation

While no definitive framework for acculturation has been defined, Berry and Sam (1997) suggest a composite framework for measuring acculturation including: societies of origin and settlement, psychological acculturation, and the moderating factors that contribute to and arise from it, and the eventual shift to psychological and sociocultural adaptation. Acculturation can be affected by a number of variables, such as age, gender, race, ethnicity, and socioeconomic status, which in turn affects the behaviors and values of a person (Maxwell, 2006). These variables all play a role in the acculturation process, though no single measurement scale has been able to extensively study all of these factors. The acculturation process is generally accepted to be bidirectional (Sam & Berry, 2006), which assumes that both cultures can change under the influence of each other, but do not necessarily reach a neutral point. Due to the complexity of acculturation, accurate measurement is challenging.

Scales have been developed to measure acculturation for a number of different ethnic groups including Mexican Americans, Chinese Americans, European Americans, and Cuban

Americans. These scales often include items assessing native and host language usage, language usage inside and outside the family, ties to country of origin, cultural familiarity and pride, length of stay in host country, personal values, and interpersonal relations. Some scales also examine concepts of independence, gender, culture, fashion, food, music, and movie preferences (Acculturation Depot, 1998; Maxwell, 2006).

Psychological Acculturation

Graves (1967) makes a distinction between acculturation as a collective or group-level phenomenon, and psychological acculturation, a change in the psychology of the individual. The internal processes of change that immigrants experience when they come into direct contact with members of the host culture constitute psychological acculturation. This construct is conceptualized as a resocialization process involving psychological changes in attitudes, values, and identification; the acquisition of new social skills and norms; changes in reference-group and membership-group affiliations; and adjustment or adaptation to a changed environment (Berry et al., 1992; Sam, 1994). Psychological adaptations to acculturation involve learning a new behavioral repertoire that is appropriate for the new cultural context (Berry & Sam, 1997). If individuals cannot easily change their repertoire, they may experience acculturative stress, the psychological, somatic, and social difficulties that may accompany acculturation processes. This stress may lead to serious psychological disturbances such as clinical depression and anxiety when environmental stressors exceed the individual's capacity to cope.

While the concept of acculturation has become widely used in cross-cultural psychology, it is important to distinguish it from the concepts of assimilation and adaptation. Assimilation is a process of cultural absorption of a minority group into the main cultural body. While acculturation implies a mutual influence in which elements of two cultures merge, assimilation implies a tendency of the ruling cultural group to enforce the adoption of their values rather than the blending of values (Maxwell, 2006). Berry (1984) defined psychological adaptation as the individual behaviors that are linked to acculturation experience, either as "shifts" of the preexisting customs or habits in language, beliefs, attitudes, values, or abilities, or as "acculturative stress" which is generated during acculturation. In the recent literature on psychological adaptation to acculturation, a distinction has been drawn between psychological and sociocultural adaptation. Psychological adaption mostly involves one's psychological well-being and satisfaction in a new cultural context, whereas sociocultural adaptation refers to one's ability to acquire culturally appropriate knowledge and skills and to interact with the new culture and manage daily life (Ward, Bochner, & Furnham, 2001).

Acculturation and Its Effect on Health Behaviors

Acculturation has been linked to changes in health behaviors – including eating, sexual health behaviors, accessing health services, and other behaviors – as well as changes in knowledge and beliefs. Studies have shown that acculturation to the USA may serve as a health risk or as a protective factor depending on the ethnic group, health behavior in question, and other variables such as gender. Acculturation may lead to the adoption of unhealthy behaviors such as smoking and eating a more high-fat diet or may lead to an increase in healthy behaviors such as exercise (Abraído-Lanza, Armbrister, Flórez, & Aguirre, 2006). Recently, Landrine and Klonoff (2004) proposed an operant model of acculturation as a way to guide to health behavior interventions. The operant model of acculturation looks at prevalence of certain health behaviors in an ethnic group's home country and new culture to predict the likelihood of adoption of those health behaviors depending on level of acculturation.

Among Hispanics and Asians in the United States, acculturation has been shown to influence diet, cancer screenings, and smoking, among other health behaviors, often with studies comparing more and less acculturated members of the same ethnic group (Landrine & Klonoff, 2004). The effects of acculturation on health behaviors differ from ethnic group to ethnic group; for example, Japanese-American men who adhere

more to Japanese culture are less likely to develop coronary heart disease (CHD) than more acculturated Japanese-American men, while this change in risk of developing CHD has not been found in Irish-American men. Other factors, such as gender, may play a role in the effect of acculturation on a health behavior. For example, acculturation has been found to increase smoking among Latino women and decrease smoking among Latino men (Perez-Stable et al., 2001). Due to the complex relationship between these variables, acculturation has been shown to have both positive and detrimental effects on an individual's health and well-being, and more research is needed to examine these processes further.

Acetylcholine

Nicole Brandt[1] and Rachel Flurie[2]

Definition

Acetylcholine is a naturally occurring monoamine neurotransmitter found in both the peripheral and

central nervous systems. It is the primary transmitter for the autonomic nervous system and the somatic efferent nerves that innervate skeletal muscle. It was first discovered in 1914 by Sir Henry Dale and colleagues. Acetylcholine is synthesized inside the terminal endings of cholinergic nerve cells where choline is taken up into the nerve terminal and reacts with acetyl coenzyme A via the enzyme choline acetyltransferase.

Description

Once acetylcholine is synthesized, it is stored in vesicles until the nerve is stimulated by calcium entry into the nerve terminal. Stimulation causes the vesicles to release acetylcholine into the synapses between the pre- and postsynaptic nerve fibers. Acetylcholine crosses the synapse and binds to receptors on the postsynaptic cell, exerting its effect. It causes increased permeability of the cell to the cations sodium, potassium, and calcium, resulting in cell depolarization. The two types of receptors on which acetylcholine acts are the nicotinic and muscarinic receptors, so named because they were discovered using the two compounds muscarine and nicotine. The nicotinic receptors are found on all preganglionic autonomic nerve fibers, somatic efferent nerve fibers that connect to skeletal muscle, and the central nervous system. Nicotinic receptors have two subtypes: muscle and neuronal. The muscle subtype is found in skeletal muscle at the neuromuscular junction. The neuronal subtype is found in the peripheral and central nervous systems and in nonneuronal tissues (adrenal medulla). The muscarinic receptors are found on all postganglionic parasympathetic nerve fibers and postganglionic sympathetic nerve fibers that terminate at sweat glands, and in the central nervous system. Muscarinic receptors have five subtypes: M_1, M_2, M_3, M_4, and M_5. The subtypes are distributed throughout different areas of the brain, in autonomic ganglia, and in certain glands (gastric, salivary, and smooth muscle).

The action of acetylcholine is terminated by the enzyme acetylcholinesterase found in the synaptic cleft. The mechanism of action of several drugs, including the drugs used for Alzheimer's disease, relies on the inhibition of this enzyme. Drugs that act on the synthesis, storage, and release process of acetylcholine are not very selective and therefore are not good as systemic therapy.

Acetylcholine affects several organs in the body. The heart has M_2 receptors, and stimulation of those receptors causes vasodilation, decreased heart rate, decreased conduction velocity of the AV node, and decreased force of contraction. Acetylcholine works on M_3 receptors in the lungs to cause bronchoconstriction. It works on M_2 and M_3 receptors in the bladder to cause inhibition of smooth muscle relaxation. In the gastrointestinal tract, acetylcholine works on M_1, M_2, and M_3 receptors to control motility and gastric and salivary gland secretions. Acetylcholine also acts on M_3 receptors in the eye to cause pupillary and ciliary muscle contraction. All five muscarinic receptor subtypes are found in the CNS and cause a variety of actions such as increased cognitive function, increased seizure activity, regulation of dopamine release, neuronal inhibition, analgesia, appetite regulation, and augmentation of drug-seeking behavior and reward.

Drugs that affect the action of acetylcholine are divided according to their physiological site of action. They are muscarinic agonists, muscarinic antagonists, ganglion-stimulating drugs, ganglion-blocking drugs, neuromuscular-blocking drugs, and drugs that enhance cholinergic transmission. Clinically, muscarinic agonists are used locally to treat glaucoma (pilocarpine) by lowering the intraocular pressure and to help with bladder emptying or stimulate gastrointestinal motility (bethanechol). Many more muscarinic antagonists are used clinically. Atropine is used in people with bradycardia and gastrointestinal hypermotility, but it is also used to reduce secretions and inhibit bronchoconstriction in the respiratory tract. Scopolamine is used to treat motion sickness. Ipratropium and tiotropium are used via inhalation in people with asthma and chronic obstructive pulmonary disease to inhibit bronchoconstriction, and ipratropium is additionally used to treat rhinorrhea. Muscarinic antagonists used to reduce frequency of muscle contractions seen in urinary incontinence include oxybutynin, tolterodine, trospium chloride, darifenacin, solifenacin, and

fesoterodine. Pirenzepine inhibits gastric acid secretion and is used to treat peptic ulcers. Drugs that cause pupil dilation and ciliary muscle paralysis are used to treat uveitis and include homatropine hydrobromide, cyclopentolate hydrochloride, and tropicamide. Benztropine mesylate, trihexyphenidyl hydrochloride, and biperiden are used in Parkinson's disease because of their regulation of dopamine. Antipsychotics used for schizophrenia and other neurologic disorders have various degrees of muscarinic antagonism, which can help decrease the extrapyramidal side effects of these drugs but also cause worsening cognition.

Drugs that act at the ganglionic and motor endplate receptors act specifically at nicotinic receptors. The only nicotinic agonists with a therapeutic use are nicotine for smoking cessation and suxamethonium for muscle relaxation, but lobeline, epibatidine, and dimethyphenylpiperazinium are also agonists of the nicotine receptor. Nicotinic antagonists have limited clinical use because nicotinic receptors are found in both divisions of the autonomic nervous system and skeletal muscle; therefore, they cause severe postural and postexercise hypotension. Trimetaphan is used for some types of anesthetic procedures, and pancuronium, atracurium, and vecuronium can be used as muscle relaxants in anesthesia.

Neuromuscular-blocking agents can work either presynaptically or postsynaptically, although all of the drugs used clinically work postsynaptically. They work by either blocking the acetylcholine receptor and ion channels or as agonists at the receptors. They are used mainly in anesthesia to produce muscle relaxation. These drugs are tubocurarine, pancuronium, vecuronium, atracurium, mivacurium, and suxamethonium.

Finally, drugs that enhance cholinergic transmission work either by inhibiting the enzyme acetylcholinesterase or by increasing acetylcholine release from the nerve terminal. These drugs work to increase the effect of acetylcholine in the autonomic nervous system, at the neuromuscular junction, and in the central nervous system. Neostigmine is used after an operation to reverse the anesthesia and for myasthenia gravis. Donepezil, rivastigmine, and galantamine are used to treat Alzheimer's disease dementia.

Acetylcholine is vital to so many systems that understanding the physiology will help to understand the mechanisms of various medications used to address multiple medical conditions.

ACTH

Definition

Adrenocorticotrophic hormone (ACTH) is a polypeptide hormone that is synthesized and secreted by the anterior pituitary gland. ACTH forms part the hypothalamic-pituitary-adrenal axis (HPA axis) and its production is stimulated by corticotropin-releasing hormone (CRH) from the hypothalamus. ACTH acts on the adrenal cortex, by increasing the conversion of cholesterol to pregnenolone, to stimulate the release of mineralocorticoids, androgenic steroids, and glucocorticoids, namely, cortisol (Martin, Reichlin, & Brown, 1977).

Along with CRH, ACTH is produced in the response to stress, stimulating an increase in production and secretion of cortisol. The secretion of ACTH is subject to negative feedback, where increased cortisol levels reduce the secretion of ACTH. It also controls its own secretion through short loop feedback via CRH. ACTH is secreted

in a pulsatile manner, which is under neural control rather than a result of stress (Martin, Reichlin, & Brown, 1977). The circadian secretion of ACTH increases prior to awakening and then declines progressively throughout the day.

Overproduction or blunted levels of ACTH can occur as a result of a disease. For example, increased levels of ACTH occur as a result of Addison's disease and Cushing's disease. Alternatively, ACTH levels may be reduced due to adrenal insufficiency or pituitary disease or as a result of a cortisol secreting tumor (Greenspan & Forsham, 1983).

Actigraphy (Wrist, for Measuring Rest/Activity Patterns and Sleep)

Definition

Actigraphy is a method of objective sleep assessment in which sleep/wake status is estimated from bodily movements, typically of the wrist.

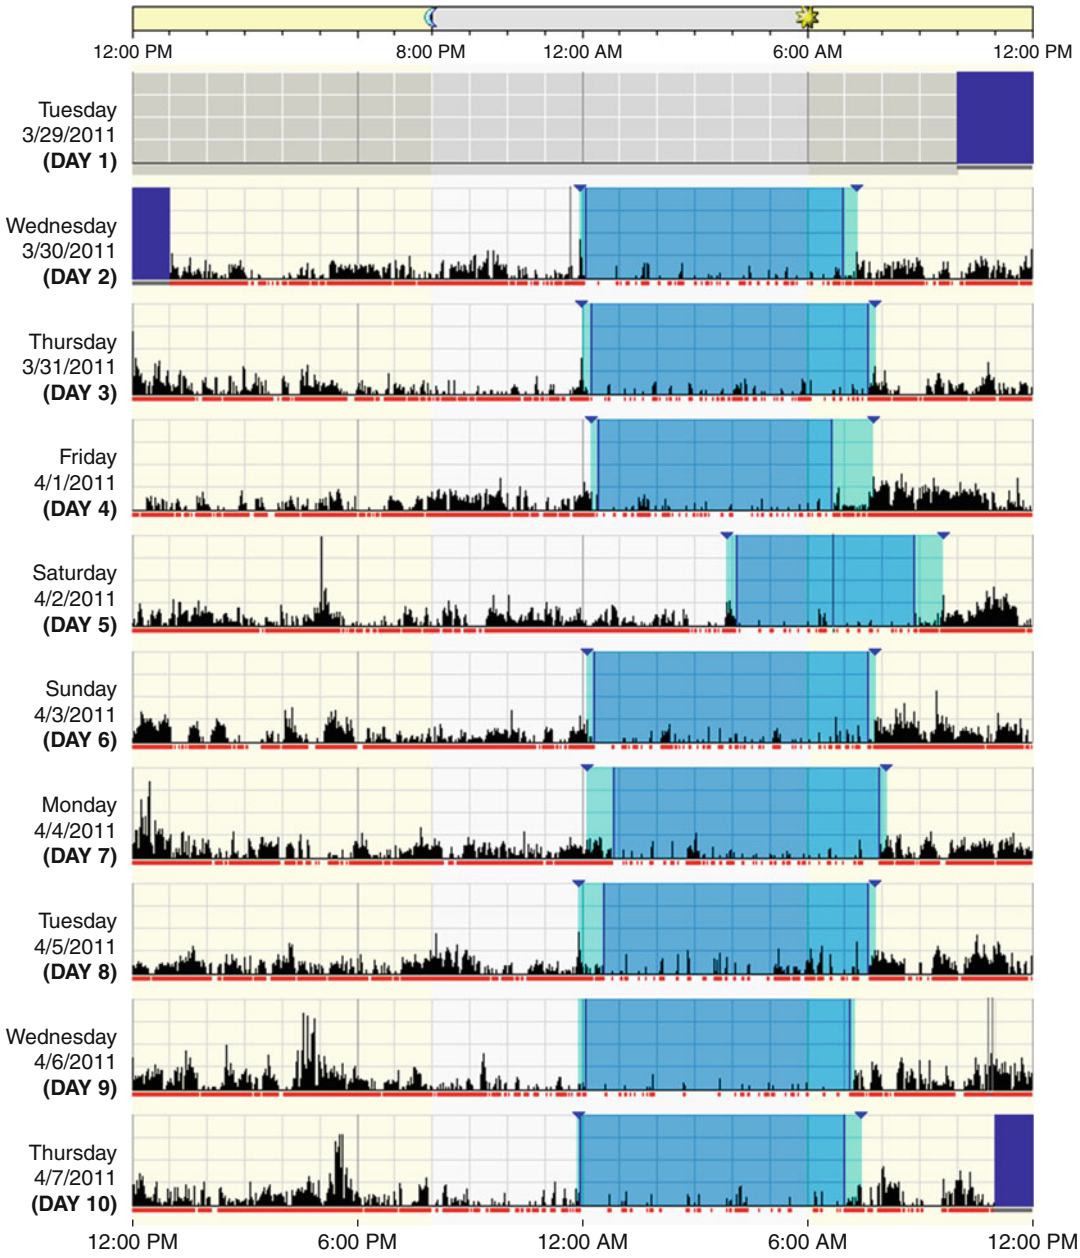
Description

Background and Use

Actigraphy is a common alternative to laboratory polysomnography (PSG) for the objective assessment of sleep/wake patterns, based on the observation that the amount of bodily movement differs between sleep and wakefulness. Although initially developed in the 1970s, there has been an exponential increase in the use and development of actigraphy over the past 15 years. Due to technological developments, actigraphs are now unobtrusive (similar in size and weight to a wrist watch) and inexpensive, capable of collecting data for multiple weeks, and able to provide rapid feedback on sleep patterns due to automated software algorithms. In addition, many actigraphs now record ambient light exposure and have the ability to mark the timing of specific events (e.g., bedtime).

Actigraphs are most commonly used for the evaluation of sleep/wake patterns in the home. Typically worn on the nondominant wrist (or ankle for infants), actigraphs continuously collect information on the frequency and intensity of movement with sensitive internal sensors. Upon download of data, each epoch of activity data is then classified as sleep or wake based upon algorithms that have typically been developed against PSG, the gold standard for objective sleep assessment. The algorithms used to estimate sleep/wake status incorporate movement counts for the epoch in question and the immediate surrounding epochs; the epoch is scored as sleep or wake based on whether the activity counts are below or above a particular threshold, respectively (see Fig. 1 for display).

Common sleep measures obtainable via actigraphy include sleep onset latency (i.e., the length of time it takes for one to fall asleep), wakefulness after sleep onset (i.e., the amount of time spent awake after initially falling asleep), time in bed (i.e., the amount of time during which sleep is attempted), total sleep time (i.e., the total amount of time spent asleep during a specified interval of time), sleep efficiency (i.e., the ratio of time spent asleep to the amount of time



Actigraphy (Wrist, for Measuring Rest/Activity Patterns and Sleep), Fig. 1 Actigraph output, providing a plot of activity counts over multiple days (Actiwatch 2, Philips Respironics Actiware v. 5.59 software, Bend, OR). Each row represents a separate 24-h period (shown here beginning at noon), with activity counts plotted for each minute of data collection. *Triangles* represent times at which the individual pressed an event marker. Light shaded areas indicate times at which the individual was in bed attempting to sleep. Dark shaded areas indicate intervals that were excluded from analysis. Used with permission from Philips Healthcare (Bend, OR)

attempting sleep), the number and duration of nighttime awakenings, and daytime napping duration. However, sleep stage assessment is not possible.

Patients are commonly instructed to wear the actigraph for at least 3 consecutive days, though longer periods of data collection (typically 1–3 weeks) are preferred. Actigraphs should be

continuously worn (i.e., 24 h a day), removing the actigraph only when it will be immersed in water, as most actigraphs are not completely waterproof. Daily sleep logs are often completed concurrent with actigraph wear, providing useful information on, among other things, when the watch was removed, times of daytime napping, the time at which sleep was first attempted (i.e., bedtime) and the time at which one got out of bed for the final time (i.e., rise time).

Although useful for evaluating the sleep/wake patterns of any individual presenting with a sleep complaint, actigraphy is especially useful for characterizing the sleep/wake patterns of insomniacs (Morgenthaler et al., 2007). Self-reported sleep patterns of insomniacs often show poor agreement with objective assessment, with substantial variability from night to night. Laboratory assessment of sleep often leads to reactivity (i.e., the "first night effect," reduced sleep due to the unfamiliar sleep environment), and multiple nights of laboratory sleep assessment would be burdensome and costly. Actigraphy is also valuable for tracking the sleep/wake patterns of individuals with circadian rhythm sleep disorders by documenting the altered timing of sleep/wake patterns.

Finally, actigraphy may serve as a valuable tool when assessing sleep-disordered breathing outside of the laboratory, which is usually performed with limited portable monitoring of respiratory and oximetry signals (Morgenthaler et al., 2007). Actigraphy has been shown to improve the estimate of total sleep time, which is used when calculating the severity of sleep-disordered breathing.

Validity

It is important to note that many actigraph devices are available for use, each utilizing different methods of movement detection and algorithms for estimation of sleep/wake status. Published validation information is not available for all actigraph algorithms, particularly across different populations (e.g., children, older adult insomniacs). Nevertheless, in general, actigraphy has been shown to provide valid estimates of total sleep time, sleep efficiency, and wakefulness after sleep onset in normal adults, with an epoch-by-epoch agreement of >80% between actigraphy and PSG for identification of sleep. Though epoch-by-epoch agreement for correctly identifying wake is low with actigraphy, whole-night averaged correlations are often strong (i.e., >.80) between measures of sleep via actigraphy versus PSG. Algorithm accuracy is reduced for individuals with significantly disturbed sleep (e.g., individuals with frequent awakenings and/or reduced total sleep time) and in populations in which there is substantial activity during sleep (e.g., children, adults with movement disorders) or minimal activity during wakefulness (e.g., insomniacs).

Despite the validity of actigraphy for estimating many common sleep parameters, there is much less validation support for the actigraphic estimation of daytime napping and sleep onset latency, particularly if there is no documentation (via event markers and/or daily log) of the timing of daytime napping or bedtime, respectively. Actigraphy often overestimates sleep during the day, as daytime periods of low waking activity are commonly estimated as sleep via actigraphic algorithms. Likewise, sleep onset latency is often underestimated with actigraphy, particularly if the patient is able to lie awake with minimal movement.

Because actigraphic devices differ in the mechanism by which movement data are collected, algorithms for sleep/wake estimation are device-specific. Furthermore, although the amount of activity during sleep may differ according to developmental stage and/or clinical morbidity (e.g., infants, individuals with sleep apnea), there have been minimal attempts to optimize algorithm accuracy for specific populations of individuals.

Advantages to Other Methods of Sleep Assessment

Laboratory PSG is considered the gold standard for objective sleep assessment. However, for assessment of sleep/wake patterns over multiple days and nights, PSG is often not feasible. In addition, participants often note that sleep is impaired during PSG due to the numerous wires, belts, and devices attached to the head and body during sleep. Therefore, actigraphy

may be a preferred alternative to PSG when large numbers of patients need to be studied, multiple nights of assessment are needed, daytime napping needs to be objectively assessed, and/or when PSG will not be easily tolerated (e.g., in children, insomniacs).

An exclusive reliance on sleep diaries for the evaluation of sleep/wake patterns is often not recommended, because sleep diary reports sometimes show significant divergence from actual sleep/wake patterns. Because actigraphy provides an objective assessment of sleep/wake activity, it is often used as a supplement or alternative to sleep diaries.

Limitations of Actigraphy

There are limits to the amount of information that actigraphy can provide. For instance, whereas PSG is able to provide detailed information on the duration and distribution of specific sleep stages (i.e., rapid eye movement (REM) sleep, stages 1–3 non-REM sleep), sleep stage assessment is not possible with actigraphy. In addition, actigraphy is limited in its ability to successfully identify wakefulness. This could explain the lack of validity for actigraphic assessment of sleep onset latency and pose problems for estimating the sleep of insomniacs and institutionalized adults who remain in bed during the day.

Due to different technologies and algorithms employed by different actigraph manufacturers, the accuracy of sleep/wake estimation can vary considerably across different actigraph models. Many algorithms have minimal to no published validation support. However, when available, it is important to note that actigraphic algorithms are device-, mode-, and (if validated) population-specific. Because there has been little standardization of actigraph models and algorithms across studies, clinicians and researchers should choose actigraphs that provide the desired technological features (e.g., light sensor, event marker) and whose algorithms have been validated in the population of interest.

Currently, there are no established guidelines on the scoring of actigraphy. As a result, considerable variation could occur between technicians and laboratories when evaluating actigraphic data. When scoring actigraphy, standard operating procedures should be developed, specifically addressing how to identify daytime nap periods, when the watch was removed, and the beginning and end of the nocturnal rest period. Use of ambient light data (when available) is helpful in identifying bedtime, since there is often a sharp decrease in light levels at this time. Furthermore, although sleep diaries are typically completed concurrent with actigraphy recording to inform the scorer of sleep/wake patterns, use of event markers should be encouraged to identify intervals of attempted sleep during the day and night. This is especially true if accurate determination of daytime napping is desired, since in some sedentary individuals multiple periods of low daytime activity could be interpreted as napping (Stone & Ancoli-Israel, 2011).

Alternative Uses of Actigraphy

Because actigraphy provides a view of multiple consecutive 24-h periods, the rhythmicity of the sleep/wake pattern can be assessed. Many actigraph software programs now allow for circadian analysis of the rest-activity rhythm. These analyses are particularly helpful in documenting circadian rhythm sleep disorders (e.g., shift work sleep disorder, advanced sleep phase disorder) (Stone & Ancoli-Israel, 2011).

Actigraphy is also able to provide a basic assessment of physical activity. Although not as sensitive as trunk placement for physical activity assessment, wrist actigraphy can estimate overall activity with adequate precision. Activity count per hour of wakefulness is the most commonly used metric, but maximal activity counts, peak activity over a predetermined duration (e.g., 10 min), or amount of time above a threshold of activity (e.g., 1,000 cpm) have been previously utilized.

Definition

Coping is the set of intentional, goal-directed efforts people engage in to minimize the physical, psychological, or social harm of an event or situation (Lazarus & Folkman, 1984; Lazarus, 1999). There are many different theoretical and empirical frameworks for understanding coping, and many different ways of classifying coping strategies, but one such classification is "active coping." In general, active coping refers to the utilization of those psychological or behavioral coping efforts that are characterized by an attempt to use one's own resources to deal with a problem situation (Zeidner & Endler, 1996). These responses are designed either to change the nature of the stressful situation or event in order to decrease the problematic nature of that situation or event, or to modify how one thinks and feels about it in order to change one's reactions to it. Examples include solving problems, reframing the meaning of the problems, or seeking information. Active coping is thought to be an adaptive way of dealing with stressful events and to be a vital component of resilience in the face of stress, health problems, and other adversity.

Definition

An activities of daily living (ADL) evaluation is an assessment of an individual's physical and sometimes mental skills. In the area of physical or occupational therapy, it reflects how well a disabled patient or someone recovering from disease or accident can function in daily life. It is also used to determine how well patients relate to and participate in their environment (Krapp & Cengage, 2006). Common examples of ADL include personal hygiene and feeding oneself.

Grade of activity

Definition

The level of activity is related to the complexity of the skills that demands and has an impact on an individual's occupational performances. This term is related to several characteristics that might influence the type and amount of effort required from the individual to perform a specific activity, task, or occupation. The term "activity level" is of great importance when designing occupational therapy interventions.

Description

When describing a person's activity level of daily living, it is possible to use the terms occupation and activity synonymously. However, these terms are not fully interchangeable as they describe two different aspects of the same function (Christiansen & Townsend, 2004; Hinojosa & Kramer, 1997). Occupation is the "active process of living: from the beginning to the end of life, . . . occupations are all the active processes of looking after ourselves and others, enjoying life, and being socially and economically productive over the lifespan and in various contexts" (Willard & Spackman's 2008). Activity is a fundamental aspect of human existence, and each activity is usually composed by several tasks to be performed. Different activities might be combined in one routine and contribute to different occupations. Activity synthesis is the integration of some or all of these performance components with an appropriate theory that is consistent with the client's goals and present status (Söderback, 2009).

Factors Influencing Activity Level

Individual's State of Flow

An individual's present activity level is influenced by the interaction between his or her present mental status and the challenge and skill level of an activity, according to Csikszentmihalyi's (1988) proposed theoretical model "Flow: The Psychology of Optimal Experience." There is a complex interaction between the emotional state, the environment, and the ability to perform a specific task. It is suggested that someone might be able to perform a task in one condition and not in another one because of the relation to different aspects, for example, environment, engagement, mood, that is, angst, arousal, flow, worry, control, apathy, boredom, and relaxation. When optimal conditions occur there is a state of flow that might allow people to feel in control of their environment and thus, able to perform a meaningful task. In this context, it is possible to find a person without any disability or mental declining health that due to anxiety or another negative feeling is unable to perform a specific task or fails to complete an assignment. In this case, the person is not per se unable to perform the tasks, but due to his or her own perception it turns into a failure. Here, some factors such as positive thinking, stable mood, and engagement might support a task toward a positive solution, and on the other hand, anxiety, negative thoughts, depression, and cognitive decline might prevent that the task is fulfilled.

Individual's Personal Factors

It is likely that an individual has a great variation in his or her activity level to perform different activities depending on his or her cognitive integrity, familiarity of the present environment, support from other people, and perception of the meaningfulness when an activity is performed (Pool, 2008). For example, in order to keep the person with cognitive impairment engaged in an activity, an enriched environment must be constructed and suitable degree of difficulty chosen to maintain flow and skills; thus, the activity is ended up with an expected product or performance.

Individual's Past Experiences

Level of engagement in an activity is related to the individual's past experiences (Kielhofner et al., 2004, 2008), which can be summarized in positive or negative thoughts and feelings regarding a specific task. An individual with a positive approach interprets difficulty as part of the situation. They will engage in correcting and improving their performances. On the other hand, an individual with a negative approach will experience difficulty as failure and therefore, stop the ongoing activity. The last aspect may be observed among people with depressive or mild cognitive impairment.

Individual's Dysfunctions

Cognitive functions and all mental processes that impair the symbolic operations, perception, and memory, creation of imagery, thinking,

reasoning, and judgment will affect how well activities are realized. Therefore, it is important to identify and assess how these cognitive functions influence the individual's activity level. These assessment's results may be helpful for therapists to guide an individual toward the most appropriate activity level he or she is able to be engaged in and is able to perform as expected (Baum, 1995; Söderback, 1988).

An important context for management of older adults with Alzheimer's disease (AD) activity level is proposed by Csikszentmihalyi (1988). The findings support the importance of keeping the person with AD engaged in occupational pursuits to sustain best functional level, and moderate, appropriate behavior and habits.

Generally, people should keep themselves actively engaged; otherwise disharmony or strain between individual and environment will arise, resulting in negative stress (Baum & Edwards, 1993).

Conclusion

Activity is an essential component of human existence. The activity level is essential to be diagnosed, evaluated, and properly treated among individuals who show a reduced activity level, due to medical diagnosis, present life situation, personality, or inappropriate present environment. In this sense, it is fundamental for therapists and health-care providers to be well prepared and having appropriate knowledge, for example, in medicine, occupational therapy and psychology to meet the challenge of upholding requested activity level.

Definition

Acupuncture is a traditional therapy used to treat a variety of health-related problems. It involves assessment of the condition and development of a differential diagnosis followed by the insertion and manipulation of thin, solid metal needles at specific locations on the body. Various techniques are used to stimulate the needles and improve the therapeutic effects, including manual manipulation or adding a mild electrical current.

There are many different types of acupuncture. For example, auricular acupuncture involves placement of stainless steel or gold (semipermanent) needles, or "studs" at specific points on the ears. These are often left in place for 3–5 days. Other treatments such as acupressure (applying pressure or massaging acupoints), *gua sha* (scraping), moxibustion, and cupping are also used as adjuncts to acupuncture therapy. Moxibustion is a technique for providing heat to the needles. It involves placement of a special herb onto the needle and igniting it to bring mild warmth to the local area. Cupping involves the creation of a negative vacuum in a jar that is placed onto the skin surface. The negative pressure causes local congestion and vasodilation and may be used to help relieve pain (Deng et al., 1997).

Description

Traditional Chinese medicine (TCM) is a complete system of healthcare delivery used for the prevention and treatment of a wide-range of health-related conditions. The therapeutic approaches of TCM include acupuncture, herbs, food therapy, *tui na* (bodywork), *tai chi* (therapeutic exercise), and *qi gong* (meditative/energy therapy). Acupuncture originated in China over 2,500 years ago and remains one of the most popular therapies within TCM today. According to the World Health Organization, it is used in over 70 countries worldwide (World Health Organization, 2002). There has been documented use of acupuncture in the United States for approximately 200 years, and in 1996, the United States Food and Drug Administration approved acupuncture needles as medical devices (US Food and Drug Administration, Department of Health and Human Services, 1996).

Acupuncture treatments are generally considered safe. Commonly reported risks include fainting, bruising, infection, and mild discomfort. Serious adverse events are rare when treatments are provided by a qualified practitioner. Licensing requirements for acupuncturists vary. Some

countries do not require a license to practice, but in the United States, training programs have a standardized, clinically based curriculum and are formally accredited by the Accreditation Commission for Acupuncture & Oriental Medicine (Accreditation Commission for Acupuncture and Oriental Medicine). The National Certification Commission for Acupuncture and Oriental Medicine (NCCAOM), a nonprofit organization established in 1982, also promotes nationally recognized standards of competence and safety by examining and certifying individuals through national board examinations. Most states require NCCAOM certification in order to obtain a license to practice acupuncture (National Certification Commission for Acupuncture and Oriental Medicine (NCCAOM)).

Acupuncturists use many different models and approaches to understand and apply treatment. These models range from a metaphysical paradigm used by those traditionally trained to a strictly neurophysiologic approach incorporated into pain control regimens. According to ancient theory, acupuncture is based on the belief that energy flows through the body in channels known as meridians. This energy is also referred to as Qi (pronounced chee). A block in the meridians denies the surrounding tissues of Qi and creates an imbalance of health. Qi flow can be restored by inserting needles at specific locations on the body. With restored Qi, imbalances in absorption of nutrients and circulation of blood and fluids to the body's organs can be corrected (Deng et al., 1997).

Although acupuncture is used to treat a wide variety of health problems, human data from rigorous randomized-controlled trials is limited. The most compelling evidence supporting its use is for management of nausea/vomiting and pain. Based on more limited research, there is some evidence suggesting that acupuncture may be useful for stimulating the immune system and for reducing hot flashes, xerostomia (chronic dry mouth), fatigue, mood disorders, sleep disturbances, and peripheral neuropathy (National Institutes of Health (NIH) & National Center for Complementary and Alternative Medicine (NCCAM); National Institutes of Health (NIH) & National Cancer Institute (NCI)).

How acupuncture works is not well understood, but laboratory, animal, and human studies have attempted to differentiate the multiple putative mechanisms involved. In the late 1970s and early 1980s, researchers demonstrated acupuncture analgesia was associated with the stimulation of endogenous opioid peptides and biogenic amines through the central nervous system (Helms, 1997). Although these findings helped give acupuncture scientific credibility, rigorous and systematic research is needed to make clear recommendations as specific mechanisms may be dependent upon the symptom being treated, which point is stimulated, and the type of stimulation used.

Definition

Acute diseases tend to have very quick onsets and typically last for only a brief period. By defining a disease as an acute disease, it does not necessarily address the severity of the disease. In fact, it typically only refers to the length of the disease or illness. Acute diseases, as opposed to chronic diseases, include a very rapid onset and/or a short course. Acute diseases can occur throughout all bodily systems. Examples of acute diseases include appendicitis, acute leukemia, and strep throat. Some acute diseases do not require hospitalization or medical treatments, such as influenza, whereas others, such as pneumonia and acute myocardial infarction, may require medical attention and extended treatment.

Definition

Acute myocardial infarction (AMI), also known as heart attack or acute coronary syndrome (ACS), is a clinical condition that occurs when blood flow to regions of the heart is suddenly interrupted, causing myocardial ischemia and eventually cell death. Most commonly, this is caused by coronary atherosclerosis and is initiated by the rupture or erosion of a complex, lipid-laden plaque that then triggers thrombus formation, causing the total or subtotal occlusion of the coronary artery in question. Rarely, non-atherosclerotic processes such as vasospasm, vasculitis, and spontaneous coronary artery dissection may also lead to myocardial infarction (Antman & Braunwald, 2008).

Description

Acute myocardial infarction is further classified into ST elevation myocardial infarction (STEMI) and non-ST elevation myocardial infarction (NSTEMI), depending on the presence of ST segment elevation on the 12-lead electrocardiogram (ECG). ST segment elevation is typically associated with thrombi that are completely occlusive, leading to a large zone of infarction involving the full or nearly full thickness of the affected portion of the ventricle. In the absence of prompt revascularization, most patients will go on to develop pathological Q waves, and the term Q wave myocardial infarction is sometimes used interchangeably with STEMI in the past (Antman & Braunwald, 2008). NSTEMIs, also referred to as non-Q wave myocardial infarction, are thought to be due to thrombi that cause subtotal occlusions severe enough to lead to myocardial necrosis. The term unstable angina (UA) is used to refer to situations in which cell deaths do not occur despite the presence of subtotally occlusive thrombi and clinical symptoms of ischemia such as chest pain (Cannon & Braunwald, 2008). These three entities, STEMI, NSTEMI, and UA, together constitute the spectrum of acute coronary syndrome, a clinically important concept that is the foundation of current diagnostic and management pathways.

Despite recent declines, acute myocardial infarction remains a significant public health burden in the United States, affecting as many as 785, 000 Americans in 2010 (American Heart Association Statistics Committee, 2010). This is in part due to the high burden of risk factors such as hypertension, hyperlipidemia, diabetes mellitus, tobacco smoking, obesity, and physical inactivity in the general population. Patients with acute myocardial infarction typically present with chest pain or pressure radiating to the arm or jaw that is worse with exertion and is associated with shortness of breath, nausea, vomiting, or diaphoresis. Elderly patients and diabetics can often present with atypical symptoms. Upon presentation, timely performance of ECG is essential to determine the presence of ST segment changes, and biomarkers such as cardiac troponins or the muscle–brain (MB) fraction of creatine kinase (CK) are used to confirm myocardial necrosis. Noninvasive imaging modalities such as stress echocardiography or nuclear stress testing can be helpful in equivocal cases (Cannon & Lee, 2008). In order to standardize case definition for both clinical practice and research, current guidelines have recommended that at least two of the following three criteria be met for the diagnosis of acute myocardial infarction: characteristic symptoms, ECG changes, and a typical rise and fall of biomarkers (Thygesen, Alpert, & White, 2007).

For patients with STEMI, the cornerstone of care is timely reperfusion therapy through percutaneous coronary intervention (PCI) or fibrinolysis, which has been shown to improve survival in multiple studies. In the absence of contraindications, it is recommended that patients undergo emergent PCI within 90 min of presentation or receive fibrinolytics within 30 min of arrival in settings where PCI is not available or will be delayed (Antman, 2008). For patients with NSTEMI, an early invasive strategy utilizing PCI is recommended for those with high-risk features such as positive biomarkers or significant ST segment changes (Cannon & Braunwald, 2008). Regardless of the type of myocardial infarction, occasionally, urgent or emergent coronary artery bypass grafting (CABG) may be

required depending on findings on coronary angiography. In terms of pharmacological therapy, both STEMI and NSTEMI patients have been shown to benefit from aspirin, antiplatelet agents such as clopidogrel, beta blockers, statins, ace inhibitors and angiotensin receptor blockers, and anticoagulants such as heparin, low-molecular-weight heparin, and bivalirudin. Nitrates and morphine are often used for symptom relief but have not been shown to improve survival (Anderson et al., 2007; Kushner et al., 2009). Despite these therapeutic advances, myocardial infarction is the cause of death for more than 140,000 Americans annually (American Heart Association Statistics Committee, 2010).

Patients who survive the initial episode of myocardial infarction are also at risk for a number of complications, including heart failure, ventricular free wall rupture or ventricular septal defect, ventricular tachyarrhythmias, left ventricular thrombus, and recurrent myocardial infarction. Careful follow-up and adherence to the prescribed medical regimen is essential for secondary prevention. In addition, lifestyle changes such as smoking cessation, regular exercise, weight loss, and dietary modifications have been shown to be beneficial, but substantial challenges remain in motivating patients to maintain healthy behavioral changes over time. Of note, psychosocial factors such as depression and poor social support have also been shown to be independent risk factors for major adverse cardiovascular events after myocardial infarction, but thus far there is only limited evidence that interventions targeting these can reduce adverse outcomes (Anderson et al., 2007; Kushner et al., 2009).

Definition

Addictive behaviors (AB) are a cluster of persistent compulsive behaviors which people feel an uncontrolled urge to perform, without which they fear experiencing loss of control or a very negative outcome. The American Psychiatric Association defines substance dependence as: "When an individual persists in use of alcohol or other drugs despite problems related to use of the substance, substance dependence may be diagnosed. Compulsive and repetitive use may result in tolerance to the effect of the drug and withdrawal symptoms when use is reduced or stopped. This, along with Substance Abuse are considered Substance Use Disorders. . .." (DSM-IV & DSM-IV-TR: Substance Dependence).

Description

AB include smoking, ingesting street and medical drugs, alcohol consumption, or even other normally healthy activities such as sports, among other behaviors. There is often comorbidity between AB and mental health problems. In the AB, there is a repetitive form of behavior lasting various periods of time from perhaps months to years, and an eventual dependence on the sought material or activity. The prevalence of AB varies according to the type of AB, gender, age group, and geographic region. For example, a national survey conducted in the USA in over 43,000 people found a lifetime prevalence of alcohol dependence of 12.5% (Hasin, Stinson, Ogburn, & Grant, 2007). Among 12th grade American students, 6.1% take marijuana daily (National Institute of Drug Abuse). When researching risk factors of AB, one needs to distinguish between abuse of certain agents (e.g., drug abuse) and dependence on such agents, resulting in AB. Risk factors of AB vary between ages and genders. In youth, these can include peer pressure and parental behavior (in favor and against). In adults, unmarried people, men, and low income are among the socioeconomic correlates of alcohol dependence (Hasin et al., 2007). A review of studies on life events and alcohol found that the type of event mattered – while health and financial problems predicted reduced alcohol intake, life events related to the spouse, friends, or retiring predicted increases in alcohol consumption in longitudinal studies

(Veenstra et al., 2006). Overattention to environmental cues associated with alcohol in alcoholics, as measured by the emotional stroop test, was found in another study to be associated with alcoholism (Lusher, Chandler, & Ball, 2004). Among the different mechanisms proposed to account for AB are operant conditioning – the consumed material produces a feeling of reward, pleasure, or reduction in distress, all which serve as reinforcements and eventually form the basis for the dependence on the consumed material and the AB. Neural mechanisms underlying AB include activation of dopamine-rich regions in the brain. One study found that the mesencephalon, a dopamine-rich region, showed higher activity specifically in response to drug-related words in cocaine users than in healthy controls (Goldstein et al., 2009). Thus, AB is a severe public health problem worldwide, with multiple risk factors spanning from socioeconomic, perceptual, environmental, and biological, hence requiring a multilevel type of intervention.

Ader, Robert

Marc D. Gellman
Behavioral Medicine Research Center, Department of Psychology, University of Miami, Miami, FL, USA

Biographical Information

Robert Ader was born in 1932. He was a native of the Bronx, New York, and a graduate of Tulane University. He received his Ph.D. at Cornell University. He then joined the faculty at the University of Rochester Medical Center and quickly rose through the ranks, becoming a professor of psychiatry and psychology in 1968. He held numerous positions and titles during his tenure at the University of Rochester, including the George Engel Professor of Psychosocial Medicine and Distinguished University Professor. He retired in July 2011 as professor emeritus. He had received an honorary doctor of science degree from Tulane and an honorary medical degree from Trondheim University in Norway.

Major Accomplishments

Ader coined the word psychoneuroimmunology to describe the field of study he helped create.

He was editor and later co-editor of the book *Psychoneuroimmunology*, first published in 1981, that details the research supporting the proposition that the brain and immune system are an integrated system. He was the founder and past president of the Psychoneuroimmunology Research Society, and also past president of the Academy of Behavioral Medicine Research and the American Psychosomatic Society. He launched the journal *Brain, Behavior and Immunity*, and in 2002, the Psychoneuroimmunology Research Society created an award, the Robert Ader New Investigator Award, to be given to promising young scientists.

His theories that the human mind could significantly affect the ability of the immune system to fight disease were initially greeted with heated skepticism and sometimes scorn when he proposed them more than 30 years ago. However, they are now applied and studied in many medical specialties, as well as by researchers around the world.

In the early 1970s, in what would become one of his most distinctive experiments, Ader was studying taste aversion conditioning in rats. In the experiment, rats drank different volumes of a saccharin solution and also were injected with a dose of Cytoxan, an immunosuppressive drug that induces gastrointestinal upset. The rats "learned," or were conditioned, to avoid consuming the solution. When he stopped giving the rats the drug but continued to give them the saccharin solution, not only did the rats avoid drinking the solution but also some of the animals died. The magnitude of the avoidance response of the rats was directly related to the volume of solution consumed. Additionally, the mortality rate varied with the amount of solution consumed. Ader believed that this orderly relationship could not be due to chance. It was through these experiments that he discovered that the rat immune system can be conditioned to respond to external stimuli. This was one of the first scientific experiments that demonstrated that the nervous system can affect the immune system.

In an interview conducted in 2010 that appeared in the newsletter of the American Institute of Stress, Ader commented as follows: "As a psychologist, I was unaware that there were no connections between the brain and the immune system so I was free to consider any possibility that might explain this orderly relationship between the magnitude of the conditioned response and the rate of mortality. A hypothesis that seemed reasonable to me was that, in addition to conditioning the avoidance response, we were conditioning the immunosuppressive effects (of Cytoxan). It seems to me that basic research on the interactions among behavior, neuroendocrine and immune processes has a bright future that promises new developments in our understanding of adaptive processes with profound consequences for the maintenance of health and for the treatment of disease."

This hypothesis was tested and confirmed in a classic study employing deliberately immunized animals, the results of which were published in 1975 in the journal *Psychosomatic Medicine*. Conditioning is one form of learning, and, as such, involves the higher centers of the brain. Ader's study, clearly demonstrating that immune responses could be modified by classical conditioning, meant there were connections between the brain and the immune system and that the mind could have profound effects on the body's functions that were thought to be independent.

In his paper published in 2010 in the journal *Psychosomatic Medicine*, Ader and his fellow Medical Center researchers described the use of a placebo effect to successfully treat psoriasis patients with a quarter to a half of the usual dose of a widely used steroid medication. Early results in human patients suggest that this new technique could improve treatment for several chronic diseases that involve mental state or the immune system. Following publication of this paper, Ader observed that "Our study provides evidence that the placebo effect can make possible the treatment of psoriasis with an amount of drug that should be too small to work. . ..While these results are preliminary, we believe the medical establishment needs to recognize the mind's reaction to medication as a powerful part of many drug effects, and start taking advantage of it."

Editors' Note: Dr. Ader passed away in 2011.

Adherence

Patient compliance

Definition

Adherence is a term used to describe the extent to which an individual's behavior coincides with health-related instructions or recommendations given by a health care provider in the context of a specific disease or disorder. The term has been used extensively in psychology and medicine in reference to acute, chronic, and preventive treatment regimens (e.g., a course of prescribed medication, wound self-care), preventive health screenings, dietary restriction, exercise recommendations, smoking cessation, and other health behaviors. Although *adherence* is synonymous with *compliance* in many contexts, the former is often preferred by behavioral scientists and allied health professionals given its emphasis of patient-provider collaboration as opposed to a more authoritarian, provider-centered exchange.

Description

Extent and Implications of Nonadherence

Despite significant advances in biomedical science related to the treatment of disease, the problem of nonadherence remains pervasive. Although estimates of nonadherence vary considerably as a function of (a) the length and complexity of the treatment regimen, (b) setting and population, and (c) assessment method, data suggest that rates of nonadherence range from 20% to 80%. From an economic standpoint, medication nonadherence has been estimated to cost upwards of $300 billion annually in avoidable medical spending in the USA alone, a figure that does not include the cost implications of nonadherence to all health care regimens. In addition to the enormous monetary cost, nonadherence also has implications for the efficacy and effectiveness of medical treatment regimens. Specifically, not only has patient nonadherence been linked to treatment failures but it also may directly undermine future treatment efficacy due to its contribution to the development of drug-resistant disease strains as well as complications regarding the establishment of empirically based guidelines for medication usage.

Assessing Adherence

Numerous strategies for assessing adherence behavior have been employed by researchers and clinicians alike. These include patient self-report, clinician judgment, clinical/health outcomes, medication measurement, electronic medication monitors, computerized pharmacy

records, biological indicators, and directly observed therapy. Each strategy is reviewed here in turn.

Patient Self-Report

Subjective patient reports remain the most widely used assessment method largely because they are quick, inexpensive, and can be administered by persons with little or no technical expertise. Furthermore, self-report may be the only method of ascertaining patient attitudes and experiences related to a specific medication regimen. For example, a patient choosing to split dosages in order to share medication with a significant other will not necessarily be identified as nonadherent through objective assessment methods (reviewed below). Despite these benefits, however, evidence indicates that patients significantly *underestimate* rates of nonadherence. In addition to memory biases inherent in retrospective recall of behavioral events, patients may be hesitant to report nonadherent behavior to health care providers or behavioral scientists for fear of rebuke.

Recognizing the limitations associated with patient self-report – particularly when requested over an extended period, such as days or weeks – many have advocated the use of *ecological momentary assessment* (EMA), a method in which patients are asked to report about their behavior over several, discrete points in time. Because EMA captures events in "real time," it minimizes recall biases; however, it is important to note that EMA does require considerably greater patient burden and still may be subject to certain methodological issues, such as poor adherence to the self-assessment protocol itself.

Clinician Judgment

Similar to evidence regarding patient self-report, health care providers also significantly underestimate rates of nonadherence in their patients. Evidence suggests that less experienced providers are the least likely to recognize nonadherence, but identification of such patients is difficult for providers at all levels and specialties. This may be due, in part, to stereotypes about what constitutes an adherent patient including gender and race, attributes which are not consistently related to adherence behavior. Collectively, this overall lack of provider awareness of patient nonadherence has clinical implications regarding adjustments to patient treatment regimens as well as the frequency and aggressiveness of patient follow-up over time.

Clinical Outcomes

Adherence researchers have also utilized clinical outcomes – such as infection resolution or changes in blood pressure – as proxies of treatment adherence. These measurements must be interpreted with caution, however. Evidence indicates that poor physical health is significantly predictive of treatment nonadherence, clouding any interpretation of an association between clinical outcomes and adherence behavior. In addition, the extent to which many clinical and health outcomes are related to adherence behavior either varies considerably or is largely unknown, further complicating the use of such measures as indicators of adherence.

Medication Measurement

Medication measurement methods, such as pill counts or the weighing of liquid medication, represent a straightforward, objective way of estimating adherence. Much like self-report methods, however, medication measurement is subject to several limitations. In particular, pill counts have been repeatedly shown to be an insensitive index of nonadherence. One possible explanation is the phenomenon of medication "dumping" in which patients choose to discard unused medication for fear of appearing nonadherent. Patients may also share medications with family members on the same (or similar) treatment regimen. Even if patients are not actively engaging in deception or sharing, medication measurement methods are further limited because they provide no indication of regimen fidelity (i.e., whether the medication, if ingested, was taken as directed).

Electronic Medication Monitors

A more advanced method of tracking medication usage is through the use of electronic medication monitors. In contrast to more simplistic

medication measurement – such as pill counts – electronic monitoring allows a clinician or researcher to capture some information regarding regimen fidelity. For example, one of the most widely used systems is the Medication Event Monitoring System (MEMS), which may be used with any regimen consisting of pills or capsules. The MEMS "Track Cap" records the date and time of each cap removal, which is stored in a small chip affixed to the bottle and may later be downloaded to a computer for analysis. Evidence indicates that systems like MEMS are a more sensitive measure of adherence when compared to other measurement methods including clinician judgment, patient self-report, and pill counts. Although electronic monitoring methods may alleviate some concerns associated with other assessment strategies, they are not without limitations. Much like pill counts, electronic methods also are tied to the assumption that medication removal may be equated with medication ingestion.

Computerized Pharmacy Records

Behavioral scientists have developed methods that utilize prescription refill records from computerized pharmacy databases to obtain estimates of adherence. These methods, often referred to as *refill compliance* (RC) measures, ascertain the timing of medication refills and calculate the percentage of time patients have a necessary supply of medication(s) during a specific time frame. RC estimates utilize a considerable amount of information including the drug name, dosage, quantity dispensed, and date of refill; thus, RC estimates may be computed for individual medications, specific classes of medications, and/or across all prescription agents taken by a particular patient.

Much like the methods already reviewed, RC estimates, too, are limited. For example, while a patient may obtain prescription refills on a regular basis, RC measures do not provide information as to whether a patient takes the drug(s) as directed. Furthermore, abrupt, provider-directed changes to a patient's regimen may not be accurately captured. Lastly, RC methods are not useful for estimating adherence to short-term or discretionary treatments, such as a brief course of antibiotics or prescription analgesics used "as needed." On balance, however, increasing evidence supports the validity of RC methods with strong associations reported between pharmacy records and other measures of adherence including medication measurement, biochemical assays, and other clinical outcomes.

Biological Indicators

Clinical analyses, such as biochemical assays and other laboratory tests, may be used to estimate adherence through measurement of medication, metabolites, or drug tracers in serum or urine. Such methods are free of subjective biases, but may be limited in several other ways. Biochemical assays are, at present, only available for a limited number of patient drugs and are influenced by individual differences in drug metabolism. Moreover, these methods are often quite costly, precluding their use in routine clinical care. Lastly, even biological indicators may be compromised if a patient alters adherence behavior close to the time of analysis.

One example of an oft-used, widely available laboratory test is the hemoglobin A1C assay (a.k.a., glycosylated hemoglobin), a reliable and valid clinical indicator of glycemic control in diabetic patients. Because diabetic patients must adhere to a complex self-care regimen in order to maintain blood glucose control (e.g., insulin injections, restricted diet, exercise, frequent blood glucose testing), self-reported adherence may be especially biased and/or difficult to capture given the array of relevant behaviors to be measured. The hemoglobin A1C assay provides a more stable – though imperfect – proxy of adherence (i.e., glycemic control) over the previous 2–3 months. Hemoglobin A1C levels are now routinely used in both clinical care and research and have become the gold standard with respect to diabetes diagnosis and care.

Directly Observed Therapy (DOT)

Finally, DOT – as indicated by its name – requires the direct observation of patients as they complete each treatment or dose to confirm adherence. DOT was developed in the context of

tuberculosis (cf. Bayer & Wilkinson, 1995), an infectious disease requiring complex, months-long treatment and, consequently, is fraught with challenges to patient adherence. In particular, those most affected by tuberculosis (e.g., IV drug users, the homeless) were also those least likely to adhere to treatment. Besides tuberculosis treatment, DOT has proven a successful adherence strategy in studies of patients with HIV, pertussis, and hepatitis C. Overall, DOT may be most useful in the context of those illnesses that mutate quickly, are highly contagious, or where patient adherence is the primary barrier to treatment effectiveness.

Determinants of Adherence

Over the past 50 years, much research has worked to identify determinants of patient adherence. Although health care providers typically attribute nonadherent behavior to patient characteristics, the determinants of nonadherence are multifaceted and quite complex. Reviewed below are several characteristics known to be associated with patient adherence.

Characteristics of the Treatment Regimen

Relative to the other general categories of adherence determinants, characteristics of the treatment regimen have been less studied. Despite the paucity of data in this context, however, research consistently indicates that the complexity of the specific treatment regimen appears to substantially influence adherence behavior. For example, much evidence demonstrates that patients have more trouble adhering to prescribed treatments when multiple (vs single) doses are required throughout the day or are attached to certain caveats (e.g., "take with food"). Moreover, multifaceted regimens have been shown to yield poor adherence behavior as well. For example, diabetic patients (i.e., those required to meet multiple, complex self-care responsibilities) often have the highest levels of nonadherence compared to other patient populations. Of note, the correlations among various facets of complex treatment regimens are known to be quite low, suggesting that otherwise adherent patients may have trouble navigating multiple, complex treatment demands.

Patient Characteristics

Research regarding patient characteristics has typically focused on either (a) sociodemographic or (b) psychological correlates of adherence behavior. With respect to the former, few consistent patterns have emerged, perhaps with the exceptions of patient age and socioeconomic status (SES). Across numerous treatment settings and patient populations, younger individuals tend to exhibit poorer adherence behaviors as compared to older adults, although not uniformly. Patients of lower SES also tend to have increased rates of nonadherence irrespective of the treatment setting.

Patient psychological characteristics, such as personality traits and individual differences related to patient beliefs and expectancies, have been extensively studied in the context of treatment adherence. For example, the Five Factor Model personality trait of conscientiousness – reflecting self-control, dependability, deliberation, and the will to achieve – has been related to adherence in some (e.g., dietary adherence in end-stage renal disease patients), but not all, contexts. In addition, *health locus of control* (HLC), or the extent to which one believes that good health is a product of one's own behaviors as opposed to external or chance factors, has been shown to be associated with better adherence in several studies. In some instances, patients believing that health outcomes are due largely to their own behaviors (i.e., *internal* health locus of control; IHLC) exhibit more favorable adherence; however, other research has failed to demonstrate any association between IHLC and adherence while still others have found it to be associated with *worse* adherence. At best, the relationship between HLC and adherence is unclear. Some have speculated that patients with an IHLC orientation may demonstrate poorer adherence in contexts where self-care demands are minimal and patient control over health outcomes is limited.

Adherence researchers have also shown a decided interest in patient self-efficacy or the extent to which an individual believes he/she is capable of performing the behavior(s) needed to bring about a certain outcome. Much evidence

has consistently demonstrated the importance of patient self-efficacy in multiple treatment contexts, including diabetes, chronic kidney disease, HIV, transplant recipients, and post-MI recovery. Notably, some evidence suggests that locus of control and self-efficacy – distinct, yet complementary constructs – best predict adherence when considered in tandem, suggesting avenues for future research.

Patient Depression

Patient experience of psychological distress, particularly depression, has been investigated extensively in the context of patient adherence. Hallmarks of clinical depression include decreased motivation, psychomotor retardation, and cognitive deficits, all of which seemingly may impact adherence intentions and subsequent behaviors. Similar to other patient characteristics reviewed above, however, evidence of any relationship between depression and patient adherence is inconsistent.

Such findings may be explained, to some extent, by the way in which depression is captured (i.e., via self-report or diagnostic interview) and the context in which adherence is measured. Any relationship between depression and nonadherence is likely to be a function of the neurovegetative symptoms of depression noted above, each of which may be less likely in patients with subclinical depression. Consistent with this line of thought, research using self-report measures to capture depressive affect (vs structured clinical interview) tends to show weaker associations with adherence outcomes. Furthermore, some evidence demonstrates that as self-care demands increase, so do associations between depression and nonadherence, making the specific disease context in which adherence is measured extremely important.

Provider Characteristics

Health care provider (and practice style) characteristics have not been extensively considered in the context of adherence, nor have many significant associations materialized. While provider age, gender, and race/ethnicity seem to have little to do with the level of patient adherence, limited evidence suggests that the degree of information provision afforded patients is related to adherence; however, this variable seems to be more strongly associated with patient satisfaction than patient adherence.

Patient-Provider Interaction

Perhaps more important is the *interaction* between patient and provider. Health care delivery is decidedly interpersonal; thus, it seems remiss not to consider the patient-provider dyad in the context of adherence. Indeed, a growing body of evidence suggests that the symmetry, or match, between a patient and his/her provider on health-related attitudes toward illness and the health care context itself may be important for patient adherence. Christensen and his colleagues have done considerable work in this area, finding that patients and providers with similar attitudes regarding control over one's health (i.e., IHLC; see above) as well as preference for self-management and shared decision-making regarding treatment are predictive of adherence. Future research regarding patient-provider interaction in the context of treatment adherence may shed additional light on some of the issues reviewed heretofore.

Socio-Environmental Characteristics

Although considerable research underscores the importance of perceived quality and availability of social support in the context of adherence, the totality of evidence is, at best, mixed. Several studies in various disease contexts have found social support to be either unrelated or inconsistently related to adherence; still, others have reported social support to be related to poorer treatment adherence within certain contexts. In such instances, researchers have speculated that social support may confer a barrier to adherence – such as increased social obligations or stigma – particularly when a regimen requires changes in dietary behavior, which is known to be heavily influenced by social factors.

Facilitating Adherence

Strategies aimed at facilitating, or increasing, patient adherence may be classified in one of

three general categories: behavioral, psychoeducational, and socio-environmental. Behavioral strategies – such as patient self-monitoring, contingency contracting, stimulus control, and behavioral cues/reminders – have been implemented widely in the context of chronic treatment regimens. Collectively, such strategies have yielded modest success in facilitating patient adherence. For example, behavioral techniques have been commonly used to help improve adherence among diabetic patients; in particular, self-monitoring strategies have resulted in improved adherence to dietary guidelines and, as such, have been touted as a crucial component of modern diabetic therapy.

Psychoeducational strategies, including the provision of written or computer-based education, appear to be most effective when patients are given explicit, tailored recommendations relative to their disease and treatment versus interventions that impart more general health-related information. Although briefer psychoeducational interventions have demonstrated reasonable success, clinicians and researchers should be aware that multifaceted regimens (e.g., those associated with diabetes, transplant recovery) likely require considerably more instruction to confer a significant benefit.

Finally, several socio-environmental strategies have also been used to facilitate adherence. The most common strategy increases contact between the patient and health care provider, such as the treating physician or study nurse, with mixed success. Similarly, patient support groups and enhancement of the patient's family support structure through counseling have been attempted with some success. Much of this work, however, has been plagued by inattention to theory and poor methodology, highlighting the need for further investigation.

Conclusions

Patient adherence is as fundamental a component of effective health care as the treatment regimen itself. However, despite extensive study over five decades, nonadherence remains a significant problem. In both research and clinical care settings, measurement of patient adherence behavior may take many forms, all with considerable strengths and weaknesses. Many determinants of adherence remain unknown, underscoring not only the remarkable complexity of patient adherence but also the difficulty in reliably predicting behaviors often associated with enormous health-related consequences and, ultimately, the need for further investigation of this dynamic phenomenon.

Definition

Adhesion molecules are the protein molecules that are situated on the surface of the cells or the intracellular organelle.

Description

The adhesion molecules attach to adjacent cells and help with binding with these cells or extracellular structures. There are several functions described like transmitting the information (cellular signaling pathways) to communicate between cells and within the cells. The adhesion molecules usually share a common basic structure that they have extracellular and intracellular domains that are connected to transcellular domain. This facilitates their function to act as messenger across the cellular membrane on either side.

Adhesion molecules are classified based on the function, structure, and location. Cadherins, integrins, selectins, and immunoglobulin (Ig)-related cell adhesion molecules (CAMS) are four major types of adhesion molecules. Brief summary of these molecules are described below.

The cadherins are calcium-dependent adhesion molecules, and they are activated when the extracellular domain is attached to calcium. The intracellular domain connects to various intracellular proteins to perform several functions. The details about epithelial (E)-cadherin, neural (N)-cadherin, and placental (P)-cadherin have been described in relation to several tissue function and also embryogenesis.

The integrins are transmembrane proteins that are composed of different subunits (e.g., alpha and beta subunits). These have been described in the signal transfer from within cell to extracellular matrix and also from extracellular to intracellular structures.

The selectins are the type of adhesion molecules, and they are glycoproteins in their composition. When the specific carbohydrate related to cellular signaling pathway attaches to the extracellular domain, these selectins transmit the signal across the cellular membrane. Platelet-selectins, leukocyte- selectins, and endothelial-selectins are subtypes of selectins, and they are involved with various functions related to platelet, leukocyte, and platelet activity at the cellular level.

The immunoglobulin (Ig)-related cellular adhesion molecules (CAM) are independent of calcium for their activity. Vascular-cell adhesion molecules (VCAM-1), neural (N)-cell adhesion molecule (NCAM), intercellular adhesion molecule (ICAM), and platelet-endothelial cell adhesion molecule (PECAM) have been related to dysregulations of the vascular system, nervous system, and platelet-thrombosis.

These adhesion molecules may be involved with each other in the process of various functions of the cellular signaling pathway. For example, during the inflammatory process, white blood cells (leukocytes) are transferred across the endothelial lining to the subendothelial layer of the vasculature which is a multistep process and an important part of the early pathogenesis of atherosclerosis. Initially, leukocytes come in close proximity to endothelial cells which are selectin mediated. The integrins activate the surface adhesion molecules in the presence of

several pro-inflammatory factors including various extracellular proteins and cytokines. The integrins also help with the attachment of the leukocytes to the endothelium. With the help of PECAM, the leukocytes migrate across the endothelium (diapedesis) to the subendothelial space. Subsequent complex changes occur, leading to the development and progression of atherosclerosis. Various adhesion molecules have been described in the context of cancer metastasis, growth of tumor cells, and embryogenesis.

Definition

Adipose tissue is a loose connective tissue composed of adipocytes. It is composed of roughly only 80% fat. Adipocytes are the cells specialized in storing energy as fat. Adipose tissue also serves as an important endocrine organ by producing hormone such as leptin (Kershaw & Flier, 2004).

There are two types of adipose tissue, white adipose tissue (WAT) and brown adipose tissue (BAT). White adipose tissue is involved in the storage of energy, whereas brown adipose tissue serves as a thermogenic organ.

Adjuvant Chemotherapy

Antineoplastic medication given following the primary cancer treatment, usually surgery or radiation, with the goal to improve relapse-free survival.

Description

Paul Ehrlich, a famous German chemist, was the first to coin the term "chemotherapy" or the use of chemicals to treat disease in the early 1900s (DeVita & Chu, 2008). While known for his work on drugs to treat infectious disease, he also worked with anticancer agents. However, his work and the work of others that followed him, usually with single agents, were fraught with challenges (DeVita & Chu). The idea that cancers could be cured with chemotherapy first became widely accepted around 1970 with successes in both childhood leukemia and Hodgkin's lymphoma using multi-agent regimens (DeVita & Chu; Frei, 1985). Prior to this time, surgery and radiation were the mainstay for solid tumor treatment. However, even for the most aggressive surgical or radiotherapy regimens, cure rates did not exceed 33% (DeVita & Chu, 2008).

Interest in adjuvant chemotherapy arose from experiments in animal models showing that chemotherapy, though minimally effective against large tumors, may be curative against microscopic disease (DeVita & Chu, 2008; Frei, 1985). Work by Howard Skipper showed that a given dose of chemotherapy killed a constant fraction of tumor cells rather than a constant number (DeVita & Chu, 2008; Skipper, 1978). This inverse relationship between tumor cell number and curability suggested that drugs used against advanced disease might work better after the tumor was eradicated with primary treatment such as surgery (DeVita & Chu, 2008).

Even after optimal local control is achieved with surgery and/or radiotherapy, advanced stage tumors and aggressive pathology findings are often associated with a high likelihood of disseminated micrometastases or microscopic residual disease (Skipper, 1978). In such cases, administration of additional or adjuvant treatment may eradicate microscopic disease and decrease chances of relapse. These concepts were first tested and reported for breast cancer in the mid-1970s with successful results (DeVita & Chu, 2008; Frei, 1985). This success triggered a plethora of adjuvant studies in breast and other tumors such as colorectal cancer (DeVita & Chu, 2008). The resulting therapies have contributed significantly to the national decline in breast and colorectal cancer mortality that has been witnessed in recent years (DeVita & Chu, 2008). Other solid tumors have also shown benefit with adjuvant chemotherapy (DeVita & Chu). These include cervical cancer, gastric cancer, head and neck cancers, pancreas cancer, melanoma, non-small cell lung cancer, osteogenic sarcoma, and ovarian carcinoma (DeVita & Chu).

Chemotherapy, radiation therapy, immunotherapy, hormonal therapy, and targeted therapy have all been used as adjuvant treatments. Each of these is associated with specific side effects that can be severe and must be weighed against the potential benefits. Side effects of chemotherapy, for example, can include nausea, vomiting, hair loss, and drops in blood cell counts. Patients who experience treatment-related adverse effects are more likely to discontinue adjuvant therapy (Burstein et al. 2010). Thus the decision to proceed with adjuvant treatment can be complicated, especially when the disease appears to be eradicated and may indeed never return, even without further treatment (Burstein et al.). This is even a more difficult decision if the primary treatment was physically and emotionally draining for the patients, such as a disfiguring and debilitating surgery (Burstein et al.). The decision to proceed with adjuvant therapy requires a thorough discussion between the patient and their surgical, medical, and radiation oncologists with thorough explanation of the potential risks and benefits.

Admixture

Abanish Singh
Duke University Medical Center,
Durham, NC, USA

Definition

The use of racial classification in medicine and biomedical research has become a popular tool and is very helpful in understanding racial and ethnic differences in the causes, expression, and prevalence of disease traits. Usually, human society is classified based on color and linguistic and cultural differences. However, these classifications often ignore the availability of interbreeding. Breeding between members of different classes can result in the exchange of genetic information which can further affect genetic disease profiles.

The phenomenon of interbreeding between the members of two or more different population groups is known as genetic admixture. It results in continued, long-term exchange of genes among the various human society classifications. The admixture process creates linkage disequilibrium between loci in a hybrid population and its magnitude is guided by several factors such as time duration, dynamics, recombination rate, and allele frequency differential in parental populations. Admixture can be estimated reliably from the genetic similarities if the accurate identities of parental populations in the hybrid population are available.

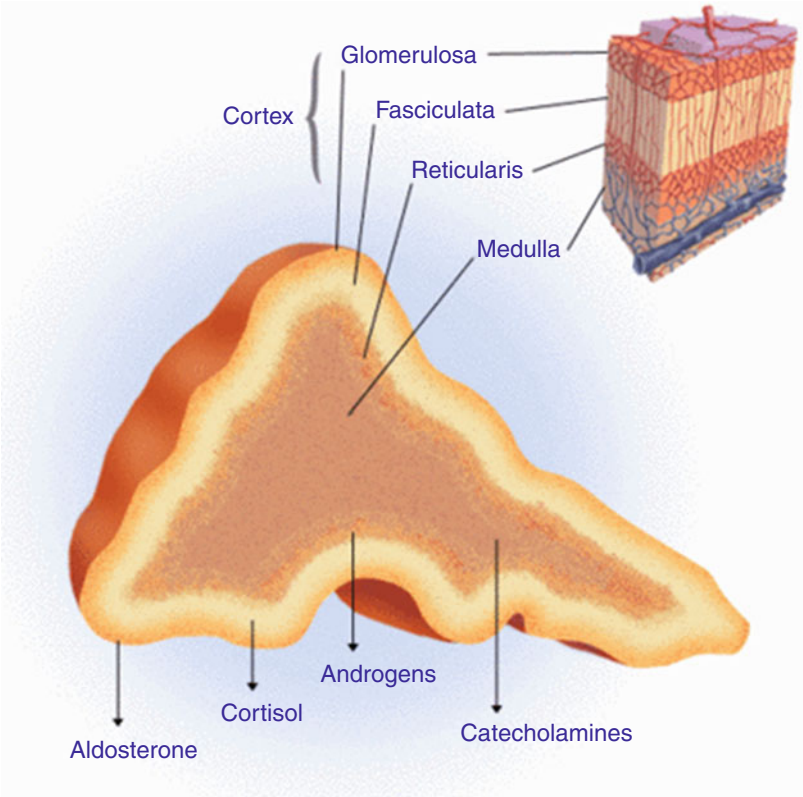
Adrenal Glands

Linda C. Baumann and Alyssa Karel
School of Nursing, University of Wisconsin-Madison, Madison, WI, USA

Definition

The adrenal glands are part of the endocrine system which is comprised of various glands



Adrenal Glands, Fig. 1 The zona glomerulosa, the zona fasciculata, and the zona reticularis

that are located throughout the body. These glands are responsible for synthesizing and producing hormones which communicate regulatory information to cells and organs. The adrenal glands are primarily responsible for the stress response in the human body secondary to physical or emotional stimuli. The two adrenal glands are pyramid-shaped organs located directly anterior to the kidneys and behind the peritoneum. Each adrenal gland consists of two distinct portions: an inner medulla and an outer cortex. Each portion has differing structures and hormonal functions, but are interrelated.

Description

The adrenal medulla synthesizes and secretes the catecholamines epinephrine and norepinephrine. Major effects of catecholemines are increased rate and force of contraction of the heart muscle, constriction of blood vessels, dilation of bronchioles, stimulation of lipolysis in fat cells, increased metabolic rate, dilation of the pupils, and inhibition of nonessential processes.

The adrenal cortex is subdivided into three layers which are primarily responsible for producing corticosteroids (see Fig. 1). The outer layer, the zona glomerulosa, is responsible for secreting the mineralocorticoid aldosterone. The middle layer, the zona fasciculata, and the inner layer, the zona reticularis, produce adrenal androgens and estrogens, and glucocorticoids such as cortisol. Aldosterone, the major mineralocorticoid, is necessary for survival and is responsible for increases in sodium reabsorption from the renal tubule, saliva, and gastric juice which results in increased reabsorption of water. Secondary actions of aldosterone include maintenance of blood pressure and potassium regulation. Cortisol, the most potent of the

glucocorticoids, is responsible for stimulation of gluconeogenesis, mobilization of amino acids from extrahepatic tissues, inhibition of glucose uptake in muscle and adipose tissue, and stimulation of fat breakdown. Cortisol also has potent anti-inflammatory and immunosuppressive properties. In the absence of corticosteroids, the stress response would induce hypotension, shock, and death.

In general, an individual will experience a stress response when a stimulus exceeds their coping abilities which can result in disturbances of cognition, emotion, and behavior. The stress response starts in the central nervous system and endocrine system. It is cyclical in nature and will continue as long as the stimulus is present. Stress responses can be either acute or chronic in nature. Acute stress responses are a result of an immediate threat; subconscious, false, or perceived. The process will elicit a reaction most commonly known as the fight or flight response. In this circumstance, individuals may exhibit behaviors secondary to physiologic changes including anxiety, rapid speech, restlessness, facial tics, teeth grinding, and nail biting to name a few. Once an acute stressor is eliminated or overcome, the body shuts down the process through a negative feedback system and hormone levels eventually return to normal. Not all stressful situations are detrimental and at times may be desirable. It can prompt individuals to work toward worthwhile goals, relieve monotony, and can play a part in pleasurable activities.

In a chronic stress response, the stress cycle is continually activated leading to elevated hormone levels. Chronic stress can be related to weight gain and obesity. Individuals crave salt, fat, and sugar in an attempt to counteract tension secondary to the sustained release of cortisol into the blood stream. Sustained levels of stress hormones have also been detected in individuals with eating disorders such as anorexia nervosa and bulimia. Chronic stress can lead to insomnia and impaired memory and concentration. It can also contribute to major anxiety, depression, and suicidal ideations, as well as behaviors such as alcoholism and drug abuse.

Personality traits, such as Type A personality, can contribute to a maladaptive stress response. Type A personality is characterized by hostility, impatience, and competitiveness. These traits can lead to an increased risk of hypertension, heart disease, job stress, alcoholism, and social alienation.

Individual reactions to stress depend on factors such as knowledge about the stress response, learned behaviors, personality type, and attitudes about controlling, altering, and adapting to stressful situations. The importance of healthy stress management can reduce some of the maladaptive behaviors associated with the adrenal glands and the stress response.

Adrenergic Activation

Debra Johnson
Department of Psychology, University of Iowa, Iowa City, IA, USA

Definition

Adrenalin/epinephrine is a neurotransmitter produced by and released from the adrenal glands. Release of this chemical activates the sympathetic nervous system through the alpha-adrenergic and beta-adrenergic receptor families and produces the classic "fight-or-flight response" including increased blood pressure, heart rate, and respiratory rate. While this system is adaptive in the context of acutely stressful events, prolonged stress can produce a chronic overactivation of the adrenergic system. This overactivation is implicated in the development and progression of chronic health problems including hypertension and coronary artery disease.

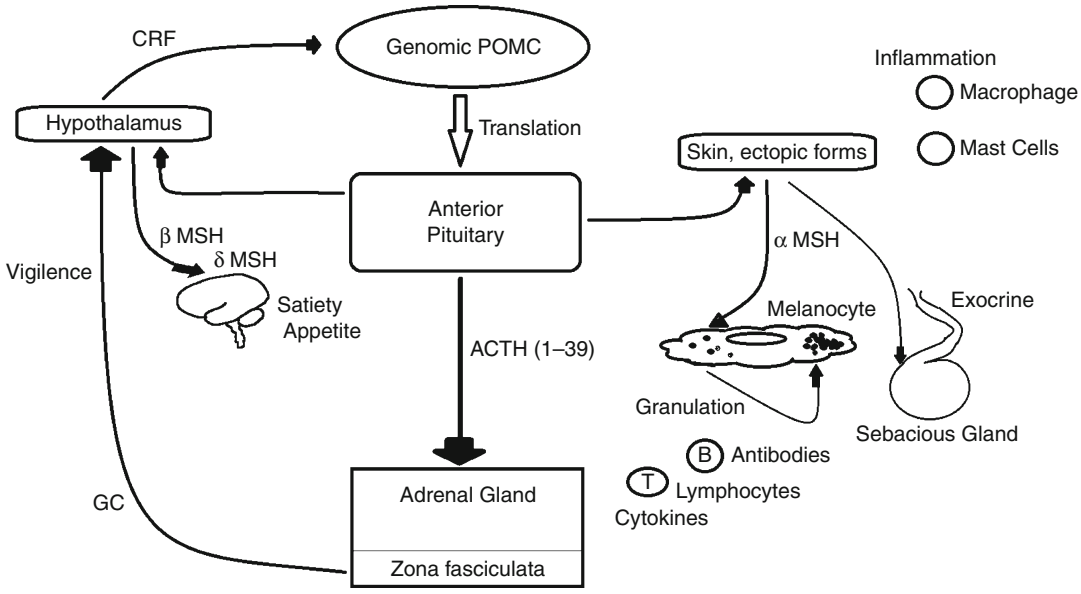
Adrenocorticotropin

Benjamin L. Clarke
Academic Health Center, School of Medicine-Duluth Campus, University of Minnesota, Duluth, MN, USA

Definition

Adrenocorticotropic hormone (ACTH) is a peptide hormone produced by corticotropin cells of the anterior pituitary. Discovery of ACTH and subsequent characterization focused on a pituitary substance known to stimulate glucocorticoid synthesis from the adrenal cortex; hence, the name reflects this tropic hormone function. Pituitary production of ACTH is stimulated by corticotropin-releasing hormone (CRH), a peptide hormone emanating from the "nuclei" neurons found in the hypothalamus (see Fig. 1). Released CRH then passes through the hypophyseal portal vessels into the anterior pituitary to target corticotropin cells. The hypothalamus provides a cognitive nexus for translating central nervous system (CNS) activity into an endocrine signaling pathway responsible for stimulating the adrenal cortex. This triad of hypothalamus-pituitary-adrenals activity is often referred to as the HPA axis. A large number of behavioral and physiological responses are controlled by the HPA in order to sustain physiological homeostasis. The canonical HPA activity is CNS control of glucocorticoid release following physical or emotional stress to promote physical responses. The "fight or flight" response is a common behavioral pattern regulated by the HPA. Heightened HPA activity increases cognitive vigilance, plasma glucose, and metabolic activity while suppressing tissue repair and anabolic processes. Excessive HPA activity is often associated with behavior conditions like anxiety and depression, and medical conditions such as fluid retention and obesity.

ACTH is coded by the proopiomelanocortin (POMC) gene located on Chromosome 2 in humans. The initial gene product is a pro-form protein that is differentially processed into active peptide hormones within corticotropin cells of the anterior pituitary. In the precursor form, POMC is a polypeptide consisting of 241 amino acids. Embedded in the polypeptide POMC are several different peptide hormones. Due to "tissue-specific processing" of POMC, a large number of peptide hormones are produced at the site of action. Specific POMC-derived hormones are revealed by the action of pro-hormone convertases (PC). This differential processing is controlled by the expression of two different PCs, (PC1 and PC2) that are localized to different tissues. The majority of POMC peptide is produced in the anterior pituitary and the proteolytic fragments are redistributed to distal sites for additional processing. Corticotropin cells in the anterior pituitary express PC1 which



Adrenocorticotropin, Fig. 1 Generation of ACTH

hydrolyzes POMC to first form pro-ACTH and beta lipotropin hormone (β-LPH). A second round of hydrolysis by PC1 on pro-ACTH produces ACTH and N-POMC. A third round of hydrolysis by PC1 on N-POMC produces pro-γ-MSH and a joining peptide (JP) fragment. The most abundant form of ACTH has 39 amino acids, ACTH (1–39); however, minor amounts of several smaller sized ACTH are also produced. Several other peptide hormones are also derived from POMC using a second convertase expressed in the hypothalamus and skin. Products from differential processing by PC1 in the pituitary are distributed to distal tissues to be further processed by PC2. This process of disseminating ACTH peptides to other sites provides specificity for biological activity. The pro-γ-MSH is converted to γ-MSH by PC2. ACTH (1–39) is converted by PC2 to form ACTH (1–17) and corticotropin-like intermediate peptide (CLIP). ACTH (1–17) is then converted into α-MSH by the sequential action of carboxypeptidase E, peptidyl-amidating monooxygenase, and N-acetyl transferase. Beta-lipotropin hormone is converted into γ-LPH and beta-endorphin by PC2, and γ-LPH is converted by PC2 into beta-melanocyte-stimulating hormone (β-MSH). The two major corticotropins, ACTH and α-MSH, share the first 13 amino acids. However, α-MSH has two important chemical changes that alter solubility and transport properties; the amino terminal serine is acylated and the carboxyl terminal valine is amidated. Common to all corticotropins is a tetra-amino acid sequence of histidine-phenylalanine-arginine-tryptophan (H-F-R-W). Point substitutions within the HFRW sequence completely oblates the activity of ACTH, α-MSH, β-MSH, and γ-MSH.

Cellular recognition of ACTH and MSH molecules has been attributed to melanocortin receptors (MCRs) (see Table 1). Five different G-protein-coupled receptors have been cloned and characterized for biological activity. Specific binding of POMC-derived peptides are dependent on the presence of the HFRW sequence embedded within the hormone sequence (see Table 2). Selectivity between potential hormone ligands is the HFRW sequence, peptide length, and chemical modification of the peptide termini. The steroidogenic receptor for ACTH is MC2R has the highest stringency requiring both the HFRW sequence plus a highly anionic tetra peptide sequence of lysine-lysine-arginine-arginine (KKRR) at positions 15–18. The MSH peptides do not possess the KKRR sequence and are not

Adverse Drug Reaction

Debra Johnson
Department of Psychology, University of Iowa, Iowa City, IA, USA

Definition

An adverse event is a negative change in health observed in individuals participating in clinical drug trials or trials of medical devices. These events may occur during the trial or within a short time after the trial ends. They may or may not be due to the drug or device and can be categorized as minor (i.e., hypotension) or serious (i.e., life-threatening complications or even death). Minor adverse events are reported to the facility's institutional review board and to the sponsor of the trial. Serious events must additionally be reported to the regulatory agencies (i.e., FDA). In recent years, several large clinical trials have been halted because of serious adverse events observed in the patient groups.

Aerobic Exercise

Rachel Millstein
SDSU/UCSD Joint Doctoral Program in Clinical Psychology, University of California, San Diego/San Diego State University, San Diego, CA, USA

Synonyms

Exercise; Moderate-vigorous physical activity

Definition

Aerobic exercise refers to the type of repetitive, structured physical activity that requires the body's metabolic system to use oxygen to produce energy. Aerobic exercise improves the capacity of the cardiovascular system to uptake and transport oxygen. Aerobic activity can be undertaken in many different forms, with the common feature that it is achieved at a heart rate of 70–80% of a person's age-appropriate maximum. Aerobic exercise is considered the cornerstone of endurance training, characterized by moderate energy expenditure over a prolonged period of time. Aerobic power or endurance is measured by VO_2 max, a person's maximal oxygen uptake.

Description

Aerobic exercise is different from, though related to, physical activity and exercise in general. Physical activity is a broad category that refers to all bodily movements that require skeletal muscle contraction and energy expenditure. Exercise is a subset of physical activity, requiring specifically planned, structured, and repetitive movements with a goal of improving performance or fitness (Caspersen, Powell, & Christensen, 1985). Aerobic exercise can be undertaken in many different forms, such as brisk walking, running, cycling, swimming, cross-country skiing, and dancing. In contrast, anaerobic exercise involves high-intensity work done for shorter periods of time. The anaerobic metabolic system does not require oxygen to be used for energy.

Aerobic exercise was popularized by Dr. Kenneth Cooper, following the publication of his 1968 book, *Aerobics*. Since that time, the research and knowledge of the health benefits of aerobic exercise have grown and are widely known. The many health benefits of regular aerobic exercise include improved cardiorespiratory endurance, improved muscular endurance and strength, improved body composition, reduced risk of type 2 diabetes, reduced risk of osteoporosis and several cancers, and improved mental health (anxiety and depression symptom reduction).

Several authoritative groups have set forth recommended aerobic physical activity guidelines for health benefits. The United States' Centers for Disease Control and Prevention (2008) recommend that adults achieve at least 150 min of moderate-intensity or 75 min of vigorous-intensity aerobic physical activity each week. Youth are recommended to accumulate 60–90 min or more, or physical activity a day. Moderate-intensity physical activity requires about 3–6 times as much energy as resting (i.e., brisk walking), and vigorous-intensity physical activity requires about 7 times as much energy as resting (i.e., jogging).

Definition

Affect is the collective term for describing *feeling states* like emotions and moods. Affective states may vary in several ways, including their duration, intensity, specificity, pleasantness, and level of arousal, and they have an important role to play in regulating cognition, behavior, and social interactions.

Description

Affect is the experiential state of feeling. In everyday language, terms like affect, emotion, and mood are often used interchangeably. Affect is the superordinate category; emotions and moods are states belonging to this category. Emotions and moods are mainly distinguished by their duration, and by whether they are directed at a specific cause. Emotions are fairly fleeting and intense experiences that are elicited in response to specific external stimuli (i.e., objects or events), and may arise relatively automatically, or following a cognitive appraisal of a stimulus (e.g., How does the stimulus relate to my goals? How personally relevant is this stimulus?). Moods last somewhat longer than emotions, and are more diffuse in nature. For instance, a generalized feeling of sadness with no specific cause would be considered a mood state. People's experiences of affect over a long period of time can be summarized to represent their subjective well-being, i.e., their global assessment of happiness and satisfaction with life.

Describing and Distinguishing Affective States

Affective states are typically distinguished along the dual dimensions of pleasure and arousal. Pleasure concerns the hedonic properties of the state, ranging from unpleasant to pleasant, and arousal concerns the level of engagement or alertness of the state, ranging from activated to deactivated. So, for example, "anxiety" is a low pleasure high arousal state. Pleasure is usually measured by self-report (i.e., asking people how pleasant they feel), while arousal can be measured by self-report or by using physiological data (e.g., heart rate, epinephrine).

There are at least five "basic" emotions – anger, disgust, fear, happiness, and sadness – that are thought to be highly idiosyncratic and distinguishable according to a particular pattern of cognitions, physiology, facial expressions, and "action tendencies" that predispose a person to act in a certain way. For instance, the emotion of fear is distinguished by the cognitive appraisal of danger, physiological arousal in terms of higher heart rate, blood pressure, and perspiration, a facial expression involving widened eyes, dilated pupils and drawn brows, and the action tendency of fleeing a situation. More complex emotions like jealousy, shame, and pride may have distinguishable

cognitive and expressive elements, but may not be reliably associated with specific patterns of physiological arousal or action tendencies.

Functions of Affect

Affect has important cognitive functions, being used as a source of information when judging the value or valance of objects or people, priming congruent memories, and influencing decision-making and information processing and possibly decisions. Positive affect appears to be linked to broadening of attention, with benefits for creativity and problem solving, while negative affect is associated with narrowing of attention, with benefits for more focused tasks. Affect also serves a function in regulating behavior. Mood states give rise to broad tendencies toward approach or avoidance behaviors (pleasant moods are associated with a drive to approach a stimulus, whereas unpleasant moods are associated with avoidance), while emotions are associated with specific action tendencies (e.g., anger is associated with the tendency to "fight"). Similarly, anticipated affect drives our behavior, such that we pursue those behaviors we deem likely to result in desirable affective outcomes, and avoid those likely to result in undesirable affect. Affect may also function to regulate social behavior, by communicating information to others about how we would like them to engage with us (e.g., guilt signals a desire to be forgiven).

Individual Differences in Affect

Some people are more prone than others to experiencing particular affective states. Those with high negative affectivity tend to experience unpleasant affect much of the time, while those with high positive affectivity tend to experience pleasant affect. People may also be more or less reactive to affective stimuli. Those who are high in trait neuroticism are thought to have a lower threshold for reacting to stimuli, and also appear to react more intensely. Individual differences in the extent to which people outwardly communicate their affect (expressivity), and the extent to which people are able to deliberately control their experienced and expressed affect (affect regulation), have also been observed.

Synonyms

Activation; Arousal; Energy; Tension

Definition

Affect arousal is the state of being activated, either physiologically or psychologically, and is one dimension of our affective response to emotional stimuli. Psychological characteristics of arousal include feelings of vigor, energy, and tension. Physiological symptoms of arousal include increased heart rate and blood pressure, among other changes.

Description

Affect arousal describes the state of feeling awake, activated, and highly reactive to stimuli. There are both psychological and physiological components to the state of arousal. Psychologically, the state of arousal is associated with the subjective experience of feelings including high energy and tension. Physiologically, the body is in a state of relative heightened responsiveness, and is prepared for action through the activation of various neural (limbic) and bodily systems (e.g., the sympathetic nervous system). The state of arousal is usually prompted by external, typically highly emotive, stimuli (such as being in a dangerous situation, or watching a scary movie). Some argue that arousal occurs immediately after exposure to an emotive stimulus; others suggest that exposure to a high arousal stimulus first prompts the person to appraise the personal meaning of the stimulus (Is it congruent or incongruent to my goals? Is it important to my survival?), with arousal experienced as a result of the appraisal.

Psychological and Physiological Components of Arousal

Affective states are typically described in terms of their valence (pleasure-displeasure) and their arousal (high activation-low activation). Thus, psychological arousal is one dimension of our affective response to external stimuli. High activation or arousal is characterized by feelings of energy for pleasurable states (e.g., excitement), or tension for unpleasant states (e.g., fear). These can be distinguished from low arousal states such as calmness and depression. Arousal can also be distinguished from intensity, which is a separate dimension; both high and low arousal states may be experienced more or less intensely. It has been argued that there is a second arousal dimension of sleepiness energy that follows circadian rhythms.

Several systems underlie physiological arousal, including the autonomic nervous system, the reticular activating system, and also the endocrine system, which releases hormones including adrenalin and noradrenalin into the bloodstream. The physiological symptoms of arousal are diverse, and include increases in heart rate, blood pressure, perspiration, respiration rate, muscle tension and metabolic rate, and changes in the electrical activity of the brain – in its regions, hemispheres, and in the connectivity between regions.

Functions of Arousal

High affective arousal prepares the body to respond to stimuli, priming us for "fight or flight." Arousal also influences cognitive processing in ways that may be adaptive for survival. Arousal appears to influence attention, with high arousal stimuli capturing attention more efficiently, thus recruiting more processing and coping resources; this may be why high arousal stimuli are also evaluated and responded to more quickly than low arousal stimuli. Arousal also has implications for memory. Studies have observed enhanced memory for arousing events, although high states of arousal can also cause short-term impairments in retrieval of memories. In addition, retrieval of memories is facilitated when experiencing a similar level of arousal to that during encoding. Arousal may also function to regulate task performance. Most agree that the relationship between arousal and performance takes the form of an inverted U-shaped curve, such that states of either extremely low or extremely high arousal are detrimental to performance.

Individual Differences in Arousal

Individual differences in arousal may underlie core personality traits. According to a theory originally proposed by Eysenck, differences in baseline physiological levels of arousal (i.e., autonomic nervous system and reticular activating systems) cause people to be more or less extraverted. For example, low baseline arousal is associated with high extraversion, because people seek the stimulation they lack from their external environment. Likewise, the trait of neuroticism is thought to reflect a person's threshold for activation in the autonomic nervous system. People with higher levels of neuroticism have a lower threshold, and are therefore less able to inhibit their emotional reactions.

Definition

Aggregate measures, or data, are summaries of observations, or measurements, derived from individuals in the group or groups of interest.

This is a wide-ranging term used in many circumstances. The key concept is that data used are not individual measures, but a summary statistic reached by aggregating large amounts of data from individual subjects, geographic regions, socioeconomic classes, etc.

Measures of central tendency are useful aggregate data. Commonly used measures include the arithmetic mean (usually called simply the mean), median, and mode. For example, median family income in a given region, state, or country would be aggregate data. Proportions are also useful, e.g., the proportion of a given identified population that smokes cigarettes.

Aging

Barbara Resnick
School of Nursing, University of Maryland, Baltimore, MD, USA

Synonyms

Alter; Changing; Grown; Progress

Definition

Aging relates to the developmental process of growth and senescence over time. *Age-related* refers to how age is taken into account in health and social systems.

Description

Many of the changes associated with aging result from gradual loss. These losses may often begin in early adulthood, but individuals are usually not affected by changes until the loss is fairly extensive. Most organ systems seem to lose function at about 1% a year beginning around age 30 years. The loss of function in an organ, for example, does not become significant until it crosses a given level. Thus the functional performance of an organ in an older person depends on two principal factors: (1) the rate of deterioration and (2) the level of performance needed. It is not surprising then to learn that most older persons will have normal laboratory values, normal heart rate and blood pressure, and normal vision and hearing. It is possible, however, when stressed such as by doing exercise that the heart then does not respond appropriately or when it is dark the eyes do not adjust in a timely fashion. The health care provider must appreciate and utilize the notion of variability in aging to help individuals make lifestyle and treatment choices to optimize their own aging. As noted, changes occur over time but there is no known way in which to predict the rate of decline in any individual. There is, however, much evidence to support the benefit of lifestyle interventions, specifically diet and physical activity that will help to overcome some of the physical changes that can occur with age, and may improve overall health and quality of life. With regard to diet, repeatedly it has been noted that there are protective effects to diets low in saturated fats and high in fruits and vegetables. Likewise, engaging in regular physical activity, at least 30 min daily, has been noted to have not only physical but mental health benefits. Behavior change interventions are critical to facilitate adherence to these behaviors at any point in the lifespan.

It is impossible to address aging without considering the psychosocial aspects that occur in addition to the more visible biological and physical changes. Transitions associated with aging are commonly noted around retirement, loss of a spouse or significant other, pet, home, car, and ability to drive, as well as the loss of sensory function (hearing and vision) or ambulatory ability or capacity. Many fear the loss of independence with age, cognitive decline and worry about having an acute catastrophic problem such as a hip fracture or stroke. Conversely, many older adults are quite resilient in the face of these losses and have much to teach the younger generation on how to respond to loss, optimize remaining function and ability, and adjust.

Recognizing the consequences and anticipated changes that will occur with age are important to help facilitate the process and optimize outcomes in adults as they progress through the lifespan. Critical to the process is adherence to healthy lifestyle behaviors as well as a willingness to

adjust and adapt to the changes that are occurring. In so doing adults can age successfully, regardless of underlying disease or disability.

At this point in time there is still relatively little known about the aging process and how to separate aging and age-related changes from disease. Behavioral medicine can help manage both sources of change, although understanding and knowing the difference is critical so as to optimize outcomes. For example, it is possible that cognitive changes are occurring because of an elevated blood sugar in the individual or a low sodium. Treating this with cognitive interventions may help but will not optimize outcomes as much as combining this treatment with medical management. Conversely, it is critical to avoid treating changes medically when behavioral interventions would result in better and safer outcomes.

Many of the changes associated with aging result from gradual loss. These losses generally begin in young to middle adulthood. Fortunately, however, the changes are not noted until there is a critical mass of cell death or functional change that alters the underlying system. The changes in organ function depend on two principal factors: (1) the rate of deterioration and (2) the level of performance needed. Thus under normal circumstances the older adult may function within normal. However, when he or she undergoes some type of stress the body is not able to compensate and changes are noted in major organs such as the brain, kidney, heart, lungs, or liver. Behavioral interventions can help to optimize response in times of stress by preparing individuals for such these experiences. An older adult who exercises regularly prior to breaking a hip or undergoing a joint replacement will recover quicker than an individual who has not been regularly exercising.

Aging is a complex and multifactorial process that combines life experiences and behaviors and genetics particularly. It is critical to remember, however, that the genetic impact of life span accounts for 35% of its variance, whereas environmental and behavioral factors account for >65% of the variance.

Changes associated with aging are believed to be a combination of normal change over time and disease. Often individuals do not notice aging until they hit a certain threshold of loss or change. For example, the loss of function does not become significant until it crosses a given level. Likewise, the loss of function in an organ such as the liver is not noticed until there is sufficient amount of cell death that functional change occurs. Thus aging is noted based on two principal factors: (1) the rate of deterioration and (2) the level of performance needed. A good example of the impact of aging on the system occurs with regard to cardiovascular function and health. An older individual may have a normal resting pulse and normal cardiac output when engaging in routine daily activities. When he or she tries to exercise, however, the heart rate and cardiac output do not respond in the way that would be anticipated in a younger individual (i.e., neither the pulse or the output increase sufficiently to withstand the activity).

Unfortunately, much of what we know about aging is based on studies doing using cross-sectional samples of individuals of different ages that are compared in terms of group averages. Such an approach generally reveals a gradual decline in organ function with age, beginning in early middle life. A few studies have followed cohorts of people longitudinally as they age. Their conclusions are quite different. When evaluated over time some characteristics and aspects of aging may actually improve rather than decline. Individual variation may be particularly important to aging. Individuals who have been physically active throughout their lifespan will be more likely to recover optimally following a hip fracture, for example, than those who have been sedentary.

Aging is not simply a series of biological changes. It is also an accumulation of life experiences and accrued knowledge. It may also be associated with multiple losses such as the loss of social roles such as work, motherhood, loss of income, loss of friends and relatives. These losses can result in fear of loneliness, financial insecurity, fear of dependency, and fear of one's own

death. Despite these fears and challenges most older adults cope with multiple losses and limitations and enjoy this time in life.

Increasingly it is recognized that aging occurs differently depending on the person. The changing composition of today's older adults compared with that of a generation ago may actually reflect a bimodal shift wherein there are both more disabled people and more healthy older people. We continue to learn more and more about healthy or successful aging through hearing the stories of the growing number of centenarians. Generally the consensus is that moderation in all areas (e.g., food intake, alcohol intake), regular physical activity, and an engaging social life are critical to successful aging.

Definition

An agonist is any molecule which binds to a receptor on a cell, which then can potentially lead to subsequent changes in the cell's functions. While agonists activate a process that follows their binding to a receptor, an antagonist inhibits these effects, and an inverse agonist results in opposite effects to those of the agonist. In pharmacology, this issue is pivotal, as certain medications can act as agonists of receptors, where they mimic the effects of a natural compound or ligand that normally binds to the same receptor. However, the synthetic compound can possibly lead to similar cellular changes without unwanted side effects. Receptors can be activated by endogenous agonists – a natural compound which binds to a receptor. In contrast, receptors can also be activated by exogenous agonists – synthetic medications or compounds which activate a receptor. An example of an endogenous agonist is acetylcholine which activates the acetylcholine receptor. One important measure concerning agonists is their affinity to a receptor – the degree to which they structurally and functionally fit a receptor. Consequently, there are full and partial agonists. These influence the subsequent effects of an agonist on a cell's function. Another measure of the efficacy of an agonist is its EC_{50} – the concentration of agonist needed to elicit half the biological response to that agonist. The potency of an agonist is inversely related to the EC_{50} value, as a more potent agonist requires lower concentrations to yield a certain response than a weaker agonist. Multiple agonists are used in research and clinical applications, of relevance to behavioral medicine as well. For example, isoproterenol is a drug that stimulates the sympathetic response since it is an agonist of beta-adrenoreceptors, mimicking the effects of epinephrine (Goodman, Gilman, & Brunton, 2008). Some compounds can have both agonist and antagonist characteristics. An intriguing example is tamoxifen, which is an antagonist of estrogen used in cancer treatment, yet it is also an agonist of breast cancer cells, which induces cell-cycle-related gene activity (Hodges et al., 2003). Thus, agonists reflect a basic biochemical process at cellular levels and play numerous roles in health and disease.

Definition

Acquired immunodeficiency syndrome (AIDS) is the final stage of the human immunodeficiency virus (HIV) defined by a marked decline in an individual's immune system. Specifically, when an individual's CD4 lymphocyte/helper T cell count falls under 200 per microliter (μL) of blood, the individual is diagnosed with AIDS (Crooks & Baur, 2005; Shibley Hyde & Delamater, 2008). AIDS is defined as a syndrome because its presence is often accompanied by a grouping of illnesses that signal the progression of HIV to AIDS (Kelly, 2008). These AIDS-defining illnesses, termed opportunistic infections, include, but are not limited to, *Pneumocystis carinii*, Kaposi's sarcoma, cervical cancer, and *Mycobacterium tuberculosis* (Crooks & Baur, 2005; Jekel, Katz, & Elmore, 2001; Shibley Hyde & Delamater, 2008; World Health Organization, 2010b).

Description

History of AIDS

AIDS was first recognized as a disease in 1981 by the Centers for Disease Control and Prevention. It was not until 1984 when Luc Montagnier's team at the Pasteur Institute in France and Robert Gallo's team at the National Institute of Health in the United States discovered that HIV was the cause of AIDS (Shibley Hyde & Delamater, 2008). In the United States, the epidemic was first extensively identified in men who have sex with men (MSM) and was therefore called "gay-related immune deficiency" (GRID; Shilts, 1987). As outbreaks of HIV/AIDS were also seen among injection drug users (IDUs), Haitian immigrants, and hemophiliacs, the disease was renamed AIDS (Shilts, 1987). Around the world, AIDS is mainly a disease affecting heterosexual individuals; in the United States, MSM still comprise the majority of HIV/AIDS cases (Crooks & Baur, 2005).

Epidemiology

HIV/AIDS is largely considered a global pandemic (Crooks & Baur, 2005). It is now the leading cause of death worldwide in women between the ages of 15 and 49 (UNAIDS, 2010a). According to the 2010 UNAIDS Global Report (2010b), there were 1.8 million AIDS-related deaths worldwide in 2009. Sub-Saharan

Africa accounts for the overwhelming majority of these deaths. By region, AIDS-related deaths are as follows (UNAIDS, 2010b):

- Sub-Saharan Africa: 1.3 million (72.2%)
- South and Southeast Asia: 260,000 (14.4%)
- Eastern Europe and Central Asia: 76,000 (4.2%)
- Central and South America: 58,000 (3.2%)
- East Asia: 36,000 (2.0%)
- North America: 26,000 (1.4%)
- Middle East and North Africa: 24,000 (1.3%)
- Caribbean: 12,000 (0.67%)
- West and Central Europe: 8,500 (0.47%)
- Oceania: 1,400 (0.07%)

On the whole, AIDS-related deaths worldwide have stabilized, mainly due to the advent of highly active antiretroviral therapy (HAART) in 1996 (UNAIDS, 2010b). North America and Central and Western Europe have seen a decline in AIDS-related deaths since 1996, while deaths in Sub-Saharan Africa and the Caribbean have been decreasing since 2005 (UNAIDS, 2010b). AIDS-related deaths in Central and South America and parts of Asia have remained constant; however, deaths in Eastern Europe and Central Asia are still increasing (UNAIDS, 2010b). Globally, 70% of infections are transmitted through heterosexual sex, especially in Africa and Asia (Crooks & Baur, 2005). In the United States, the epidemic is still predominantly in MSM, but rates are rising in heterosexuals, especially ethnic minority women (Crooks & Baur, 2005). In Russia, and other parts of Eastern Europe, the epidemic is due mainly to injection drug use.

Diagnosis

AIDS is the final stage of HIV and is diagnosed when the individual's immune system becomes severely compromised. Specifically, a diagnosis of AIDS is given when CD4 levels fall below 200 per microliter (μL) of blood (normal levels are between 600 and 1,200; Crooks & Baur, 2005; Shibley Hyde & Delamater, 2008). On average, HIV progresses to AIDS 8–11 years after contracting HIV (Crooks & Baur, 2005). An AIDS diagnosis is often accompanied by a number of opportunistic infections and other AIDS-related illness. Opportunistic infections are illnesses that are usually not present in humans and signal a severely weakened immune system (Shibley Hyde & Delamater, 2008); these include *Pneumocystis carinii*, Kaposi's sarcoma, toxoplasmosis, advanced cervical cancer, meningitis, encephalitis, and *Mycobacterium* tuberculosis (Crooks & Baur, 2005, Jekel et al., 2001; Maartens, 2008; Shibley Hyde & Delamater, 2008). Other AIDS-related symptoms include severe weight loss ("wasting syndrome"), diarrhea, neurological decline, and infection of most organs (NIAID, 2009b). AIDS is the end stage of HIV and is eventually fatal. However, life can be prolonged with antiretrovirals, which suppress the virus, usually resulting in an increase in CD4 cell count.

Treatment

There is no known cure for HIV/AIDS. In 1996, highly active antiretroviral therapy (HAART) was introduced (Wood, 2008), which combines multiple types of antiretrovirals to suppress HIV viral load in order to stop the progression of AIDS. There are five classes of antiretrovirals (NIAID, 2009a):

1. Reverse transcriptase inhibitors: prevent HIV from replicating in healthy cells
2. Protease inhibitors: block protease, which is used to replicate HIV
3. Fusion/entry inhibitors: block HIV from binding to healthy cells
4. Integrase inhibitors: block integrase, which helps HIV combine its RNA with the healthy cell's DNA
5. Multidrug combination products (HAART): a combination of the above classes of drugs; the World Health Organization currently recommends combining at least three classes of drugs (2010a)

Adherence to these medications is vitally important. Nonadherence can result in resistance to antiretrovirals and a resurgence of the virus in the individual (NIAID, 2010). Adherence is difficult, due to the many side effects that accompany these drugs (Shibley Hyde & Delamater, 2008) and myths that circulate about the dangers of antiretroviral use (Kalichman et al., 2009). It is also important to keep in mind the treatment

of psychological side effects of HIV/AIDS, including depression (Shibley Hyde & Delamater, 2008).

Prevention

There are two types of prevention relevant to HIV/AIDS interventions. Primary prevention is concerned with preventing an HIV− individual from contracting the disease; secondary prevention is concerned with preventing someone who is HIV+ from transmitting the virus to someone who is HIV− (Jekel et al., 2001). Behavioral HIV/AIDS prevention interventions typically include three components: information, motivation, and behavioral skills training (Fisher & Fisher, 2000). Interventions typically address how HIV/AIDS is transmitted and how to prevent it. Known behaviors that can decrease the likelihood of HIV/AIDS transmission include consistent condom use, using clean needles to inject drugs, abstinence, decreasing number of sexual partners, and remaining monogamous (NIAID, 2009c). Additionally, interventions are conducted at multiple levels (individual, dyadic, small group, community, mass media, structural).

The Centers for Disease Control and Prevention (CDC, 2009b) have put forth criteria to define what constitutes an effective behavioral HIV/AIDS prevention intervention. These criteria set guidelines for quality of design, implementation, and data analysis, as well as what constitutes support for intervention effectiveness. In addition to targeting high-risk behaviors (usually sex- or drug-related), the results of these interventions must show (a) a marked decrease in risk behaviors (sex- or drug-related), (b) a decrease in the rate of new infections, and/or (c) an increase in protective behavior (e.g., condom use). To date, there are over 40 best evidence prevention interventions that meet these criteria and can be found on two websites (CDC, 2009a; DEBI, 2010). Known as DEBIs (Diffusion of Effective Behavioral Interventions), these HIV/AIDS prevention interventions are conducted at the individual, group, and/or community level and are targeted toward specific groups (HIV + individuals, HIV − individuals, heterosexuals, MSM, IDUs, males, females, racial minorities, transgender individuals, couples, etc.).

Biologically, using antiretroviral therapy can prevent transmission of HIV/AIDS from mother to child (Shibley Hyde & Delamater, 2008). A vaccine to cure AIDS is not yet available, though research continues. Recently, preexposure prophylaxis (PrEP; CDC, 2010), microbicides (Kelly, 2008; Shibley Hyde & Delamater, 2008), and circumcision (CDC, 2008) have all offered promising results in the prevention of HIV/AIDS. PrEP is a chemoprophylaxis; it is thought that by having antiretrovirals present in the body's system before HIV enters the body, infection can be prevented (CDC, 2010). Microbicides are gels or other substances that can be inserted into the vagina or rectum with the potential to kill HIV before it can enter the individual's body (Shibley Hyde & Delamater, 2008). Finally, circumcision has been repeatedly shown in interventions to decrease the rate of HIV transmission because circumcision decreases the amount of Langerhans cells and skin tears present on the male penis, where HIV can enter the body (CDC, 2008). Research is continuing to make great strides in the fight to prevent and treat HIV/AIDS.

Definition

Alcohol abuse (AA), as defined by the DSM-IV, is characterized by a maladaptive pattern of alcohol use that leads to clinically significant impairment or distress, manifesting in at least one of the following recurrent symptoms: failure to fulfill major role obligations at work, school, and/or home; use in situations in which it would be physically hazardous (e.g., while driving); alcohol-related legal problems; and/or interpersonal problems associated with alcohol use (American Psychiatric Association [APA], 2000). The most commonly endorsed symptom of alcohol abuse is use in physically hazardous situations, and the most common situation is driving while under the influence (Harford, Grant, Yi, & Chen, 2005; Hasin & Paykin, 1999). A diagnosis of AA, therefore, is characterized not by obtaining a certain level of alcohol consumption but by the experience of alcohol-related problems. It is a widespread problem in the United States that has estimated 12-month and lifetime prevalence rates of 4.7% and 17.8%, and prevalence rates have increased steadily over the past two decades (Grant et al., 2004; Hasin, Stinson, Ogburn, & Grant, 2007). It is most prevalent in younger, white, unmarried men, yet there is evidence to suggest that this gender difference is decreasing in younger age cohorts. AA often co-occurs with other mental health disorders, including other substance abuse, nicotine dependence, panic disorder, depression, and bipolar disorder (Swendsen et al., 2010; Zvolensky, Bernstein, Marshall, & Feldner, 2006). The existence of preexisting mental health disorders predicts the transition from regular alcohol use to AA, and the odds of developing AA greatly increase when three or more mental health disorders are present (Swendsen et al., 2010).

Alcohol dependence (AD), as defined by the DSM-IV, is characterized by a maladaptive pattern of alcohol use leading to clinically significant impairment or distress. The pattern is manifested by the existence of three or more of the following symptoms: tolerance; withdrawal; using alcohol in larger amounts or over a longer period of time than intended; persistent desire or unsuccessful efforts to cut down; spending a great deal of time to obtain, use, or recover from alcohol; giving up social, occupational, or recreational activities because of alcohol use; continuing alcohol use despite knowledge of a persistent or recurrent physical or psychological problem that is likely to have been caused by alcohol. AD can occur with or without physiological dependence. Once a diagnosis of AD exists, a person cannot again meet criteria for AA (APA, 2000). Epidemiological estimates from 2001 to 2002 indicate that the 12-month prevalence rate of AD is 3.81%, which is a decrease from the 1991 to 1992 12-month prevalence estimate of 4.38% (Hasin et al., 2007). Rates of AD are higher in males (5.42%) than females (2.32%). Whites, Native Americans, and Hispanics have higher rates of AD than Asians. Lifetime prevalence of AD is estimated to be 12.5% (Hasin et al., 2007). The clinical course of AD includes fluctuations in the intensity of difficulties with alcohol and a high likelihood of recurrent cycles of abstinence that last several months or more followed by recurrent use (see Schuckit, Tipp, Smith, & Bucholz, 1997). Broadly, interpersonal and occupational problems, as well as tolerance, escalate by the mid- to late 20s, and more serious medical problems and alcohol-related abstinence syndromes are experienced by the mid-30s to early 40s (Schuckit, Daeppen, Tipp, Hesselbrock, & Bucholz, 1998). Those with physiological dependence experience more binge drinking, alcohol-related problems, physiological complications, and more alcohol-related psychiatric problems (Schuckit et al., 1998).

Definition

Alcohol consumption, as the term is used in clinical and research applications, refers to the act of ingesting – typically orally – a beverage containing ethanol. Ethyl alcohol or ethanol (CH_3CH_2OH) is the only type of alcohol that is safe for human consumption. Other types of alcohol, such as isopropyl and methyl alcohol, are toxic and potentially lethal. Alcoholic beverages that are typically consumed may include beer, wine, distilled spirits, and beverages that contain combinations of these or other additives, including malt liquor, fortified wine, liqueur, and cordials.

Description

Relevance to Behavioral Medicine

Alcohol consumption is an important construct in behavioral medicine because alcohol is a psychoactive substance that affects the body in various ways. In addition to its acute effects, it can have longer-term medical, psychiatric/psychological, social, economic, and occupational effects on individuals, families, communities, and society at large.

Cultural and Historical Factors Influencing Alcohol Consumption

Alcoholic beverages have been crafted and consumed for millennia. Alcohol consumption patterns have, however, varied widely depending on

broader macrofactors, such as historical time, cultural context, and geopolitical forces, as well as microfactors such as individuals' gender, family background, local environment, religion, and socioeconomic position (Edwards, 2000; Gately, 2008). Alcohol consumption is often regulated by law and may be shaped by cultural norms, values, and local knowledge. Some early cultures and developing communities have relied on alcoholic beverages to quench thirst when clean water was unavailable, to supplement their diet, and to stave off hunger when food was scarce (Blocker, 2006; Denning, 2000; Martin, 2006; Molamu & Macdonald, 1996). Consequently, alcohol has been provided in rations as a form of payment to workers throughout history, from ancient Egyptian builders to feudal European serfs to US troops during the Vietnam War (Gately, 2008). Alcohol consumption has also played key roles in religious and spiritual ceremonies, social celebrations, and medicine (Gately, 2008). Recent statistics from the World Health Organization (World Health Organization [WHO], 2004) suggest that per capita alcohol consumption is currently highest in certain areas in Europe (see Fig. 1 for per capital alcohol consumption in various areas of the world).

Neurobiological Effects of Alcohol Consumption

When alcohol is consumed, it is absorbed into the bloodstream via the stomach lining and small intestines, and then crosses the blood–brain barrier to affect the central nervous system. Its effects are dose dependent and include changes in memory, cognition, perception, coordination, and emotion (Dodgen & Shea, 2000). Table 1 shows possible effects of alcohol at different blood alcohol levels. These changes in the brain likely result from ethanol's effect on dopamine, acetylcholine, serotonin, NMDA, and GABA receptors (Shuckit, 2000). Studies have suggested that the activation of $GABA_A$, a specific GABA subtype, and decreased NMDA glutaminergic neurotransmission both lead to the increased sedation and decreased anxiety that are hallmarks of alcohol intoxication (Nestler & Self, 2010).

Alcohol Metabolism

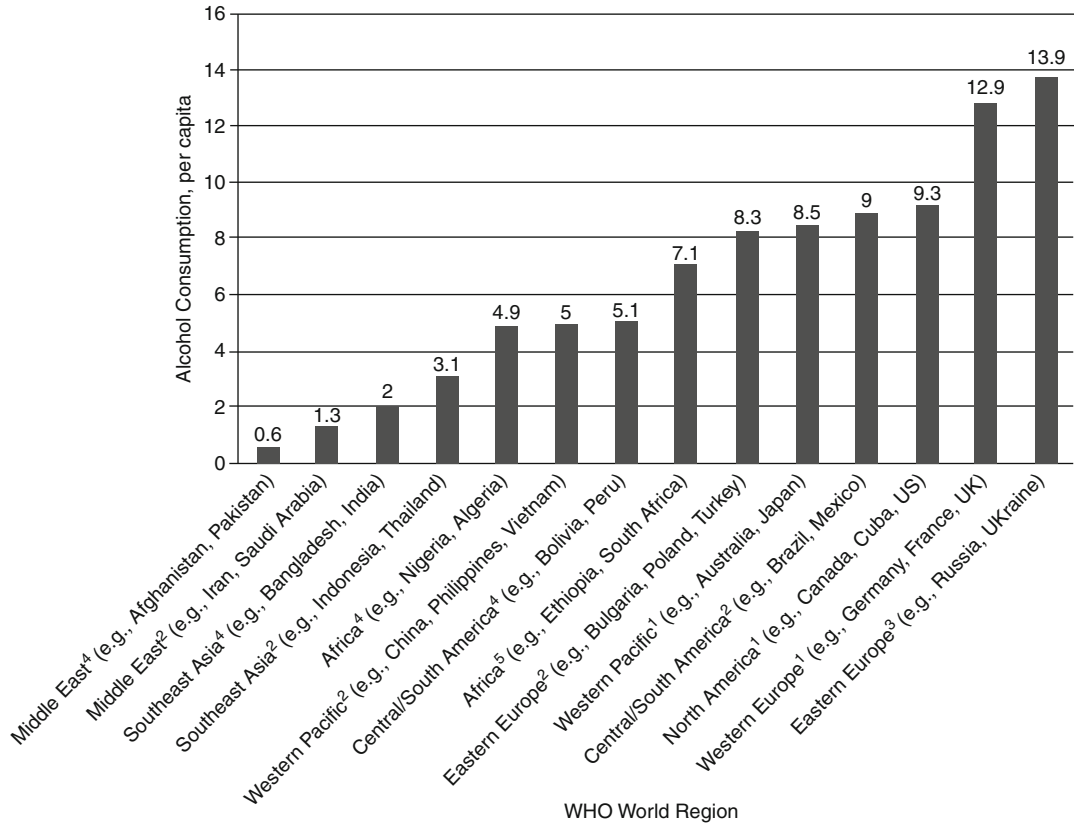
Alcohol is metabolized in the liver, where an enzyme called alcohol dehydrogenase (ADH) transforms it into acetaldehyde (CH_3CHO). Acetaldehyde is a toxic compound that is, in turn, quickly metabolized by another enzyme, aldehyde dehydrogenase (ALDH), into a less toxic compound called acetate. Acetate is finally broken down into water and carbon dioxide by various other tissues and eliminated from the body. The toxic compound, acetaldehyde, is believed to play a causal role in some alcohol-related morbidity, such as liver cirrhosis and cancer (Zakhari, 2006).

Subjective Effects of Alcohol Consumption

Although pharmacological research has indicated that alcohol is a depressant, alcohol consumption has been associated with subjectively perceived biphasic effects (Winger, Woods, & Hofmann, 2004). Thus, drinkers may report experiencing feelings of stimulation and euphoria during the ascending curve of their blood alcohol level. At higher levels of alcohol consumption (blood alcohol levels $>.08$) and/or during the descent of the blood alcohol curve, drinkers may report experiencing more depressant effects of alcohol, including sedation and/or dysphoria. Drinkers with lower sensitivity to these depressant effects of alcohol may be at greater risk for alcohol-use disorders (Schuckit & Smith, 2000). Although recent research has indicated some support for these biphasic effects, it has also shown that subjective experiences of alcohol effects vary widely and warrant further study (Morean & Corbin, 2009).

Consequences Associated with Alcohol Consumption

According to the WHO (2004), alcohol consumption is responsible for 3.2% of deaths recorded worldwide and a global loss of 58.3 million disability-adjusted life years. The alcohol-related disease burden is precipitated in part by acute intoxication, which is known to decrease reaction time, perceptual/motor skills, and inhibitions and is thereby associated with increased risk for traffic accidents, self-inflicted injury/suicide, falls,



Alcohol Consumption, Fig. 1 Numbers are based on WHO (2004) data. Alcohol consumption data are represented in liters of pure alcohol consumed per capita (inhabitants ages 15 and older) based on both recorded and unrecorded estimates. Statistics are grouped by approximate geographical regions and adult and child mortality rates

drownings, alcohol poisoning, and interpersonal violence. Longer-term effects of alcohol consumption also contribute to the disease burden by way of various medical conditions (e.g., cancer, cardiovascular disease, and liver cirrhosis) and psychiatric disorders (e.g., depression; alcohol dependence and abuse).

While the global alcohol-related disease burden is considerable, low-to-moderate alcohol consumption has been shown to have protective effects against cardiovascular heart disease, ischemic stroke, diabetes, and gallstones. "Moderate" alcohol consumption has been variously defined across cultures. According to a report on national health agency guidelines in over 30 countries, moderate alcohol consumption guidelines range from 14 g (one standard drink) to 70 g (approximately five standard drinks) per day (International Center for Alcohol Policies, 2003). According to US measurement standards, a "standard drink" refers to a 12 oz of beer, 5 oz of wine, or 1.5 oz of distilled spirits (National Institutes on Alcoholism and Alcohol Abuse [NIAAA], 2005). US guidelines distinguish between (a) "moderate drinking," which is defined as daily alcohol consumption $\leq$1 standard drink for women and $\leq$2 for men (US Department of Agriculture & US Department of Health and Human Services, 2010); and (b) "low-risk drinking," which is defined as consuming $\leq$3 standard drinks a day and $\leq$7 per week for women or $\leq$4 per day and $\leq$14 per week for men (National Institutes on Alcoholism and Alcohol Abuse [NIAAA], 2005).

Assessment of Alcohol Consumption

Measuring alcohol consumption and its potential effects on an individual is an important and challenging task for health-care professionals that often requires triangulation among self-report measures, diagnostic interviews, behavioral observation, psychological testing, examination of archival data, collection of collateral data, and biological measurement. Measures used should evince adequate reliability and validity, and if applicable, sensitivity and specificity. Screening measures such as the 4-item CAGE (Mayfield, McLeod, & Hall, 1974), 25-item Michigan Alcoholism Screening Test (MAST; Selzer, 1971), and Alcohol Use Disorder Identification Test (AUDIT; Babor, Higgins-Biddle, Saunders, & Monteiro, 1991) are often used to indicate the need for further questioning regarding alcohol consumption. Health-care providers should then inquire about the quantity and frequency of alcohol consumption during typical and peak drinking occasions within a clinically relevant time period to document current use. Quantity and frequency questions also assess for potential heavy-drinking episodes, which put a people at increased risk for alcohol-related negative consequences (e.g., four or more for women and five or more for men on a single drinking occasion; Wechsler et al., 2002). Retrospective (e.g., Timeline Followback; Sobell & Sobell, 1992) or prospective (drinking diary) measures may be used to document daily drinking over time and thereby identify individuals' longitudinal drinking patterns. Assessment of drinking patterns is important because research has indicated that alcohol consumption – even among heavier drinkers – may be best conceptualized as fluid and dynamic (Klingemann, Sobell, & Sobell, 2010; Pandina & Johnson, 2005).

The potential negative psychological effects of alcohol consumption may be assessed using structured diagnostic interviews, such as the Structured Clinical Interview for the DSM-IV-TR (SCID; First, Spitzer, Gibbon, & Williams, 2002) or the WHO's Composite International Diagnostic Interview (CIDI; World Health Organization [WHO], 1990), which systematically assess the lifetime and current presence of alcohol-use disorders (e.g., hazardous drinking, alcohol dependence, abuse, alcohol withdrawal, and/or intoxication) according to either DSM-IV-TR or ICD-10 criteria. Finally, negative physiological effects of alcohol consumption may be assessed using blood tests to detect elevated liver enzymes (GGT, ALT, AST), increased red blood cell size (MCV), and/or carbohydrate-deficit transferrin (CDT), which, taken together, may indicate damage due to heavy alcohol use (Warner & Sharma, 2009).

Allele

J. Rick Turner
Cardiovascular Safety, Quintiles, Durham, NC, USA

Definition

Alleles are alternate forms of a gene, with any given gene having one or more alleles. While humans, for example, share the same genes, each human does not have an identical pattern of alleles. If the two alleles at a particular locus are the same, that locus is homozygous; if they are different, it is heterozygous. Alleles influence phenotypes and contribute to the differences between individuals. Alleles for genes occur in pairs.

Imagine that a specific gene has two alleles, represented by the upper case letter G and the lower case letter g. At a certain address on each of two homologous chromosomes, there will be one of these alleles. There are four possible combinations:
G and G
G and g
g and G
g and g

The combination of the two alleles determines what phenotype results from a particular pairing of alleles. If the allele G is dominant (and the allele g is therefore recessive), the phenotype encoded by the G allele will occur for each of the first three combinations. Only in the fourth combination, where the recessive allele is present on both chromosomes, will the phenotype encoded by the g allele occur. The terms autosomal dominant inheritance and autosomal recessive inheritance are used in this context.

Allele Heterogeneity

Abanish Singh
Duke University Medical Center, Durham, NC, USA

Definition

The complement of an individual's genes is known as the genotype, and observable traits such as physical characteristics (height, weight, skin color and eye color, etc.) and disease status such as diabetes and heart disease are known as phenotypes. A process known as natural selection provides a mechanism of evolution along with mutation, migration, and genetic drift in DNA. Mutations cause changes in genetic code and create diversity or allelic variation in genotypes. The alteration in DNA sequence at a single nucleotide is known as single nucleotide polymorphism (SNP). Though often it was believed that a phenotype is caused by a single SNP or a cluster of SNPs in linkage disequilibrium, it remains no more a rule. There have been several lines of evidence that different SNPs within a gene can cause the same phenotype. This phenomenon of different mutations at a single locus causing the same phenotype is known as allelic heterogeneity.

There are several examples where allelic heterogeneity has been observed, such as β-thalassemias, in which several mutations in β-globin locus cause the disease phenotype. Different mutations in dystrophin locus causes Duchenne dystrophy, and multiple mutations in CFTR cause cystic fibrosis.

Allergy: Behavioral Treatment, Risk Factors, Psychosocial Aspects

Yori Gidron
Faculty of Medicine and Pharmacy,
Free University of Brussels (VUB), Jette,
Belgium

Definition

Allergies are a group of immune-mediated diseases characterized by excessive inflammatory responses to otherwise innocuous environmental compounds. Allergies include excessive white blood cell recruitment, due to elicitation of immunoglobulin E, upon exposure to such compounds. Allergies include allergic rhinitis, asthma, hay fever, eczema, food sensitivities, and hypersensitivities to insect bites (Kay, 2000). Allergic disorders are highly prevalent, and some estimate that 25% of children are affected by them (Torres-Borrego, Molina-Terán, & Montes-Mendoza, 2008). Symptoms of allergic rhinitis include excessive sneezing, tearing, runny nose, and itching nose, throat, eyes, and ears. Symptoms of asthma include wheezing, coughing, shortness of breath, and chest pain and tightness. Symptoms of food allergies are very heterogeneous and include swelling or tingling in the mouth and lips, swelling in other body parts, wheezing and nasal congestion, breathing problems, abdominal pain, nausea, vomiting or diarrhea, dizziness, and in rare occasions shock or fainting.

No clear consensus exists for their risk factors, but these may include genetic predisposition and exposure to pollution (e.g., diesel fuel). Several studies have proposed that psychosocial factors increase the risk of various types of allergies including asthma. Yet, many studies were cross-sectional, making the inferential validity questionable. One important research has also shown that family (parental) stress synergistically interacts with exposure to traffic pollution in prospectively predicting new onset of asthma: the effects of pollution on asthma onset were stronger and significant only in children with parental stress (Shankardass et al., 2009). Furthermore, allergies have profound effects on patients' physical, psychological, and social dimensions of quality of life.

A few meta-analyses were conducted testing the overall effects of psychological interventions on asthma. While some promising effects emerged on medication needs, other effects were weaker, and study quality and heterogeneity did not enable to draw firm conclusions (Yorke, Fleming, & Shuldham, 2007). Clearly, the role of psychosocial factors in allergies is an important domain for further investigation, given the high prevalence and impact of such health problems.

Allostasis, Allostatic Load

Yoshiharu Yamamoto
Educational Physiology Laboratory, Graduate School of Education The University of Tokyo, Bunkyo-ku, Tokyo, Japan

Definition

Allostasis: Achieving stability through change; the ability to adapt successfully to the challenges of daily life by feedforward mechanisms to maintain viability, emphasizing the biological imperative that "an organism must vary all the parameters of its internal milieu and match them appropriately to environmental demands" (Sterling & Eyer, 1988). This is an extension of homeostasis, i.e., stability through constancy, maintaining constancy of a vital variable by sensing its deviation from a set point and providing feedback to correct the error. Allostasis describes mechanisms that change the variable by predicting what level will be needed and then overriding local feedback to meet anticipated demand (Sterling, 2004). As such mechanisms require higher brain functions, in most cases, the allostasis deals with cephalic involvement in systemic physiological regulation, including behavioral and/or psychosocial impact. Feedforward mechanisms associated with fear, anxiety, addiction, etc., are typical examples. The neuroendocrine system, autonomic nervous system, and immune system are the primary mediators. When they are in a state of heightened activity, this is referred to as an allostatic "state."

Allostatic Load: A measure of the cumulative burden that reflects the continued operation of the allostatic state or over-activation of allostatic responses. When the adaptive responses to challenge lie chronically outside normal operating ranges, wear and tear on regulatory systems occurs, and the allostatic load accumulates as a "cost" of adaptation (McEwen, 1998). Best known and studied is the effect of the primary hormonal mediators of the stress response, glucocorticoids and catecholamines, where in the short term, they are essential for adaptation, maintenance of homeostasis, and survival, but over longer periods of time, they exact a cost that can accelerate disease processes (McEwen, 2000). The resultant secondary outcomes associated with increased risk of diseases include neuronal atrophy or hippocampal loss, atherosclerotic plaques, abdominal fat deposition, left ventricular hypertrophy, glycosylated hemoglobin, high cholesterol, low high-density lipoprotein, and chronic pain and fatigue associated with imbalance of immune mediators (McEwen, 2004). This diversity of the secondary outcomes – which demarcates the allostatic load from Selye's general adaptation syndrome – sharing the primary mediators is considered to explain the presence of a variety of comorbidity patterns of chronic illnesses (e.g., depression and diabetes, colon cancer and coronary heart disease, depression and cardiovascular disease), especially in the elderly. Thus, the allostatic load, if successfully measured, is expected to be an early warning system of biomarkers that can signal early signs of dysregulation across multiple biological systems (Singer, Ryff, & Seeman, 2004). Various attempts have been made to quantify the cumulative burden by accounting for abnormalities in the primary mediators (e.g., urinary cortisol and catecholamines) and the secondary outcomes (e.g., blood pressure and glycosylated hemoglobin), but there is as yet no established measure for the allostatic load. This is partially because

the primary mediators also vary dramatically as normal physiological responses in the allostatic state, and profiling the secondary outcomes tends to focus on specific, not diverse, pathophysiology. The characterization of the allostatic load (and state) to overcome these limitations is the future challenge.

Alpha-Amylase

Urs M. Nater
Department of Psychology
University of Marburg, Marburg, Germany

Description

Salivary measures have become increasingly important in behavioral medicine. Substances such as the hormone cortisol or the immune parameter salivary IgA can be measured in saliva as meaningful markers for various normal and pathological processes in the body. The salivary enzyme alpha-amylase (sAA) has been suggested to reflect stress-related changes in the body. Its secretion is known to be elicited by activation of the autonomic nervous system which controls the salivary glands.

Salivary alpha-amylase (a-1,4-a-D-glucan 4-glucanohydrolase; EC 3.2.1.1) is one of the most important enzymes in saliva. It accounts for 40–50% of the total salivary gland-produced protein, most of the enzyme being synthesized in the parotid glands (80% of the total). It is a calcium-containing metalloenzyme that hydrolyzes the a-1,4 linkages of starch into glucose and maltose. However, sAA has also been shown to have an important bacterial interactive function.

The components of saliva are primarily produced by acinar cells. Acinar cells are innervated by both the sympathetic and the parasympathetic branches of the autonomic nervous system (ANS). The afferent pathways for the transmission of taste are via the facial and glossopharyngeal nerves to a solitary nucleus in the medulla. Salivary glands receive their input from higher centers in response to smell, sight, etc. As parasympathetic efferences, the facial nerve innervates the sublingual and submandibular glands via the submandibular ganglion, while the glossopharyngeal nerve innervates the parotid glands via the otic ganglion. The sympathetic postganglionic pathways are from the cervical ganglion of the sympathetic chain. Norepinephrine released from sympathetic neurons binds to both alpha- and beta-adrenergic receptors on the acinar cell leading to an increase of the second messenger cyclic adenosine monophosphate (cAMP) and thus increasing saliva secretion.

In the release of sAA, beta-adrenergic mechanisms are the main contributing factors, as numerous animal and human studies have demonstrated. For example, studies have shown a sympathetic response by cold water immersion or by administering propranolol (a beta-adrenergic blocker). Exposure to cold water raises sAA activity in the parotid gland, whereas

propranolol leads to a reduction of sAA concentrations. It has also been shown that yohimbine hydrochloride, an alpha-2-adrenergic receptor antagonist, resulted in significant increases in sAA concentration relative to a placebo condition. These findings suggest that changes in sAA might be regarded as an indirect indicator of changes in autonomic activation.

Since the release of sAA is governed by activation of the ANS, an increase in sAA may be expected during psychological stress, i.e., when autonomic activation is high. In a seminal paper, Chatterton, Vogelsong, Lu, Ellman, and Hudgens (1996) published their findings of increases in sAA during a written examination. sAA increases have also been reported in response to other psychologically stressful conditions, such as experience of medical procedures, adverse musical stimuli, mothers watching their children being exposed to a stressful task, the cold pressor test, achievement and interpersonal stress, a driving simulation, use of noise exposure, a mental arithmetic task, oral academic examination, affective picture viewing, etc. Almost uniformly, these tests have resulted in sAA increases. This suggests that sAA is a highly sensitive parameter reflecting changes caused by *acute* psychological stressors. In contrast, only a handful of studies have reported associations between *chronic* stress and sAA. According to this small number of studies, there is a broad potential of measuring sAA as an index of chronic stress in selected high-risk populations.

Applications of Salivary Alpha-Amylase Measurement

Based on the knowledge that has been accumulated about the role of stress and its underlying physiological mechanisms in the secretion of sAA, it seems reasonable to conclude that sAA activity can serve as an index for pathological dysregulation of the ANS in specific clinical and subclinical conditions. As an example, anxiety-related conditions are accompanied by autonomic changes. Consequently, the measurement of sAA might provide insight into alterations in the autonomic nervous system in anxiety patients.

In addition, sAA might also be measured in the context of somatic disorders, in which autonomic dysregulation has been observed. Exaggerated autonomic responses to different stimuli or basal autonomic dysregulation can be observed in hypertensive patients, or patients with HIV or with atopic diseases. Also, a number of functional somatic syndromes, such as chronic fatigue syndrome or irritable bowel syndrome, have been shown to be associated with a dysregulation of the ANS. It will be particularly interesting to see whether these alterations are reflected in altered sAA levels. Given findings of the role of stress in clinical populations, the use of sAA to measure the effects of stress management training is expected to be a promising approach for studies of treatment effects. In general, measurement of sAA in clinical populations seems very useful in ambulatory settings where saliva collection might present an easy, noninvasive, and efficient sampling method.

Summary

sAA activity is a potential indicator for autonomic activation. Numerous studies have shown that changes in sAA can be elicited by stressful stimuli, whether they are physiological or psychological in nature. The biological meaning of this phenomenon remains to be clarified, though. Physiological stress reactions comprise orchestrated actions throughout the body, putting the organism in a state of overall preparedness to engage in fight or flight. Thus, increases in amylase activity may be one of many actions involved in activating the body's resources to cope with stressful events or threats to homeostasis. However, this explanation only applies to responses to short-term, acute stressors. Further studies are needed to examine long-term changes in sAA activity which are of particular interest in disorders associated with autonomic dysfunction.

Further studies are needed to elucidate the mechanisms underlying elevations in sAA in response to stress. Although a variety of studies have examined the physiological mechanisms of sAA production and secretion in animals, studies

in humans are scarce. Use of pharmacological agents that inhibit or activate the ANS may prove particularly useful here, providing more detailed insights into the branches of the ANS responsible for increases in sAA. Also, electrical stimulation techniques in awake or anesthetized humans, e.g., in the clinical context of a hospital, may be useful. Measurement of direct sympathetic nerve activity via microneurography is considered to be the most accurate technique for assessing sympathetic activation. Beyond peripheral measurements, the relationship between central parameters and changes in sAA might prove very interesting.

Future studies will show to what extend sAA will play a role within the research of pathophysiological mechanisms and treatment of stress-related disorders.

Complimentary and alternative medicine; Integrative medicine

Definition

Complementary and alternative medicine (CAM) encompasses a broad and diverse range of therapies, practices, and products which are not considered a part of conventional scientific medicine. It may be utilized in conjunction with

(complementary) or in place of (alternative) conventional health care. They are widely utilized by patients to improve health and well-being; however, they have not yet had adequate research, are not commonly taught in the health-care professional curriculum, and are not incorporated in health-care systems, although this has been rapidly changing over the last two decades, with rising patient interest, federally funded research, and education initiatives. Patient utilization is significant, with approximately 38% of US adults aged 18 years and over and approximately 12% of children using some form of CAM (Barnes, Powell-Griner, McFann, & Nahin, 2004; Eisenberg 2005).

What Are the Types of Modalities Encompassed in the CAM Definition?

The NCCAM classifies CAM modalities into four broad groups. Some modalities may belong to more than one group (http://nccam.nih.gov/health/whatiscam/#types).

1. Natural products: This include herbs, vitamins, minerals, fatty acids, and digestive enzymes, to name a few. Many of these products are regulated as dietary supplements (see below).
2. Mind-body medicine: These practices bring together the mind, body, and brain to improve health. Some of the modalities include meditation, Yoga, Tai Chi, acupuncture, and guided imagery. Some of these modalities are thousands of years old.
3. Manipulative or body-based therapies such as chiropractic care and massage therapy.
4. Other forms of healing include energy medicine such as healing touch and Reiki, movement therapies such as Alexander technique and Feldenkrais, and whole systems of healing such as TCM, Ayurvedic medicine, and naturopathy.

What Is a Dietary Supplement, and How Are These Regulated by FDA ?

The 1994 Dietary Supplement and Health Education Act (DSHEA) defines dietary supplements as products intended to supplement diet; they may include a vitamin or mineral, a herb or botanical, enzymes, amino acid, or other extracts. They are regulated under the general umbrella of food and not drugs. Manufacturers are responsible for appropriate product labeling and following good manufacturing practices. The FDA must prove that a product is unsafe before it can be removed from the market. Patient's use of dietary supplement is substantial. In the US adult population aged 20 and over, the percentage of people who used at least one dietary supplement increased from 42% in 1988–1994 to 53% in 2003–2006 (www.fda/gov Gahche et al., 2011).

Description

As health-care complexity, knowledge basis, and technology grow with resulting improved life expectancy and quality of life, patients are growing more interested in a health care perceived as more holistic and congruent with their values and philosophical beliefs (Eisenberg 2005).

Unfortunately, this growth in patient engagement and health-care knowledge is not being matched at the same speed by health-care training in a more participatory and collaborative health care. While medicine is moving toward a patient-centered care, this is too slow of a movement in a field where health-care students and practitioners still have very limited curriculum preparing them to incorporate patients' beliefs, values, and cultural background in the health-care plan. Many providers have very limited knowledge and skills in addressing the use of complementary and alternative care by patients, including use of dietary supplements and nutrition and collaboration with holistic medicine providers, while their patients' knowledge and CAM use are growing rapidly (Kronenberg 2008; Wallace 2007).

In an age of spiraling health-care costs and national debt, health-care reform will be inevitable. This is a time where patient engagement, empowerment, and knowledge provide a significant opportunity to explore a health-care system geared toward wellness and prevention and to pursue healthier living in body and mind, where patients and health-care providers can work collaboratively toward a more sustainable and

holistic health care. Patient and consumer interest and engagement are reflected on the fact that out-of-pocket expenditure for CAM exceeds that for traditional health-care expenditure (Davis, West, Weeks, & Sirovich, 2011; Eisenberg 2007; Nahim 2007).

A new discipline called integrative medicine has emerged over the last two decades where health-care providers bring together scientific evidence-based medicine with complementary and alternative therapies to provide patients a more holistic and values-centered care. A growing number of academic centers now offer integrative medicine programs, and medical schools' curriculum and residencies are offering more training programs on how to integrate the evidence-based medical knowledge with CAM. The academic organization "Consortium of Academic Health Centers for Integrative Medicine" has brought together academic centers dedicated to conducting research, education, and providing patient care in this exciting new health-care field, which brings together many conventional health-care practitioners such as physicians, behavioral health specialists, nutritionists, and CAM providers such as acupuncturists, chiropractors, and massage therapists.

While some of the modalities utilized in CAM and integrative medicine are ancient, Yoga and Tai Chi, for example, have been practiced for thousands of years. Others have emerged in the last decade or so. What unifies this vast and diverse field of treatments and techniques is the lack of adequate research on efficacy, safety, and the understanding of their mechanisms of action. Since 1998, however, the National Institutes of Health through the National Center for Complementary and Alternative Medicine (NCCAM) has been funding and conducting extensive research on this broad field and better understanding on how these therapies work is growing (http://nccam.nih.gov/).

Definition

Alzheimer's disease, the most common form of cortical dementia, was first described by Alois Alzheimer in 1906. It is a progressive dementia characterized by a downward decline in cognitive functioning, typically ending in death within 15 years.

Description

While memory loss is a common symptom of Alzheimer's disease, memory loss by itself is not pathognomic. Patients experience significant impairments in intellectual functioning that interfere with normal activities and relationships. They lose functionality in many realms of cognitive functioning – including the ability to use language, to think abstractly, to solve problems, and to maintain emotional control. Additionally, they may experience personality changes and behavioral problems, such as agitation, delusions, and hallucinations.

Early in the disease, word-finding difficulties are common. Memory impairments impact short-term memories, while long-term memories tend to remain intact until much later in the progression of the disease. Eventually, long-term memory and knowledge bases are compromised. Communication becomes more and more difficult, and the person loses the ability to perform activities of daily living (dressing, preparing meals, personal hygiene). In the very advanced stages of the disease, individuals with the disease may become incommunicative and require significant care taking.

Alzheimer's disease is characterized by profound changes in the brain. At a gross level, the brain shows significant volume reduction. The loss of tissue results in widening of the sulci and gyri and smoothing of the brain surface. Microscopic inspection of brain tissue reveals loss of neurons throughout the brain as well as the presence of large numbers of pathological changes. Neurofibrillary tangles (aberrant strands of intracellular tau protein) and senile plaques (aggregates of extracellular amyloid protein) are evident throughout the brain. The development of these pathologies is thought to be mediated by abnormal proteins (tau and beta-amyloid) (Tiraboschi, Hansen, & Thal, 2004). Many neurotransmitter systems including acetylcholine, glutamate, and norepinephrine have been implicated in the development and progression the disease.

There are two widely recognized forms of the disease – a sporadic/age-related form and a genetic/familial form. In the vast majority of cases, the slow steady buildup of risk factors over a lifetime are thought to produce pathological brain changes which in turn produce changes in cognitive functioning. Not surprisingly, prevalence of the disease increases dramatically with advancing age. Overall prevalence in the USA is 1.6% in the 65–74 age group but in it rises to 19% in people aged 75–84 and 42% in the 84+ age group (Liddell, Williams, Bayer, Kaiser, & Owen, 1994).

The genetic form (also called "early-onset AD") is atypical – accounting for less than 5% of all cases – and is associated with onset of symptoms before the age of 65. This form of the disease is particularly aggressive – with progression to death happening more rapidly than in the age-related form. Autosomal dominance patterns involve three gene families – presenilin 1, presenilin 2, and amyloid precursor protein (APP). All of these gene families code for the production of brain proteins thought to produce the cellular level changes associated with the disease.

Although sporadic cases lack autosomal dominant genetic determination, genetic predispositions have been identified. For example, individuals with the E4 allele of the apoprotein E (APOE) gene are at an increased risk of developing AD (Hebert, Scherr, Bienias, Bennett, & Evans, 2003). People with one copy of the E4 allele have a three times greater risk than those without the E4 allele, while people with two copies of the E4 allele have a 15 times greater risk of developing the disease. It is important to note that the E4 allele is one of many risk factors that have been identified. Other risk factors include increased age, poverty, and history of head injury. It is most likely that environmental and lifestyle factors interact with genetic risk factors to produce the disease.

Studies find that people who lead interesting, active lives (intellectually stimulating, socially involved, physically active) have a lower risk of developing the disease.

Several pharmaceutical agents are available to palliate the cognitive decline associated with disease, but no cure exists. Most of these drugs are cholinergic agonists, although one is an NMDA receptor antagonist.

Affecting more than 26 million people worldwide, Alzheimer's disease places enormous strains on families and social institutions. Governmental agencies in many countries struggle to meet the needs of the increasing numbers of patients as our populations continue to age (Brookmeyer, Johnson, Ziegler-Graham, & Arrighi, 2007).

Real-life blood pressure monitoring

Definition

Ambulatory blood pressure is arterial blood pressure measured in real-life settings by an automatic device.

Description

Blood pressure (BP) was first measured in the eighteenth century by Halles following Harvey's

work on the circulation of blood. It has been measured in the clinic and operating theater since the early part of the twentieth century and its utility as a predictor of cardiovascular disease established in the second half of the century. The ambulatory measurement of BP (ABPM) outside the clinic or laboratory is a development of the later part of the century. Despite its comparatively recent origin, it is now regarded as the measure of choice clinically since it provides a more reliable and valid measure of an individual's BP and is a better predictor of later disease, perhaps because it reduces "white coat" hypertension, the elevation of BP produced in some individuals when BP is measured in a medical setting. The majority of ambulatory BP monitors are automatic miniaturized versions of the standard sphygmomanometer and can measure systolic and diastolic BP at predetermined times, often every 20 or 30 min during the day, less frequently when the participant is asleep. There are also devices that measure BP continuously, the most successful of which use the vascular unloading technique first described by Penaz (1973). Continuous measurement is not widely used but has considerable advantages for psychophysiological studies since it greatly improves the power of studies to detect the relationship between BP and environmental events or psychological phenomena that might be transitory, as well as providing repeated measurement during more enduring events. The Penaz-derived devices also enable one to determine the mechanisms, vascular or cardiac, that underlie the elevations in blood pressure. Alternatively, the underlying mechanisms can be determined by combining intermittent ABPM with cardiac output measured by ambulatory measures of cardiac impedance. Whether infrequent or continuous ambulatory blood pressure is affected by many factors that are often noise with respect to the question under study. The most important of these are movement and posture, and they are usually controlled either through questionnaires completed at the time of measurement or, more satisfactorily, through direct measurement and recording with accelerometer-based devices.

While ABPM was developed to deal with clinical issues, it has great relevance for behavioral medicine. Most psychophysiological studies of the cardiovascular system are conducted in the laboratory for reasons of convenience, control, and the accuracy of measurement. ABPM allows the study of the psychological processes that in part determine BP to be extended to real life with obvious benefits in ecological validity (although at the cost of loss of control) and a potential increase in understanding of the role of stress in hypertension and cardiovascular disease. ABPM can also provide insight into psychological process that have effects on the cardiovascular (CV) system by providing sophisticated measures of autonomic arousal that illuminate or index processes that cannot be studied by observation or self-report.

BP is elevated in many situations that are conventionally seen as stressful, such as public speaking or examination. This was originally shown in laboratory studies but has been confirmed in field studies using ABPM when it is often found that the responses are considerably larger than in the laboratory simulations of these situations. Interpersonal conflict, often difficult to study meaningfully in the laboratory, is also associated with elevated BP in field settings. Perhaps unsurprisingly, it has also been shown that heightened subjective feelings of anxiety or arousal are associated with increased BP, as are variations in the demand that people feel they are under or their perception of the control that they feel they have over the situation since high demand and low control has been widely shown to be associated with increased strain. Such effects are moderated by personality with, for example, some studies showing that highly hostile people had high BP whatever their mood, while the less hostile had high BP only when in a negative mood. The highly hostile are also less likely to show a reduction in stress-related BP with social support. There is in additional evidence of gender moderating the effects of stress on BP with women benefiting more than men from social support during stressful situations. The effects of social interaction are subtle with interactions with a person with whom one has an ambivalent relationship leading, in one study, to greater BP elevations than interactions with

people that were more clearly either liked or disliked. Such studies have also shown that it can be the nature of the relationship rather than the nature of a specific interaction that relates to BP. This information on complex and subtle social situations could only be obtained in real life using ABPM.

BP is determined by the interplay of cardiac output and vascular resistance. Laboratory studies suggest that objectively different situations and subjectively different appraisal of these situations can affect the determinants of BP. Tasks that involve active coping or the related appraisal of situations as challenging are associated with cardiac effects, while tasks involving passive coping or the appraisal of a situation as threatening, leading to a vascular response. While this has not been studied extensively in real life, in one study, challenge appraisals were related to cardiac effects in people making an academic presentation and threat with a more vascular response. More vascular responses have been reported in lonely people who are hypothesized to adopt passive coping strategies.

An enduring issue in laboratory and ambulatory studies of the effects of stress has been the extent to which responses seen in the laboratory generalize to real life. The response to laboratory stressors is a poor candidate as an index of the risk of disease if it relates only weakly, or not at all, to the response in real life. The issue is controversial, but the most recent studies using the best available measurement and analytic techniques suggested that reliable CV (heart rate and BP) responses to laboratory stressors, obtained by combining the responses to several stressors, do relate to the CV response to objective stressful environments, negative emotions and perceptions of the situation as stressful.

The reactivity hypothesis has been the dominant theory in cardiovascular behavior medicine since 1980. In its simplest form, this theory states that individuals who show an excessive CV response to stress, the hyperreactive, are at increased risk of CV disease. Prospective studies using the CV response to laboratory stressors to predict cardiovascular disease endpoint have had mixed findings at best. However, hyperreactivity is not enough since a hyperreactive person has to be reacting to something. A vulnerability factor, like hyperreactivity, needs an appropriate environment to actually become a risk factor. Laboratory studies only establish the vulnerability. Ambulatory studies can go some way to establishing if the appropriate environment also exists. Unfortunately, while ambulatory BP is a better predictor of CV disease than clinic BP, there do not appear to be studies seeking to link BP elevations to stress in real life and subsequent disease.

Ambulatory Monitoring

Derek Johnston
School of Psychology, University of Aberdeen, Aberdeen, Scotland, UK

Definition

In behavioral medicine, ambulatory monitoring has two components: the measurement in real life

of some physiological parameter and the real-time measurement of behavior, emotion, or psychological process. Studies can, but do not always, involve both types of measurement

Description

The initial drivers for ambulatory physiological recorders were largely clinical. The ambulatory recording of physiological signals started with Holter's experimental development, shortly after the Second World War, of a very bulky physiological ambulatory monitor which later became a useful device to measure and record the electrocardiogram (ECG, Holter, 1961). Such devices, often still called Holter monitors, were developed primarily for diagnostic purposes and are routinely used in the diagnosis of coronary heart disease. Much later, this was followed by ambulatory blood pressure monitors (ABPM) which are now the method of choice in the diagnosis and management of hypertension. Advances in the miniaturization of electronic devices and developments in solid-state memory (and to a lesser extent telemetry) have lead to the development of a variety of multipurpose ambulatory recorders that can record and store virtually all the systems that were once measured solely in the laboratory. This includes ECG, electroencephalogram (EEG), electromyogram (EMG), blood pressure (BP) measured both discontinuously and continuously, the impedance cardiogram, measures of local blood flow with photoelectric devices, skin temperature, and skin conductance. These measures are derived from conventional electrophysiological techniques, impedance technology, BP from sophisticated fast-acting pumps on finger cuffs, and many functions from devices placed in purposely built vests or shirts worn by participants (sometimes called smart clothes). From these devices, one can measure a wide range of cardiovascular and respiratory parameters including heart rate and heart rate variability, blood pressure, cardiac output and vascular resistance, and features of cardiac activity like pre-ejection time, as well neural signals. Many of these measures reflect the functioning of the autonomic nervous system. The advances in electronic technology has been matched by developments in software, and most systems are sold with sophisticated software packages to handle signal detection, data reduction, and other aspects of data processing. There are also standalone software packages that work with a variety of ambulatory recording systems.

As well as measures of physiological systems, there are devices based on accelerometers that can measure activity, posture, and details of limb movement and gait. The simplest of these are single axial accelerometers mounted in some convenient place, such as the waist, to measure activity through to complex systems of multiple accelerometers attached to different parts of the body that are claimed to be able to measure different categories of movement such as speed of walking or running, cycling, standing, and rate of change of such activities. One device uses the combination of heart rate from the ECG and activity from a chest-mounted accelerometer to derive well-validated measures of energy expenditure. Such activity measures are also important in interpreting the autonomic measures since heart rate and blood pressure are profoundly influenced by metabolic demand, and it is very helpful to account for this when interpreting changes in cardiac activity.

The measurement of some aspects of behavior can be achieved by direct objective measurement of limb movement and, in much prescribed circumstances, by body-mounted cameras or by direct observation. However, most behavioral measurement in real life is through self-report; participants' record in real time what they are doing, thinking, and feeling. Such methods, often called ecological momentary assessment or experience sampling, are most often achieved by used electronic devices on which the participants complete questionnaires about their current behavior. Such devices, which are readily programmed using specialist software or purchased from specialist companies, are generally acceptable and provide high-quality time-stamped information. Traditional paper and pencil diaries can also be used and have the obvious advantage of cheapness but lack time stamping, and hence, the investigator cannot know then the

diary entry was actually made. However, with well-motivated participants and when information is gathered quite infrequently, perhaps weekly, then they may well be the most cost-effective method. The electronic measurement is usually on PDAs (personal data assistant), smart phones, or, if recording is infrequent and of a summary nature, on home personal computers using the internet. Responses can be self-ratings, text, or brief audio recordings. The smart phone and internet realizations of EMA allow the possibility of interaction with the recording system so that it can respond to missing data or particular responses or to deliver interventions, perhaps contingent on behavior. Global positioning systems are also being used in conjunction with EMA devices to gather information on a participant's behavior and to target appropriate interventions.

An interesting variant of EMA is the Day Reconstruction Method (DRM) developed by Kahneman, Krueger, Schkade, Schwartz, and Stone (2004) and colleagues for use in large surveys where EMA is impractical. In DRM, participants retrospectively structure their day into meaningful units then recall and rate their behavior or mood during these units. This method has been implemented face to face, singly, or in groups and can be used online. It produces systematic data that relates sensibly to known diurnal variations in mood and arousal, heart rate measured throughout the day, and mood assessed in real time using EMA. The method has been influential in attempts to estimate national well-being by economists.

The rapid developments in ambulatory physiological and behavioral measurement technology have been matched by the increasing sophistication of the statistical tools used to analyze such repeated, heavily autocorrelated, and multilevel data. Multilevel random effects modeling of ambulatory data is now almost universal, and most widely used statistical packages allow some form of multilevel modeling, and the specialist programs have become much more user friendly.

The methods of ambulatory physiological and activity recording and EMA have been successfully applied to a wide range of practical and theoretical problems in many areas of behavioral medicine and related fields such as clinical, health, and occupational psychology. Among the issues illuminated by such methods are cardiovascular reactivity, hypertension, addiction, disability, pain, adherence to treatment regimes, sleep, occupational and other kinds of stress, the effects of surgery, and patient and staff safety in medical settings.

American Cancer Society

Youngmee Kim
Department of Psychology, University of Miami, Coral Gables, Miami, FL, USA

Basic Information

The American Cancer Society (ACS) is the nationwide, community-based, voluntary health organization dedicated to eliminating cancer as a major health problem by preventing cancer, saving lives, and diminishing suffering from cancer through research, education, advocacy, and service. Headquartered in Atlanta, Georgia, the ACS has 12 chartered divisions, more than

900 local offices nationwide, and a presence in more than 5,100 communities. The Society's Research Program is composed of two main divisions: extramural and intramural research. The Extramural Grant Department reviews and administers both Research Grants and Health Professional Training Grants. The ACS focuses its extramural funding on investigator-initiated, peer-reviewed proposals. Intramural Research is composed of six programs: Epidemiology, Surveillance Research, Health Services Research, International Tobacco Control Research, the Behavioral Research Center, and the Statistics and Evaluation Center. All intramural department staff conduct applied cancer research in-house.

Major Impact on the Field

The Extramural Grant Department has supported groundbreaking studies. Forty-four investigators who were supported by ACS went on to win the Nobel Prize. The Society's Intramural Research Program has provided population-based surveillance systems and other national and international databases to evaluate trends and population variability in cancer incidence and mortality, behavioral risk factors, early detection and treatment patterns, and economic factors in tobacco control. This research has helped monitor progress in cancer control and provide evidence for policy and advocacy initiatives. In addition, a series of Cancer Prevention Studies (CPS-I, CPS-II, CPS-II Nutrition Survey, and CPS-3) have been landmarks in the field, providing mortality trends and identifying dietary factors related to cancer incidence and mortality. Overall, findings from the CPS-I and CPS-II have made major contributions to the field by (a) advancing our knowledge of the environmental, behavioral, and biological causes of cancer and cancer survivorship and (b) informing the development of cancer prevention and survivorship strategies, policies, and practice. The ACS is one of the first organizations to recognize the importance of psychosocial and behavioral factors in cancer prevention and control.

The ACS has also implemented numerous programs in communities, guided by its mission statement. For example, to help people stay healthy, ACS distributes the Healthy Living Newsletter, which provides educational materials about healthy lifestyle habits that have been found to reduce the risk of cancer and other major diseases. Other programs for this effort are for employees (the Active For Life program) and school-age children (the School Health program) to become more active and to improve healthy diet. The Society's website, cancer.org, provides the most up-to-date information about cancer information and support available at the local and the national level for patients, survivors, and caregivers. Some example programs include the Cancer Survivors Network, the online community by and for people with cancer and their family; the Road to Recovery, which provides transportation service for cancer patients who need rides to treatment; the Hope Lodge, which is free lodging available for patients and their families; the I Can Cope, which provides educational classes about cancer and treatment, and which is available in person or on line; and the Patient Navigator Program, a personalized cancer guide.

Several events organized by the ACS, such as Making Strides Against Breast Cancer and Relay For Life, raise funds to support the community and research effort in making a difference in the fight against cancer.

American Diabetes Association

Della Matheson
Diabetes Research Institute, Miller School of Medicine, University of Miami, Miami, FL, USA

Basic Information

The American Diabetes Association (ADA) is a leading United States-based nonprofit organization providing funding for diabetes research, professional and lay education, and advocacy for people with diabetes. Their mission as stated is: "to prevent and cure diabetes and to improve the lives of all people affected by diabetes."

The organization was founded in 1940 by a group of physicians and scientists with the goal of providing education and support to physicians and health-care professionals. In the 1960s, the organization expanded its membership to include general members and heightened its services to provide education and support to the community at large. There are currently 97 local affiliate offices distributed throughout 47 states.

Major Impact on the Field

ADA programs and activities include:

Publications – a large library of informational books, magazines, and journals for both medical professionals and consumers are available.

Professional meetings – serve to educate and stimulate collaborative efforts in the delivery of health care to people with diabetes and to enhance research efforts of scientists involved in diabetes research. The two largest meetings that occur annually are the ADA Postgraduate Course held in winter of each year and the ADA Scientific Sessions held in the summer each year.

Public meetings – in addition to multiple local chapter offerings, the Diabetes Expo provides a 1-day public program in major markets throughout the USA that includes lectures, large vendor display area, and informational services.

Funding of research – supports basic and clinical diabetes research aimed at prevention, better treatment, and a cure. The research funding program is designed to complement government-funded research through the National Institutes of Health which serves to amplify the effectiveness of the millions of dollars provided by ADA ($42.5 million in 2008).

Family link – a program that provides information to families about living with diabetes and provides information and tool kits for families of children newly diagnosed with diabetes, parent to parent mentoring programs, and school initiatives aimed at enhancing safety for children with diabetes while in school.

Diabetes camps – there are over 60 camps for children between the ages of 4 and 17 years supported by the ADA. Camps consist of residential week-long programs, day camps, family camps, and teen adventure camps. The camping experience offers children with diabetes the opportunity to interact with other children with diabetes, increase their knowledge of diabetes self-management, and enhance independence in a safe environment, while also having fun!

Fund-raising events – Walk to Fight Diabetes, Tour de Cure, School Walk for Diabetes, and Bikers Against Diabetes. The ADA website also includes links for personal gifts as well. ADA currently receives over $250 million dollars through their fund-raising efforts annually.

Advocacy – this mission involves a goal of improving access to health care for people with diabetes and to eliminate discrimination against people at school, in the workplace, or elsewhere in their lives. On a biennial bases, the ADA has organized an event, the Association's Call to Congress, that facilitates the meeting of advocates and members of the ADA to meet with their US Representatives and Senators to discuss how diabetes affects their lives and how health-care legislation can be directed to improve living with diabetes.

American Heart Association

Brooke McInroy
The University of Iowa, Iowa City, IA, USA

Basic Information

The American Heart Association (*AHA*) is a nonprofit health organization in the United States. Its headquarters are in Dallas, Texas, and it maintains offices in 48 states and Puerto Rico. Founded in 1924 by a group of cardiologists, the current mission of the organization is to "build healthier lives, free of cardiovascular diseases and stroke." Its main website is www.heart.org.

The main expenditures of the AHA are on research and educational programs, including an emphasis on cardiopulmonary resuscitation (CPR) and first aid training. The AHA publishes scientific journals and offers a membership program for science and health-care professionals as well as research grants and fellowships. The AHA is affiliated with the American Stroke Association (ASA), which was founded in 1997 with a focus on "prevention, diagnosis, and treatment to save lives from stroke."

American Psychological Association Division 38 (Health Psychology)

Christopher France
Department of Psychology, Ohio University, Athens, OH, USA

Basic Information

With more than 154,000 members as of 2011, the American Psychological Association (APA) represents the largest scientific and professional organization of psychologists in the world. The mission of APA is to advance the creation, communication, and application of psychological knowledge to benefit society and improve people's lives. In addition to this primary association, there are currently 54 divisions of APA which represent specific interest groups and maintain their own memberships, eligibility criteria, and officers.

APA Division 38 (Health Psychology) was established in 1978 and currently has approximately 3,000 members. From the beginning, APA Division 38 has been broadly focused on issues related to both the science and practice of health psychology, and this broad mission has included the following three components: (1) advancing psychology's contributions to the understanding of health and illness through basic and clinical research and through the integration of biomedical information about health and illness with current psychological knowledge, (2) promoting professional education and services related to health and illness, and (3) ensuring that the psychological, biomedical, and lay public communities are aware of the results of current research and service activities in this area.

The importance of health psychology as a discipline is best illustrated by the fact that behavioral factors predispose, precipitate, and perpetuate many of the leading causes of illness and death in the USA and around the world. And, perhaps more importantly, behavioral and psychological interventions have been shown to encourage disease prevention, enhance coping with acute and chronic illness, and improve health outcomes when delivered in isolation and in conjunction with existing medical procedures. To promote further progress in each of these areas, APA Division 38 supports the educational, scientific, and professional efforts within psychology to understand the etiology, promotion, and maintenance of health in the prevention, diagnosis, treatment, and rehabilitation of physical illness; conduct research related to the psychological, social, emotional, and behavioral factors that contribute to physical illness; make active contributions to improving the health care system; and assist in the formulation of health policy.

Consistent with its goal of promoting the science and practice of health psychology, APA Division 38 maintains an active website (www.health-psych.org); publishes the leading scientific journal in the field, *Health Psychology* (www.apa.org/pubs/journals/hea/index.aspx), as well as a Division newsletter, *The Health Psychologist* (http://www.health-psych.org/ResourcesNewsletters.cfm); and maintains a range of educational and training resources for those interested in the profession. Participation and affiliation with APA Division 38 is encouraged through a variety of mechanisms, including professional membership (open to existing APA members), professional affiliates (including psychologists, physicians, and other health professionals who are not APA members), international affiliates (including health psychologists living and working outside of the United States or Canada), and student affiliates (including those enrolled in accredited programs of psychology, medicine, and related fields).

As models of health care evolve in the United States and around the world, APA Division 38 is working to establish liaisons between researchers, clinicians, and policymakers to encourage the use of psychological science in the promotion of health and prevention of illness.

American Psychosomatic Society

Shin Fukudo, Emiko Tsuchiya and Yoko Katayori
Department of Behavioral Medicine, School of Medicine, Tohoku University Graduate, Aoba-ku, Sendai, Japan

Basic Information

History

There has been a perception of mind–body interaction in many fields of study in recent centuries (Levenson, 1994, p. 1). The American Psychosomatic Society (APS) was founded in response to the desire for cross-discipline study of the people of psychiatry, internal medicine, physiology, and other fields.

With philanthropic support, *Psychosomatic Medicine* was published in 1939 and the journal's board voted to establish the "American Society for Research in Psychosomatic Problems" in December 1942. These founders included Drs. George Daniels, George Draper, and Helen Dunbar.

The name was changed to "The American Psychosomatic Society" in 1948 (American Psychosomatic Society, 2010a).

Today, APS has become an international society. It offers a website, journal, and annual meeting. Researchers and clinicians use various approaches to investigate the links among mind, brain, body, and social issues for curing disease and promoting health (American Psychosomatic Society, 2011a). The Council members have expanded pediatrics, neuroanatomy, physiological sciences, neurophysiology, psychophysiology, clinical psychology, sociology, anthropology, and public health. (American Psychosomatic Society, 2010a).

Major Impact on the Field

Mission

The mission of the APS is "to promote and advance the scientific understanding and multidisciplinary integration of biological, psychological, behavioral and social factors in human health and disease, and to foster the dissemination and application of this understanding in education and health care (American Psychosomatic Society, 2011b)."

Awards and Scholarships

Awards include Alvin P. Shapiro Award, American Psychosomatic Society Scholar Awards, Cousins Center Global Outreach Awards, Donald Oken Fellowship, Herbert Weiner Early Career Award, Medical Student/Resident/Fellow Travel Scholarships, Minority Initiative Awards, Patricia R. Barchas Award in Sociophysiology, Paul D. MacLean Award, President's Award, and Travel Awards for MacLean Scholars (American Psychosomatic Society, 2011b).

Annual Meeting

The APA holds an annual 3-day open meeting in March. In this scientific and clinical assembly, investigators communicate, consider problems of conceptual relationships, and develop ideas that will stimulate further research (American Psychosomatic Society, 2011b). During the meeting, the APS members present scientific papers, participate in symposia, workshops, poster sessions, and invited lectures and addresses.

Journal

Psychosomatic Medicine: *Journal of Biobehavioral Medicine* founded in 1939 by the editor Dr. Dunbar, is the official and international peer-reviewed journal of APS. It is devoted to experimental and clinical research of interdisciplinary fields: behavioral biology, psychiatry, psychology, physiology, anthropology, and clinical medicine. It includes experimental and clinical studies on various perspectives and effects of the relationships among social, psychological, and behavioral factors, and physical processes in humans and animals. It publishes in print nine times a year, and most articles are online ahead of print (American Psychosomatic Society, 2010b).

Committees and Memberships

There are 10 committees such as Ad-Hoc Journal, Ad-Hoc Website, Awards, Fundraising, Liaison, Membership, Nominating, Past Leaders, Professional Education, and Program Committees (American Psychosomatic Society, 2010a).

There are four categories of memberships – Regular, Emeritus, Corresponding, and Associate (for students and trainees). Committee members are professionals and specialists from medical and health-related fields in behavioral and social sciences. A short membership is available as well (American Psychosomatic Society, 2011b).

Membership benefits (American Psychosomatic Society, 2011b) include:

- Subscription to printed and online *Psychosomatic Medicine*.
- Discount registration fees for the APS annual meeting.
- Networking and professional development in the society.
- Newsletter and e-newsletter (both three times a year).
- Opportunity of becoming a member of committees.
- Awards for professionals, students and trainees.
- Access to the APS international online membership directory.

Analgesia

Martin Deschner
Psychiatry, Division of Psychology,
The University of Texas Southwestern Medical Center at Dallas, Dallas, TX, USA

Definition

The term "analgesia" derives from the Greek words *an* (without) and *algesis* (pain) for "without pain" (Webster's Ninth New Collegiate Dictionary, 1988). It refers to relief from the sensation of pain or the loss of ability to feel pain while still remaining conscious. This term is to be distinguished from the broader term "anesthesia," which refers to a loss of sensation of all types, including pain, with or without loss of consciousness.

Analgesia can refer to partial or total relief from pain. When pain is reduced, some sensation persists but often without it being experienced as painful. Analgesia is often discussed in terms of medications or medical procedures. For example, opiate medications such as morphine, oxycodone, or hydrocodone are frequently used for their analgesic effects as are steroidal and nonsteroidal anti-inflammatory medications. Devices such as spinal cord stimulators, TENS units, and intrathecal pain medication pumps, as well as injections such as selective nerve root blocks, facet injections, or epidural steroid injections are also used for their analgesic effects, with varying degrees of success.

Behavioral medicine addresses analgesia from a biopsychosocial perspective. Psychologists and other behavioral health specialists frequently work in conjunction with medical and other professionals such as physical therapists, to help patients reduce and learn to cope with their acute or chronic pain. By improving the patient's understanding of his or her pain and emotional coping behaviors while also improving his or her capacity to reduce somatic tension and arousal, perceived pain is often reduced. Capacity to cope with remaining pain is generally increased through greater understanding of issues related to pain and mastery of pain management techniques.

Behavioral medicine approaches frequently involve education to improve understanding of the pain-causing condition. Education tends to reduce the patient's fear, feelings of powerlessness, and tendency to distort or catastrophically appraise their painful condition based on faulty information or assumptions.

Behavioral medicine uses cognitive behavioral therapy (CBT) approaches to help the patient to examine and change his or her irrational beliefs generally, and dysfunctional pain-specific beliefs in particular. CBT focuses on improving emotional coping skills, using cognitive behavioral training techniques such as reframing, correcting negative thinking patterns such as catastrophizing

or overgeneralizing, and improving communication and assertiveness skills. Correcting negative thinking patterns improves the patient's sense of mastery and provides him or her with effective tools to cope rationally with pain (Okifuji & Ackerlind, 2007).

Stress management training reduces the patient's somatic reactivity to pain by improving the patient's capacity to activate their parasympathetic response to pain. Patients are often taught such skills as diaphragmatic breathing, progressive muscle relaxation, meditation, and imagery techniques to help them break the vicious cycle of stress intensifying pain. Biofeedback training is often used to help the patient graphically see his or her somatic reactivity and also provides the patient with objective evidence as to the efficacy of the stress management techniques they are learning.

Anderson, Norman B. (1955–)

Norman B. Anderson
American Psychological Association, Washington, DC, USA

Biographical Information

A graduate of the North Carolina Central University in Durham, NC, Norman B. Anderson earned masters and doctoral degrees in clinical psychology from the University of North Carolina at Greensboro. He received additional clinical and research training at the Schools of Medicine at Brown and Duke Universities, including postdoctoral fellowships in psychophysiology and aging at Duke.

Anderson is the Chief Executive Officer and Executive Vice President of the American Psychological Association (APA). With 137,000 members and affiliates, APA is the largest and oldest of the world's psychological societies. Headquartered on Capitol Hill in Washington, DC, APA has a staff of over 550 and an annual budget of over $112 million. As the Chief Executive Officer, he is responsible for overseeing the overall management of the Association and works closely with the APA Board of Directors.

Major Accomplishments

Among his numerous accomplishments at APA, Anderson recently led a successful effort to create the first strategic plan in the 120-year history of the Association and oversaw APA's efforts to foster the inclusion of integrated care, health promotion and disease prevention, and mental health care in the new health care reform legislation.

Anderson was the founding Associate Director of the National Institutes of Health (NIH) in charge of behavioral and social science and was the first Director of the NIH Office of Behavioral and Social Sciences Research (OBSSR). At NIH, he was charged with facilitating behavioral and social sciences research across all of the [then] 24 Institutes and Centers of the National Institutes of Health. Under his purview was behavioral and social research in such areas as cancer, heart disease, child health, mental health, diabetes, aging, oral health and others. His special interest at NIH was advancing an integrated, transdisciplinary approach to health science, prevention, and health care.

Appointed to NIH in 1995, Anderson worked closely with the scientific community nationally to quickly establish the Office's long-term goals and to develop strategies for achieving them, resulting in the first OBSSR strategic plan. Under his leadership, the Office organized trans-institute funding initiatives totaling over $90 million in 5 years. The success of the Office prompted Congress to triple its budget, enabling it to have greater latitude in developing NIH-wide collaborative funding activities.

Anderson has held faculty appointments at both Duke University School of Medicine and the Harvard School of Public Health. He is well-known for his research and writings on health disparities and health behavior. He has received several awards for his research, including the 1986 New Investigator Award from the Society of Behavioral Medicine, the 1991 Award for Outstanding Contributions to Health Psychology from the American Psychological Association, and at least ten other significant awards from scientific societies and universities He has been awarded three honorary doctorate degrees.

Anderson is a Fellow of the American Association for the Advancement of Science, American Psychological Association, Association for Psychological Science, the Society of Behavioral Medicine, and the Academy of Behavioral Medicine Research. He is a Past President of the Society of Behavioral Medicine, served as President of the Board of Directors for the Starbright Foundation of Los Angeles (now the Starlight Children's Foundation), and is currently a Trustee of the Starlight Children's Foundation. He currently serves on the National Advisory Council for the National Institute on Aging at NIH the National Academic Affiliations Council in the Department of Affairs, the Board of Directors for the American Psychological Foundation, and the Board of Directors for the Excellence Foundation of the University of North Carolina at Greensboro. He also chaired the National Academy of Sciences Panel on Understanding Racial and Ethnic Health Disparities in Late Life.

He is the author and editor of several books, including serving as Editor-in-Chief of the two-volume *Encyclopedia of Health and Behavior*. He is also Editor-in-Chief of the flagship journal of APA, the *American Psychologist*.

Androgen

Definition

Androgens are a group of hormones that are present in males and females (though at lower levels)

and which primarily promote the development, and maintenance, of masculine traits. Androgens are produced in the testes, ovaries, placenta, and adrenal cortex. The most prominent androgen is testosterone. Other androgens include androstenedione, androstenediol, androsterone, dehydroepiandrosterone (DHEA) and dehydroepiandrosterone sulfate (DHEA sulfate), and dihydrotestosterone (DHT). Androgens are necessary for differentiation of male reproductive organs during fetal development, sexual maturation, spermatogenesis, genital function, and the development of male secondary sexual characteristics (Chang, 2002). Increases in androgens are associated with the maturational changes that occur in puberty. In addition, they play a role in the growth and functioning of muscles, bones, kidneys, liver, and the regeneration of red blood cells (Bagatell & Bremer, 2003). Androgens also influence aggression (Giammanco, Tabacchi, Giammanco, Di Majo, & La Guardia, 2005) and sexual desire, performance, and satisfaction (Hutchinson, 1995).

Androgens can reduce the risk of cardiovascular diseases, obesity, diabetes, bone loss, and Alzheimer's (Clarke & Khosla, 2009; Manolakou, Angelopoulou, Bakoyiannis, & Bastounis, 2009). In men with prostate cancer, hormone therapies may be used that reduce androgen levels in order to slow the growth of cancer cells. Low levels of androgen can increase the risk of cardiovascular diseases, obesity, diabetes, bone loss, Alzheimer's, and high cholesterol (Jordan & DonCarlos, 2008). Low levels of androgens are also related to reduced libido, erectile dysfunction, anemia, loss of muscle mass, weight gain, fatigue, and depression. Androgen supplements can often protect against these risks.

In women, high levels of androgen are associated with hirsutism, balding, acne, menstrual disorders, ▶ insulin resistance, ▶ diabetes, high ▶ cholesterol, high ▶ blood pressure, and cardiovascular diseases. Low levels are associated with low libido, ▶ fatigue, depression, and increased susceptibility to bone disease (Cheung, 1999).

Anger Management

Mark A. Lumley and Lindsay Oberleitner
Department of Psychology, Wayne State University, Detroit, MI, USA

Synonyms

Anger; Emotion; Emotion regulation; Stress management

Definition

Anger management is a broad term referring to various techniques designed to help individuals manage or reduce their experience and expression of anger so that they will have better psychological, physical, and social health.

Description

Anger is a normal human emotion that is adaptive when elicited by appropriate social circumstances, specifically threatened or actual violation of something that one values. The experience and expression of anger in such circumstances can be healthy, but anger that is experienced or expressed too intensely or frequently and in inappropriate circumstances can contribute to many problems, including mood and anxiety disorders, cardiovascular disease, persistent pain, digestive problems, substance abuse, relational difficulties, and social disorder (Miller, Smith, Turner, Guijarro, & Hallet, 1996). Anger management, therefore, is targeted for patients whose anger is viewed by themselves or others as excessive, out of control, or having negative effects. People sometimes recognize their excessive anger and seek to manage it better, but more often, anger management is recommended or required by others who recognize that a person is too angry or expressing it too often or intensely (Saini, 2009).

Anger management typically refers to a program of specific intervention techniques that target different processes in the sequence of anger elicitation, experience, and expression. Anger management strategies can be placed in two general categories – strategies that directly avoid or reduce the experience and expression of anger, and strategies that facilitate identifying, experiencing, and adaptively expressing anger. The first category is more popular and is how anger management is traditionally defined (Glancy & Saini, 2005). This approach stems from research and practice on people who have excessive anger, such as cardiac patients with the Type A behavior pattern or people referred for treatment of aggressive behavior. The second category represents a newer, alternative view of the value of anger and other emotions (Gross, 2002). These two categories are discussed next.

Anger Avoidance and Reduction Strategies

A basic strategy to decrease anger is to identify and avoid specific anger triggers. For some individuals, anger is reliably elicited by certain people, situations, and activities, such as interacting with difficult coworkers or participating in competitive sports. An initial strategy, especially if other approaches are less successful, is to simply avoid those triggers.

Yet, behavioral avoidance often is not feasible or desirable and typically is considered a rather unsophisticated approach. Other anger management strategies can be used when encounters with anger triggers are inevitable. One such strategy is to reduce physiological activation when angered.

This typically is done by applying relaxation techniques (e.g., deep breathing, imagery, and progressive muscle relaxation) or distraction by engaging in pleasurable activities (e.g., exercise, playing a game, and reading). Such downregulation techniques can lower cardiovascular activity, increase calmness, and reduce tension until thoughts and feelings of anger have subsided. These techniques are particularly appropriate when situations are not controllable or when anger is only experienced occasionally ("state anger") (Del Vecchio & O'Leary, 2004).

Cognitive reappraisal techniques are used to identify, question, and modify the thoughts or interpretations that underlie anger. Reappraisal often involves evaluating and changing patterns of faulty thinking that are especially potent in anger, such as overgeneralization and exaggeration. For example, beliefs like "the world is always against me" can be examined and challenged with contradictory information. A specific cognitive reappraisal program has been developed by Williams and Williams (1993) that teaches people to question whether an anger-inducing situation is important, whether anger is appropriate and will change the outcome, and whether the expected outcome is worthwhile. Such questioning requires a pause in the anger experience, and allows the person to examine the situation and his or her reactions more logically. If any of the key questions are answered in the negative, then the anger experience can be aborted, or some alternative anger management strategy can be used, such as downregulation. Affirmative answers to these questions can lead to a decision to express anger in an adaptive manner.

There are several higher order, more sophisticated cognitive strategies to help manage anger. Perspective-taking or empathy-building refers to the ability to "walk in someone else's shoes," to feel what another person is feeling, and to see a situation from another's point of view. This approach may be helpful when the behavior of the anger-inducing person is not changeable, or when anger stems from victimization or abuse during childhood or when committed by strangers (e.g., being mugged or assaulted). The angry person is challenged to understand the circumstances that may have led to the offender's actions. This technique may help to attenuate anger, especially when added to the next technique.

An approach that stems from perspective-taking is to engage in forgiveness or "letting go." Anger typically follows victimization, and although anger may be justified, chronic anger eventually harms the person experiencing it. Forgiveness exercises help offended people free themselves from ongoing resentment, first by perspective-taking, and then by volitionally deciding to reduce the blame of the other person and to forgive them or let go of the resentment, whether or not the other person has apologized or made amends. Forgiveness or letting go returns control to victims, allowing them to view themselves as having the power and ability to heal. Although not necessary for forgiveness, many people incorporate this technique as part of their religious or spiritual practices (Lin, Mack, Enright, Krahn, & Baskin, 2004).

Anger Awareness, Experience, and Expression Strategies

It is important to recognize that anger is a vital, evolutionarily based, adaptive emotion when experienced and expressed appropriately. The experience of anger informs the person about actual or potential victimization or unjust experiences and motivates action to protect oneself or loved ones. Anger energizes and directs needed defense, protection, and the righting of social wrongs. Thus, it can be maladaptive to deny, disavow, or suppress anger, or transform it into sadness, guilt, or shame. Although in many social situations it is wise to suppress the expression of anger, a lack of anger awareness and chronic anger suppression can be detrimental (Iver, Korin, Higginbotham, & Davidson, 2010). Research suggests that the suppression of anger can increase pain, disrupt cognition, trigger depression, and impair intimacy (Burns, Quartana, & Bruehl, 2008). Furthermore, chronic anger sometimes stems from the failure to express one's needs, opinions, or dissatisfactions directly and effectively toward the appropriate person or target. Therefore, alternative approaches to managing anger

involve strategies or techniques that facilitate the awareness and adaptive expression of anger. Anger awareness and expression strategies can be divided into two types – assertiveness training and experiential exercises.

Assertiveness training is a popular approach found in many anger management programs, but it is fundamentally different from the anger reduction strategies described above. Training in assertion helps a person directly and honestly express thoughts and feelings to another person, while remaining mindful of the desired outcome and respecting the other person's experience. Assertive communication requires identifying one's own thoughts or desires and then directly yet skillfully expressing them verbally and nonverbally, without excessive apology, blame, or threat. Such direct assertion adaptively expresses anger, decreases feelings of victimization and helplessness that trigger mood and health problems, and helps prevent the inappropriate transfer or generalization of anger to innocent targets (Rakos, 1991).

Experiential techniques are relatively new approaches to dealing with anger. Training in mindfulness or meditation appears to help people recognize and experience their anger and other emotions in a nonjudgmental manner, and to distinguish awareness from action. Written emotional disclosure, or expressive writing, is a technique that helps people voice suppressed thoughts and feelings and narrate them into a story, thereby facilitating extinction of anger and/or the making of meaning and changes in understanding (Graham, Lobel, Glass, & Lokshina, 2008). Finally, experiential psychotherapy has developed several techniques that help people to experience and process unexpressed anger, including empty chair work and two-chair dialogues. All of these techniques can help people identify, clarify, and voice emotions, including anger, thereby helping them to develop insight, resolve conflicts, and make needed behavioral and interpersonal changes.

It is likely that the optimal approach to dealing with anger depends on individual differences among people in their usual anger regulation style. People who experience excessive anger or express it too readily likely need some of the traditional anger reduction techniques such as trigger avoidance, arousal downregulation, distraction, cognitive reappraisal, perspective-taking, and forgiveness. In contrast, people who are prone to excessive anger inhibition or suppression are more likely to benefit from techniques that help them experience and adaptively express anger, including assertiveness training and experiential exercises. This proposal, however, awaits empirical study.

Definition

Assessment of states of anger or of the personality disposition for anger responses.

Description

Anger is usually considered as a basic emotion that emerged during evolution because it served the function of preparing the organism for fight against enemies and to overcome obstacles (Plutchik, 1994). Therefore, it is associated with a specific response pattern that communicates to the environment preparedness for fight and that supplies the body with metabolic demands for fight or flight. The response pattern is thought to be independent of cultural influences while so-called display rules regulate under which conditions the expression of anger is appropriate or not. Another component characteristic of the state of anger is specific cognitions (appraisals). Measurements of anger aim at assessing responses of one or more of these components. Consequently, instruments for collecting self-reports, behavioral observations, and physiological measures for the assessment of anger have been developed. Measures of anger should be able to discriminate anger from other emotional states, provide some quantification of anger, and deliver results that are free from deliberate manipulations by respondents.

Self-reports

The most common way to assess anger is the use of psychometric self-reports in which individuals respond to statements describing their cognitions, feelings, attitudes, and behavior. Anger can be measured as a state, that is, an acute condition of feelings ranging in intensity from mild irritation or annoyance to intense fury and rage, or anger can be measured as a trait, that is, an enduring behavior disposition for anger states. Individuals high in trait anger are assumed to experience state anger more often, more intensely and longer than individuals low in state anger (Spielberger et al., 1985). Table 1 lists some often-used instruments for the assessment of anger.

Self-reports are usually specific to anger and provide an easy means of quantification (e.g., counting the "Yes" answers) but they can also easily be manipulated by respondents.

Behavioral Observations

The experience of anger often goes along with a characteristic facial expression but it does not have to. Depending on situational conditions, social norms, and individual differences, the expression of anger is more or less appropriate. However, if anger is expressed in the face, the inner eyebrows are lowered and brought closer together. Often, this is accompanied by glaring eyes, widened nostrils, lips that are tightly pressed together, or flashing of the teeth. This facial behavior pattern can be coded using the Facial Action Coding System (FACS; Ekman & Friesen, 1978). The central and most important movement for anger is the constriction of the eyebrows. The facial expression of basic emotions such as anger is assumed to be hereditary. It can already be observed in young children. Figure 1 shows the facial expression of a 5-year-old boy after he was asked to display anger.

While facial expression can validly be assessed by trained raters, this measure provides only a moderate quantification of anger. Usually, one can discriminate between weak and strong anger. Though humans can control facial expressions, they are difficult to manipulate convincingly to an experienced rater.

Physiological Measures

The state of anger is associated with feelings of hyperactivation, restlessness, tension, and power. These feelings are caused by an activation of the sympathetic branch of the autonomic nerve system combined with vagal withdrawal. This activation can be measured using, for example, blood pressure and heart rate readings or by registration for electrodermal activity. Physiological response patterns of emotional activation are usually unspecific and it is not possible to draw conclusions from the observed pattern of activation to the underlying emotional quality. However, when people report being angry it is usually accompanied by increases in systolic and particularly diastolic blood pressure and total peripheral resistance. Also, increased heart rates, number of skin conductance responses, and muscle activity are often reported (Stemmler, 2010).

Studies using brain-imaging methods (fMRI, PET) report activation of the orbitofrontal cortex during episodes of anger (Murphy, Nimmo-Smith, & Lawrence, 2003). Further, anger seems to be associated with an asymmetric activation of the frontal cortex. Measuring spontaneous EEG activity, Harmon-Jones (2003) reported greater activation of the left frontal brain relative to the right frontal brain.

Physiological measures provide very exact, but unspecific quantifications. Many physiological responses can be observed during other emotional states as well. So far, no response pattern has been defined that is unique to the state of anger. Though biofeedback studies show that physiological states, too, can be manipulated after extensive training, there is almost no way to do this spontaneously.

Conclusion

Anger manifests itself on the level of subjective experiences, observable behavior, and physiological activation. For each of these qualities, there are standardized measures for the assessment of anger: self-reports, facial expression coding, and physiological registration. However, since each of these measures has specific strengths and weaknesses, anger should be assessed on at least two different levels.

Definition

Angina pectoris is the classic manifestation of cardiac ischemia, which occurs when there is a mismatch between myocardial oxygen supply and demand. The sensation is typically described as substernal chest pressure or tightness, often accompanied by shortness of breath, and often radiates to the jaw, neck, and left arm or shoulder.

It can also be associated with nausea, vomiting, and diaphoresis. The onset typically occurs over several minutes and is frequently triggered by physical activity and emotional stress (Panju, Hemmelgarn, Guyatt, & Simel, 1998).

The most common cause of angina pectoris is coronary atherosclerosis, either via stable but flow-limiting stenotic lesions or via acute rupture of a vulnerable plaque that causes total or subtotal occlusion of a coronary artery. Other conditions that limit myocardial oxygen supply and thereby cause angina include coronary vasospasm, vasculitides of the coronary vasculature, myocardial bridge, dissection of the coronary arteries, or other congenital anomalies of the coronary arteries that can cause impairment of blood flow. Conditions that can increase myocardial oxygen demand include aortic stenosis or hypertrophic cardiomyopathy or general conditions such as tachycardia, anemia, sepsis, or thyrotoxicosis that often exacerbate cardiac ischemia in patients with underlying coronary atherosclerotic disease (Cannon & Lee, 2008). The appropriate management of angina pectoris depends on the underlying cause.

Angioplasty is a medical technique that allows for visualization of the inside of blood vessels and various organs of the body. This is a moderately invasive procedure, which involves a widening of narrowed or obstructed blood vessels to increase blood flow (http://www.nhlbi.nih.gov/health/health-topics/topics/angioplasty/). This procedure may involve the insertion of a mesh stent or balloon to open the blocked arteries (Fischman et al., 1994, New England Journal of Medicine). Angioplasty is a common procedure for atherosclerosis, which is the buildup of a fatty substance, called plaque, in the arteries. The angiogram is the physical record produced from the procedure.

Angiotensin

Definition

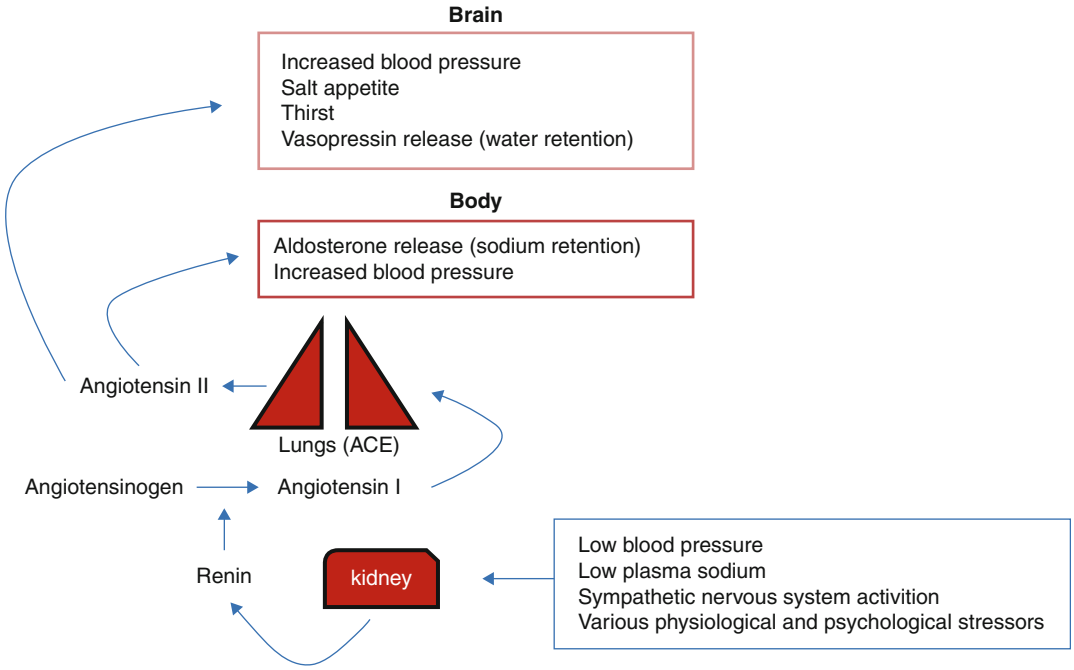
Angiotensin II is a polyfunctional octapeptide generated in response to stress and challenges to body fluid homeostasis. This peptide primarily acts on metabotropic angiotensin II type 1 (AT_1) receptors to accomplish its behavioral and physiological effects. Angiotensin II acts as both a hormone and, in the brain, as a neuromodulator.

Biosynthesis – Angiotensin II is the product of a multienzyme, multisubstrate biosynthesis pathway known as the renin-angiotensin system (RAS). In the classic and best studied RAS, renin is released from the granular cells of the juxtaglomerular apparatus cells of the kidney by various stimuli, including activation of the sympathetic nervous system. Renin acts on constitutively present angiotensinogen in the plasma to catalyze the conversion of angiotensinogen to angiotensin I, an inactive precursor to angiotensin II. Circulating angiotensin I is converted by angiotensin-converting enzyme, located primarily in the lungs, into the bioactive peptide angiotensin II. Researchers are now aware that there are many RASs. In contrast to angiotensin II's system-wide generation, many cells including cardiac myocytes and brain neurons have localized intracellular components of the RAS.

Stimuli for release – Common stimuli for activation of the RAS are perturbations of body fluid homeostasis. For example, loss of extracellular fluid and low plasma sodium activate the RAS. Environmental stressors also stimulate renin release from the kidneys and downstream angiotensin II synthesis via activation of the renal sympathetic nerve. Thus, angiotensin II is a stress hormone. Furthermore, pathologies such as hypertension and heart failure are associated with elevated activity of the systemic or cellular RASs.

Physiological effects – Initially, circulating angiotensin II was studied for its pressor effects in the periphery. In addition to a direct effect on cardiovascular smooth muscle, angiotensin II enhances the release of norepinephrine from sympathetic neurons and potentiates the effects of norepinephrine on vasoconstriction. Importantly, through AT_1 receptors in the brain, angiotensin II acts to promote water- and salt-seeking behaviors, release vasopressin, and initiate a centrally mediated pressor response. Vasopressin acts as a hormone at the kidney to decrease diuresis and thus conserve water. In addition, angiotensin II stimulates the adrenal gland to release aldosterone. Aldosterone is a hormone that signals the kidney to retain sodium and the brain to promote salt-seeking behaviors (Jackson, 2010).

Psychological effects – Since the discovery that angiotensin II acts as a neuromodulator in the brain, researchers have been interested in psychological effects of angiotensin II, for example, recent evidence has supported a role for angiotensin II in the stress response. Stressors cause increased angiotensin II synthesis and release. Administration of candesartan, an AT_1 receptor antagonist, in doses that access the brain attenuates the hormonal response to stressors in rats, including decreases in corticosterone, adrenocorticotropic hormone, epinephrine,



Angiotensin, Fig. 1 Synthesis and effector pathway for hormonal angiotensin II. Various stimuli cause renin release from the kidneys which acts on constitutively present angiotensinogen in blood plasma to generate angiotensin I. Angiotensin I is converted by angiotensin converting enzyme into bioactive angiotensin II. Angiotensin II acts in the brain and in the body to protect body fluid homeostasis

norepinephrine, and aldosterone. Evidence from preclinical models also indicates that angiotensin II produces anxiety-like behavior, and blocking angiotensin II ameliorates these effects. Furthermore, it is likely that angiotensin II has a role in depression. Preclinical models of depression show that angiotensin II antagonists reduce depressive-like behavior and antidepressants antagonize the thirst and smooth muscle contraction effects of angiotensin II (Gard, 2002; Saavedra et al., 2005). Drugs that inhibit the synthesis of angiotensin II are also reported to be mood enhancing. Finally, in nonhuman animals learning and memory are enhanced through central AT_4 receptor activation (Wright & Harding, 2004).

Given the various psychological effects of angiotensin II, it is likely that individuals with cardiovascular disorders associated with increased circulating angiotensin II, such as hypertension and chronic heart failure, are more likely to suffer psychological disorders. Numerous studies have found an association between heart failure and depression, and preclinical models show that heart failure can cause anhedonia, a symptom of major depressive disorder (Johnson & Grippo, 2006). Furthermore, evidence indicates an association between hypertension and depression (Lobo-Escolar et al., 2008). Whether blocking angiotensin II ameliorates psychological pathologies in patients with cardiovascular disorders remains to be validated (Fig. 1).

The classic renin-angiotensin system. Stimuli such as low blood pressure, plasma sodium, or environmental stressors cause the kidney to release renin into blood plasma. Renin is an enzyme that catalyzes the conversion of plasma angiotensinogen into angiotensin I. Circulating angiotensin I is converted by angiotensin-converting enzyme, located primarily in the lungs, into angiotensin II. Angiotensin II acts through the periphery and central nervous system to expand body fluids.

Angiotensin-Converting Enzyme Inhibitors (ACE Inhibitors)

Seth Hurley
Department of Psychology, University of Iowa, Iowa City, IA, USA

Definition

Angiotensin-converting enzyme (ACE) inhibitors are a class of drugs that inhibit ACE activity. ACE is a key enzyme of the renin-angiotensin system (RAS), the synthesis pathway of angiotensin II. Antagonizing ACE activity prevents the conversion of biologically inactive angiotensin I into bioactive angiotensin II (for details of the RAS and the effects of angiotensin II, see ▶ Angiotensin, this volume).

Therapeutic use – ACE inhibitors are commonly used to treat cardiovascular disorders such as hypertension and chronic heart failure. Both of these disorders are associated with increased activity of the renin-angiotensin system, which through angiotensin II action has detrimental effects on the cardiovascular system. In addition to increasing blood pressure, angiotensin II causes both cardiovascular remodeling (changes in cardiovascular tissue distribution) and cardiovascular hypertrophy (increased growth of cardiovascular tissue). In hypertensive patients, ACE inhibitors are used to reduce blood pressure. In patients with left ventricular systolic dysfunction, ACE inhibitors are particularly effective in delaying or preventing congestive heart failure. Finally, in patients with myocardial infarctions, ACE inhibitors reduce overall mortality.

ACE inhibition and aldosterone breakthrough – ACE inhibitors chronically reduce circulating angiotensin II; however, they may only acutely reduce circulating aldosterone. In a phenomenon known as aldosterone breakthrough, aldosterone, a downstream hormone activated by the renin-angiotensin system, rises after chronic ACE inhibition. Aldosterone breakthrough occurs in hypertensive and heart failure patients receiving ACE inhibitors. Aldosterone has detrimental effects on the cardiovascular system and synergizes with angiotensin II to increase blood pressure and produce cardiovascular remodeling and hypertrophy. Thus, combined treatment of aldosterone synthesis blockers and ACE inhibitors is reported to be more successful in treating cardiovascular disorders (Jackson, 2010; Sato & Saruta, 2003).

Psychological effects of ACE administration – Consistent with the idea that angiotensin II contributes to lowered mood (see ▶ Angiotensin, this

volume), ACE inhibitors are reported to enhance mood in samples with cardiovascular disorders. One study reported a greater incidence of depressed mood associated with anxiety and decreased cognitive function in patients with hypertension. These deficits were absent in hypertensives taking ACE inhibitors (Braszko, Karwowska-Polecka, Halicka, & Gard, 2003). Interestingly, patients taking ACE inhibitors or angiotensin II receptor antagonists are more likely to continue drug therapy compared to patients taking other antihypertensive medications (Elliott, Plauschinat, Skrepnek, & Gause, 2007). However, it is unclear if this is caused by mood-elevating effects of ACE inhibitors or less severe side effects of ACE inhibitors relative to other cardiovascular disorder medications.

Anorexia Nervosa

Anna Maria Patino-Fernandez
Department of Pediatrics, University of Miami, Miami, FL, USA

Definition

The *Diagnostic and Statistical Manual of Mental Disorders*, fourth edition, text revision (APA, 2000) includes as the essential features of anorexia nervosa the following: (1) refusal to maintain body weight: weight at least 15% below what is considered normal for others of the same height and age; (2) intense fear of gaining weight or becoming fat; (3) disturbance in body image or denial of seriousness of current low body weight; belief that the one is overweight though in reality they are underweight; and (4) amenorrhea: missing at least three consecutive menstrual cycles (if a female of childbearing age).

There are two types of anorexia nervosa: restricting and binge-eating/purging (APA, 2000). Many individuals with anorexia will severely restrict their calories sometimes taking in only a few hundred calories a day or just water. This is called the restricting type. Other individuals who eat and then fear weight gain may vomit or exercise; this type of anorexia is called the binge eating/purging type. The majority of patients with this disorder are female. This is a potentially very dangerous psychiatric disorder as fatal health complications may occur if untreated.

Warning signs for anorexia nervosa include the following (NIMH, 2011):

(a) Intense, persistent fear of putting on weight.
(b) Low self-esteem related to appearance.
(c) Desire to lose weight.
(d) Body dissatisfaction.
(e) Food preoccupation.
(f) Deliberate self-starvation with weight loss.
(g) Refusal to eat or highly restrictive eating.
(h) Excessive facial/body hair because of inadequate protein in the diet.
(i) Compulsive exercise.

(j) Abnormal weight loss.
(k) Sensitivity to cold: People with anorexia nervosa often complain of feeling cold (hypothermia) because their body temperature drops.
(l) Absent or irregular menstruation.
(m) Hair loss: Individual may develop lanugo (a term used to describe the fine hair on a newborn) on their body.

Treatment of Anorexia Nervosa

The first goal for treatment is to ensure the person's physical health, which involves restoring a healthy weight. Reaching this goal may require hospitalization. Once a person's physical condition is stable, treatment usually involves individual psychotherapy and family therapy. Supportive group therapy may follow, and self-help groups within communities may provide ongoing support. Based on existing, limited evidence, it appears that behavioral family therapy may be considered a reasonable first-line approach for treatment of anorexia in adolescents (Lock et al., 2010).

Another positive development in the treatment of anorexic patients who have regained their weight is in the area of psychopharmacology. While drug treatments such as antidepressants have had little effect combating the symptoms of anorexia, researchers are now finding that medication can help if the patient's weight has returned to normal. In one study (Couturier & Lock, 2007), two thirds of anorexics who took Prozac after they had recovered their weight did not relapse, compared with 16% who took a placebo. Atypical antipsychotics, especially olanzapine, have been tried in open-label non-randomized single-case studies and suggest a possible benefit in increasing weight and decreasing weight obsession. At present, there are no randomized trials using psychopharmacological interventions in children.

Definition

Antibodies are proteins secreted by white blood cells (B lymphocytes). Their task is to circulate in the body and tag, destroy, or neutralize bacteria, viruses, or other harmful or foreign materials (antigens). They do this by opsonizing or coating foreign materials which marks them for destruction or neutralization.

Antibodies are also called immunoglobulins (Ig), which are present on the surface of B cells and act as receptors for foreign materials. Immunoglobulins can be classified into several classes: IgA, IgE, IgM, IgG, and IgD, some of which have further subtypes. Each type of antibody has a range of different immune functions. IgA is found at the mucosal surfaces (e.g., mouth, nose, gastrointestinal tract) and can be measured in saliva. IgM is the first type of antibody produced in response to a novel foreign material. IgG is the most common antibody found in the body. Vaccines work by presenting a dead or altered form of an antigen to the immune system in order to provoke an antibody response.

Effective drugs for treatment of patients with depressive disorders

Description

History of antidepressants began in the 1950s when imipramine, currently known as one of the tricyclic antidepressants (TCA), appeared. Imipramine was initially developed as a derivative of chlorpromazine (antipsychotic agent), and it was hoped that imipramine would be an effective antipsychotic drug (Hales & Yudofsky, 2003; Sadock & Sadock, 2003). Interestingly, imipramine did not have antipsychotic efficacy; however, it was shown to be effective in the treatment of depression. Subsequently, many other antidepressants have been developed, and there are approximately 30 different antidepressants now, although some antidepressants are not available in some countries.

Antidepressant medications are most popular treatments for patients with depressive disorders, especially patients with mild to moderate major depression (Association American

Psychiatric, 2010). Although there are several different types of antidepressants including TCA, tetracyclic antidepressants, selective serotonin reuptake inhibitors (SSRI), serotonin noradrenaline reuptake inhibitors (SNRI), monoamine oxidase inhibitors (MAOIs), and other antidepressants, the effectiveness of these antidepressant medications is generally comparable between classes and within classes of medications (Association American Psychiatric, 2010; Hales & Yudofsky, 2003; Sadock & Sadock, 2003). On the other hand, side effect profiles clearly differ among the different classes of antidepressants.

Antidepressants affect the serotonergic and/or catecholaminergic systems in the central nervous system, and these changes are considered to be associated with treatment effect for patients with depressive disorders. The effect of the antidepressants will be gradually observed after a couple of weeks since implementation of the pharmacotherapy.

Most TCAs inhibit the reuptake of norepinephrine, serotonin, and, to a lesser extent, dopamine. Furthermore, TCAs also block muscarinic cholinergic receptors, H1 histamine receptors, and α1-adrenergic receptors. Most side effect profiles of the TCAs are mainly produced by these mechanisms. Potential side effects of TCAs include arrhythmias, orthostatic hypotension, sedation, constipation, dry mouth, urinary hesitancy, and so on. Currently available TCAs are imipramine, amitriptyline, nortriptyline, clomipramine, etc. Tetracyclic antidepressants are developed to reduce side effect profiles of TCAs; however, these drugs have similar side effect profiles. Tetracyclic antidepressants include maprotiline and mianserin.

In 1980s, SSRIs, specifically inhibiting the reuptake of serotonin, were developed as antidepressants. First, SSRI is fluoxetine and other SSRIs, including paroxetine, sertraline, citalopram, escitalopram, and so on, are also available now. Side effects of SSRIs are nausea, vomiting, insomnia, activation (e.g., restlessness, agitation), sexual dysfunction, gastrointestinal bleeding, etc. We can also use some SNRIs which specifically inhibit the reuptake of serotonin and norepinephrine. Usable SNRIs are venlafaxine, milnacipran, duloxetine, and so on. In general, side effect profiles of SNRIs are similar to the ones of SSRIs; however, some SNRIs can cause hypertension and urinary retention.

MAOIs increases concentration of monoamines through inhibiting monoamine oxidase. MAOIs currently used as antidepressants include phenelzine, moclobemide, and so on. MAOIs have unique pharmacological property, and this have been characterized by showing to be effective in treating depressed patients, with atypical features (e.g., reactive mood, sensitivity to rejection).

Other types of antidepressants include bupropion (dopamine norepinephrine reuptake inhibitor), mirtazapine (norepinephrine-serotonin modulator), trazodone (serotonin modulator), nefazodone (serotonin modulator), and so on. Bupropion is classified as a dopamine norepinephrine reuptake inhibitor, the effect of dopamine, however, is relatively weak. Mirtazapine is thought to work through noradrenergic and serotonergic mechanisms despite of not being a reuptake inhibitor.

In addition to efficacy for depressive disorders, antidepressants are also effective for treatment of patients with anxiety disorders (Hales & Yudofsky, 2003; Sadock & Sadock, 2003). Recent studies suggest that antidepressants are also useful for treating other medical condition such as neuropathic pain and depressive and negative symptoms of schizophrenia. Some antidepressants have efficacy for other medical conditions. For example, SSRIs are used for treatment of bulimia nervosa. Bupropion can be a choice for patients who would like to quit smoking. Thus, although antidepressants were initially developed for treatment of depression, these medications have been known to be useful for broader medical conditions.

Definition

Antigens are antibody generators, any foreign material which is recognized by the body as foreign and causes the production of antibodies.

Antigens can be bacteria, viruses, toxins, or foreign nonself materials. A molecular part of a microorganism or foreign material that is recognized by immune cells is the part which is called antigen. Certain cells of the immune system (B and T lymphocytes) recognize antigen by their specific receptors. B cells (matured in the bone marrow) are the immune cells that recognize antigen via their surface receptors or antibody. T cells (matured in the thymus) recognize antigen via their T cell receptor, but only after antigens have been processed into smaller peptides by antigen-presenting immune cells. Vaccines work by presenting a dead or altered form of an antigen to the immune system in order to provoke a response. For further information, see Goldsby, Kindt, Osborne, & Kuby, 2003.

Definition

Antihypertensive medications are a class of medicines/drugs that are used to treat hypertension or high blood pressure. High blood pressure has been associated with kidney malfunction, heart disease, stroke, and other conditions. By decreasing blood pressure, antihypertensive medications may help to alleviate, if not prevent, these conditions from developing and/or progressing. As with most medical conditions, lifestyle changes tend to be the first direction to take when a person suffers from hypertension. These changes may include decreased salt intake, altered diet, increased physical activity, and stress reduction techniques. If the initial approaches and methods are not effective in reducing blood pressure, then the medicinal route is often the next step in treatment. There are many classes of antihypertensive medications. Some examples include thiazide diuretics, which decrease the amount of fluid in blood vessels and help to dilate blood vessels, increase blood flow, and decrease blood pressure. Another type of antihypertensive medication includes angiotensin-converting enzyme (ACE) inhibitors. ACE inhibitors act on the renin/kidney-angiotensin-aldosterone system to reduce blood pressure by blocking the conversion of certain proteins, which ultimately increases cardiac output, decreases circulation of sodium throughout the system, and increases sodium excretion. Beta-adrenergic blocking agents, or beta-blockers, are also commonly administered to lower blood pressure by blocking the effects of epinephrine, or adrenaline, and other stress-related hormones; however, beta-blockers have also been associated with adverse effects in other bodily systems and, for this reason, are not commonly the first antihypertensive medication prescribed. Calcium channel blockers (CCBs) may also be administered to treat hypertension. CCBs decrease cardiac contractions, which results in a decrease in cardiac output, and, ultimately, a decrease in blood pressure throughout the entire body. There are other antihypertensive medications that, depending on the patient, severity of hypertension, and potential secondary bodily system consequences, may be more effective. Although antihypertensive medications are effective in reducing high blood pressure, it is important to consider each patient's medical history, lifestyle, and potential complications when prescribing antihypertensive medications, such as cardiac disease, history of stroke or epilepsy, or other serious medical conditions.

Nonsteroidal Anti-inflammatory Medications (NSAIDs)

Definition

Anti-inflammatory medications work by suppressing the inflammatory process in the body caused by certain disease states, immune reactions, or any type of noxious agent. There are several clinical symptoms that present when the body's inflammatory process is stimulated: warmth, pain, redness, and swelling. The process of inflammation is a sequence of events that lead to local vasodilation and increased capillary permeability, recruitment of leukocytes and phagocytic cells to the inflamed area, and tissue degeneration and fibrosis.

There are many classes of drugs that affect different cells involved in the inflammatory process (e.g., antihistamines, leukotriene modifiers, glucocorticoids) but the classic anti-inflammatory agents are those that inhibit an enzyme called cyclooxygenase. Cyclooxygenase converts arachidonic acid to prostaglandins (PG) which are essential to the inflammatory process. There are two cyclooxygenases: COX-1 and COX-2. COX-1 is responsible for creating PG involved in gastrointestinal protection, platelet aggregation, vasoconstriction, and renal function. COX-2 is responsible for creating PG involved in renal function, vasodilation, platelet aggregation, inflammation, pain, and fever. The primary target of anti-inflammatory drugs is COX-2, but selectivity is difficult to achieve due to the conformation of the active sites on the enzymes.

The biggest class of anti-inflammatory drugs are the nonsteroidal anti-inflammatory drugs (NSAID). As a class, they are competitive, reversible, active site inhibitors of the COX enzymes. Within the class, they can be further divided based on their chemical makeup and their selectivity of the COX enzymes (i.e., selective, nonselective). Inhibition of COX-2 provides the basis for the therapeutic effect of NSAIDs (antipyretic, analgesic, anti-inflammatory) while inhibition of COX-1 leads to a majority of the adverse effects (gastrointestinal). Aspirin is an irreversible inhibitor of COX-1 and COX-2, and therefore, the duration of action of aspirin depends on the lifetime of the COX enzyme at different target tissues. Of note, the inhibition of COX-1 that leads to platelet disaggregation lasts for the lifetime of the platelet (8–12 days). This is why aspirin is used for cardiovascular and stroke prevention.

Anti-inflammatory medications can be used for a variety of disorders and disease states. They provide symptomatic relief from pain and inflammation associated with musculoskeletal disorders such as rheumatoid arthritis and osteoarthritis. Their analgesic effects are generally only effective for mild to moderate intensity pains and especially when inflammation is the underlying cause of the pain.

Definition

An antioxidant is a substance that has the ability to prevent oxidation. An antioxidant can act to inhibit an oxidant or reactions promoted by reactive oxygen species. Reactive oxygen species (ROS) comprise free radicals (pro-oxidant molecules such as superoxide) and non-radical species (such as hydrogen peroxide) and are produced in normal bodily processes such as metabolism or respiration. ROS are aptly named as they are indeed very reactive, and will oxidize proteins,

lipids, or DNA that they come into contact with, causing adducts or altering the function of these bodily molecules. Antioxidants serve to prevent damage or dysfunction by balancing ROS production and effectively neutralizing them. Examples of antioxidants in the body may be endogenous (produced by the body) or exogenous (taken in via the diet). Endogenous antioxidants, including the enzymes superoxide dismutase and catalase, may be upregulated, or increased, in response to ROS release. Examples of exogenous antioxidants include vitamins A, C, and E.

Definition

Anxiety may be defined as an "apprehensive anticipation of future danger or misfortune accompanied by a feeling of dysphoria or somatic symptoms of tension," (American Psychiatric Association, 2000, p. 820) (American Psychiatric Association, 2000). The origin of the word anxiety is "to vex or trouble," and is often associated with feelings of fear, worry, discomfort, and dread (Antony & Barlow, 1996). Anxiety is often considered synonymous with *fear*, and though related, they are, in fact, conceptually and clinically distinct. Whereas anxiety may be conceptualized as a negative mood state that may occur in the absence of a specific trigger, fear is better conceptualized as an emotional response to a real or perceived threat. Fear is also more closely related to escape and avoidance behaviors, where anxiety may be experienced in situations that are perceived as either uncontrollable or unavoidable (Cannon, 1929).

Description

Anxiety has many dimensions, including emotional, cognitive, behavioral, and somatic, which characterize many of the responses seen in anxious individuals (Dugas & Ladouceur, 2000). For example, anxiety-related emotional responses include feelings of fear, worry, and apprehension; anxiety-related cognitive responses include anticipation of negative outcomes, biases in information processing, and distorted beliefs; anxiety-related behavioral responses include distraction, procrastination, avoidance, compulsions, and distraction; and anxiety-related somatic or physiological responses include those that signal increases in autonomic (i.e., sympathetic) responses such as increased heart rate, blood pressure and respiration rate, sweating, dizziness, and trembling. Anxiety also has some well-established *biological bases* beyond being associated with increased sympathetic arousal. For example, neural circuits involving the amygdala (emotion-processing center of the brain) and hippocampus (memory center of the

brain) have been strongly implicated in various manifestations of anxiety. Moreover, low levels of at least two neurotransmitters, *gamma*-aminobutyric acid (GABA), which reduces activity in the central nervous system, and serotonin, a neurotransmitter implicated in mood regulation, have both been associated with increased anxiety (Cannon, 1929).

Normal Versus Abnormal Anxiety

Like other negative mood states (e.g., depression, anger), anxiety may be experienced only briefly, and may often be considered a normal or adaptive reaction to situational demands or stress by promoting effective coping. One example of adaptive anxiety relates to performance. Optimal performance on various behavioral tasks (e.g., playing a musical instrument, sharp shooting) may require experiencing at least moderate levels of anxiety (known as the *Yerkes-Dodson law*) (Selye, 1956), which dictates that performance generally increases with moderate increases in mental and physiological arousal. However, performance starts to decline when anxiety (and mental and physiological arousal) becomes too intense. This relationship is often illustrated graphically by an inverted U-curve. Other adaptive forms of anxiety may also be closely tied to the "*fight or flight*" response, originally proposed by Walter Cannon (1929) (Ohman, 2000). Cannon's theory postulated that animals react to stressful situations, particularly those involving threats of bodily harm or injury, with a sudden activation of the sympathetic nervous system, which is said to prime the animal for fighting or fleeing the threat. This theory was later extended to humans and recognized as the initial stage of the *general adaptation syndrome* (described by Hans Selye) (Riggs & Keane, 2006) that regulates stress responses among humans and other organisms.

On the other hand, when anxiety becomes excessive or exaggerated, which may be determined by its intensity and rationale in relation to a particular event or situation, it may be classified as an *anxiety disorder* (discussed in greater detail in the next section). Anxiety disorders represent a group of syndromes that are described in the Diagnostic and Statistical Manual of Mental Disorders-4th Edition Revised (DSM-IV-R) (American Psychiatric Association, 2000), that characterize various types of abnormal or pathological anxiety. The DSM-IV-R has defined six anxiety disorders, including generalized anxiety disorder, panic disorder (with or without agoraphobia), obsessive-compulsive disorder, phobias (including social anxiety disorder), posttraumatic stress disorder, and childhood anxiety disorders (including separation anxiety disorder). Anxiety disorders are very common, and are estimated to affect approximately 18% of Americans (American Psychiatric Association, 2000).

Anxiety Subtypes

Aside from pathological or "psychiatric" levels of anxiety that generally characterized anxiety disorders, there are several other forms of anxiety that tend to fall somewhere between normal and pathological, and will probably be experienced by most people at some point in their lives.

1. Performance anxiety

   As mentioned above, Yerkes and Dodson (Selye, 1956) described a phenomenon linking anxiety-related arousal to performance on various behavioral tasks. They discovered that a moderate level of mental and physiological arousal was necessary to ensure optimal performance on various tasks, and that performance decreased as anxiety either increased or decreased from this minimal or moderate level. This is best depicted by an inverted U-shaped curve, and became known as the Yerkes-Dodson law (Selye, 1956). This phenomenon is what best describes modern day test anxiety and its associated performance.
2. Stranger and social anxiety

   Although "social anxiety disorder" represents one of the anxiety disorders described in the DSM-IV-R, there exist milder, less debilitating forms of stranger or social anxiety. This type of anxiety is normally experienced in childhood when introduced to new or unfamiliar people and may be adaptive (i.e., prevent abduction or abuse by strangers); however, this type of anxiety may persist into adulthood

with little to no purpose (American Psychiatric Association, 2000).

3. Choice or decision anxiety

   Anxiety induced by the need to choose between similar options is increasingly being recognized as a problem for individuals and for organizations, as it has been related to increased procrastination and lost productivity. This type of anxiety, when it becomes exaggerated, closely resembles one of the manifestations of "generalized anxiety disorder," which characterizes individuals with a high intolerance to uncertainty and a high tendency to worry about the negative consequences of making a wrong decision (Yerkes & Dodson, 1908, Dugas & Ladouceur, 2000).

4. State versus trait anxiety

   Anxiety can either be experienced acutely and briefly, or represent a more stable and enduring underlying personality trait. The term "state" anxiety has been used to describe anxiety experienced "in the moment" in response to a particular event or situation. It is typically brief and short lived. In behavioral medicine, this can be manifested, for example, by a person experiencing state anxiety related to a medical procedure such as a blood test or undergoing brain scanning. On the other hand, the term "trait" anxiety has been used to describe a more stable tendency to respond with state anxiety when anticipating or faced with potentially threatening situations. Historically, "trait anxiety" has been closely linked to the personality trait of "neuroticism." Trait anxiety has also been related mainly to self-reported negative health outcomes, but also to objectively defined outcomes.

Definition

Anxiety is an emotional response to a situation, which has both psychological and physiological consequences. Anxiety may be a normal response to daily life situations. However, a heightened or an inappropriate level of anxiety may lead to several deleterious consequences to overall health. There is mounting research about the role of anxiety in the pathophysiology of heart disease.

Description

In the past decade, there has been increasing interest in the relationship between anxiety and heart disease. As reviewed by Rozanski, Blumenthal, and Kaplan (1999) prior to 1999, there were a limited number of prospective studies demonstrating a relationship between anxiety and subsequent cardiovascular disease (CVD) outcomes in healthy populations and in patients with prevalent CVD.

After these initial studies, additional prospective studies examining the relationship between anxiety and CVD outcomes in participants without prior CVD history have been published. For example, Albert, Chae, Rexrode, Manson, and Kawachi (2005) investigated the relationship between anxiety and CVD events in women without a history of CVD and found that anxiety was associated with a higher risk of sudden cardiac death and fatal coronary heart disease. However, these relationships were attenuated after adjustment for medical factors. On the other hand, Shen et al. (2008) showed that in older men without CVD history, anxiety was associated with incident myocardial infarction even after adjustment for medical factors, medication use, adverse health behaviors, and other psychosocial factors including depression. More recently, Janszky, Ahnve, Lundberg, and Hemmingsson (2010), showed that in young Swedish men, anxiety was associated with an increased risk of incident coronary heart disease events including myocardial infarction during long-term follow-up (mean = 37-year follow-up) in unadjusted and adjusted multivariable models. In 2010, Roest, Martens, de Jonge, & Denollet (2010) published a meta-analysis of 20 studies showing that anxiety was associated with incident coronary heart disease events and cardiac death, independent of medical factors and health behaviors. No relationship was found between anxiety and nonfatal myocardial infarction in five studies that examined myocardial infarction as a separate outcome.

Additional prospective studies have also examined the relationship between anxiety and CVD outcomes in participants with prevalent CVD. For instance, Shibeshi, Young-Zu, and Blatt (2007) showed in patients with coronary artery disease that a high level of anxiety over time predicted an increased risk of nonfatal myocardial infarction or death after adjustment for possible confounders. Huffman, Smith, Blais, Jannuzzi and Fricchione (2008) showed that anxiety was associated with an increased risk of CVD complications during a hospitalization for a myocardial infarction in adjusted models. More recently, Martins, de Jonge, Beeya, Cohen, and Whooley (2010) demonstrated that anxiety was independently associated with CVD events in men with stable coronary artery disease. In 2010, Roest, Martens, Denollet and Jonge (2010) published a meta-analysis examining the relationship between anxiety and CVD outcomes in post-myocardial infarction patients. Anxiety was associated with an increased risk of CVD events independent of other prognostic factors.

Although the evidence base is growing in the area of anxiety and heart disease, several questions remain.

First, given that depression is highly comorbid with anxiety, it has not been determined with a high level of certainty whether the relationship of anxiety with CVD events is independent of depression. In the meta-analysis by Roest et al. (2010), which included participants without CVD history, only 5 of the 20 studies adjusted for depression, although the associations in 4 of the 5 studies remained significant. In patients with preexisting CVD, this issue may be more complex. Few studies have ascertained the independent contributions of anxiety and depression

on CVD outcomes. Strik, Denollet, Lousberg, and Honig (2003) found that although both anxiety and depression were separately associated with increased CVD events in post-myocardial infarction patients, the association between anxiety (and not depression) and CVD events remained significant when both psychosocial factors were placed into the same multivariable model. Doering et al. (2010) showed that in adjusted models, the combined presence of persistent anxiety and depression over 3 months was associated with mortality in patients with ischemic heart disease, whereas persistent anxiety only and persistent depression only were not. In addition to depression, some evidence suggests that the combination of anxiety and Type D personality may be cardiotoxic. van den Broek et al. (2009) showed that anxiety was associated with ventricular arrhythmias in patients with implantable cardioverter-defibrillators but only in the presence of Type D personality. Therefore, the CVD risk associated with anxiety may depend on comorbid depression and/or Type D personality. The contributions of other psychosocial/personality factors remain unknown.

Second, the mechanisms underlying the association between anxiety and CVD events also are unknown. Possible candidates include accelerated subclinical atherosclerosis, autonomic dysregulation, ventricular electrical instability, unhealthy lifestyles, and reduced treatment adherence.

Third, the construct of anxiety is broad, and it is unclear what constitutes the main "ingredients" of anxiety-associated CVD risk. In the prospective studies of non-CVD and CVD participants, anxiety has been assessed using self-report measures and also by interviewer assessment. Further, phobic anxiety, generalized anxiety, neurotic anxiety, somatic symptoms of anxiety, social introversion, manifest anxiety, and psychasthenia are among the different manifestations of anxiety that have been associated with increased CVD risk.

Lastly, it is currently not known whether treating anxiety using pharmacologic or non-pharmacologic strategies reduces the risk of CVD events.

Definition

Anxiety is a psychological and physiological state characterized by cognitive, physiological, and behavioral components. It is described as the "apprehensive anticipation of future danger or misfortune accompanied by a feeling of dysphoria or somatic symptoms of tension" (American Psychiatric Association [APA], 1994, p. 764). The ICD-10 defines anxiety as feelings of apprehension, motor tension such as fidgeting or muscle tension, and autonomic overactivity such as lightheadedness or sweating (World Health Organization [WHO], 1993). These components can be measured through self-report instruments, clinical interview, and behavioral observations.

Description

Several types of assessment measures can be used in the evaluation and treatment of anxiety. Screening questions and instruments are often used first when anxiety is suspected in a clinical setting. These can include single-item questions or brief screening instruments to determine whether further evaluation is warranted. Self-report measures are commonly used in both research and clinical settings. Individuals complete these measures individually and report their perspective of the symptoms they are experiencing. This type of measure allows the individual to complete the information independently, minimizing assessor's time investment. However, this format does not allow individuals to elaborate on their answers and decreases qualitative information obtained regarding the symptoms. Clinical interviews may consist of structured or unstructured series of questions asked by the administrator regarding the client's symptomatology. This format allows for the administrator to gather more information from the client regarding their answers, and structured interviews can be formatted in such a way that symptoms are unlikely to be missed. One disadvantage of clinical interviews is a greater time investment from the administrator to conduct the interview. Finally, anxiety may be assessed by behavioral observation, particularly via observation of a client in an anxiety-provoking situation.

Selection of an appropriate measure depends largely on what information the assessor wishes to obtain and what purpose the information will serve. Functions of anxiety measurement include data collection, differential diagnosis, clinical description, case formulation, treatment planning, and evaluating outcome. If differential diagnosis is the purpose of assessment, it is particularly important to ensure that the measure or technique chosen addresses the suspected disorder. Some measures (i.e., the structured clinical interview Anxiety Disorder Interview Schedule or ADIS), are designed to assess all diagnoses classified by the DSM-IV as anxiety disorders whereas many self-report measures address only specific disorders or symptoms (i.e., the Yale-Brown Obsessive Compulsive Scale). Measures used to aid clinical description can help to identify particular symptoms of concern, as well as provide information to help the assessor better understand the individual's experience. For example, the Beck Anxiety Inventory measures

specific physical symptoms related to an individual's anxiety, as well as the degree of severity or frequency with which the anxiety is experienced. Although these measures are not sufficient unto themselves for a diagnosis of an anxiety disorder, they provide a better understanding of the individual's perception of the problem. Similarly, assessment measures may be used to clarify case conceptualization and treatment plan. Use of a measure such as the Trimodal Anxiety Questionnaire can help focus treatment onto the aspect of anxiety most distressing to the client: somatic, behavioral, or cognitive. Anxiety measures may also be used to address treatment outcome. This may be done in one of several ways. Measures with a particular diagnostic cutoff score (such as the ADIS) can be used to help determine if the individual continues to meet criteria for diagnosis. Other measures, like the Beck Anxiety Inventory, which measures symptoms along a continuum, may be used to assess improvement of certain symptoms over time.

There are several important factors to consider when selecting a measure of anxiety, including the age, culture, and education level of the individual or group of individuals (Derogatis & Lynn, 2000). This factor is particularly important when assessing children/adolescents or older adults. In both groups there are measures developed to specifically address the presentation of anxiety unique to that age. Language and cultural considerations are also important. Anxiety is often expressed differently across cultures; for example, an individual from a culture that expresses anxiety primarily somatically would score inappropriately low on a measure of anxiety that focuses on cognitive components. Intellectual ability and reading level are other factors to consider in choosing an assessment measure. Effort should be made to match the measure to the individual's ability, particularly on self-report measures that require the individual to interpret and respond to question without the assessor's assistance. Finally, time commitment and cost of the measure should be considered. A screening questionnaire may be appropriate for a large-scale research study, whereas a lengthy clinical interview would be impractical.

There are numerous measures of anxiety that utilize different formats and address different symptoms of anxiety disorders. Though not exhaustive of all available measures of anxiety, listed below are samples of the measures available that have been empirically validated (Table 1) (Roemer, 2001). Included in the table is the main reference for the measure, the type of measurement (specifically self-report or clinician administered), a brief description of what the measure intended to address, and the appropriate age range for administration.

The measurement of anxiety serves one of several functions and can encompass one or more aspects of its presentation. Peter Lange, a prominent theorist in the field of anxiety, suggested that anxiety consists of three components: cognitive, physiological, and behavioral (Antony, 2001). Cognitive aspects of anxiety consist of thoughts and beliefs that are irrational or otherwise unhelpful to the situation. Examples may include the thought that if something can go wrong it will, or the belief that it is best to prepare for the worst possible outcome of a situation. These thoughts are related to physiological aspects of anxiety such as sweating, accelerated heart rate, or muscle tension. Physiological components of anxiety may be misinterpreted by the individual, as well as by health care providers, as symptoms of physical illness. For example, chronic gastrointestinal issues may be the result of underlying anxiety or, panic-induced heart palpitations and shortness of breath may be misinterpreted as a heart condition. Behavioral responses to anxiety include the methods an individual uses to cope with distressing thoughts and physical reactions such as avoiding triggers to anxiety or engaging in behaviors designed to prevent negative events from occurring. Different anxiety disorders have specific behavioral responses to anxiety, such as compulsive behaviors present in obsessive compulsive disorder, or avoidance of social interactions in social phobia. In addition to the three components identified by Lange, an emotional aspect of anxiety has been recognized. Similarly to depression and fear, anxiety has been conceptualized as the experience of high negative affect and low positive

Synonyms

Anxiety; Stress disorder

Definition

Anxiety disorders are a group of disorders characterized by intense or excessive fear, nervousness, dread, or worry. While normal anxiety can create feelings of stress or worry, it typically abates once a stressor is eliminated. Pathological anxiety, of the type experienced in an anxiety disorder, is of a high intensity, lasts for a long duration (typically over 6 months), and interferes with daily life. It is estimated that about 8–18% of the U.S. adult population experiences at least one anxiety disorder each year.

Description

There are eight types of anxiety disorders recognized by the American Psychiatric Association's Diagnostic and Statistical Manual of Mental Disorders (4th edition; DSM-IV-TR). Each has different specific symptoms, but the symptoms all involve elements of excessive fear or worry. Cognitive Behavioral Therapy and medication are commonly used treatment approaches that have been empirically supported for a variety of anxiety disorders.

Panic Disorder With or Without Agoraphobia

Description and Symptoms

Panic disorder occurs when a person experiences repeated, unexpected, and feared panic attacks. A panic attack is a sudden, discrete (approximately 5–30 min), and intense anxiety reaction that typically includes several of the following symptoms: pounding heart or accelerated heart rate, sweating, trembling or shaking, feelings of smothering or shortness of breath, feelings of choking, chest pain, nausea, feeling dizzy or faint, feeling detached from reality or oneself, fear of losing control or going crazy, fear of dying, chills or hot spells, and numbness or tingling. Panic disorder is diagnosed by the presence of panic attacks, plus the accompanying fear of having attacks in the future or their implications. A commonly held fear of a person suffering from panic disorder is experiencing an embarrassing or noticeable attack while in public. Thus, agoraphobia is often comorbid with panic disorder. Agoraphobia is the fear and avoidance of being in public places, crowds, or places from which escape may be difficult.

Treatment

Treatment is inherently individualized, and includes analyzing the triggers of panic attacks, restructuring distorted anxious and catastrophic thoughts, relaxation training, habituation to the somatic symptoms of panic, lifestyle changes, and medication usually (SSRI antidepressants or benzodiazepines).

Generalized Anxiety Disorder (GAD)

Description and Symptoms

GAD is characterized by persistent worry on most days for at least 6 months. The worry may focus on two or more stressful situations, or it may be generalized to most life domains. The worry involved with GAD is out of proportion of the actual stressors and causes distress or impairment in daily life. Symptoms of GAD include feeling restless or on edge, being easily fatigued, difficulty concentrating or remembering, irritability, muscle tension, and sleep disturbance.

Treatment

Common therapeutic techniques for GAD include relaxation training, cognitive restructuring of dysfunctional thoughts, problem solving, lifestyle changes and distraction, and medication.

Social Phobia

Description and Symptoms

Social phobia (or social anxiety disorder) is the excessive or irrational fear of public embarrassment or perceived scrutiny. Social phobia can cause people to avoid certain social situations or endure them with distress, to the point where the fear negatively impacts quality of life. People with social phobia recognize that their fear is excessive. Common social phobias involve public speaking, eating in public, blushing, writing in public, and using public restrooms.

Treatment

Social phobia typically responds well to Cognitive Behavioral Therapy to examine and replace distorted thoughts that perpetuate the fears. Relaxation training, exposure to feared situations, social skills assertiveness training, and medications are also empirically supported treatments. Group therapy can he helpful for people with social phobia.

Specific Phobia

Description and Symptoms

Specific phobias are excessive and irrational fear or avoidance of one or more objects or situations. The types recognized by the DSM-IV-TR include animals (e.g., snakes, spiders), natural environment (e.g., heights, storms), blood or injections, situational (e.g., flying, elevators), and others (e.g., vomiting, loud sounds). Criteria for diagnosis of a specific phobia, like social phobia, include persistent anxiety and fear of the object or situation, recognition that the fear is excessive, avoidance of the feared stimulus or enduring it with distress, and interference with daily life.

Treatment

Like social phobia, specific phobias respond well to Cognitive Behavioral Therapy and relaxation training. Graded exposures are very common and effective for phobias. People suffering from a phobia are asked to develop a hierarchy of imaginal and real stimuli that evoke the fear. Clients are then exposed to each step of the hierarchy gradually, with the support of a therapist and relaxation practice, until they can face the highest or most feared object or situation.

Obsessive-Compulsive Disorder (OCD)

Description and Symptoms

Obsessions are anxiety-inducing repeated, intrusive, unwanted, and uncontrollable recurrent thoughts or ideas. Compulsions are excessive, ritualistic, repetitive, intentional behaviors, rules, or thoughts done to allay the anxiety associated with obsessions. OCD involves having obsessions and/or compulsions that are time consuming (more than 1 hour a day), recognition that they are irrational, and cause a person significant distress and impairment of daily functioning. Common obsessions are contamination/germs, symmetry, and hoarding. Common compulsions are washing, checking, and counting.

Treatment

OCD can respond well to Cognitive Behavioral Therapy and/or medication, depending on a variety of factors including severity. Psychological treatments include relaxation training, cognitive restructuring of catastrophic or maladaptive thoughts, and exposure and response prevention (ERP). ERP involves exposure to the obsessional object or thought, and then enforced (by a therapist or companion) prevention from performing the compulsion or gradually reducing the number of times it is performed, until the behavior is extinguished and the obsession becomes less anxiety provoking. ERP is an empirically supported treatment for OCD.

Posttraumatic Stress Disorder (PTSD)

Description and Symptoms

PTSD can occur after witnessing or having experienced a severe trauma that involved the threat of or actual violence and/or death and feelings of horror or helplessness. Not everyone who experiences a traumatic event will develop PTSD, and the precise mechanisms of etiology are unknown but likely involve a complex interplay of genetic predisposition, environmental, personality, and other psychological factors. The symptoms of PTSD fall into three groups: re-experiencing the trauma in dreams or intrusive thoughts (flashbacks), emotional numbing, detachment, and avoidance, and hyperarousal that includes irritability and excessive startle responses to stimuli. PTSD may be acute or chronic, depending on the duration: (whether or not symptoms last longer than 3 months).

Treatment

PTSD responds to several of the cognitive and medication methods described for the previous anxiety disorders. Exposure therapy is used heavily, to assist the person with re-experiencing the feared experience, with the goal of ultimately reducing anxiety and arousal

through habituation and cognitive restructuring. Support groups for PTSD may also be helpful. Eye-movement desensitization and reprocessing therapy (EMDR) is a newer empirically supported treatment for PTSD. It involves having the victim hold the feared memory in his or her mind, and then watching the therapist's fingers move rapidly in a diagonal, back-and-forth motion, to alter the vividness and anxiety provoked by the images.

Acute Stress Disorder

Acute stress disorder is a newer diagnosis that may be a precursor to PTSD. It involves developing anxiety responses (similar to those in PTSD) following a stressful event. However, for this diagnosis, the symptoms must appear and retreat within a month.

Anxiety Disorder due to a General Medical Condition and Substance-Induced Anxiety Disorder

Description and Symptoms

Both of these types of anxiety disorders draw on externally identifiable stimuli as the primary source of the anxiety; the anxiety displayed is not better attributable to one of the other, previously described disorders.

Treatment

Treatment of the anxiety in both of these situations involves treating the underlying cause: medical or drug related.

Several of the above-mentioned anxiety disorders can be associated with health conditions and may also have medical consequences of relevance to behavioral medicine. For example, PTSD has been found to result in some people from myocardial infarctions, and PTSD predicts future cardiac events.

Antianxiety drug; Minor tranquilizer

Definition

Anxiolytics can be defined as a drug used to treat anxiety. In current medicine, however, anxiety is treated using a variety of drugs including antidepressants, antipsychotics, and anticonvulsants. Recent evidence indicates that even the first choice for the treatment of anxiety disorders such as panic disorder and social anxiety disorder is antidepressants. Therefore, the term anxiolytics is recently defined more appropriately as a drug whose main target symptom is anxiety. Anxiolytics are originally referred to as minor tranquilizers to be distinguished from antipsychotics as major tranquilizers.

Description

Main examples of anxiolytics are barbiturates, benzodiazepines, azapirones, and hydroxyzine. In the historical point of view, barbiturates were the first drugs used to treat anxiety. But later on, they have been prescribed rarely and were replaced by benzodiazepines because they have strong physical and psychological addiction potential. On the other hand, barbiturates are still used for the treatment of epilepsy and general anesthesia, and for the short-term treatment of severe insomnia, especially in case of benzodiazepine-refractory insomnia.

In 1960, chlordiazepoxide, the first benzodiazepine anxiolytic, was made available, followed by diazepam in 1963. The mechanism of action of benzodiazepines includes their bindings to gamma amino butyric acids (GABA)-A receptors, which increase the affinity of GABA and their receptors, resulting in the increase of opening frequency of GABA-A receptors and therefore of potentiating GABAergic neurotransmission. Benzodiazepines have been used widely in clinical practice for the treatment of, for example, anxiety associated with psychiatric disorders including anxiety disorders, mood disorders, insomnia, seizures, alcohol withdrawal syndrome, and agitation. Most of the side effects caused by benzodiazepines are related to their sedating and muscle relaxing effects, such as drowsiness, lightheadedness, lack of coordination, and amnesia. Apart from these side effects, benzodiazepines are basically safe and effective in the short term. But in the long term, they may cause tolerance, dependence, and withdrawal. Risk factors of benzodiazepine dependence include a longer duration of use and a history of substance (alcohol or drug) abuse. Short-half-life benzodiazepine agents are more likely to develop withdrawal symptoms. Therefore, when long-term users of short-half-life benzodiazepine agents stop the use, gradual decrease or once switching with long-half-life benzodiazepine agents may be necessary to prevent withdrawal symptoms.

Azapirones are one of the alternatives to benzodiazepines. They exert their antianxiety effects by potentiating postsynaptic serotonin1A receptors. Only three agents, buspirone, gepirone, and tandospirone, are currently available for clinical use. Effectiveness of azapirones on anxiety associated with general anxiety disorder was shown by meta-analysis. Efficacy of azapirones on anxiety associated with other anxiety disorders has not been established yet. The advantage of azapirones over benzodiazepines is that they do not cause sedation, cognitive dysfunction, or addictive/dependence potential. But azapirones may not be superior to benzodiazepines in the antianxiety effects. Common side effects are headaches, dizziness, nausea, and diarrhea.

Hydroxyzine, an antihistamine, also possesses anxiolytic properties. Although little evidence indicates the usefulness of hydroxyzine in clinical anxiety, it was shown that it is as effective as benzodiazepines in the treatment of generalized anxiety disorder while causing fewer side effects.

Apolipoproteins: APOA-I, APOA-IV, APOE

William Whang
Division of Cardiology, Columbia University Medical Center, New York, NY, USA

Definition

Apolipoproteins are proteins that bind to lipids and are required for the assembly and function of lipoproteins, which transport lipids through the blood and lymph systems. ApoA-I is synthesized in the liver and intestine and is found on virtually all high-density lipoprotein particles. ApoA-I Milano, a naturally occurring variant identified in rural Italy, is associated with very low high-density lipoprotein levels and lower-than-expected risk of coronary artery disease (Nissen et al., 2003). A randomized trial of recombinant ApoA-I Milano administered intravenously produced significant regression of coronary atherosclerosis as measured by intravascular ultrasound. ApoE, synthesized in the liver, is present in chylomicrons, very low-density lipoproteins, and intermediate-density lipoproteins and is important in the metabolism of triglyceride-rich particles (Corder et al., 1993). The isoform ApoE4 has been associated with increased risk of Alzheimer's disease and coronary artery disease. A meta-analysis of ApoE genotypes found relationships to low-density lipoprotein cholesterol and coronary artery disease risk (Bennet et al., 2007). APOA-IV, synthesized in the intestine, is present in chylomicron remnants, intermediate-density lipoproteins, and high-density lipoproteins (Rader and Hobbs, 2008). Its function in lipoprotein metabolism is currently unknown. Please also refer to the "▶ lipoprotein" entry in this encyclopedia for related information.

Appetite and Appetite Regulation

Definition

Appetite is the desire for food intake that may be produced by normal metabolic and energy needs or be other cues that may increase desire for food intake, including appearance, taste, and smell.

Description

The desire for food intake is important in addressing energy and metabolic needs for survival of the organism. The process is regulated by several central brain and peripheral mechanisms. These mechanisms are governed by both homeostatic needs and external cues that may influence desire for food consumption. Several well-studied factors, which regulate food desirability, directly influence appetite, including biological, behavioral, cognitive, and hedonic factors. For example, sensory information and memorial representations of food and associated emotions and motivation state may increase appetite for certain food items.

The involvement of central nervous system in appetite occurs at different levels. For example, signaling related to metabolic needs are received by the brain from different parts of the body that are involved in metabolic activities. One of the receiving structures is the arcuate nucleus (ARC) of the hypothalamus. The ARC coordinate with other nuclei within the hypothalamus information related to the metabolic-homeostatic needs. Experimental research has demonstrated the role of the ARC as a feeding control center. Research has shown that lesion of the ARC leads to overeating and obesity.

The ARC integrates hormonal signals and contains populations of neurons that express neuropeptide Y (NPY) which is involved in regulating energy balance. In addition to NPY, neurons within the ARC express agouti-related protein and proopiomelanocortin. The latter produces α-melanocyte-stimulating hormone, an important appetite regulating peptide and energy regulation; evidence suggests that animals and humans who genetically lack this hormone are likely to be obese. In addition to the ARC, the ventromedial hypothalamus (VMH), the paraventricular nucleus (PVN), and lateral hypothalamic (LH) are also involved in energy balance. Lesions to the PVN, for example, lead to increased feeding behavior and weight gain. These central structures receive information from other parts of the brain through both neuronal and hormonal signaling systems. Vagal afferent pathways and peripheral peptides carry information related to energy needs and metabolic status to the ARC and other structures where additional sensory information is also integrated to influence appetite.

There are several hormones that are directly involved in regulating appetite and energy balance. These are briefly described here, but will also be presented elsewhere in this encyclopedia. Leptin is a hormone involved in regulating energy homeostasis and is released from adipose tissue. Administering leptin reduces food intake and may result in loss of body weight. Ghrelin is released mostly by the stomach and is involved in meal initiation and termination. In contrast with leptin, there is inverse association between ghrelin and adiposity. Administering ghrelin increases food intake in humans. Glucagon-like peptide 1 (GLP-I) is a hormone produced primarily by L cells of the small intestine and is usually increased following a meal. This hormone reduces appetite and food intake. Insulin has a direct impact on metabolic status and dietary intake. It is produced by the pancreas, and similar to leptin, it is associated with energy balance and total body fat stores and fat distribution.

Its secretion increases immediately following a meal. Animal studies have shown that administering insulin reduces food intake and body weight.

Cognitive-hedonic processes, including sensory perceptions of food and food-related memory representations and emotions, have potent effects on appetite regulation. Experiments have shown that perceptions or memory representations of food or food-related cues modulate not only neural activity in specific brain areas involved in cognitive control of eating behaviors, but also eating-related physiological responses such as saliva, gastric acid, and insulin secretion. Recent findings suggest that neural circuits in the nucleus accumbens and ventral pallidum play key roles in the neuromechanism of liking palatable food. In addition, dopaminergic system from the ventral tegmental area of midbrain to the nucleus accumbens is critical to the neuromechanism of wanting of food.

Appetite and Obesity

Dysregulation of metabolic homeostatic and cognitive-hedonic appetite regulatory processes dispose people to obesity. In this case, increased appetite leads to excessive energy intake, and this energy excess is readily stored as fat by the body for later use. Several possible causes of appetite dysregulation have been identified and are currently under active investigation. These causes include abnormal nutrient sensing, overstimulation of food-related reward mechanisms, emotion dysregulation, and negative environmental influences. Pharmacological interventions for obesity and targeting at the dysregulation endocrine and neuronal appetite regulatory processes are also under development. Although many signaling chemicals and brain areas involved in appetite regulation have been identified. The therapeutic potential of this knowledge and individual differences relevant to how they increase risk for obesity remain to be elucidated. Psychotherapeutic interventions, aiming at enhancing self-control over excessive appetite and promoting healthy food-related choices and lifestyles, are believed to be more effective than pharmacological interventions in the fight against obesity.

Applied Behavior Analysis

Definition

Applied behavior analysis (ABA) reflects a systematic description and implementation of a therapeutic intervention to change a given behavior, based on the principles of the science of learning and behavior (Sulzer-Azaroff & Mayer, 1991). This process involves an analytic investigation of various triggers that determine and modulate behavior. The determinants are usually environmental and include reinforcements or punishments, and these are time-linked to observed behavioral responses. This is often

done in clinical psychopathological studies but has also been used to investigate behavior at the workplace.

One area where ABA has been extensively used is the study and treatment of autism (Vismara & Rogers, 2010). Interventions in developmental disorders would, for example, include an initial analysis of existing behavior as a function of its environmental modulators (e.g., aggression in a child with developmental disorders, in response to a material reinforcement). The child then learns self-control as modulated by an intervention (signaling delayed rewards). The ABA enables to observe systematic changes in behavior due to existing environmental determinants or due to therapeutically manipulated interventions, using multiple observations and a within-subject detailed observation and recording of behavior.

ABA is also useful to analyze and treat behaviors which may result from or that occur in the context of medical procedures. Surgery for removal of a chraniopharygioma often results in physiological and behavioral changes. In one case study, a 6-year-old girl exhibited severe aggression following surgery for this rare tumor. The aggression was negatively reinforced by escaping certain task demands and positively reinforced by preferred food. Following a highly structured behavioral intervention with extinction, her aggression declined to 88% from baseline levels (Hammond & Hall, 2011). These results exemplify how ABA is very useful for analyzing the determinants of aberrant behavior and how it may be successful as a therapeutic intervention in various clinical settings.

Area under the curve across all time

Definition

A common use of the term "area under the curve" (AUC) is found in pharmacokinetic literature. It represents the area under the plasma concentration curve, also called the plasma concentration-time profile. It is of interest to know the area under the curve, i.e., the area defined by the plasma concentration curve at the top and the x-axis (time) at the bottom. The AUC is a measure of total systemic exposure to the drug.

AUC is one of several important pharmacokinetic terms that are used to describe and quantify aspects of the plasma concentration-time profile of an administered drug (and/or its metabolites, which may or may not be pharmacologically active themselves). These include:

- C_{max}: The maximum concentration or maximum systemic exposure
- T_{max}: The time of maximum concentration or maximum systemic exposure
- $t_{1/2}$ or half-life: The time required to reduce the plasma concentration to one-half of its initial value

Integral calculus is used to calculate AUC, as can be done for other areas defined by a curve. This calculation requires a starting point and an ending point. The starting point is typically the time of administration, represented as time zero, to any subsequent time point, represented as t. This is denoted as $AUC_{(0–t).}$ It is also common to calculate AUC across all time, which is a measure of total systemic exposure. This is denoted as $AUC_{(0–infinity).}$

Arrhythmia

Definition

A normal heart beat in a healthy individual consists of electrical impulses, which engage all four ventricles of the heart, producing a smooth ebb and flow of electrical impulses and contractions to pump blood throughout the human body. An arrhythmia is an aberrant heart rhythm, which is either a change in the speed or pattern of the heart. Palpitations, near syncope and syncope (suddenly feeling light-headed or losing consciousness), chest pain, and shortness of breath are symptoms commonly associated with arrhythmias (American Heart Association, 2011). Arrhythmias can result in tachycardia (increase in heart rate) or bradycardia (decrease in heart rate) which in severe cases could lead to sudden death.

There are four main types of arrhythmias: premature beats, supraventricular arrhythmias, ventricular arrhythmias, and bradyarrhythmias. Premature beats are the most common type of arrhythmia. They are often asymptomatic and do not require treatment. They can occur in the atria (the two upper chambers of the heart; premature atrial contractions) or in the ventricles (the two lower chambers of the heart; premature ventricular contractions). Premature beats often occur in healthy adults, but certain heart diseases can cause premature beats. Stress, exercise, or excessive caffeine intake or nicotine use can trigger premature beats. Supraventricular arrhythmias are tachycardias that start in the atria or the atrioventricular node. Types of supraventricular arrhythmias include atrial fibrillation, atrial flutter, paroxysmal supraventricular tachycardia, and Wolff-Parkinson-White syndrome. Supraventricular tachycardia is the most common abnormal tachycardia in children. Of the more severe arrhythmias, atrial fibrillation is the most common. It occurs when the heart's electrical signal does not travel as it should through the chambers, and as a result, blood is not pumped into the lower two chambers of the heart. Ventricular arrhythmias can be life threatening and need immediate medical attention. Bradyarrhythmias cause the heart to beat slower than normal which may result in decreased blood flow to the brain and loss of consciousness (National Heart Lung and Blood Institute, 2009).

In an otherwise healthy adult heart, arrhythmias can be caused by scar tissue as a result of a heart attack, heart disease, high blood pressure, diabetes, hyperthyroidism, smoking, and excessive alcohol and/or caffeine intake, illegal drug use, stress, or prescription medications as well as dietary supplements. Arrhythmias can also occur as a comorbid condition due to a diseased or deformed heart, which is typically the case with pediatric patients. Some arrhythmias occur without significant effects, but others can result in fainting, cardiac arrest, severe organ damage, and/or stroke. In the most severe cases, cardiac arrhythmias may result in sudden death.

Treatment of arrhythmias depends on severity. More mild cases may be treated solely with medication. The disadvantage of being treated with medication is that pills must be taken daily and indefinitely. Common side effects include nausea, fatigue, headaches, dizziness, palpitations, and skin rash (Horovitz, 1997). One of the more concerning side effects is proarrythmia, which results in recurrent subsequent arrhythmias which can be more intense than the original arrhythmias. Medication side effects often result in a lack of adherence. Other cases may require surgery to either permanently stop tachycardia or implant a pacemaker to regulate the heart beat. The most severe cases may require radiofrequency catheter ablation, an invasive procedure which requires several catheters to be inserted into the heart through a vessel in the groin or arm. The catheter is moved to the site of the arrhythmia, and radiofrequency ablation (very-high-frequency radio waves are used to heat the tissue) or cryoablation (an extremely cold substance is used to freeze the tissue) is used to destroy the site.

Arteries

Linda C. Baumann and Alyssa Karel
School of Nursing, University of Wisconsin-Madison, Madison, WI, USA

Definition

Arteries are blood vessels that carry blood away from the heart. In most cases, arteries carry oxygenated blood. The exception is pulmonary arteries which carry deoxygenated blood from the heart to the lungs to become oxygenated. Because the arterial system is a high-pressure system due to the pressure created by ventricular contraction, arterial walls are generally thick in structure. The two main arteries branching from the heart are the pulmonary artery, which carries blood to the pulmonary circulation, and the aorta, which carries blood into systemic circulation.

Arteries contain smooth muscle and elastic fibers to allow arterial walls to stretch with ventricular contraction and then recoil pushing blood forward. Large arteries such as the aorta and pulmonary artery are composed mainly of elastic tissue and a smaller proportion of smooth muscle, while smaller arteries or arterioles are composed mostly of smooth muscle with little elastic tissue. The contraction and relaxation of smooth muscle dilates or constricts the arterioles and controls blood pressure and blood flow distribution.

Structurally, arteries have three layers. The outermost layer is called the tunica adventitia. It mostly consists of fibrous connective tissue and provides support and prevents tearing of the vessel walls. The middle layer is the tunica media, and is composed of a layer of smooth muscle and a layer of elastic tissue. This is the thickest layer and is responsible for the changes in diameter when the artery contracts and dilates. The innermost layer is referred to as the tunica intima and is made up of endothelium, which form a smooth lining.

Atherosclerosis is a common disorder of the arteries in which plaque – the accumulation of fatty acids, cholesterol, calcium, and other cellular waste products – forms in the arteries and can block blood flow. Although the exact cause of atherosclerosis is unknown, there are many behavioral risk factors. These include excessive alcohol use, high-fat diets, obesity, and smoking.

Arthritis

Joint inflammation; Joint pain

Definition

Arthritis is a general term used to describe inflammation of one or more joints of the body and/or

their surrounding connective tissues. This is can be a progressive condition in which the articular cartilage covering the bones at the joint surfaces begins deteriorating, leading to a loss of smooth and friction-free movement. The cartilage is also responsible for absorbing some of the mechanical forces transmitted through the joint. As the cartilage is lost, the joint space between the articulating bones begins to narrow, altering the distribution of mechanical forces through the joint. As the arthritis progresses, it may lead to bone cyst or osteophyte formation, as well as exposure of the subchondral bone surfaces.

The symptoms of arthritis often include pain, swelling, and stiffness of the involved joints, which all may lead to limited range of motion and mobility. Treatment of arthritis is based upon its cause, but it is initially directed toward reducing pain and swelling and restoring mobility. Exercise is known to be beneficial for bone and joint health, as it helps to maintain range of motion as well as to increase bone and muscle strength. Continual activity and movement of joints is also necessary to provide nutrients and remove wastes, since articular cartilage lacks its own blood supply.

While it is known that trauma, bacteria, or infections may cause arthritis, often the trigger for the pathology is unknown. Some of the most common forms of arthritis include osteoarthritis, rheumatoid arthritis, juvenile idiopathic arthritis, psoriatic arthritis, infectious arthritis, and reactive arthritis.

Osteoarthritis (OA), also known as degenerative joint disease, commonly affects the major weight-bearing joints of the knee and hip, but it can affect any joint in the body. It is a result of an imbalance in the remodeling process of joints, as connective tissue and bone destruction outweighs its repair. This imbalance affects the joint capsule, and many individuals with OA may complain of joint instability.

Rheumatoid arthritis (RA) is an autoimmune condition in which the synovial lining of a joint is affected. It is characterized by periods of exacerbation and remission, and it also includes systemic symptoms, such as fatigue, fever, and impaired cardiopulmonary function.

Juvenile idiopathic arthritis (JIA) is a catch-all term for arthritides that begin before the age of 16, with each type having unique characteristics and impairments.

Psoriatic arthritis is a type of arthritis that occurs in patients with the skin condition psoriasis. Most often, the joints in the spine and at the ends of the fingers and toes are affected.

Sometimes bacteria, a fungus, or a virus may infect a joint and lead to arthritis. This is known as septic or infectious arthritis. The effects from this type of arthritis are local, affecting the specific joint in the body that the foreign organism attacks. It also typically has an acute onset, and it may be accompanied by other symptoms, such as fever or chills.

Reactive arthritis is similar to infectious arthritis. It is caused by an infection; however, the arthritic symptoms will occur at a site other than the one actually infected. This type of arthritis is often associated with Reiter syndrome, a condition which includes arthritis, urethritis, and conjunctivitis.

The psychosocial aspects of arthritis encompass both stable and dynamic psychological and social factors that play a role in the etiology of and adaptation to musculoskeletal pain conditions.

Description

Psychosocial Factors in Arthritis

Because the course of arthritis varies considerably across individuals, investigators have attempted to identify factors that predict the extent to which patients with arthritis are able to minimize symptoms and maximize well-being. Somewhat surprisingly, radiographic and other objective assessments of disease activity do not reliably predict the experience symptoms and disability among patients. In contrast, psychosocial factors play an important role in the etiology and course of rheumatic diseases, over and above objective disease markers.

In this chapter, stress and stress responses are considered central to understanding how psychosocial factors contribute to adaptation in rheumatic disease. A stressor is defined as an event that is perceived as threatening or beyond one's ability to cope and that evokes physiological, affective, cognitive, and behavioral responses. Stressors may be brief or long term and range in magnitude from minor events to major or traumatic events. In this framework, the pain, disability, and other demands imposed by the pain condition itself can act as a stressor. Stress responses vary between individuals, depend on current context, and may be key mediators in the link between stress and mental and physical health outcomes in rheumatic illness. Thus, it is useful to ask not only *who* is most affected by illness and other stressors but also *when* are individuals most vulnerable.

Much of the literature on stress and adaptation has focused on factors that place individuals at greater risk of poor functioning. More recently, though, research efforts have broadened to include not only risk but also "resilience factors," that is, factors that help individuals recover from episodes of stress and preserve their well-being despite pain and other stressors. In the sections that follow, affective, cognitive, and social factors that moderate responses to stress in patients with arthritis are first considered, followed by discussion of interventions that target these factors to promote better adaptation among individuals with rheumatic conditions.

Stress

The association between stressful life events and the etiology and course of rheumatic disease depends on the timing and magnitude of the events. For example, traumatic events experienced in childhood, including abuse, neglect, and parental loss, significantly increase the risk of developing chronic inflammation and chronic pain and have been linked to the severity of pain in adulthood (Von Korff et al., 2010). Traumatic events in adulthood also increase disease severity, particularly for individuals who experience post-traumatic stress disorder (PTSD) symptoms. Several mechanisms may account for the trauma-disease severity link. Trauma exposure may trigger PTSD and other affective symptoms, which in turn increase symptom severity. Additionally, traumatic events may disrupt the hypothalamic-pituitary-adrenal-cortical axis (HPAC), an important component of physiological stress response system. For example, childhood maltreatment reported by women with fibromyalgia and osteoarthritis (OA) have been linked to elevated cortisol, a key stress hormone associated with the HPAC (Nicolson, Davis, Kruszewski, & Zautra, 2010). HPAC dysregulation, reflected in

both hypo- and hypercortisol reactivity, has been associated with traumatic experiences and PTSD and with vulnerability to disease activity.

Major and minor life events also predict symptom severity in rheumatic illness. For example, patients with rheumatoid arthritis (RA) experienced reduced symptoms in the weeks following a major life event, but increased symptoms in the weeks following minor stressors (Potter & Zautra, 1997). One possible explanation for this finding is that a major event can elicit an increase in cortisol, which acts to dampen immune functioning. Minor life events, on the other hand, may enhance immune stimulating hormones and make cortisol less effective in dampening immune function (Davis et al., 2008). Clearly, stressors themselves are important factors in the experience of chronic pain, but psychological and social factors that influence coping responses are also likely to play a significant role. Coping factors can be categorized as primarily affective, cognitive, or social.

Affective Components

The stable trait-like aspects as well as the fluctuating state aspects of affect have both been linked to adaptation in rheumatic disease. Although much of the literature has focused on the detrimental role of negative affect, positive affect also plays a role in determining how individuals respond to stress. One of the most frequently studied affective disorders in rheumatic disease patients is depression. Depression is so highly prevalent among chronic pain patients that some investigators have suggested that depressive symptoms should be considered part of the experience of pain. In fact, neuroimaging studies have revealed that pain activates brain regions associated with both sensory and affective components of pain (Tolle et al., 1999). Current depression as well as a history of recurrent depression predict greater pain during episodes of increased stress and more distress during episodes of increased pain among RA patients (Zautra et al., 2007). Because depression and stress are both associated with inflammatory activity in RA, each of these factors may increase disease activity. Thus, depression may increase vulnerability to increased pain and inflammation during episodes of stress among patients with rheumatic disease.

Individual differences in negative and positive affectivity have also been linked to vulnerability to the detrimental effects of stress among pain patients. For example, neuroticism is a personality trait characterized by elevated negative affect and has been linked to elevated pain in both cross-sectional and longitudinal studies of pain patients (Charles, Gatz, Pedersen, & Dahlberg, 1999). Conversely, greater positive affectivity is related to decreased pain and increased functional ability in patients with rheumatic disease (Villanueva, Cornett, Yocum, & Castro, 1999).

Within-person changes in affect may also have implications for illness severity and course. Studying the day-to-day variations in mood can yield information about times *when* patients are most or least vulnerable to the effects of stress. Because both negative and positive emotions make unique contributions to quality of life and adaptation, it is important to consider how variations in both affective states over time relate to the course of rheumatic disease. Increases in negative affect have been linked to increased pain and greater sensitization to pain, as well as to increases in stress (Janssen, 2002). Thus, negative affect may be not only a part of the experience of pain itself but also a response to stress in pain patients. Positive affect, in contrast, helps to decrease vulnerability to both pain and stress in rheumatic patients (Zautra, Johnson, & Davis, 2005).

Cognitive Components

Cognitive stress responses reflect patients' appraisals of the stressor and of their ability to manage it and typically have been characterized as dimensions of coping. A key aspect of this appraisal process is the extent to which individuals perceive a sense of control or lack thereof. In the case of rheumatic illness, an important sense of control centers on an individual's confidence in her or his ability to manage pain and other symptoms that are often unpredictable. One widely used instrument developed to quantify these control beliefs, the Arthritis Self-Efficacy

Scale, yields scores that reflect a sense of control over pain, function, and other arthritis symptoms (Lorig, Mazonson, & Holman, 1993). High arthritis self-efficacy scores consistently relate to better functional health in arthritis patients. For example, higher levels of arthritis self-efficacy relate to higher pain thresholds and increased tolerance to standardized pain stimuli in RA (Keefe et al., 1997). Similarly, arthritis self-efficacy predicts lower pain and better physical functioning in OA.

In contrast to arthritis self-efficacy, pain catastrophizing is characterized by beliefs about a lack of control of symptoms. Among arthritis patients, catastrophic pain beliefs relate to higher ratings of pain intensity, more frequent pain behaviors, and greater pain-related disability, disease activity, and health-care utilization (Keefe, Lumley, Anderson, Lunch, & Carson, 2001). Neuroimaging studies have linked pain catastrophizing with greater activation of brain regions associated with anticipation of pain, emotional aspects of pain, and attention to pain (Gracely et al., 2004). Pain catastrophizing is also related to decreased noxious inhibitory control of pain, indicating less effective modulation of pain signaling at the level of the spinal cord. Thus, pain catastrophizing may impact pain via a number of mechanisms, including directly by amplifying the central nervous system's processing of pain and indirectly by hampering the endogenous descending inhibitory pathway.

Arthritis self-efficacy and pain catastrophizing are among the most frequently studied cognitive factors in rheumatic disease, but others have received some empirical attention as well. More recently, interest has been directed toward evaluating the contribution of pain acceptance to adaptation in rheumatic disease. The capacity to accept pain without trying to alter or avoid it has emerged as a moderator of pain-related disability and distress among arthritis patients. For example, OA and fibromyalgia patients who were more versus less able to accept their pain showed smaller increases in negative affect during weeks of elevated pain and reported higher overall levels of positive affect (Kratz, Davis, & Zautra, 2007). In instances of uncontrollable pain in particular, pain acceptance may be a valuable cognitive resource to preserve affective and physical health. Beyond cognitive factors that are specific to pain or stress management, those that reflect broader beliefs regarding one's own resilience are emerging as key to health in rheumatic disease. For example, recent evidence suggests that a sense of a purpose in life and belief in one's own capacity to bounce back from difficulty relate to faster habituation to thermal pain stimuli (Smith et al., 2009). Thus, "resilience" factors are gaining traction as important predictors of successful coping.

Social Factors

Social relationships are ever-present sources of both stress and fulfillment in everyday life and play an important role in adaptation to rheumatic disease. Social pain is recognized as a concept that focuses on the interplay between social relationships and physical pain. Social pain is an emotional response to perceived exclusion from desired social relationships or perceived devaluation or rejection from significant members of an individual's social network. Just as physical pain is adaptive in signaling a threat of physical harm, social pain is adaptive because it signals a need for social connectedness. Findings from neuroimaging studies suggest that the neural circuitry underlying physical and social pain overlap; the affectively distressing components of both activate the anterior cingulate cortex. Social pain may have special relevance for patients with rheumatic conditions for several reasons. Patients may experience social pain related to their condition, when they perceive that important others do not understand their pain. The resulting sense of stigma and estrangement can further exacerbate their physical and social pain. In addition, physical pain episodes themselves may make patients more vulnerable to social pain, potentially creating a downward spiral of increasing pain, isolation, and disability.

On the positive side of social relations, social connectedness can reduce pain intensity, increase pain tolerance, and dampen stress-related changes in mood and symptoms. One proposed pathway through which social connectedness

affects health outcomes is by buffering individuals from the negative effects of increased pain and stress. For example, an investigation of fibromyalgia patients revealed that when a significant other was present, patients reported less sensitivity to thermal pain and showed diminished pain-related brain activity, compared to when they were alone (Montoya, Larbig, Braum, Preissl, & Niels, 2004). Thus, social connections are double-edged; they can both help and hinder rheumatic patients' capacity to respond effectively to pain and stress. To sustain health and well-being, individuals with rheumatic conditions must have the ability not only to sustain strong social connections but also to draw on them during difficulty.

Psychosocial Interventions for Arthritis

At present, cognitive-behavioral treatment (CBT) for pain is widely considered to be among the most efficacious behavioral interventions available (Morley, Eccleston, & William, 1999). CBT explicitly targets maladaptive ways of thinking, feeling, and behaving in response to the illness and yields improvements in pain, coping, and social role functioning compared to other psychosocial treatments and standard medical care. However, it yields less substantial improvements in mood disturbance, possibly because it does not target the emotion regulation problems that are common among rheumatic disease patients.

Accruing evidence highlights the potential value of a mindful-acceptance-based approach to enhance the capacity of patients to manage the physical, emotional, and social demands of their illness. Rather than encouraging control of pain and dysfunctional thoughts, an approach grounded in mindful-acceptance targets enhanced awareness and acceptance of current experiences, including pain and other stresses. An expanded awareness of current experience also incorporates attention to the positive features of the moment. Some treatments go further and explicitly include an emphasis on engagement in rewarding activity to bolster social connectedness and positive affect. The goal of these approaches is to build both psychological and social resources and the capacity to access and utilize those resources when needed. Further, the benefits of an acceptance-based approach may be most apparent for those patients who are most vulnerable to emotion dysregulation. For example, in RA patients with a history of recurrent depression, mindful-acceptance treatment yielded greater improvements in pain, fatigue, positive and negative affect, and inflammation at posttreatment and 6 month follow-up compared to CBT and an education control (Zautra et al., 2008). Thus, the capacity to attend to both positive and negative experiences in an intentional way and to build greater social connectedness may be key to promoting functional health in arthritis patients.

Existing evidence points to the key roles of psychosocial risk and resilience factors in adaptation to rheumatic disease and encourages continued efforts to advance understanding of how biological, psychological, and social factors interact to promote health and well-being in patients with rheumatic conditions.

Definition

Drug that inhibits platelet aggregation.

Aspirin inhibition of the enzyme cyclooxygenase-1 (COX-1) in platelets prevents arachidonic acid-induced production of thromboxane A2, a potent mediator of platelet aggregation, as well as vasoconstriction. The half-life of aspirin is only 20 min in the plasma, but due to its irreversible effects on COX-1, the therapeutic effects can last the lifetime of the platelet, up to 1 week following administration (Patrono et al., 1985). Aspirin has been shown to reduce cardiovascular events in the setting of acute myocardial infarction and acute stroke (Antithrombotic Trialists' Collaboration, 2002). It is also recommended that aspirin be administered (300–350 mg) to patients undergoing stent placement (Schwartz et al., 1988). Higher doses of aspirin ($\geq$300 mg/day) have been shown to

produce a greater effect on COX-2, thereby achieving anti-inflammatory and analgesic properties as well. Aspirin at those higher doses, though, has been shown to have gastrointestinal side effects such as bleeding by eroding the protective prostaglandins in the gut mucosa (Roderick, Wilkes, & Meade, 1993).

For primary prevention of cardiovascular events, meta-analyses have indicated a reduction in myocardial infarction risk that is offset by an increase in risk of major gastrointestinal and extracranial bleeding. However, no reduction in cardiovascular events has been shown in a meta-analysis of studies involving patients with diabetes (Antithrombotic Trialists' (ATT) Collaboration, 2009; Stavrakis, Stoner, Azar, Wayangankar, & Thadani, 2011).

Assertiveness Training

Yori Gidron
Faculty of Medicine and Pharmacy, Free University of Brussels (VUB), Jette, Belgium

Definition

Assertiveness training (AT) is a behavioral intervention, often part of cognitive behavior therapy (CBT), stress management, or anger management. In AT, people learn to express themselves in social contexts, despite having barriers. These include learning to express socially "unaccepted" emotions such as anger, disliking others' behavior, and requests for someone to change their behavior. In an assertive statement, there are often: a problem in another person's behavior, a request to change, and, if needed, a statement of the consequences if one's request is not met. Such a statement can also include one's attitude or experienced emotions due to the other person's behavior. Yet, all these need to be done while respecting the other person.

AT is often taught in a group format and is usually done in a gradual manner. People first learn to state simple requests such as "I cannot see, can you please move a bit?" until they are able to state difficult statements such as "yesterday, you made me angry and humiliated me in front of everyone. I ask you please not to say those things again in public, otherwise, I will need to consider our friendship." In an intervention done on hostility reduction, Gidron and Davidson (1996) and Gidron, Davidson, and

Bata (1999) used AT as part of a CBT intervention. Their CBT yielded greater reduction in hostility in healthy and cardiac patients and greater reductions in blood pressure in the latter study, compared to a minimal attention education-control group. Furthermore, in a reanalysis pertinent to AT, Davidson, Macgregor, Stuhr, and Gidron (1999) found that greater constructive anger expression mediated the effects of hostility reduction on blood pressure changes. Constructive anger expression was the aim of the AT element of their program. In another study, hypertensive patients were found to exhibit less assertiveness than normotensive patients. Additionally, especially during confrontation, overt anger expression led to elevated physiological responses in hypertensive patients (Larkin & Zayfert, 2004).

In other domains in behavior medicine, AT can be of great importance. For example, training patients to communicate their concerns and symptoms more adequately to physicians could be an important application of AT in medicine. This can be important in empowering patients to take more control over their health care. AT could be especially important for patients with an introverted or type D personality, who were found not to communicate their symptoms to doctors (Schiffer, Denollet, Widdershoven, Hendriks, & Smith, 2007). AT may be of benefit for such patients. Another example is the use of AT in communication between health professionals working in teams, often under immense psychosocial pressures such as in the operating room (Buback, 2004). The domain of AT exemplifies the multiple roles of behavior medicine – increasing the knowledge of the effects of behavior on the body and implementing such knowledge in patient interventions and in medical teams as well.

Assessment

Definition

Assessment in behavioral medicine aims to evaluate the biological, psychological, and social functioning of a patient. This may involve assessing physiological, mood, cognitive, and social functioning and integrating these findings to inform appropriate research and practice.

Description

The overall purpose of assessment is to examine characteristics of patients or research

participants. Assessment in behavioral medicine can include a wide variety of possible domains (e.g., physical, cognitive, mood, quality of life, health behaviors, etc.). Assessment can also take on different forms, such as a patient-reported survey, a rating scale filled out by a health-care practitioner, or a device which measures physiological functioning. Users of such assessments are tasked with using and administering assessment instruments that have demonstrated reliability and validity. Regardless of the manner in which assessment data are gathered, they can be used to identify health problems, guide practitioners in making treatment decisions, and measure progress of health interventions.

Assessing physical functioning is a common practice in behavioral medicine as it can identify physical health problems or risk factors for future problems and provide benchmarks for treatment (Vingerhoets, 2001). Common examples of physical assessment are biofeedback, electrocardiography, and endocrine system function. These assessments may be carried out by physicians, nurses, or other health-care providers. In each of these cases, the assessment tool can yield important information about a patient's current physical status, which can then be used to recommend appropriate interventions, if necessary.

Cognitive assessments may be used when deficits of learning, memory, and problem-solving capabilities are suspected. These instruments frequently involve hands-on tasks such assembling figures and solving visual puzzles as well as more verbal types of tasks that require basic problem-solving abilities and general knowledge. The Wechsler Adult Intelligence Scale-IV is a good example of one such cognitive test (Lichtenberger & Kaufman, 2009). Cognitive assessments are often administered by psychologists, and the findings may used to guide psychological, medical, or occupational interventions.

Assessing psychological characteristics relative to mood states and personality is another useful assessment activity conducted by behavioral medicine practitioners. These tools are most often paper and pencil surveys which assess various symptom constellations. Psychological assessments range in length and time required to complete the inventory. The Beck Depression Inventory-II, for example, has 21 multiple-choice items and takes about 5 min to complete. The Minnesota Multiphasic Personality Inventory-II has several 100 items and takes at least an hour to complete (Butcher, 2011). Psychologists are the most frequent administrators and interpreters of these types of tests.

Identifying and measuring health behaviors is yet another type of assessment conducted in behavioral medicine. This might involve measuring diet, alcohol intake, exercise activity, or sleep habits, among others. Such behaviors are often the focus of interventions in behavioral medicine and are often associated with both psychological and physical health status (Vingerhoets, 2001). Further, health behavior assessment can be used to identify risk factors for diseases such as diabetes, substance dependence, or hypertension.

An increasingly popular area of assessment is in patient quality of life (Ware & Gandek, 1998). These assessments are patient-reported surveys that include measures of physical disability, pain and suffering, and self-efficacy. A common example is the Short Form-36 health survey, a 36-item survey of daily functioning and health status. These survey data are commonly used in research and practice to evaluate the effectiveness of pharmacological or surgical treatments and establish functional benefit for patients (O'Connor et al., 2009).

Finally, it should be noted that in most areas of medicine, especially in clinical trials, a typical approach for assessing patient outcomes is to include both disease-specific and overall quality of life measures. This approach to assessment ensures that both changes to specific disease processes and also patient-relevant outcomes in terms of functional abilities are equally considered.

Assessment can take on many forms and purposes in behavioral medicine. Assessment is a commonplace and useful tool for the behavioral medicine practitioner. It can be used to identify risk for pathology, inform interventions, and mark progress to change.

Assisted Living

Josh Allen
Care and Compliance Group, Inc. American Assisted Living Nurses Association, Wildomar, CA, USA

Definition

Assisted living is a state regulated and monitored residential long-term care option. Assisted living provides or coordinates oversight and services to meet the residents' individualized scheduled needs, based on the residents' assessments and service plans and their unscheduled needs as they arise.

Services

Services allowed are typically outlined in state law and regulation, and typically include:

- 24-hour awake staff to provide oversight and meet scheduled and unscheduled needs
- Provision and oversight of personal and supportive services (assistance with activities of daily living and instrumental activities of daily living)
- Medication management
- Health-related services (e.g., coordination of nursing services, hospice, home health, etc.)
- Social services
- Recreational activities
- Meals and snacks
- Housekeeping and laundry
- Transportation

A resident has the right to make choices and receive services in a way that will promote the

resident's dignity, autonomy, independence, and quality of life (Adapted from the Assisted Living Workgroup report, 2003).

Environment

Assisted living has a look and feel that is distinctly different from the physical plant in more institutional long-term care settings. The assisted living environment emphasizes the creation of a homelike atmosphere, and while health services are often provided or directed onsite, they are carried out in a manner that encourages privacy. For example, most institutional nursing facilities feature a large "nurses station" that houses charts, medical equipment, and personnel. While many assisted living communities have a similar space, it is usually held behind closed doors so as not to dominate the environment.

Definition

Asthma is one of the most common chronic diseases and may develop at any age, although new-onset asthma is less frequent in the elderly. Many adolescents experience a remission of childhood asthma symptoms before they have fully matured, with recurrence several years later.

Asthma is characterized by a chronic inflammatory disorder of the airways, airflow obstruction which could be at least partly reversed, and bronchial hyperresponsiveness. In not a few cases, asthma can be diagnosed on the basis of a patient's symptoms and medical history. The patient has history of any of the following: cough, recurrent wheeze, recurrent chest tightness, and recurrent difficult breathing. These symptoms are usually associated with airflow limitation and occur or worsen in the presence of various stimuli, including animals, changes in temperature, drugs (aspirin), respiratory infections, smoke, exercise, and emotional stress. The patient also might have atopic diseases and a family history of asthma. The airway obstruction measured by lung function test may help confirm the diagnosis of asthma (Weiss & Speizer, 1993).

When asthma is well controlled, the patient can avoid various unpleasant symptoms, risk of exacerbations is reduced, and decline in lung function slows down. In order to achieve this goal, various components of treatment are required (Global Initiative for Asthma [GINA], 2009; National Heart & Blood Institute, 2007).

First of all, the development of a partnership between the patients and their health-care team is required. The shared vision of the goal is essential. The patients also have to acquire a certain level of knowledge about asthma, which enables them to avoid risk factors, take medications correctly, monitor their status, and seek medical help appropriately.

Next, the patients should avoid the risk factors that make their asthma control worse, including smoke, drugs, food, house dust, and animals. For example, up to 28% of adult patients with asthma response to aspirin, resulting in asthma exacerbations. The drugs that cause symptoms should be completely avoided. Influenza vaccination is also recommended for the patients because infection itself worsens asthma control.

Medications take a starring role in controlling asthma, which are divided into two categories, reliever medication and controller medications. Reliever medication (preferably a short-acting beta agonist (SABA)) provides the patient a quick relief from acute symptoms. The patient should be encouraged to take it as needed. However, SABA does not treat the airway inflammation underlying asthma, although useful for symptom control. No patient with persistent asthma should be treated by SABA alone. They need to take regularly one or more controller medications. These medications prevent symptoms or attacks from occurring. Inhaled glucocorticoids (often called inhaled corticosteroids (ICS)) are recommended as the initial and primary therapy in all patients with moderate persistent asthma. Other controller medications include a long-acting beta agonist (LABA) (combination inhaler with ICS is in widespread use), theophylline, and leukotriene-modifying agents. The difficult-to-treat asthma patient might be introduced of oral glucocorticoids and/or anti-IgE treatment.

Definition

It is well accepted that stress is a modulator increasing the frequency, duration, and severity of the asthma symptoms. However, little is known about the underlying mechanisms, although there are some reasonable models, such as decreased corticosteroid signals. Further investigations are needed.

Description

Asthma had been long considered as primarily psychogenic, often called asthma nervosa, until the inflammatory basis of the disease was revealed in the latter half of the twentieth century. In recent years, it is widely accepted that asthma is caused by chronic inflammation in the airway, and inhaled glucocorticoids which can inhibit the inflammation are recommended as the initial and

primary therapy. Furthermore, because asthma itself in turn produces stress, the correlation between asthma and stress might be arise only from asthma-induced stress. Still, various observational studies indicate that asthma is greatly influenced by psychosocial factors and stress. Between 20% and 30% of patients with asthma experience acute exacerbations when they are really feeling the stress. Nowadays, stress is seen as a modulator that accentuates the airway inflammatory response to environmental triggers, increasing the frequency, duration, and severity of the symptoms.

Stress is considered the common state that occurs when demands from environmental challenge an individual's adaptive capacity, or ability to cope. It is still under investigation through which mechanism stress worsens asthma control. However, there are some popular hypotheses (Chen & Miller, 2007; Haczku & Panettieri, 2010; Vig & Forsythe, 2006).

When the body is challenged physically or psychologically, short-term activation of neuroendocrine and autonomic nervous systems adapts to the stress for surviving during the period of challenge. Acute stress, which you have to adapt to quickly, causes the immediate activation of hypothalamic-pituitary-adrenal (HPA) axis and sympathetic-adrenal-medullary (SAM) axis, which induce the release of various hormones. It might be said that the HPA axis and the SAM axis can convert the stress detected by brain to the physiological signal.

It is well known that the activation of HPA axis increases the secretion of corticosteroids from the adrenal cortex, and the activation of SAM axis causes the increased release of epinephrine and norepinephrine. This fact evokes a certain paradox. Corticosteroids inhibit the inflammation in the airways, and beta-stimulants such as epinephrine might work as a bronchodilator. These hormones seem to be beneficial in controlling asthma.

Explanations that could resolve this paradox are mainly based on the hormone depletion and the resistance of receptors under chronic stress, matters more than acute stress in the issue of clinical practice. There is some evidence that the prolonged stress continues the releases of various stress hormones, which is exhausted at last. When chronic stress first begins, there is an initial elevation of the corticosteroids level. But as time passes, this elevation diminishes. It is also argued that receptors for stress hormones become downregulated after prolonged exposure, making immune cells less sensitive to not only endogenous signaling but also medications.

Stress could worsen asthma in other ways. Stress can have an influence on self-management of asthma, including drug adherence and avoidance of risk factors, which might make the control of asthma difficult (Alvarez & Fitzgerald, 2007). Stress also can change a perception of asthma symptoms and make the patients believe that their condition is getting worse. In extreme cases, an occurrence of hyperventilation caused by a panic disorder makes a medical treatment for asthma exacerbation complicated, and increases the frequency of hospitalization. Others suggest that psychological stress might be associated with increased risk of respiratory infection, which is an exacerbating factor of asthma.

It is true that the above models are reasonable enough, but there remain many problems to be solved. Does stress worsen asthma symptoms eventually by increasing inflammatory responses? To what extent is decreased sensitivity to glucocorticoids and epinephrine responsible for excessive inflammation in the patients with asthma? To answer these questions, well-organized prospective investigations in human clinical research are needed, in which clinical, immunological, and psychological variables are correctly and frequently evaluated (Busse & Kiecolt-Glaser, 1995).

Definition

The National Asthma Education and Prevention Program (NAEPP) was initiated in March 1989 by the National Heart Lung and Blood Institute (NHLBI) to address the needs of those affected by asthma in the United States. The goals of the NAEPP include raising awareness of asthma as a serious chronic illness, teaching how to recognize symptoms of asthma and facilitating appropriate diagnosis, promoting effective control of asthma via treatment, and conducting education programs (National Heart Lung and Blood Institute [NHLBI], n.d.). Some of the recommendations for education programs provided by the NAEPP include educating patients from the time of diagnosis and integrating education into every phase of asthma care, education being provided by all members of the health care team, teaching asthma self-management while being culturally sensitive, developing treatment goals with the patient rather than for the patient, having a written action plan (especially for those with moderate-to-severe asthma), and promoting adherence through communication and family involvement.

Description

Various asthma education programs are in existence, and some have been empirically tested. Gibson and colleagues (2009) reviewed 36 trials that compared self-management education for adults with asthma to usual care. Overall, results indicated that self-management education reduced complications, emergency care visits, unscheduled visits to the doctors, decreased number of days off from work or school, and improved quality of life. Changes in lung function as a result of participating in these interventions were minimal. The conclusions from this meta-analysis stated that asthma self-management programs that include self-monitoring of symptoms or peak flow readings in conjunction with regular medical visits and written action plans are the most effective at improving health outcomes for adults. One factor to consider when creating and assessing these types of programs is the audience they are intended for. Inadequate health literacy has been identified as an area of concern for many adults and parents of children with chronic conditions. In adults with asthma, health literacy has been strongly correlated with poorer disease knowledge and improper metered-dose inhaler (MDI) use (Williams, Baker, Honig, Lee, & Nowlan, 1998).

In the pediatric asthma literature, Bernard-Bonnin and colleagues (1995) did not report findings nearly as positive as those seen in the adult literature. From their meta-analysis of 11 randomized controlled trials of self-management programs for children with asthma, they concluded that self-management teaching did not reduce the number of days missed from school, asthma attacks, hospitalizations, or the number of emergency room visits. The authors recognized the

limitations of their review, including the small number of studies included, the pooling of studies without regard for sociodemographic factors or disease severity, and the broad study criteria for being included in the analysis. Yet at the present time, this is the only pediatric asthma education program meta-analysis currently available. Other, more recent, pediatric programs in the literature have exhibited success across morbidity, knowledge, and psychosocial outcomes. For example, Krishna and colleagues (2003) examined the effectiveness of a self-management education program delivered through interactive multimedia sessions conducted during a family's standard clinic visit compared to just receiving standard-of-care asthma education. Compared to those children who only received standard education, those who participated in the interactive multimedia program displayed increased asthma knowledge, decreased number of days asthma symptoms were experienced, and decreased number of emergency department visits and used lower daily doses of inhaled corticosteroids at a follow-up visit.

Definition

It is well accepted that psychogenic factor has a close relationship with asthma symptoms. Some patients with asthma experience acute exacerbations preceded by emotional stress. This fact has made us expect the use of psychological in addition to conventional physical and pharmacological interventions, in order to achieve the successful management of asthma. Relaxation training, systematic desensitization, and assertive training were tested with enthusiasm especially in the 1970s, but later experiments and analyses have thrown doubt on them. Application of biofeedback techniques to asthma treatment has been still discussed (Ritz & Dahme, 2004).

Biofeedback techniques consist of direct and indirect techniques. In direct techniques, including respiratory resistance feedback, spirometric biofeedback, and trachea-noise biofeedback, lung function itself is measured and modified. Most of indirect techniques have targeted facial muscle EMG, heart rate, and heart rate variability. However, it has not been proved that they can contribute as adjunctive treatments of asthma. Furthermore, these techniques are technically difficult in practice, and the procedure, especially in the case of direct techniques, might worsen asthma symptoms.

The self-management of asthma plays a central role in asthma treatment, and psychological factors may influence not only the symptoms but also the management of asthma in many ways (Clark & Mitchell, 2009). The patients have to acquire a certain level of knowledge about asthma, which enables them to avoid risk factors, take medications correctly, monitor their status, and seek medical help appropriately. It is clear that self-management encompasses very much more than patient education. It implies involving patients in the care they receive and encouraging them to become active partners in managing their illness. Behavioral and cognitive process, such as operant behavior, in the self-management has also been eagerly investigated. The successful performance of self-management skills to avoid an asthma attack is, conversely, an example of negative reinforcement. Adequate coping can facilitate the self-management. Conditioned fear and anxiety to asthma derived from previous traumatic experiences such as acute exacerbation sometimes alters the way of recognition of asthmatic symptoms (Creer, 2008). Inadequate symptom perception might be associated with an overuse of reliever medication, irrespective of lung function, causing the unnecessary side effects. It is, therefore, suggested that psychological interventions may be appropriate for patients who are unable to achieve the self-management of asthma because they might have behavioral or cognitive problems.

There is not enough evidence that behavioral treatment can contribute substantially to the treatment of asthma (Dahl & Gustafsson, 1990; King, 1980). This is due to the poor methodology of the studies as well as the inherent problems of conducting such trials. It is recommended that larger and well-conducted randomized trials use valid outcome measures to evaluate the effectiveness of psychological interventions for adults with asthma.

Definition

Atherosclerosis is the thickening and hardening of artery walls that occurs as the immune system responds to injuries to the single-layer endothelial wall of an artery. These injuries can be caused by a variety of insults, including cigarette smoke derivatives, toxins, infectious agents, elevated circulating lipids or glucose, and increased blood pressure. Monocytes and platelets are recruited to the site of injury. Monocytes cross the endothelial layer into the subintimal space where they become macrophages and phagocytose oxidized lipoproteins, forming foam cells. These foam cells accumulate in the subintimal space forming fatty streaks on the endothelial wall. Smooth muscle cells wall off the lipid plaque, forming a layer of collagen known as a fibrous cap between the plaque in the subintima and the endothelial wall. Eventually, the plaque may bulge into the arterial lumen, partially occluding the artery. If the artery becomes so occluded that blood flow is critically decreased, an infarct occurs. If this occurs on a coronary artery, a myocardial infarct, or heart attack, occurs. Health behavior change is a critical component in atherosclerosis prevention. Helping patients stop smoking and prevent or treat hypertension, hyperlipidemia, and impaired glucose tolerance are effective methods for preventing the progression of atherosclerosis.

Atrial Fibrillation

William Whang
Division of Cardiology, Columbia University Medical Center, New York, NY, USA

Definition

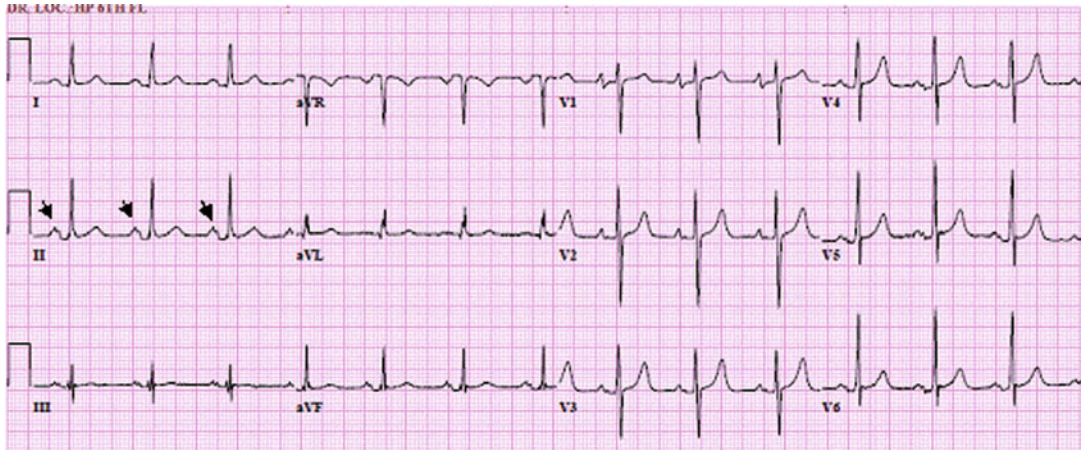
Atrial fibrillation is a cardiac rhythm disorder characterized by chaotic atrial electrical activation, resulting in an irregular heartbeat.

Description

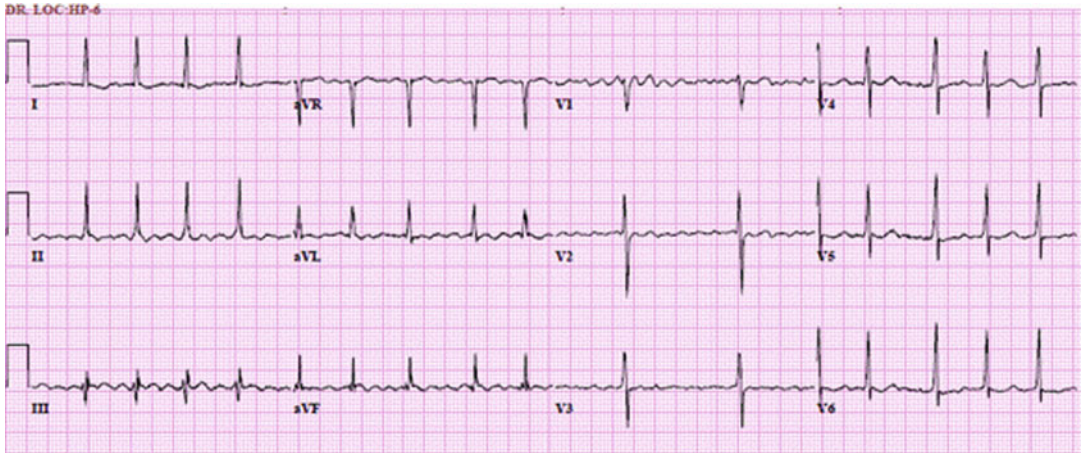
Atrial fibrillation (AF) is the most common type of cardiac rhythm disorder and affects 1–2% of the general population (Camm et al., 2010). It is characterized by chaotic electrical activation in the left and right atria, usually at rates of 200–300 beats per minute. Normally, cardiac activation begins with depolarization in the sinus node in the right atrium. The right and left atria are activated via intercellular gap junctions, and atrial depolarization is represented on the surface electrocardiogram (ECG) by the P wave (Fig. 1). The difference between normal rhythm and atrial fibrillation is exemplified by the ECGs seen in Fig. 2. AF is usually diagnosed on ECG by the presence of an irregularly irregular cardiac rhythm, without visible P waves.

Numerous factors are associated with the development of AF, including cardiovascular conditions such as hypertension, heart failure, and coronary artery disease and valvular heart disease (Camm et al., 2010). Aging, hyperthyroid, obesity, and diabetes mellitus have also been related to risk of AF.

Individuals with AF usually present with symptoms including palpitations, fatigue, shortness of



Atrial Fibrillation, Fig. 1 12-lead electrocardiogram during normal sinus rhythm, with arrows pointing to P waves that indicate organized atrial activity



Atrial Fibrillation, Fig. 2 12-lead electrocardiogram during atrial fibrillation, with lack of P waves and an irregularly irregular rhythm

breath, and/or light-headedness. However, a significant proportion of patients with AF are asymptomatic, especially older patients. In observational studies, AF is associated with worse cardiovascular prognosis, including increased risk of stroke, heart failure, cardiac hospitalizations, and mortality. However, it is not yet clear whether mitigation of AF itself improves these risks or whether it is more a marker of other pathology.

The most established health risk for most patients with AF is the risk of stroke, and this risk is related to several possible mechanisms (Camm et al., 2010). For instance, patients with AF have been shown to have relative stasis of blood flow in the left atrium, which is thought to lead to greater risk of clot formation. Abnormalities of the inner surface of the heart, the endocardium, and clotting and platelet activation have also been described. The decision to treat with anticlotting medication (anticoagulants) to prevent stroke is usually based on the number of stroke risk factors.

The CHADS2 score is often used to estimate clinical suspicion for stroke in the setting of AF

(Camm et al., 2010). The components of the CHADS2 score include congestive heart failure, hypertension, age >75, diabetes, and history of stroke (counted twice). The estimated risk of stroke for someone with CHADS2 score of zero is about 1.9% per year, and this risk increases to about 18.2% per year for someone with the maximum CHADS2 score of 6. Meta-analyses of stroke prevention trials have estimated that a relative risk reduction of 64% versus placebo from anticoagulant medication such as warfarin.

Over time, long-lasting atrial fibrillation leads to changes in atrial size including dilatation and scarring. The typical pattern of AF involves a progression from short, infrequent episodes to longer frequent attacks, to sustained AF. AF is categorized by the length of time it lasts with each episode. Paroxysmal AF terminates spontaneously and lasts as long as 7 days at a time (Camm et al., 2010). Persistent AF lasts longer than 7 days or requires termination through antiarrhythmic medication or with DC cardioversion. Permanent AF occurs when the constant presence of AF is accepted by both patient and physician, and efforts are directed at controlling the heart rate despite continued presence of an irregular rhythm.

Independent of treatment for stroke prevention, strategies for therapy of AF are broadly divided into rate control and rhythm control. Rate control consists of an emphasis on preventing sustained episodes of fast heart rate (>100 beats per minute), usually through medications that can slow conduction from the atria to the ventricles such as beta blockers, calcium channel blockers, and digoxin. Rhythm control involves a focus on maintaining normal sinus rhythm usually through antiarrhythmic medications or through surgical or catheter-based procedures to treat AF. The Atrial Fibrillation Follow-Up Investigation of Rhythm Management (AFFIRM trial) showed in a group of 4,060 patients with AF who were 65 or older or who had other risk factors for stroke, rate control and rhythm control (which consisted mainly of treatment with amiodarone) were equivalent in terms of 5-year mortality (Wyse et al., 2002). In a number of patients, however, symptoms from AF are detrimental to quality of life such that this becomes the main reason to pursue a rhythm control strategy.

Ablative therapy for AF is a growing treatment that involves creating barriers to electrical conduction in atrial tissue, typically with radiofrequency energy often delivered via catheters. In particular, tissue at the junction of the left atrium and the pulmonary veins has been noted to be a frequent trigger of AF, and electrical isolation of the pulmonary veins is especially effective at reducing AF in patients with paroxysmal episodes.

There is some evidence that psychosocial symptoms may be related to atrial fibrillation. Lange and colleagues showed in a group of 54 patients with persistent AF that depressive mood was associated with greater risk of recurrence after DC cardioversion (Lange, 2007). In a triggering analysis that used event monitoring and electronic diaries, Lampert and colleagues observed in 75 patients with paroxysmal or persistent AF that arrhythmia episodes were more likely preceded by negative emotions and less likely by happiness (Lampert et al., 2008). Analyses of the Framingham Offspring Study have found that baseline levels of tension, anger, and hostility predicted increased 10-year risk of AF in men, but not in women (Eaker, Sullivan, Kelly-Hayes, D'Agostino, & Benjamin, 2004, 2005).

Atrophy

Definition

Atrophy in the simplest sense is a type of cellular adaptation in which a cell, tissue, or organ of the body reduces in size. It is often the result of chronic stressors being applied to the body. Chronic stressors are things such as a physical injury, disease pathology, or immobilization and disuse. It is commonly seen as a symptom in neuromuscular and musculoskeletal conditions or injury, but atrophy may affect any body system or structure.

Description

When cells of the body are under stressors such as those listed above, there is a potential for cellular injury and cell damage. These cellular injuries may include lack of blood flow to the area, which is known as ischemia, infection, immune system responses, lack of adequate nutrition, or physical trauma. If the stressors persist, cells will attempt to make cellular adaptations in order to maintain homeostasis to withstand them. Examples of cellular adaptations include atrophy, hypertrophy, hyperplasia, metaplasia, or dysplasia may occur. By adapting, the cells are able to avoid injury or cell death.

In the human body atrophy may occur for physiologic or pathologic reasons. Physiologic atrophy is associated with the natural aging process, and it usually involves things such as general muscle wasting and bone loss. Pathologic atrophy is the result of some form of cellular injury, such as a neuromuscular condition, cancer, peripheral vascular disorders resulting in inefficient blood flow, or spinal cord injury.

The musculoskeletal system can become atrophied for two general reasons: disuse atrophy or neurogenic atrophy. With disuse atrophy, skeletal muscles may atrophy due to immobilization and disuse, which often occurs following an injury, such as an ankle sprain, or surgery, such as a joint replacement procedure. Individuals may also immobilize themselves if movement causes significant pain or discomfort. In neurogenic atrophy, the nerve supply to the affected muscle is disrupted in some way. This type of muscle atrophy may also occur with a lower motor neuron injury, such as a cut peripheral nerve or spinal cord injury. After this type of injury, the involved muscles become partially or completed denervated, meaning that the nerve supply to the muscle is disrupted. This results in less voluntary movement and control of the involved muscles. It is thought that this lack of use is responsible for the physiological changes that occur in muscles that ultimately result in their atrophy.

Several morphological changes occur in the muscles when they atrophy. A loss in the contractile proteins actin and myosin occurs, as well as changes in the blood supply, as the capillary density of these muscles decrease. When these skeletal muscle proteins are lost, a decrease in muscle fiber length and diameter will occur, and ultimately atrophy of the muscle as a whole. This loss of muscle mass also leads to weakness, as the muscles are no longer capable of producing the same amount of force. This is an important factor

for patients undergoing surgery. Postsurgical patients are a population of individuals that often have disuse atrophy of their muscles. For example, patients undergoing an anterior cruciate ligament (ACL) repair surgery tend to have weak, atrophied quadriceps after the surgery. For this reason, patients often participate in strengthening programs before the surgery.

Atrophy does not need to be caused by an injury as described above. It can also be due to a genetic condition. Spinal muscular atrophy (SMA) is a genetic condition resulting from loss of ventral horn cells in the spinal cord that are responsible for motor function. Individuals with this condition suffer from skeletal muscle atrophy, weakness, and hypotonia. Complaints of fatigue are also common in this population. Those with SMA may experience respiratory problems as well because the diaphragm is a skeletal muscle often affected. As the condition progresses, the use of assistive devices, such as a wheelchair, for mobility may become necessary.

The treatment of atrophy depends upon its cause as well as its impact on the individual. Those with disuse atrophy may reverse the effects of atrophy from physical therapy or a simple exercise program. If the cause of the atrophy is more genetic or permanent in nature, like that occurs with SMA or spinal cord injury patients, exercise will still be beneficial, but the treatments may need to be augmented with the use of adaptive equipment, such as splints or braces.

Bowlby (1969, 1988) described an attachment as an emotional bond that is characterized by the tendency to seek out and maintain proximity to a specific attachment figure, particularly during times of distress.

Description

Overview of Attachment Theory

Normative processes. Bowlby's attachment theory (e.g., Bowlby, 1969, 1988) suggests that humans' most intimate relationship partners serve important functions related to distress alleviation. More specifically, he theorized that *people* rely on *their* primary caregivers, or *attachment figures*, for feelings of comfort and security, especially during times of distress. According to Bowlby, the attachment system evolved in order to keep vulnerable human infants within close proximity to their caregivers. Normatively, when an infant experiences distress, the attachment system will be activated. The infant will then signal its distress to the

caregiver who will respond in an appropriate manner and the infant's distress will be alleviated. Over time, the infant develops an emotionally primary bond with its caregiver such that caregiver proximity in and of itself provides feelings of comfort/security. Bowlby suggested that four specific attachment behaviors are present in such relationships. First, the infant relies on the attachment figure as a source of comfort, or *safe haven* to turn to when distressed. Once a sense of comfort and security is established, the infant uses the caregiver as a *secure base* from which to explore the environment. Because the attached person relies on the caregiver for feelings of comfort and safety, infants *seek proximity* to their attachment figures and experience significant distress when separated from them (*separation distress*).

With increasing age, individuals rely less on actual proximity to attachment figures and more on *internalized representations* of these individuals (Bowlby, 1969, 1988; Brethereton, 1985). Specifically, through repeated emotionally relevant interactions with attachment figures, people are theorized to develop unconscious representations of those relationships, termed *internal working models* (IWMs). Under conditions of distress, in which the attachment system is activated, individuals derive feelings of emotional security through the IWM when their attachment figures are not physically present.

While Bowlby (1969, 1988) initially conceptualized attachment theory with regard to relationship processes during infancy and childhood, such bonds are thought to be influential during adolescence and adulthood as well. In adulthood, attachment bonds are formed primarily within the context of romantic relationships (e.g., Hazan & Shaver, 1987; Weiss, 1988). Adult romantic relationships have increasingly been conceptualized as attachment bonds characterized by the same central components as attachment bonds in infancy: heightened proximity maintenance, resistance to separation, and utilization of the partner as a preferred target for comfort- and security-seeking (Hazan & Zeifman, 1999). As noted earlier, attachment theory proposes that internal working models are representations of the caregiving, distress-alleviating functions of attachment figures. If, as Bowlby argued, the attachment system operates in this fashion "from the cradle to the grave," then it follows that internalized representations of *adult* attachment figures – romantic partners – should function to promote distress alleviation among adults in the same way that internalized representations of caregivers are hypothesized to do in infancy and childhood. A growing body of research suggests that romantic partners do, in fact, seek one another out during times of distress and, alternatively, offer comfort and support to their partners (e.g., Collins & Feeney, 2000).

Internal working models were originally conceptualized as a set of expectations about the self and close others, based in previous experiences, which guide cognitive, emotional, and behavioral responses to current experiences. More recently, however, such models are thought to reflect an individual's capacity and typical strategies for managing positive and negative emotional arousal, processes that are collectively known as *emotion regulation* (Mikulincer & Shaver, 2007). The increasing attention paid to the emotion regulating functions of the internal working model is important in light of the concurrent focus on emotion processing as one mechanism through which close relationships influence health (Diamond, 2001; Diamond & Fagundes, 2010; Diamond & Hicks, 2004; Ryff, Singer, Wing, & Love, 2001).

Individual differences. The normative perspective contends that all humans are innately predisposed to form attachment bonds. Yet, attachment theory suggests that not all attachment relationships are of similar *quality*. Specifically, individuals whose caregivers provided consistent and responsive distress alleviation are theorized to develop secure working models of attachment (Ainsworth, Blehar, Waters, & Wall, 1978; Bowlby, 1969, 1988). Conversely, those who did not experience consistent or responsive caregiving develop insecure models. A student of Bowlby's, Mary Ainsworth, and her colleagues identified three patterns. Each pattern is thought to reflect a specific history of caregiver interaction and emotion processing. Specifically, *secure*

persons are described as having experienced consistent and responsive caregiving. As a result, they associate proximity to caregivers with effective distress alleviation, see others as willing to provide responsive care, and themselves as worthy of it. *Anxious* persons are described as having experienced inconsistently responsive caregiving, resulting in uncertainty about whether proximity to caregivers will result in distress alleviation. They therefore develop an internal working model in which they are unworthy of love and comfort and in which attachment figures are unreliable. *Avoidant* persons are described as having experienced consistently unresponsive caregiving. Hence, they do not associate proximity to caregivers with feelings of comfort or distress alleviation, and therefore develop an interpersonal style that emphasizes self-reliance and involves distancing themselves from others during times of stress. Such "attachment styles" were initially conceptualized as a relatively stable trait-like individual difference dimension. Individual differences in patterns of attachment are thought to shape emotional processing, relational cognition, and relationship behavior over the life course.

Much like the normative aspects of attachment, there are also parallels between infant caregiver and adult romantic relationships on the individual difference dimension. In their groundbreaking study, Hazan and Shaver (1987) found evidence for three similar patterns of difference in adults with respect to their romantic partners. For example, adults that were identified as *secure* reported feeling comfortable with closeness and experiencing reciprocal support provision in relationships. Those identified as *anxious* reported wanting more closeness than relationship partners were willing to provide, and feeling uncertain about their partners' devotion. Adults classified as *avoidant* reported feeling uncomfortable with closeness and preferring more emotional distance from their partners.

Measurement. Across the lifecourse, measures of attachment assess the extent to which one is comfortable relying on their attachment figure when under distress. Such measures aim to tap into the content of the internal working model and differentiate between those with a secure, anxious, or avoidant "attachment style." The primary measure to assess attachment in infancy is the *strange situation*, a laboratory procedure during which the infant experiences brief separations and reunions with the primary caregiver providing the opportunity for researchers to observe the infants' tendency to seek proximity to and derive comfort from the caregiver when under distress (Ainsworth, Blehar, Waters, & Wall, 1978). Methods for assessing attachment from middle childhood through adolescence have been slower to emerge. As noted earlier, with increasing cognitive capabilities, children come to rely less and less on actual physical proximity to the caregiver and more on representations of the attachment relationship that are contained within the internal working model. From middle to late childhood three different measurement approaches have been utilized to assess the child's attachment representation/s. These methods include projective measures of attachment (e.g., Separation Anxiety Test), structured interviews (e.g., Child Attachment Interview), and questionnaires (e.g., Security Scale). During adolescence, methods which mirror those used with adults are utilized. A slightly modified version of the Adult Attachment Interview assesses adolescents' states of mind with regard to attachment. Other studies use a revised version of the Experiences in Close Relationships (described below) to identify attachment-related anxiety and avoidance in primary attachment relationships.

When considering issues of measurement in adulthood, it is important to note that adult attachment research has grown almost independently within two research traditions (reviewed by Crowell, Fraley, & Shaver, 2008). The measures used by the two traditions reflect differences of opinion regarding the extent to which the content of the internal working model is consciously accessible. The first line of work uses measures that tap into nonconscious perceptions and beliefs about close relationships. These measures assess either (1) adults' current state of mind with respect to early attachment relationships, as assessed by the Adult Attachment Interview, or (2) the coherence of adults' descriptions of their current romantic relationships, as

assessed by the Current Relationships Index. The second line of research uses the Experiences in Close Relationships (ECR) inventory; a paper and pencil measure assessing consciously accessible levels of comfort with closeness to and heightened vigilance regarding the availability of romantic partners. Finally, although attachment patterns have historically been viewed as discrete prototypes (i.e., secure, anxious, and avoidant), more current research measures these dimensions as continuous, rather than categorical, attributes (i.e., Fraley, Waller, & Brennan, 2000). The current entry will make reference secure, anxious, and avoidant "types" for the sake of clarity and to reflect the categorical approach pervasive in prior literature.

Implications for Behavioral Medicine

The last 15 years have seen a dramatic proliferation of research evidence pointing to the influence of attachment experiences and relationships on important markers of physical health. One important theoretical framework that helps ground this work emphasizes the influence of attachment histories and relationships on emotion regulation as one important mechanism linking attachment to health outcomes (Diamond & Hicks, 2004). This perspective aligns nicely with a growing body of research implicating emotions as a central mechanism in links between relationships and health (Ryff et al., 2001). Thus, it is important to integrate this discussion of the health implications of attachment with a brief review of the impacts of attachment processes on emotional experience. Research evidence examining links between relationships and health suggests that both the normative and individual differences components of attachment relationships are important.

Attachment security conveys multiple emotion regulation benefits during childhood and adolescence. Securely attached children are more likely to view themselves as worthy of love and caring as noted above. As such, they value their health and well-being. Perceiving attachment figures as available and helpful in times of distress allows securely attached children to acknowledge their discomfort and seek support when needed. The adaptive emotion regulation strategies that secure children use promote healthy social (i.e., increased social competence, positive peer and family relationships), emotional (i.e., lower levels of depression, anxiety, and social anxiety, and fewer concerns about loneliness), and behavioral functioning (i.e., fewer somatic complaints, fewer behavioral concerns or conduct problems).

Unlike their securely attached counterparts, insecurely attached children develop strategies that are less adaptive. Anxiously attached children tend to utilize hyperactivating strategies, and display heightened distress to promote proximity to attachment figures. Because they are so sensitive to distress and use such ineffective support-seeking strategies, they are unable to effectively regulate their negative affect. Anxious children therefore more often display frequent and intense expressions of negative affect (i.e., tantrums), behavioral dysregulation, anxiety, and depression. Anxiously attached children and adolescents also tend to be clingy toward attachment figures, display a high need for approval, and report having lower self-esteem. In contrast, avoidant children have learned to use deactivating emotion regulation strategies that minimize negative affect and support-seeking behaviors. However, their deactivating strategies may not be very effective at regulating negative emotion, as avoidantly attached adolescents are more likely to display conduct disordered and criminal behavior than those with other attachment organizations.

Attachment and emotion regulation. As with attachment patterns in infancy and childhood, adult attachment styles are associated with robust individual differences in emotion regulation processes (e.g., Mikulincer & Shaver, 2007). Attachment theory maintains that internal working models impact attention and processing of affectively relevant information. For example, secure individuals are more likely to interpret benign stimuli in more neutral or even positive ways, and they are more likely to offer the benefit of the doubt when a relationship partner engages in ambiguous, yet potentially threatening behaviors. Individuals with more secure working models are also more comfortable relying on others for

support during times of distress. They also report engaging in more constructive intra- and interpersonal regulatory strategies. It follows, then, that secure individuals report more frequent and intense bouts of positive emotion, and less frequent and less intense negative emotion.

While secure attachment is conceptualized as a resource that promotes effective regulation, attachment insecurity appears to interfere with the ability to effectively modulate emotional experience. Specifically, those characterized as *anxious* are likely to interpret neutral stimuli as more hostile and negative. They are also more likely to make negative, blaming attributions of partners' ambiguous behaviors. They tend to engage in indirect and ineffective support seeking and less constructive regulatory strategies. Not surprisingly, then, anxious individuals report more intense and more frequent negative emotional experiences. They report less positive emotions as well, and do not always derive the same benefits from positive events or experiences. Attachment avoidance is conceptualized as involving minimization and suppression of emotional experience. Supporting this view, persons endorsing high levels of avoidance report low levels of both negative *and* positive emotions, and high levels of emotional control. Rather than seeking support, avoidant individuals tend to distance themselves from others especially when levels of distress appear to be high. Recent research suggests that avoidant individuals report such low levels of emotional activation because they use a preemptive strategy of focusing attention away from affectively relevant stimuli and events.

Attachment and health. In general, research demonstrating associations between attachment and physical health across the life span takes three different approaches. The first describes a developmental neuroscience-based approach for understanding how early experiences with primary caregivers "tune" developing neurobiological systems' sensitivity to stress, and in essence predispose individuals toward regulatory strategies that are highly influenced by early attachment experiences. The second emphasizes the moderating effects of attachment on "microlevel" physiological processes, such as autonomic nervous system and hypothalamic pituitary adrenocortical (HPA) axis functioning. The third takes a more macrolevel approach, investigating the incidence and management of specific diseases and conditions. The most robust findings from each of these literatures are described below.

An emerging neuroscience literature has begun to demonstrate compelling links between affectively rich, synchronous mother-infant interactions with the development and functioning of the relational right brain and the orbitofrontal system. These neuroanatomical structures are directly responsive to the infant's affective and relational environment; in this way, the affective tone of repeated interactions with caregivers influences the "hardwiring" of pathways that are implicated in emotion regulation (Schore, 2000). Thus early experiences serve to create a template for emotion regulation at the neurophysiological level. This compelling research suggests that one of the ways relationships "get under our skin" is that they shape the development of stress responses through psychoneurobiologically mediated pathways.

Studies linking adult attachment HPA axis functioning typically assess salivary cortisol, while those examining sympathetic and parasympathetic branches of the autonomic nervous system typically assess heart rate, blood pressure, respiratory sinus arrhythmia, and electrodermal activity. Each of these systems is important from a behavioral medicine perspective, as dysregulation of each system has been linked to potentially deleterious health outcomes. This research primarily emphasizes differences in baseline, or resting levels as well as short-term reactivity to laboratory stressors (though at least one study had examined reactivity to daily relationship events). In general, insecurely attached individuals show heightened HPA and ANS stress reactivity. For example, anxious individuals are found to experience heightened electrodermal, heart rate, and blood pressure reactivity to general laboratory stressors (such as difficult mathematical tasks with frustrating interruptions). They also demonstrated greater electrodermal and HPA reactivity during laboratory conflict with their

romantic partners. Consistent with their heightened concerns around attachment figure availability, anxious persons have also demonstrated heightened cortisol to stimuli priming thoughts of abandonment in a laboratory, as well as heighted daily cortisol output during a brief travel-related separation from their romantic partner. In terms of basal levels, anxious persons have been found to have suppressed resting parasympathetic and HPA activity, both presumed to indicate a dysregulation in those systems. All of these findings are consistent with the evidence demonstrating anxious individuals' heightened emotional reactivity as well (discussed earlier).

Avoidant individuals, on the other hand, tend to report blunted emotional experiences; they report neither high negative nor positive emotions generally, and demonstrate little emotional reactivity to laboratory stressors. Yet, they have been found to demonstrate heightened physiological reactivity to lab stressors. For example, avoidant individuals showed heightened HPA reactivity to an in-lab conflict with their romantic partners, as well as to exposure to stimuli priming thoughts of abandonment. In other studies, they experienced heightened sympathetic and electrodermal reactivity to nonrelationship laboratory stress tasks (i.e., stressful mathematical tasks). Further, they have been found to show a blunted basal parasympathetic activity. Thus, some researchers suggest that avoidant individuals' defensive regulatory strategy, while effective at suppressing intense affective states, may come at a physiological cost.

Another line of research examines empirical associations between attachment and health across a range of health-related domains. While some studies find that having a chronic illness itself does not increase one's odds of developing an insecure attachment, other researchers find a greater frequency of insecure attachment classifications, particularly anxious attachment, among pediatric populations (i.e., among premature infants, infants with congenital heart disease, and in pediatric patients with cerebral palsy, epilepsy, cleft lip, and cystic fibrosis; Feeney, 2000; Minde, 1999). Although the influence of child and disease-specific factors is likely to exert some influence on attachment, poor maternal and family relationship quality are thought to provide a more robust influence on children's attachment organizations. Insecure attachments among adolescents and adults have also been associated with psychosomatic illnesses, physical complaints, symptom reporting, anxiety, and depression (Maunder & Hunter, 2001). Attachment insecurity has also been linked to greater emotion-focused coping among children with asthma and also among healthy university students. Among adults with diabetes mellitus, avoidant attachment has been associated with poor metabolic control, adherence, and less health care utilization. Diabetic adults with anxious attachments had high health care utilization costs and, surprisingly more optimal metabolic control levels (Ciechanowski et al., 2004).

A growing and compelling literature suggests that attachment-related processes broadly predict personal well-being, coping, physiological responses to stress, and health-related behaviors and illness management across the life span. Additional research that examines the emotion regulation pathways by which these associations are mediated will increase the field's understanding of how primary attachment relationships interact with critical psychobiological mechanisms to influence health across the life span.

Definition

An attitude is broadly defined as a tendency to evaluate a particular entity with some degree of favor or disfavor (Eagly & Chaiken, 1993).

Ajzen and Fishbein (2005), two preeminent attitude researchers, have distinguished between two general types of attitudes: attitudes toward objects and attitudes toward behavior. Attitudes toward behavior, specifically health behavior, are more relevant to behavioral medicine.

Description

Attitudes and Health Behavior

Current understanding of attitudes is based in an expectancy-value framework in which an attitude toward a behavior is a function of (a) beliefs that engaging in the behavior will result in certain outcomes (positive and negative), and (b) evaluations associated with outcomes that result from engaging in the behavior (positive and negative). For example, a person's attitude toward engaging in physical activity is a function of his or her beliefs about the consequences of exercising (e.g., improved health and appearance, time taken from other activities) and evaluations associated with the outcomes of exercise (e.g., increased energy, body soreness). The belief and evaluation components can also be conceptualized as cognitive (beliefs) and affective (evaluations) components.

Attitudes toward engaging in health behaviors are central to understanding how people make health-related decisions. A person's belief about whether taking his or her hypertension medication is beneficial to his or her health, jointly with an evaluation of whether the effects of taking the medication are positive or aversive, will to some degree, influence his or her decision to take the medication. The centrality of attitudes to health decision making is evidenced in the fact that (a) attitudes are found in all prominent theories of health behavior, and (b) health message campaigns are largely based on the assumption that changing attitudes will result in behavior change. In the next section, the most prominent health behavior theories will be described, including how attitudes are conceptualized in the models and the evidence for the influence of attitudes on behavior. In the following section, different approaches to changing health behavior through changing attitudes will be described. Finally, a brief overview on the limits of the influence of attitudes on behavior will be provided.

Health Behavior Theories

Health Belief Model. The Health Belief Model (HBM) includes six constructs that are proposed to guide decisions to engage in health-related behaviors. The constructs are (1) perceived susceptibility to the health threat, (2) perceived severity of the health threat, (3) perceived benefits of engaging in the behavior, (4) perceived barriers to engaging in the behavior, (5) cues to action, and (6) self-efficacy to engage in the behavior. Although not explicitly described as attitudes, the constructs of perceived benefits and perceived barriers to engaging in the behavior fit the definition of attitudes well. The measurement of these two constructs captures people's positive (benefits) and negative (barriers) beliefs and evaluations of engaging in the behavior. According to the HBM, both constructs have a direct influence on behavior.

Across a variety of health behaviors, evidence suggests that higher benefits and lower barriers (i.e., more favorable attitudes) are associated with a greater likelihood to engage in health behaviors. For example, higher benefits and lower barriers have been shown to be associated with higher levels of mammogram adherence (Friedman, Neff, Webb, & Latham, 1998) and condom use (Volk & Koopman, 2001). The strength of the influence of benefits and barriers on behavior, as well as the influence of other constructs in the model, varies across different domains. Perceived barriers, however, have been shown to be the strongest predictor of behavior across all behavioral domains (Champion & Skinner, 2008).

Theory of Planned Behavior. The Theory of Planned Behavior (TPB) suggests that health behaviors are influenced most proximally by intentions to engage in the behavior. Intentions are influenced by attitudes toward the behavior, perceived norms to engage in the behavior, and perceived control over the behavior. In the model, attitudes are conceptualized and measured as both beliefs about engaging in the behavior and

evaluations of the associated outcomes. Because attitudes are thought to be proximal predictors of intentions rather than behaviors, attitudes have an indirect influence on behavior through intentions.

Evidence across a variety of health behavior domains, including exercise, smoking cessation, cancer screenings, substance use, and safe sex practices indicate that attitudes are an important predictor of behavior. As with the HBM, however, the strength of the influence of attitudes varies across different behavioral domains (Ajzen, Albarracin, & Hornik, 2007).

Transtheoretical Model of Behavior Change. The Transtheoretical Model (TTM) of behavior change assumes that behavior change is best understood as a process through which people progress through a series of discrete stages. Specifically, people go from not thinking about the behavior (precontemplation), to thinking about the behavior (contemplation), to considering the behavior (preparation), to engaging in the behavior (action). There is also a stage that considers continued behavior over time (maintenance). An important factor in the progression of stages is the weighing of the pros and cons for engaging in the relevant behavior. The TTM labels this factor decisional balance. As with the HBM, decisional balance is not explicitly described as an attitude but it captures people's beliefs and evaluations of the benefits (pros) and costs (cons) of engaging in the behavior. Thus, it fits the definition of attitudes well. According to the TTM, as people progress through the stages toward engaging in the behavior, decisional balance systematically changes such that pros increase and cons decrease.

The systematic shifting in pros and cons is characteristic of stage progression, and there is evidence for this shifting across many health behavior domains (e.g., smoking cessation, exercise, sunscreen use, safer sex practices; Prochaska, Redding, & Evers, 2008). In fact, evidence across many health domains suggests that moving from precontemplation to action requires a 1 standard deviation increase in perceived pros of engaging in the behavior (pros) and a .50 standard decrease in the perceived cons. Thus, people's evaluations of the benefits and costs of engaging in the behavior are central to behavior change.

Precaution Adoption Process Model. The Precaution Adoption Process Model (PAPM) is also a stage-based model of behavior change in which it is assumed that people progress from being unaware of the health issue to acting through a series of discrete stages. Unlike the TTM, the PAPM specifies the processes that are thought to guide movement between specific stages. For example, when people progress from being undecided about acting (Stage 3) to deciding to act (Stage 5) or not (Stage 4), beliefs about the effectiveness and difficulty of engaging in the behavior are thought to be critical at that stage (Weinstein, Sandman, & Blalock, 2008). These particular beliefs are thought to be less important, however, at other stages of the change process. As with the HBM and TTM, beliefs about the effectiveness and difficulty of engaging in the behavior are not explicitly described as attitudes. Yet, as with the other models, these beliefs capture people's evaluations of the behavior that fits the description of attitudes well.

Unlike the other models, there is much less evidence from research on the PAPM on the specific role of attitudes in influencing behavior. There is evidence that PAPM-based interventions are effective (Weinstein et al., 2008), but little attention has been paid specifically to the influence of beliefs about effectiveness and difficulty on behavior.

Attitude Change to Change Health Behavior

Evidence from persuasion research suggests that persuasive messages can change attitudes through two processes: one in which people process message content deeply and deliberately, the other in which peripheral aspects of the message (e.g., credibility of the source, people's mood) influence attitudes (Chaiken, Liberman, & Eagly, 1989; Petty & Cacioppo, 1986). Depending on the circumstances in which the communication occurs, attitudes can be influenced through one process or the other, or they can operate jointly. Attitudes are more likely to change and persist, however, when the message content is processed deeply and

deliberately. Message content is more likely to be processed deeply and deliberately when it is personally relevant.

Health campaigns are largely based on the assumption that changing attitudes will result in behavior change. This is evidenced by the fact that many health campaigns focus on making people aware of the costs and benefits of engaging (or not engaging) in behaviors. Different types of health communications and messages have been shown to be effective in changing attitudes and behavior. Three types of health messages are described below.

Message Framing. The effect of a health message on attitudes and health behaviors can differ depending on whether the message content is framed in terms of what one stands to gain (gain frame) or what one stands to lose (loss frame) by engaging (or not engaging) in a behavior. Whether a gain- or loss-framed message is more effective depends on the level of risk or uncertainty associated with engaging in the behavior. When risk or uncertainty is high, loss-frame messages should be more effective; when risk or uncertainty is low, gain-frame messages should be more effective. For example, loss-frame messages (i.e., what one stands to lose by not engaging in the behavior) are more effective in promoting illness-detecting behaviors (e.g., cancer screening) because there is some uncertainty about whether one will detect an unwanted outcome (e.g., a lump in a breast). In contrast, gain-frame messages (i.e., what one stands to gain by engaging in the behavior) are more effective in promoting prevention behaviors (e.g., sunscreen use) because there is little or no uncertainty associated with engaging in the recommended behavior (Rothman & Salovey, 1997).

Message Tailoring. Messages that are individually tailored to a person's attributes, interests, and/or concerns tend to be more effective in changing people's attitudes and health behaviors than standardized messages (Noar, Benac, & Harris, 2007). For example, a person who is not yet convinced of the health benefits of regular exercise should find a message that focuses on the benefits of exercise (i.e., tailored to current concerns) to be more relevant and convincing than a message that focuses on the variety of ways one can exercise (i.e., not tailored to concerns). The reason that tailored messages are more effective than standardized messages is because they are more personally relevant to the recipients, and thus people are more likely to process the message content (Kreuter, Bull, Clark, & Oswald, 1999).

Fear Appeals. Fear appeals are messages that are designed to evoke fear and worry about a health threat as a means to change attitudes and behavior. The rationale underlying fear appeals is that if people are made to feel anxious or worried about a health threat, they will develop a more favorable attitude about taking preventive action and will be more likely to behave accordingly. Thus, fear appeals target the affective component of attitudes. The effectiveness of fear appeals in changing behavior is mixed. Evidence suggests that fear appeals that contain clear and simple recommendation about how to take preventive action are more effective than appeals lacking behavioral recommendations (Witte & Allen, 2000)

Limits of the Influence of Attitudes on Behavior

It seems intuitive that prior to engaging in any health behavior, a sufficiently favorable attitude toward the behavior is needed. For example, it is quite unlikely that a person would get a colonoscopy without the belief that doing so would be beneficial to his or her health. But even when people hold favorable attitudes toward the behavior, they may not engage in it. In other words, attitudes are best thought of as a necessary, but not sufficient, influence on behavior.

There are various reasons why attitudes might not be sufficient to influence behavior change, or why messages aimed at changing attitudes are not effective. First, factors other than attitudes also influence behavior. Drawing from the Theory of Planned Behavior, social norms, perceived behavioral control, and behavioral intentions are other constructs known to influence behavior. In some contexts, people may hold favorable

attitudes toward engaging in a behavior, but because of normative influences or a lack of control over the behavior, they will be unlikely to engage in the behavior. For example, young adult women may hold a favorable attitude about getting the HPV vaccine, but because they believe their parents would not approve (social norms), or they lack the proper insurance coverage (control), they would be unlikely to receive the vaccine.

Second, health communications and messages typically target the cognitive component of people's attitudes (e.g., beliefs that engaging in the behavior will result in beneficial outcomes), often ignoring the affective component (i.e., evaluation of the outcomes of the behavior). For example, women may believe that having a mammogram is a good thing for their health (cognitive component), but also may feel discomfort or embarrassment about the procedure (affective component). To the extent that health messages focus only on the health benefits, and fail to address aspects of engaging in the behavior that are affective in nature, their effectiveness in changing attitudes and behavior may be limited.

Third, attitudes and behavior must be assessed at the same level of specificity in order for a strong relation between the two to exist. For example, a general attitude about overall health behaviors (e.g., "How do you feel about engaging in healthy habits?") is unlikely to have a strong relation with exercising regularly, eating sufficient amounts of fruits and vegetables, seeing a physician for regular medical screenings, *and* engaging in safe sex practices. Instead, attitudes that are as specific as the behaviors (e.g., "How do you feel about exercising regularly?") will have a stronger relation to the behaviors than a more general attitude. Thus, attitudes toward a behavior need to be targeted (e.g., in health communications) at the same level of specificity as the target behavior.

Attribution theory is concerned with the conventions that individuals use in attempting to explain their behavior (Weiner, 1986).

Description

According to Bernard Weiner, one of the main contributors in this area, there is no one single attribution theory. Rather, there are a number of attribution-based theories, and attribution is better described as a field of study than as a single encompassing theory (Weiner, 2008). Notwithstanding this clarification, the idea of an attribution-based theory of motivation has been around for years. The premise is simple enough – interpretation of what caused an outcome is proposed to direct future behavior. In terms of motivation, it has been suggested that individuals seek the causes of outcomes because they want to understand and explain those outcomes and predict future behavior. As causes are sought for most important outcomes, especially those where the outcome was not expected (e.g., individuals might ask why they did not get a job or why they only got a B on the test), it should come as no surprise that seeking an explanation for health outcomes is no exception. As an example, individuals who ask why they did not finish all of their cardiac rehabilitation classes and then generate responses such as too busy, lazy, tired, or the instructor was poor are using an attribution-based theory of motivation.

It is important to recognize that one's explanations are perceptions and may or may not capture the actual cause. In the previous example, one's failure to attend all the cardiac classes may have actually been caused by poor time management skills (too busy), but the individual may attribute it to laziness. An individual's perceptions of what caused an outcome can influence expectations for future behavior, emotions, persistence, and ultimately future behavior. Using this example, it might be assumed that the individual who attributed not finishing all of the classes to the cause of being lazy, while feeling some shame, would likely put little effort into being active in the future because the perception might be that laziness is a character trait that is not going to change! On the other hand, an explanation that time management skills were not effective provides some hope as these skills could be improved, which could translate into actually being more active. So, it would appear that attributions might matter.

This was certainly the stance adopted by Fritz Heider, who is known as the "father" of attribution. In his 1958 book, *The Psychology of Interpersonal Relations*, Heider laid out his common-sense approach that captured the beliefs of the "person in the street." In his naïve action of analysis, Heider (1958) reasoned that individuals endeavor to structure and control at least part of their actions by understanding the causes of outcomes thereby improving the prediction of future events. In terms of perceived causes of success and failure for an outcome, Heider identified two internal causes (ability and effort) and one external cause (task difficulty). While the contributions of a number of other researchers helped to deliver the idea of attributions into main stream social psychology, arguably, it was the publication of the book *Attribution: Perceiving the causes of behavior* (Jones et al., 1972) that served to solidify the study of attribution as a legitimate form of inquiry that endures today.

One of the editors of that seminal book, Weiner, extended Heider's common-sense approach to postulate that individuals search for the causes of important outcomes because it was

reasoned that the interpretation of the past (perceived causes of past events) determined what will be done in the future. Weiner (2010) suggested that individuals often use four factors to explain outcomes – ability, effort, task difficulty, and luck. For instance, one's failure to resist eating that very tasty, but calorie-rich, bowl of chocolate ice cream while on a diet could be ascribed to a lack of willpower (ability as a type of personal trait), not trying hard enough to resist (lack of effort), the appeal of the ice cream (task too difficult), or the fact that it was served during a state of hunger (bad luck), or some combination of these causes.

While identifying causes for outcomes is important, Weiner (1986) argued that the properties underlying the specific causes may be of greater significance, as they are believed to influence emotions, future expectations, and motivation. Although Weiner (2010) suggested the possibility of other causal properties, his attribution-based theory affords the classification of causal ascriptions along three property dimensions – locus, stability, and controllability. First, a causal locus denotes that we tend to attribute causes to factors either within ourselves or within the environment (i.e., internal or external to ourselves). Second, as some causes are relatively constant while others may be variable, stability of attributions also is important (stable vs. unstable). For example, while ability is typically perceived as stable, effort may fluctuate. Third, while some attributions are under volitional control, others are not (controllable vs. uncontrollable). For example, failure to comply completely with a physician's prescription to lose weight that is ascribed to the cause of low effort may be controllable, whereas failure because of illness may not.

Beyond qualification of attributions along dimensions, one of the main tenets of Weiner's model of attribution theory is that these dimensions lead to predictable psychological consequences (cognitive and affective). While the dimensions of locus of causality and controllability are believed to interact with perceived outcomes in determining affective reactions, the stability dimension is believed to result in cognitive consequences in terms of expectations regarding future outcomes (Weiner, 2010).

In terms of affective consequences, Weiner (1986) makes it clear that both outcomes and attribution dimensions are believed to be important precursors. The important contribution of an attribution-based theory is the assertion that how we explain the outcomes (i.e., attributions), and not just the outcomes themselves, may influence affective experiences. For example, Weiner (2010) notes that feelings of pride and self-esteem following an outcome are expected to be influenced by locus. Increases in pride and self-esteem are expected when a positive outcome is attributed internally (e.g., high aptitude). Also, guilt and shame are believed to be influenced chiefly by the controllability dimension. Guilt is expected when a negative outcome is seen as caused by something personally controllable (e.g., lack of effort), while shame is expected when a negative outcome is caused by a personal attribute about which one can do nothing (e.g., low aptitude). Further, all of these emotional responses are believed to influence future decisions and actions (Weiner, 1986).

In terms of specific predictions for future expectations, it would be posited that one would expect a similar future outcome when an outcome is attributed to a stable cause (e.g., task was too difficult). It is less clear, however, whether expected future outcomes will be similar or not when an outcome is attributed to an unstable cause that could change (e.g., lack of effort). Future expectations, in turn, are believed to play an important role in determining intentions and future behavior (Weiner, 1986).

Attributions have certainly played out in the health area. For instance, an examination of the wellness end of health behavior has revealed that using attributions that are stable (e.g., an explanation that one is good at managing time around exercise) to explain typical exercise levels (health-enhancing behavior) predicted intention to maintain those levels during a forthcoming time period (Spink & Nickel, 2010). Those who felt that the causes of their typical levels of moderate and mild exercise were stable also intended to maintain those levels throughout a subsequent period. In addition to relationships with health-enhancing behaviors, attributions also have been

associated with self-efficacy, which has been identified as an important cognition that has been consistently associated with an array of health behaviors. Self-efficacy is defined as beliefs in one's capabilities to successfully execute a course of action (Bandura, 1997). As one example of the attribution/self-efficacy relationship, it has been demonstrated that the interpretation of one's past activity behavior (as reflected in attribution dimensions) improved the prediction of self-efficacy over and above that predicted by past behavior only (Nickel & Spink, 2010).

Attributions also appear to be associated with the illness end of the health continuum. In a meta-analysis examining psychological adjustment to disease, Roesch and Weiner (2001) reported that, for the most part, individuals who explained their disease as being caused by more internal, unstable, and controllable causes (e.g., overweight) also reported that they used more adaptive forms of coping (e.g., coping self-efficacy) and were ultimately more well adjusted than those who used more external, stable, and uncontrollable causes (e.g., exposure from the environment). In contrast, those who experienced negative psychological adjustment tended to use stable and uncontrollable attributions (e.g., it is in the genes) to explain their illness. These patterns would appear consistent with Weiner's (2010) contention that attributing failure to stable causes impedes hope and motivation, whereas ascribing failure to unstable causes creates hope and facilitates motivation.

The fact that attributions are perceptions suggests that interventions could be designed that alter unhealthy behavior by changing maladaptive attributions. One study examining the activity of older adults underscores this point (Sarkisian, Prochaska, Davis, & Weiner, 2009). Consistent with other research, it was assumed that older adults would report the cause of a failure to be active as "old age." As theory would suggest that stable and uncontrollable attributions for failure are especially detrimental to motivation, these individuals were retrained to attribute failure to be active to controllable factors. After the attribution retraining, it was revealed that the older adults increased their walking by over four kilometers per week. Results such as these are encouraging and suggest that attribution retraining programs may provide an effective method to improve health-type behavior when perceived causes for failure are maladaptive and, at the very least, deserve future research attention.

Definition

Autonomic activation refers to an increase in the activity of the autonomic nervous system, the physical system responsible for nonconsciously maintaining bodily homeostasis and coordinating bodily responses. It is assessed by comparing autonomic values obtained during a test period to those obtained during a rest or baseline period. Baseline measures commonly are taken shortly before test periods. However, they can be taken well in advance of test periods or after them. Autonomic activation can pertain to neuronal activity or activity of visceral structures affected by it, such as the ones involved in circulation, respiration, and digestion. The distinction between neuronal activation and visceral structure activation is not trivial given that an increase in the activity of a visceral structure may be caused by a decrease in neuronal activity. For instance, increases in the frequency of the heart beat – which are often interpreted as signals of autonomic activation – can be due to reduced activity in the parasympathetic branch of the autonomic nervous system.

Definition

There is growing evidence for the role of the autonomic nervous system (ANS) in a wide range of somatic and mental diseases. The ANS is generally conceived to have two major branches: the sympathetic system, associated with energy mobilization, and the parasympathetic system, associated with vegetative and restorative functions. Normally, the activity of these branches is in dynamic balance. When this changes into a static imbalance, for example, under environmental pressures, the organism becomes vulnerable to pathology.

Resting heart rate (HR), by virtue of its dominant control via parasympathetic mechanisms (Levy, 1997; Uijtdehagge & Thayer, 2000), can be used as a rough indicator of autonomic balance, and several large studies have shown a largely linear, positive dose-response relationship between resting HR and all-cause mortality (see Habib, 1999, for a review). This association was independent of gender and ethnicity, and showed a threefold increase in mortality in persons with resting HR over 90 beats per minute (bpm) compared to those with resting HRs of less than 60 bpm.

Brook and Julius (2000) have detailed how autonomic imbalance in the sympathetic direction is associated with a range of metabolic, hemodynamic, trophic, and rheologic abnormalities that contribute to elevated cardiac morbidity and mortality. Autonomic balance has been shown to be associated with diabetes mellitus, and decreased HRV has been shown to precede evidence of disease provided by standard clinical tests (Ziegler, Laude, Akila, & Elgwhozi, 2001). In addition, autonomic balance and decreased parasympathetic activity is also associated with immune dysfunction and inflammation, which have been implicated in a wide range of conditions including cardiovascular disease, diabetes, osteoporosis, arthritis, Alzheimer's disease, periodontal disease, and certain types of cancers as well as declines in muscle strength and increased frailty and disability (Ershler and Keller, 2000; Kiecolt-Glaser, McGuire, Robles, & Glaser, 2002). The common mechanism seems to involve excess pro-inflammatory cytokines such as interleukin 1 and 6 and tumor necrosis factor. Importantly, increased parasympathetic activity and acetylcholine (the primary parasympathetic neurotransmitter) have been shown to attenuate release of these pro-inflammatory cytokines, and sympathetic hyperactivity is associated with their increased production (Tracey, 2002; Thayer & Sternberg, 2010). Thus, autonomic imbalance may be a final common pathway to increased morbidity and mortality from a host of conditions and diseases.

Although the idea is not new (Sternberg, 1997), several recent reviews have provided strong evidence linking negative affective states and dispositions to disease and ill health (Friedman & Thayer, 1998; Kiecolt-Glaser et al., 2002; Thayer, Yamamoto, and Brosschot, 2010). All of these reviews implicate altered ANS function and decreased parasympathetic activity as a possible mediator in this link. An additional pathway between psychosocial stressors and ill health is an indirect one, in which psychosocial factors lead to poor lifestyle choices, including a lack of physical activity and the abuse of tobacco, alcohol, and drugs. Both sedentary lifestyle and substance abuse are associated with autonomic imbalance and decreased parasympathetic activity (Ingjaldsson, Laberg, & Thayer, 2003; Thayer & Lane, 2007; Thayer et al., 2010). In fact, the therapeutic effectiveness of smoking cessation, reduced alcohol consumption, and increased physical

activity rest in part on their ability to restore autonomic balance and increase parasympathetic activity.

Definition

The autonomic nervous system (ANS) is a part of the efferent (i.e., outgoing) division of the peripheral nervous system. It adapts the organism to internal and external changes, maintaining bodily homeostasis and coordinating bodily responses.

Description

The autonomic nervous system (also known as the visceral nervous system and vegetative nervous system) combines with the somatic nervous system to form the efferent (i.e., outgoing) division of the peripheral nervous system. It innervates glands, the heart, and smooth muscles of all visceral structures and adapts the organism to internal and external changes by regulating a wide range of bodily functions such as blood circulation, body temperature, respiration, and

digestion. The basic tasks of the autonomic nervous system are to maintain bodily homeostasis and coordinate bodily responses. In contrast to regulatory processes of the somatic nervous system, regulatory processes of the autonomic nervous system do not require conscious or voluntary control.

Anatomical Structure

The autonomic nervous system is comprised of two main branches or subsystems, (1) the sympathetic nervous system and (2) the parasympathetic nervous system. A third nervous system – the enteric system – is considered by some physiologists to be a part of the autonomic nervous system and by others to be independent of that system. The enteric nervous system consists of two large nerve networks located in the walls of the digestive tract, identified as the submucosal plexus and the myenteric plexus. It innervates the smooth muscle cells of the digestive tract as well as exocrine and endocrine cells, controlling local activity within the digestive tract (e.g., secretion of digestive juices and digestive motility). The enteric system can act autonomously, but also in response to sympathetic and parasympathetic input.

Basic functional units of the sympathetic and the parasympathetic nervous systems are preganglionic and postganglionic neurons. Preganglionic neurons have cell bodies in the spinal cord or brainstem and axons that extend to cell bodies of postganglionic neurons. Postganglionic neurons have cell bodies that are clustered in so-called ganglia and axons that innervate target visceral structures. Notably, preganglionic neurons typically synapse with more than one postganglionic neuron. Similarly, postganglionic neurons typically synapse with visceral structures in multiple locations, allowing pervasive structural influence. An anatomical exception to the above is seen in the adrenal medulla. Although the adrenal medulla is a part of the adrenal gland, its cells are modified postganglionic neurons directly innervated by preganglionic neurons.

The major anatomical difference between the sympathetic nervous system and the parasympathetic nervous system is the location of neuronal cell bodies. Sympathetic preganglionic neurons are located in the thoracic and upper lumbar segment of the spinal cord, whereas parasympathetic preganglionic neurons lie in the brainstem and the sacral spinal cord. Postganglionic neurons of the sympathetic system are located either in one of the sympathetic ganglion chains (sympathetic trunk, also called paravertebral ganglia) along the spinal cord or in the prevertebral ganglia in front of the spinal cord. Parasympathetic postganglionic neurons are located either in terminal ganglia that lie near the target organ or directly in the organ wall. Given the difference in the position of the ganglia, sympathetic preganglionic fibers are usually shorter than parasympathetic preganglionic fibers and sympathetic postganglionic fibers are usually longer than parasympathetic postganglionic fibers.

Sympathetic and Parasympathetic Innervations of Visceral Structures and Functioning

Most visceral structures have both sympathetic and parasympathetic innervations. Exceptions are the skin, most blood vessels and most sweat glands, which are only sympathetically innervated. In visceral structures with dual innervations, the sympathetic and parasympathetic systems work together to regulate bodily function. It is common for the sympathetic and parasympathetic systems to exert complementary influences on visceral structures, with sympathetic arousal leading to adjustments suitable for high activity ("fight and flight") and parasympathetic arousal leading to adjustments suitable for low activity and bodily restoration ("rest and digest"). Examples of high activity adjustments are constriction of blood vessels in the gastrointestinal (GI) tract, dilation of blood vessels in the skeletal muscles and lungs, and improved heart rate and contraction force. Examples of low activity and restorative adjustments are the reverse: dilation of blood vessels in the GI tract, constriction of blood vessels in the

skeletal muscles and lungs, and decreased heart rate and contraction force. However, there are multiple exceptions to this complementary influence rule. Consider, for example, sympathetic and parasympathetic influence on salivation. Both sympathetic arousal and parasympathetic arousal increase salivary flow, although to different degrees and yielding different compositions of saliva. It also is noteworthy that the systems may exert an activating or an inhibiting effect depending on the innervated structure. For instance, increased sympathetic arousal increases heart rate but decreases motility in the digestive tract. Parasympathetic activity activates digestion, but slows heart rate.

In working together, the sympathetic and parasympathetic nervous systems typically do not function in an all-or-none fashion, but rather activate to different degrees. Depending on the affected visceral structure and situation, one of the two systems may be more active than the other. For instance, at rest heart rate is mainly under parasympathetic nervous system control, subject to a negligible sympathetic influence. By contrast, at high levels of physical activity, it is mainly under sympathetic nervous system control. Shifts in sympathetic and parasympathetic influence can occur locally within a single visceral structure (e.g., the eye) or across visceral structures. Shifts in local influence occur to meet highly specialized demands (e.g., the change in pupil size to adapt to a change in ambient light). Global shifts adapt the body to large-scale environmental changes (e.g., the appearance of a substantial physical threat).

Neurotransmitters and Receptors

In addition to differing anatomically, the sympathetic and the parasympathetic nervous systems differ with respect to their neurotransmitters and the receptors that mediate their effects on visceral structures. The most important receptors are (1) cholinergic receptors stimulated by the neurotransmitter acetylcholine and (2) adrenergic receptors stimulated by the neurotransmitters norepinephrine and epinephrine. Acetylcholine is the neurotransmitter between all pre- and postganglionic neurons as well as between parasympathetic postganglionic neurons and visceral structures. Acetylcholine is also the neurotransmitter of the sympathetic postganglionic neurons that innervate the eccrine sweat glands and of sympathetic postganglionic neurons that innervate skeletal muscle vessels and cause vasodilation. All other sympathetic postganglionic neurons release norepinephrine. The adrenal medulla constitutes an exception. Despite the fact that cells of the adrenal medulla are modified sympathetic postganglionic cells, they release epinephrine and norepinephrine directly into the blood stream. It is noteworthy that acetylcholine and norepinephrine are the major neurotransmitters of the sympathetic and the parasympathetic nervous system, but cotransmitters like vasoactive intestinal polypeptide (VIP), adenosine triphosphate (ATP), or neuropeptide Y are frequent.

Central Control

An afferent (i.e., incoming) nervous system conveys information about the current state of the organism to structures in the central nervous system. These structures exert a regulatory impact by way of autonomic efferents. Central nervous system structures that control autonomic nervous system activity vary depending on afferent information that is received. The hypothalamus plays a central role in regulating activity of the autonomic nervous system by integrating autonomic, somatic, and endocrine responses that accompany different organism states. This central nervous system structure receives afferent input from visceral sensory neurons and is subject to the modulating impact of other central nervous system structures such as the amygdala and insular cortex. It influences autonomic centers located in the brainstem and can directly affect preganglionic neurons.

Summary

The autonomic nervous system is a part of the efferent (outgoing) division of the peripheral

nervous system. It innervates glands, the heart, and smooth muscles of all visceral structures and adapts the organism to internal and external changes, maintaining bodily homeostasis and coordinating bodily responses without requiring conscious or voluntary control. Two branches or subsystems of the autonomic nervous system are the sympathetic nervous system and the parasympathetic nervous system. These commonly – but not always – work in a complementary fashion to regulate bodily function, with sympathetic arousal leading to adjustments suitable for high activity ("fight and flight") and parasympathetic arousal leading to adjustments suitable for low activity and bodily restoration ("rest and digest"). In working together, the sympathetic and parasympathetic branches do not function in an all-or-none fashion, but rather activate to different degrees. Shifts in sympathetic and parasympathetic influence can occur locally within a single visceral structure or across visceral structures, with local shifts occurring to meet highly specialized demands and global shifts adapting the body to large-scale environmental changes. The sympathetic and the parasympathetic nervous systems differ anatomically and with respect to their neurotransmitters and the receptors that mediate their effects on visceral structures. Autonomic control is maintained by structures in the central nervous system that receive visceral information by way of an afferent (incoming) nervous system. A key central nervous system structure is the hypothalamus, which integrates autonomic, somatic, and endocrine responses that accompany different organism states.

Definition

Approach and avoidance represent two fundamental organizing principles underlying human behavior. Avoidance involves movement away from threats or negative outcomes, while approach involves movement toward rewards or positive outcomes. These avoidance and approach tendencies can be expressed in cognitive, affective, and behavioral domains. In the context of behavioral medicine, avoidance has been commonly examined in the context of avoidance coping and through avoidance-based self-regulation activities. Generally speaking, avoidance coping and self-regulation are associated with poorer psychological and physical health outcomes than are approach-based activities, although there are contexts when avoidance may be relatively adaptive (e.g., in the early stages of coping with stress; when there is little that can be done to alter the stress).

Description

Introduction

Human behavior is widely believed to be regulated by an approach system that orients appetitive behavior toward potential rewards and an avoidance system that orients behavior away from potential threats and punishment. These two systems have distinct underlying neurobiological substrates, where approach behaviors characterized by heightened sensitivity to reward are organized by the behavioral activation system (BAS) and avoidance behaviors characterized by heightened sensitivity to threat are organized by the behavioral inhibition system (BIS) (Gray, 1990). Avoidance can thus be defined as a system that regulates behavior around escaping or distancing oneself away from threats or punishments. Within behavioral medicine, avoidance has been most commonly examined in the context of avoidance coping and avoidance motivation.

Avoidance Coping

Coping refers to behavioral, cognitive, and affective strategies one engages in to reduce the experience and impact of stressful events. Avoidance coping represents one of several broad dimensions of coping strategies characterized by efforts to escape or distance oneself from stressful events and associated feelings of distress. This contrasts with approach coping strategies which are characterized by efforts to engage with and directly alter the demands of the stressor. Avoidance coping strategies can take different forms. Folkman and Moskowitz (2004) distinguished between distancing strategies where one recognizes the stressor but makes efforts to put it out of mind and strategies to escape the stressor or its implications such as using alcohol or other substances. Avoidance coping shares features with emotion-focused coping strategies, which involve efforts to minimize the emotional consequences of stressful events rather than to alter the stressor directly. However, the recent coping literature suggests that emotion-focused coping strategies can include both emotion-approach and emotion-avoidance strategies.

The use of avoidance coping is likely to reflect both individual and contextual factors. Individuals who have personality traits that are linked to the behavioral inhibition system (e.g., neuroticism) have been found to be more likely to utilize avoidance coping strategies than those who have traits that are linked to the behavioral activation system (e.g., extraversion). One's personal and environmental resources also influence the likelihood of using avoidance coping strategies. Holahan and Moos (1987), for example, found that avoidance coping was more common among individuals who had fewer personal (e.g., self-efficacy beliefs; internal locus of control), economic, and social resources. Finally, avoidance coping is partially determined by the demands of the stressor. Most people utilize multiple types of coping strategies in the course of dealing with the changing demands of stressful events. Avoidance coping is more common when one is dealing with situations that cannot be actively altered. For example, Lazarus and Folkman examined the coping strategies

of students before and after an important exam. Most students utilized more active approach-based coping strategies before the exam when their efforts would be effective at enhancing achievement. After the exam, however, when students could do little more than simply wait for their results, avoidance strategies increased.

As a general rule, avoidance coping is less adaptive than approach coping, as evidenced by its associations with poorer subjective well-being, psychological adjustment, and physical health. These associations may occur for several reasons. First, avoidance coping by definition does not alter the stressful situation. Thus, to the extent that one's coping efforts may be beneficial to health by minimizing the intensity, duration, or recurrence of a stressful event, avoidance coping may be harmful because it increases exposure the health-damaging consequences of stress. Second, avoidance coping requires effort and may consume resources that are not then available for other more adaptive coping strategies. Finally, some avoidance strategies may be damaging because they involve unhealthy behaviors that have fairly direct adverse health effects. For example, escape-avoidance strategies that involve trying to minimize distress through alcohol or substance use and poor dietary practices may have direct adverse health consequences.

Although avoidance coping is generally related to poorer health outcomes, there are some exceptions when avoidance coping may not be harmful and may even be adaptive. Avoidance strategies that occur in the early stages of dealing with a stressful event appear to be adaptive (Suls & Fletcher, 1985), potentially because one needs time to develop resources and skills to manage effectively. Similarly, avoidance strategies such as distancing may be adaptive when dealing with uncontrollable stressful events such as those associated with loss and bereavement (Carver, 2006; Folkman & Moskowitz, 2004).

Avoidance Motivation, Goals, and Self-Regulation

Self-regulation models argue that human behavior is motivated by a set of hierarchically arranged goals. The highest and most abstract goals reveal self-defining principles (e.g., to be of service to others), while the lowest and most concrete goals reflect behaviors that can be taken to reach the higher level goal (e.g., donate time and money to the food bank). Although multiple goals are likely to be active simultaneously, and may even conflict with each other, behavior is organized around movement toward accomplishing salient goals. Through positive and negative feedback loops analogous to a thermostat or a homeostatic process, individuals are believed to feel distress when their movement toward goal achievement is thwarted. From this perspective, stress can be conceptualized as the disruption of one's goal pursuits.

There are individual differences in the extent to which one has a predominantly approach or avoidance motivational orientation, and these differences have important implications for motivating health behavior and health behavior change. A given health behavior can be framed as an approach goal by focusing on the positive outcomes the behavior may achieve (e.g., flossing my teeth will result in healthy gums and fresh breath) or an avoidance goal by focusing on the negative outcomes the behavior may avoid (e.g., flossing my teeth will prevent gum disease). Mann and colleagues (Mann, Sherman, & Updegraff, 2004; Sherman, Mann, & Updegraff, 2006) demonstrated that health behavior messages were more likely to motivate behavior change if the frame of the message was congruent with an individual's predominant motivation. That is, individuals with a predominant avoidance orientation were more likely to change their behavior when the message frame emphasized an avoidance goal.

Definition

Pain located between the base of the neck and the gluteal folds that can also be associated with radiating pain in the lower extremities.

Description

Back pain is one of the most prevalent and costly conditions in the industrialized world. An estimated 80% of individuals will experience back pain at some point in their life. The vast majority of back pain episodes have an unknown etiology and are self-limiting. Approximately 80–90% of cases resolve within the first 6 weeks of onset. The relatively small percentage of individuals who develop chronic back pain (symptoms lasting longer than 3 months), however, account for the majority of the disability expenditures that are associated with this condition.

Criteria used to classify back pain are numerous and, in certain instances, divergent. For example, the classification of back pain has been based on the duration and location of symptoms, the underlying spinal pathology, the presence of spinal instability, and the quality of spinal movements. Current biopsychosocial models emphasize the importance of classifying back pain based on the presence of risk factors for severe illness or prolonged disability.

A detailed history and physical exam are used to screen for the presence of *Red Flags* and *Yellow Flags* in individuals presenting with acute back pain (less than 6 weeks since the onset of symptoms). Red Flags are signs and symptoms that suggest the possibility of serious pathology, such as carcinoma, immunodeficiency, damage to the spinal cord or cauda equina, and inflammatory disorders. Red Flags are identified via the following signs and symptoms: a history of severe trauma, significant weight loss, neurological signs and symptoms, severe worsening of pain, and/or systemic illness. Emergency medical attention is required in the relatively rare incidence in which a patient with back pain presents with a Red Flag. In the absence of Red Flags, screening for Yellow Flags is indicated. Yellow Flags are psychosocial signs and symptoms that suggest an elevated risk for prolonged pain and disability. Yellow Flags include: depressed mood, belief that physical activity and pain are damaging, job dissatisfaction, and a history of back pain or work disability. The presence of Yellow Flags calls for

risk-factor-targeted interventions that aim to prevent long-term disability.

In the absence of Red or Yellow Flags, clinical practice guidelines recommend minimal treatment for acute back pain. Recommendations emphasize the importance of reassuring patients that back pain is not commonly associated with serious pathology, that back pain typically resolves in the first 6 weeks following symptom onset, and that a prompt return to regular physical activities is indicated. Simple analgesic medication, such as acetaminophen (paracetamol) or Nonsteroidal Anti-Inflammatory Drugs (NSAIDs), and a brief course of manual therapy have been shown to be effective for symptom management. Imaging investigations are not warranted in these instances.

Weight loss surgery

Definition

Bariatric surgery is a surgery for weight loss.

Since original bariatric surgery, jejunocolic bypass, was introduced in 1954, safer procedures have been developed.

Weight loss is thought to be achieved by reducing gastric volume and/or by causing intestinal malabsorption. It is also implied that changes in the entero-endocrine axis might affect body weight (Tadross & le Roux, 2009). Only bariatric surgery can produce durable long-term weight loss (Colquitt, Picot, Loveman, & Glegg, 2009).

Procedures commonly performed are as follows (Bult, van Dalen, & Muller, 2008; Jaunoo & Southall, 2010):

1. Adjustable gastric banding. This procedure involves placing a silicon band horizontally around the proximal part of stomach. The band can be inflated via a subcutaneous port and be adjusted to an extent of restriction without an operation.
2. Roux-en-Y gastric bypass. This procedure includes division of the upper stomach to the small pouch and connection of intestine to the pouch. This procedure achieves both reduction of gastric volume and malabsorption.
3. Biliopancreatic diversion (with duodenal switching). This procedure is developed as a malabsorptive procedure. Biliopancreatic duct and duodenum are removed from the tract and anastomosed to a more distal part of the ileum.

4. Sleeve gastrectomy. Though this procedure has been performed as the first stage of biliopancreatic diversion with duodenal switching in high-risk patients, it has been proved to achieve significant weight loss in some patients. If patients fail to lose weight with this procedure, the last part of biliopancreatic diversion is performed.

The mean percentage of excess weight loss was 61.2% for all patients undergoing bariatric surgery (Buchwald et al., 2004). Mortality at 30 or less days after bariatric surgery was 0.1% for purely restrictive procedure, 0.5% for gastric bypass procedures, and 1.1% for biliopancreatic diversion (Buchwald et al.).

Major complications of bariatric surgery are vomiting and leakage. Malabsorptive procedures may cause anemia and protein malnutrition.

Bariatric surgery is recommended for obese patients with a BMI over 40 kg/m^2 or with a BMI between 35 and 39.9 and a serious obesity-related health problem such as type 2 diabetes, coronary heart disease, or severe sleep apnea (National Heart Lung and Blood Institute, 2000; NICE clinical guideline 43, 2006).

Preoperative comprehensive assessments including psychosocial assessments are necessary for a risk-benefit analysis. While there are no uniform guidelines for psychosocial assessments, psychosocial assessments are usually focused on knowledge about bariatric surgery, weight and diet history, social status, and psychiatric comorbidity such as depression, eating disorders, and personality disorders (Bauchowitz et al., 2005; Wadden & Sarwer, 2006).

Contraindications to bariatric surgery include poor myocardial reserve, significant chronic obstructive airways disease or respiratory dysfunction, noncompliance with medical treatment, and psychological disorders of a significant degree (Jaunoo & Southall, 2010; Walfish, Vance, & Fabricatore, 2007).

Baroreceptors

David McIntyre
School of Sport and Exercise Sciences,
The University of Birmingham, Edgbaston,
Birmingham, UK

Definition

Baroreceptors are mechanoreceptors that contribute to the autonomic regulation of blood pressure. Baroreceptors can be divided into the arterial

baroreceptors, primarily involved in the short-term regulation of blood pressure, and the cardiopulmonary baroreceptors, which react to changes in blood volume or central venous pressure.

Arterial baroreceptors, situated in the aortic arch and carotid sinus, increase their afferent output in response to distension of the arterial wall caused by increases in blood pressure within the vessel. They are sensitive to absolute pressure and rate of change of pressure, both of which vary over the cardiac cycle. The arrival of the pulse pressure wave at the baroreceptors causes distension of the vessel wall and generates pulse synchronous afferent firing that is maximal during early systole (Eckberg & Sleight, 1992).

The afferent traffic from the arterial baroreceptors provides the primary input to the baroreflex mechanism, which maintains short-term blood pressure homeostasis primarily by regulating heart rate and peripheral resistance via parasympathetic and sympathetic pathways. Increased baroreceptor activation depresses heart rate via vagal parasympathetic motor neurons and leads to dilation of blood vessels within the musculature through decreased sympathetic outflow. Conversely, decreased activation of the arterial baroreceptors leads to increased heart rate and constriction of blood vessels within the musculature (Jordan, 1995).

Behavioral interactions with arterial baroreceptor activation and the baroreflex are well documented. For example, physiological arousal is associated with an inhibition of the baroreflex (Marshall, 1995) and increased activation of the arterial baroreceptors has been associated with a dampening of cortical and behavioral activity (Berntson & Cacioppo, 2007; Eckberg & Sleight, 1992).

Cardiopulmonary baroreceptors are mechanoreceptors situated in the walls of the heart chambers and in the large blood vessels leading to the heart. Their primary role is in the regulation of blood volume such that increases in blood volume or central venous pressure result in reflex forearm vasodilation together with increased salt and water excretion (Eckberg & Sleight, 1992). There is evidence that cardiopulmonary baroreceptors also have an interactive effect on central arterial baroreflex interneurons (Eckberg & Sleight, 1992).

Basal Metabolic Rate

Masayoshi Kumagai and Naoya Yahagi
Department of Metabolic Diseases, Graduate School of Medicine The University of Tokyo, Bunkyo-ku, Tokyo, Japan

Definition

Basal metabolic rate (BMR) is the minimum level of energy required to sustain vital functions of organs such as the heart, lungs, liver, kidneys, intestine, nervous system, sex organs, muscles, and skin. It is measured at complete rest, in

a neutrally temperate environment, in a fasting state, and measured by the heat production or oxygen consumption per unit time, and expressed as the calories released per kilogram of body weight or per square of body surface per hour. Although there are several equations to estimate BMR, it is affected by a variety of factors such as age, hormones, exercise, body temperature, nutritional status, climate, or pregnancy.

Total energy expenditure (TEE) is the amount of energy needed by a person to meet the overall physical demands, which is the sum of basal metabolic rate (BMR), dietary-induced thermogenesis, and energy consumption during activity (Ravussin, Lillioja, Anderson, Christin, & Bogardus, 1986). BMR is the largest component of TEE, accounting for about 60–80% of TEE in ordinary people (Ravussin & Bogardus, 1989). Energy consumed by muscles accounts for up to 20% of BMR, and the brain, heart, liver, and kidneys also account for a large proportion in BMR (Elia, 1992a). BMR is the concept that was born in an attempt to evaluate minimum energy required for human to survive, and the word "basal metabolism" was first described by Magnus-Levy in 1899. It represents the integration of minimal activity of all the tissues or organs in a body under a steady-state condition.

Although accurate measurements of BMR require strict conditions and equipments, approximate estimation can be acquired through an equation. There are several predictive equations for BMR. In the early twentieth century, DuBois produced an equation using "surface area law" (DuBois & DuBois, 1915). It was later superseded by Harris-Benedict equation, which is now widely used (Harris & Benedict, 1919):

$$\text{BMR for males (kcal/day)}: \\ 66.4730 + 13.7516W + 5.0033S - 6.7750A$$

$$\text{BMR for females (kcal/day)}: \\ 665.0955 + 9.5634W + 1.8496S - 4.6756A$$

(W = weight in kilograms, S = stature in centimeters, A = ages in years)

Although Harris-Benedict equation might overestimate BMR in some cases (Daly et al., 1985), it is widely used because of its simplicity and usability.

Baseline

J. Rick Turner
Cardiovascular Safety, Quintiles, Durham, NC, USA

Definition

The determination of an intervention's efficacy requires a comparison between a measure of the biological characteristic of interest (including psychological parameters) before the intervention is administered and at the end of its administration.

Data collected before its administration are called Baseline data.

Calculation of efficacy requires comparison of the Baseline and end-of-treatment data, usually presented in the form of a change score(s) of some type. If the characteristic of interest is a continuous variable, e.g., blood pressure (BP), a subject's end-of-treatment BP can be subtracted from his or her Baseline BP. In a study of an intervention to lower blood pressure, it may be seen that, overall, subjects' BPs are lower at the end of treatment than at Baseline. This reduction can be calculated in absolute terms as the mean reduction in millimeters of mercury (mmHg), e.g., 15 mmHg, or in percentage terms, e.g., 8%. Analyses can then be conducted to determine if the treatment has led to a statistically significant reduction in BP as compared with similar data collected from a control treatment group.

For other characteristics, other analyses are appropriate. For example, subjects may be rated at Baseline as mildly depressed, moderately depressed, and severely depressed based on their score(s) from an appropriate questionnaire/assessment tool. In this case, a shift analysis can be conducted to determine the numbers (and percentages) of subjects who moved category. In the case of a behavioral intervention for depression (perhaps cognitive behavioral therapy given for a certain number of weeks/sessions), it may be seen that a certain percent of the subjects "shifted" from the moderately depressed category at Baseline to the mildly depressed category at the end of the treatment period, and a different percentage shifted from the severely depressed category to the mildly depressed category.

Definition

The Beck Depression Inventory is a 21-item multiple choice self-report inventory widely used measure of the presence and degree of depression in adolescents and adults.

The most recent version is the Beck Depression Inventory®-II (BDI®-II), constructed by Aaron T. Beck and colleagues (Beck, Steer, Ball, & Ranieri, 1996). The BDI®-II can be self-administered or verbally by a trained administrator, is validated for completion by 13- to 80-year-old individuals, and is available from http://www.pearsonassessments.com/HAIWEB/Cultures/en-us/Productdetail.htm?Pid=015-8018-370&Mode=summary. It has high test-retest reliability (Pearson $r = 0.93$) (Beck, Steer, & Brown, 1996). It also has high internal consistency (Alpha 0.91) (Beck, Steer, Ball, et al., 1996).

The BDI includes both cognitive and somatic symptoms of depression, unlike the Hospital Anxiety and Depression Scale which was developed for use with somatic illness patients, and therefore excludes somatic symptoms of depression to reduce confounding. The inclusion of somatic symptoms in the BDI enables the user to identify different types of depression in individuals (Canals, Blade, Carbajo & Domenech-Llaberia, 2001).

Behavior change is the process of modifying a behavior, often to produce a desired outcome. Behavior change involves the substitution of one pattern of behavior for another.

Description

Many health conditions can be prevented or delayed if preventive actions are performed. Accordingly, national and international health agencies encourage people to engage in a range of behavioral strategies, including attending cancer screenings, being physically active, refraining from tobacco use, and using methods that protect against sexually transmitted diseases and infections (U.S. Department of Health and Human Services, 2010; World Health Organization, 2010). Moreover, behavior change is often a central component in the treatment of various health conditions, especially the management of chronic disease. For instance, dietary changes and restrictions are essential in the management of diabetes mellitus and celiac disease (American Diabetes Association, 2008; Green & Cellier, 2007). Behavior change is thus a cornerstone of preventive measures and treatments that aim to promote, protect, and restore health and well-being.

The significance of behavior change has prompted the development of several theoretical models that delineate the processes underlying behavior change and elucidate conditions that inhibit and facilitate behavior change. These models focus predominantly on individual-level factors (e.g., attitudes, perceived norms, intentions) and fall into one of two categories. Continuum-based models rely on linear combinations of specified variables to predict the likelihood of behavior (e.g., theory of planned behavior (Ajzen, 1991); social cognitive theory (Bandura, 1986)). In contrast, stage-based models assume that behavior change involves movement through a series of qualitatively distinct stages and that the factors that facilitate transitions between stages are unique (Weinstein, Rothman, & Sutton, 1998; e.g., transtheoretical model of behavior change (Prochaska & Velicer, 1997) precaution adoption process model (Weinstein, 1988)).

Behavior change is a process that unfolds over time. The behavior must first be initiated and

then, depending on the nature of the behavior, must be maintained over time (Rothman, 2000). For instance, simple preventive behaviors, such as vaccinations, typically require a single performance of the target behavior to achieve the desired health benefit. In contrast, more complex behaviors, such as physical activity or taking antiretroviral drugs, must be sustained over time in order to achieve the desired health benefit. However, extant models of behavior change have tended to focus on elucidating factors that predict the initiation of the behavior change process and given relatively less consideration to factors that predict maintenance of the target behavior. Indeed, most models of behavior change fail to distinguish between initiation and maintenance phases of the behavior change process.

Initiation and maintenance of behavior have been conceptualized as distinct phases in the behavior change process, and distinct factors are thought to influence the behavioral decisions that are made during initiation and maintenance (Rothman, 2000). The distinction between the initiation and maintenance of behavior has been further refined into a four-phase process model (Rothman, Baldwin, Hertel, & Fuglestad, 2011). Each phase is qualitatively distinct, and transition between stages is determined by a distinct set of decision criteria. The initial response phase encompasses the initial effort put forth by an individual seeking to make a behavioral change. For instance, a person may decide to become physically active and begin attending exercise classes. If one has strong efficacy beliefs and positive expectations about the outcomes associated with the target behavior, the target behavior is likely to be enacted reliably. Consistent performance of the target behavior demarcates the beginning of the continued response phase, in which one continues to expend effort in order to establish the target behavior. During this phase, the individual struggles to remain motivated to engage in the behavior and to manage the conflict between continuing to enact the new behavior and the challenges and unpleasantness associated with the new behavior. For example, a person who has recently started an exercise program may struggle to continue attending exercise classes after encountering barriers, such as sore joints or financial constraints.

The realization of initial rewards, sustained self-efficacy beliefs, sustained outcome expectations, and the ability to overcome obstacles facilitate movement from the continued response phase to the maintenance phase. During the maintenance phase, individuals no longer struggle to engage in the behavior; however, enactment of the behavior still requires effort. Individuals also remain sensitive to the costs and benefits associated with the behavior and are particularly attuned to the value of achieved outcomes (Rothman et al., 2011). Thus, someone who has been exercising regularly may be conscious of the physiological changes that have resulted from exercising and will compare the benefits of these outcomes to the costs of exercising. Satisfaction with the outcomes of the new pattern of behavior becomes a key determinant of maintenance. If the perceived costs of the behavior exceed the perceived benefits of the outcomes, then the behavior will be discontinued. Finally, the transition from maintenance to the habit phase, in which the behavioral pattern becomes self-perpetuating and automatic, occurs when people cease to regularly assess the perceived value of the behavior and its associated outcomes.

Models of behavior change are particularly useful in that they permit the identification of precise constructs to target when seeking to change behavior. Thus, theoretical models guide the design and implementation of interventions that promote behavior change (Michie & Prestwich, 2010). By identifying candidate targets for interventions, theoretical models also provide insight into the relative effectiveness of intervention strategies because intervention strategies are differentially suited to target particular constructs. For instance, a theoretical model may suggest that skill acquisition is a chief antecedent of behavior change and, thus, identifies skill development as a central goal of an intervention.

Models of health behavior change that focus on individual-level factors (e.g., attitudes, perceived norms, intentions) guide the design of

interventions that seek to change how people think and feel about particular behaviors. However, some models adopt an ecological perspective and focus on the structural and environmental factors that promote and inhibit behavior change (e.g., Stokols, 1992). These types of models are useful in guiding the development of structural interventions, such as policy changes. Several attempts have been made to integrate individual-level and ecological models (e.g., Kremers, 2010). Such integrative frameworks are useful in designing multilevel interventions because they suggest how specific combinations of individual-level (e.g., attitudes, perceived norms, intentions) and structural-level factors (e.g., laws, access to resources) interact.

When thinking about behavior change, it is also important to consider how the many properties of the behavior itself may influence the change process. For example, behavior change may involve the adoption or cessation of a behavior. Adoption requires the performance of a new behavior, such as beginning a new exercise routine (e.g., going to the gym three times a week), whereas cessation involves discontinuing a behavior, such as quitting smoking. Some behavior change may involve concurrent adoption and cessation behaviors. For instance, changing one's eating behavior can involve beginning to eat vegetables with dinner and ceasing to eat fried foods at dinner. The nature of the target behavior offers insight into the theoretical model that is best suited to guide behavior change. For instance, operant conditioning theory distinguishes between reinforcement and punishment (Skinner, 1938). Reinforcement involves the use of strategies that increase the frequency of the target behavior. In contrast, punishment involves the use of strategies that decrease the frequency of the target behavior. Accordingly, reinforcement-based models might be best suited for thinking about how to promote adoption behaviors, whereas punishment-based models might be best suited for thinking about how to promote cessation behaviors.

It is also important to recall that there are particular challenges associated with changes in specific behavioral domains. Simple preventive behaviors, such as getting a vaccine, require that the behavior in question be enacted once, or very infrequently, to achieve the desired outcome. Conversely, complex preventive health behaviors, such as exercising regularly, require that a behavior be enacted repeatedly before the desired outcome is obtained. Moving toward the maintenance and habit phases of the behavior change process is thus particularly important for complex preventive health behaviors.

In conclusion, behavior change is an important process in the prevention and treatment of illness. Several theoretical models have been developed to elucidate the processes involved in behavior change. Many prominent models focus on predictors of behavior change at the individual level; however, it is important to also consider environmental and structural influences on behavior change. Although many theoretical models fail to distinguish between the initiation and maintenance of behavior, these phases are qualitatively distinct and are driven by distinct factors. Theoretical models are essential in the development of effective behavior change interventions. The properties of the target behavior can also have implications for the intervention strategy that is adopted.

Behavior Change Techniques

Definition

A behavior change technique (BCT) is a systematic procedure included as an active component of an intervention designed to change behavior.

The defining characteristics of a BCT (Michie, Abraham et al., 2011) are that it is:

- Observable
- Replicable
- Irreducible
- A component of an intervention designed to change behavior
- A postulated active ingredient within the intervention

In this context, a definition of behavior, agreed across disciplines of psychology, sociology, anthropology, and economics, is "anything a person does in response to internal or external events. Actions may be overt (motor or verbal) and directly measurable, or covert (activities not viewable e.g., physiological responses) and indirectly measurable; behaviours are physical events that occur in the body and are controlled by the brain" (Hobbs, Campbell, Hildon, & Michie, 2011). This was arrived at via a Delphi exercise of 14 members of a multidisciplinary advisory group, starting with a shortlist of definitions of behavior compiled through library catalogue searching and using key reference sources such as the *American Psychological Association Dictionary* and the *Oxford Concise Dictionary of Sociology*. The definition was synthesized from constructs that were included in at least 50% of the definitions reaching an agreed threshold of perceived usefulness.

A BCT is thus the smallest component compatible with retaining the postulated active ingredients, that is, the proposed mechanisms of change, and can be used alone or in combination with other BCTs. A BCT should be well specified so that effectiveness of the BCT can be evaluated (e.g., in randomized controlled trials, in factorial experimental designs (Collins et al., 2011), or N-of-1 studies). However, the evidence base for effectiveness may or may not have been established. Examples of BCTs are as follows: "Prompts/cues," "Information about health consequences," "Incentive," "Goal setting," "Self-monitoring," "Action planning," "Behavioral rehearsal/practice," "Graded tasks," "Social support/encouragement," "Persuasive communication," and "Habit formation."

BCTs specify the minimum content of *what* must be delivered, that is, minimum content that would allow identification of that technique (e.g., feedback must involve providing the target audience with information about their specific behavior). A BCT does not specify the *how*, that is, the mode of delivery, and it is possible for a given BCT to be delivered in many different ways. For example, feedback may be delivered by letter or face to face, to groups or to an individual, on one occasion or frequently, by a therapist or by an automatic electronic message.

Description

Behavior change interventions include one or more BCTs. Some well-recognized behavior change interventions contain reliable combinations of BCTs, for example, relapse prevention includes both *problem solving* and *action planning*, whereas more general labels may contain variable combinations of BCTs, for example, the contents of "cognitive behavior therapy" are very variable (Gatchel, Peng, Peters, Fuchs, & Turk, 2007). For full specification of a behavior change intervention, both the active content, that is, the BCTs, and the mode of delivery need to be described (Davidson et al., 2003).

Behavior change interventions may influence behavior in several ways: behavior can be initiated or terminated, or increased or decreased in frequency, duration, or intensity. For most behaviors, there is variation between people and within individuals over time in all of these dimensions, influenced by environmental, social, cognitive, and emotional variables. Studies of how behavior varies within and between people have led to an understanding of how to use external factors to modify behavior. Technologies of behavior change have been developed within disciplines of applied psychology (e.g., clinical, educational) and adopted and extended in a wide variety of intervention functions and policies, such as commercial advertising and social marketing (Michie, van Stralen, & West, 2011). These technologies are made up of individual BCTs.

Why Are Behavior Change Techniques Important?

The importance of behavior change in improving health is illustrated by the increasing evidence that behavior influences health outcomes, and increasing investment by funding governments and scientific bodies in the development and evaluation of interventions to change population, patient, and practitioner behaviors. An example is the US National Institutes of Health's Office of Behavioral and Social Sciences Research (OBSSR) which was founded in 1995 with a budget of $27 million a year, in recognition of the key role that behavioral and social factors often play in illness and health.

Interventions to change behavior are typically complex, involving many interacting components (Craig et al., 2008). BCTs are the active ingredients of these interventions but are often poorly described in research protocols and published reports (Michie, Fixsen, Grimshaw, & Eccles, 2009). Components may be described in terms that are vague, general, and/or ambiguous and with labels, for example, "behavioral counseling," that can mean different things to different researchers or practitioners, thus acting as a barrier to replication, the essential cornerstone for scientific progress. In contrast, biomedical interventions are precisely specified (e.g., the pharmacological "ingredients" of prescribed drugs, their dose, and frequency of administration).

This lack of precision and lack of consensually agreed terms lead to problems in replication in primary research, in evidence synthesis in systematic reviews, and in implementation in practical applications. It also undermines the task of establishing those that are effective in changing behavior and understanding the causal mechanisms underlying behavior change. If intervention descriptions are idiosyncratic or ambiguous, and cannot therefore be interpreted reliably, it is impossible to aggregate the evidence to ascertain their effectiveness. Additionally, there is no value in evaluating an intervention if one cannot accurately identify and describe what is being evaluated and how competently it was delivered; it

would be impossible to implement if shown to be effective. The absence of an internationally agreed method to specify and report the content of behavior change interventions hampers the development of effective interventions.

Although the CONSORT statement for randomized trials of "nonpharmacologic" interventions calls for precise details of interventions in research, including a description of the different intervention components (Boutron, Moher, Altman, Schulz, & Ravaud, 2008), it gives no guidance as to what details. The UK Medical Research Council's guidance (Craig et al., 2008) for developing and evaluating complex interventions acknowledges this problem and also the problem of lack of consistency and consensus in use of terminology (Michie, Johnston, Francis, Hardeman, & Eccles, 2008).

The Development of a Method of Specifying BCTs

These problems have been addressed by the development of systematically generated and applied collections or "taxonomies" of BCTs. These have been constructed by identifying BCTs within written reports of the interventions, or texts describing interventions, in a bottom-up, inductive fashion and, to date, their hierarchical structures have not been established. They have been developed in relation to different behavior types: physical activity and healthy eating (Abraham & Michie, 2008; Michie, Ashford et al., 2011), smoking (Michie, Hyder, Walia, & West, 2011; West, Evans, & Michie, 2011), excessive alcohol use (Michie et al., 2012), and condom use (Abraham, Good, Warren, Huedo-Medina, & Johnson, 2011).

Using such taxonomies with standardized labels and definitions will improve current practice by ensuring that, when the taxonomy is used, a technique is always described by the same label and that a label is always used for the same technique. In current practice, the same component techniques within behavioral interventions may be described in protocols and published reports with different labels (e.g., "self-monitoring" may be labeled "daily diaries"). Conversely, the same labels may be applied to different techniques (e.g., "behavioral counseling" may involve "educating patients" or "feedback, self-monitoring, and reinforcement."

Specifying interventions by BCTs allows multivariate statistical analysis to identify specific BCTs associated with effective interventions, the "active ingredients." Heterogeneous, complex interventions have been synthesized to identify effective component BCTs in systematic reviews using the statistical technique of meta-regression. This has been conducted for physical activity and healthy eating (Dombrowski et al., 2012; Michie, Abraham, Whittington, McAteer, & Gupta, 2009), alcohol (Michie et al., 2012), smoking cessation (West et al., 2010), and HIV prevention behaviors (Albaraccin et al., 2005; de Bruin, Viechtbauer, Hospers, Schaalma, & Kok, 2009; Good, Warren, Huedo-Medina, Abraham, & Johnson, 2011). "Active ingredients" have also been identified in the English Stop Smoking Services by analyzing protocols for behavioral support for smoking cessation in terms of BCTs and investigating associations with a national database of carbon monoxide verified quit rates (West, Walia, Hyder, Shahab, & Michie, 2010).

Since the first taxonomy with demonstrated reliability was published in 2008 (Abraham & Michie, 2008), this method has been widely used internationally, for example, to specify interventions (Araujo-Soares, McIntyre, MacLennan, & Sniehotta, 2009), synthesize evidence (see above), and design interventions (McKenzie et al., 2008). However, further development is necessary for maximal usefulness. The number of BCTs included, the BCTs relevant for changing a wider range of behaviors, the precise and unambiguous specification of each BCT, the acceptability and feasibility of using the methods, as well as the need for a structure that goes beyond a list to develop a true taxonomy are required. Therefore, this work is being taken forward using consensus methods on an international basis (Michie, Abraham et al., 2011).

In addition to specifying the BCTs, it will be important to develop shared methods of reporting on both the methods of delivery (Gatchel et al., 2007) and the competence with which they are delivered. Frameworks for the specification of professional competences for the delivery of

BCTs are being developed and have been used to advise national governments (Dixon & Johnston, 2010) and as a basis for a national training program (NHS Centre for Smoking Cessation and Training (NCSCT), 2011).

The Benefits of the BCT Approach

1. *Developing behavior change interventions*: Intervention developers will be able to use a comprehensive list of BCTs (rather than relying on the limited set they are aware of) to design interventions and will be able to report the intervention content in well-defined and detailed ways.
2. *Reporting interventions*: Specifying intervention content by BCT will facilitate the accurate, replicable description of behavior change interventions. Both intervention and control conditions can be specified using BCTs in randomized controlled trials.
3. *Implementing effective interventions in practice*: BCT specification will facilitate faithful implementation of interventions found to be effective.
4. *Replicating interventions and control conditions*: Specifying interventions by BCTs will help the replication of both intervention and control conditions.
5. *Synthesizing evidence*: Systematic reviewers will be able to use a reliable method for extracting information about intervention content, thus identifying and synthesizing discrete, replicable, potentially active ingredients associated with effectiveness.
6. *Linking to theory*: Linking BCTs with theories of behavior change allows reviewers to investigate possible mechanisms of action (Michie et al., 2009; Dombrowski et al., 2012).
7. *Accumulating scientific knowledge about behavior change*: A shared terminology for specifying behavior change interventions allows the more efficient accumulation of knowledge and investigations of generalization across behaviors, populations, and settings.

Advancing the Science of Behavior Change

A well-developed system of defining and labeling BCTs would allow the science of behavior change to accumulate evidence and advance theory of behavior change. The BCT approach is already providing a method for doing this. Early versions of BCT taxonomies have allowed reviewers to synthesize heterogeneous interventions to identify effective component BCTs. Evaluation of the effectiveness of combinations of BCTs can help test theories of behavior change. So, for example, the finding that interventions with a combination of self-monitoring and feedback were effective supports the mechanisms of change proposed by Carver and Scheier's Control Theory (Carver & Scheier, 1982). Further evidence is needed to develop theory. If we are to better understand both the effects and processes of behavior change interventions, we need to develop a method to link BCTs to mechanisms of action.

For these methods to maximize scientific advance, a shared system for describing behavior change interventions is necessary, and this will require collaborative work to develop agreed labels and definitions and reliable procedures for their application across disciplines and countries. Even the "best" taxonomy is inevitably a work-in-progress as new BCTs are likely to continue to emerge from ongoing research and practice, in the same way that the labeling of peptides and botanical taxonomies continue to be developed.

Definition

Behavior modification is to change behavior by techniques to improve behavior, such as altering behavior and reaction to stimuli through positive and negative reinforcement of adaptive behavior and/or the reduction of maladaptive behavior through positive and negative punishment. The techniques used in behavior modification are based on principle of learning.

Description

Behavior modification and behavior therapy have been used almost interchangeably in literature, although they have some very minor differences. Some people think behavior modification to be a part of behavior therapy; other people think that behavior modification contains behavior therapy. In addition, some people use term behavior therapy only in the context of the medical field.

The term behavior modification was created earlier than behavior therapy because the first use of the term behavior modification appears to have been by Edward Thorndike in 1911, and afterward, Skinner, B.F., continued to use the term behavior therapy. The principles to change behavior in the behavior modification or behavior therapy will be introduced. In the treatment of mental disorders, please refer to the page on behavior therapy.

The Representative Theory and Technique of the Behavior Therapy/ Behavior Modification

Applied Action Analytical Model

Skinner, B. F., paid attention to the action of an individual and its relationship to the environment, and he came up with operant conditioning. He proved through experiments that frequency of behavior freely changes by operating on its environment. Behavior analysis chooses a target behavior to become the object of the treatment and clarifies contingency as a result of this method. In behavior analysis, they investigate mutual relations of antecedent, behavior, and consequence and inspect the hypothesis on the causes which results to the target behavior. Reinforcement plays a key role for intervention, and it is called by techniques such as shaping or token economy. Refer to a page on operant conditioning for more details.

Neobehavioristic Mediational S–R Theory

This is a theory based on drive reduction theory proposed by Hull, C.L. In this theory, it is explained that the motivated behavior is roused by a drive, and the desire is the intervening variable, and the behavior that these drive and desire satisfies and reduced is reinforced. For Skinner, B.F. who aimed at predicting and controlling behavior (a dependent variable) only in an environmental condition (an independent variable), this model considers drive to be any factors in the living body (a parameter). With this model, Eysenk, H.J., and Wolpe, J., produced cures for neurotic behavior that focuses on fear as the drive among these neurotic behaviors. Systematic desensitization method or flooding is nominated for representative technique.

Social Learning Theory Model

This is the model that was proposed by Bandura, A. Observational learning plays a key role in social

learning, and the person takes action not only in reaction to the stimulation from the outside world but also by mediation of cognition. He raised external reinforcement, expectation, and self-efficacy as factors of behavior modification. Modeling and self-control are representative techniques.

Cognitive-Behavioral Therapy Model

This is a model I consider when I regard cognition as important as an intervening factor in modifying actions because cognition always influences behavior. A change of the cognition is indispensable since this is the goal of behavior change and treatment. Cognitive restructuring and self-instructional training are representative techniques.

Definition

"Behavioral immunology" refers to the branch of behavioral medicine concerned with bidirectional interactions between behavior and the immune system.

Description

The field of psychoneuroimmunology is providing growing evidence that psychosocial factors can influence immunity and health through both direct and indirect routes, including behavioral modifiers.

The brain is considered an "immuno-privileged" organ, protected from normal inflammatory processes by the blood–brain barrier, a network of endothelial cells that form tight junctions with brain capillaries and prevent the entry of blood-borne substances to the brain. There are, however, a number of pathways of communication between the distributed elements of the immune system and the central nervous system that provide potential mechanisms of interaction.

Cytokines, chemical messengers used by the immune system, are able to signal to the brain. It has been shown that following infection by a pathogen (e.g., virus or bacteria) macrophages (a type of white blood cell) release the cytokine interleukin-1 (IL-1) into the bloodstream. Circulating IL-1 is known to induce alterations in brain activity and changes in the metabolism of central brain chemicals and neurotransmitters such as norepinephrine, serotonin, and dopamine in discrete brain areas.

Cytokines are large molecules and as such are not able to cross the blood–brain barrier. However IL-1, and possibly other cytokines too, are able to communicate with the brain via peripheral nerves such as the vagus nerve. The vagus nerve is a branch of the autonomic nervous system with both afferent and efferent fibers and is ideally situated to convey immune information. The peripheral IL-1 signal is transduced into neuronal information, which is transmitted to the brain by the vagus nerve. This signal is then retransduced into chemical information in the form of IL-1 synthesized centrally in the brain itself (Evans, Hucklebridge, & Clow, 2000).

In addition to neuronal transduction via the vagus nerve, immune information can be sent by afferent nerve fibers from the lymphoid organs themselves. These fibers have receptors for cytokines and other similar molecules produced by immune cells.

Once an immune signal is interpreted by the brain, it is able to influence monoamine activity. Monoamines (noradrenaline, serotonin, and dopamine) are neurotransmitters that operate in those parts of the brain involved in the regulation of mood, reward, appetite, sleep, and reproduction. A single administration of inflammatory cytokines induces changes in monoamine activity in a manner similar to changes induced by stress. There are therefore multiple potential mechanisms of connectivity between the brain and immune system.

Accordingly, the brain is capable of influencing immune processes. Long before the mechanisms of interaction between the brain and immune system were known, it was discovered that the immune system of rats could be trained by classical Pavlovian conditioning to respond to a neutral stimulus previously paired with a stimulus with direct immune-modulatory properties (Ader & Cohen, 1975 in Evans et al., 2000). Humans have since been shown to respond in the same way.

The effects of conditioning are varied, so it is likely that a number of mechanisms are involved. Some evidence suggests that T cells may play an important role in conditioning of the immune system. Other research has suggested that conditioning of the immune system requires the involvement of opioid-mediated circuits within the central nervous system. However, the exact mechanism is yet to be elucidated.

The field of behavioral immunology is also concerned with the effect of volitional behavior, such as sleep, physical activity, nutrition, and substance abuse on the workings of the immune system. Smoking, alcohol use, and cocaine have all been shown to affect the immune system.

Smoking cigarettes has effects on the immune system which may be direct, or may occur via

endocrine-mediated mechanisms. Nicotine is reported to affect both humoral and cellular immunity. Compared to nonsmokers, adult smokers have higher white blood cell counts and lower natural killer (NK) cell activity (Irwin & Cole in Vedhara & Irwin, 2007).

Alcohol use is also known to suppress immune system functioning and may act directly or indirectly via gonadal steroid hormones (Penedo & Dahn in Vedhara & Irwin, 2007). Further, alcohol use in the context of clinical depression acts in a synergistic manner to suppress the immune system; while alcohol and depression each have a suppressant effect on the immune system, the interaction of alcohol substance abuse and affective disorders may result in significantly greater immune impairment than either condition alone.

Cocaine is thought to negatively alter the responsiveness of the immune system via its effects on the functioning of NK cells, T cells, neutrophils, and macrophages, and by dysregulating the production of cytokines.

In diseases of the immune system, such as HIV, health behaviors that can directly influence immune functioning, such as substance abuse and adherence to medication regimes, have serious clinical implications (Pereira & Penedo in Vedhara & Irwin, 2007). Among HIV+ individuals cigarette smoking increases the risk of developing opportunistic respiratory infections, oropharyngeal candidiasis, and cervical and anal neoplasia. Alcohol consumption is associated with impaired immune and viral responses to antiretroviral treatment among HIV+ individuals, while cocaine use has been linked to impaired immune functioning, enhanced HIV infectivity, and replication.

Physical exercise has also been shown to influence immune parameters in a variety of populations; however the majority of studies researching this topic have been conducted with HIV+ individuals. These have shown positive effects of physical exercise on CD4 and CD8 cell number, NK cell number, NK cell count, and better immunological control of latent viruses (e.g., herpes). In healthy older adults, increased physical activity is associated with higher in vitro measures of immune functioning. However studies in this area have been flawed by small sample sizes, short follow-up periods, limited number of immune parameters, and uncontrolled confounding variables such as uncertainty regarding adherence to the exercise program.

Lack of sleep is another behavioral factor thought to be important for immune functioning. It has been suggested that loss of sleep, or disordered sleep, adversely affect resistance to infection, increases cancer risk, alters inflammatory disease progression, and reduces NK cell counts. Normal sleep is associated with redistribution of circulating lymphocyte subsets, increase of NK cell activity, increases in certain cytokines, and a relative shift toward Th1 cytokine expression. It has even been suggested that disordered sleep, a symptom of clinical depression, may be a crucial behavioral factor that mediates the relationship between depression and alterations in immune system functioning.

The relationship between sleep and immune functioning is a bidirectional one; animal studies have shown cytokines to have both sleep-promoting and inhibitory effects on sleep depending on the cytokine in question, plasma levels, and circadian phase. Less is known about the interaction between sleep and cytokines in humans. Human studies are necessarily limited by a lack of means to measure cytokine levels in the brain as systemic levels of cytokines may not be an accurate reflection of brain cytokine activity. However these basic findings have informed theories on the role of the cytokines in clinical contexts, including the inflammation theory of depression and daytime fatigue in conditions such as chronic fatigue and cancer.

In some clinical conditions, such as cancer or hepatitis C, large doses of cytokines are given therapeutically. Treatment such as this is often associated with depressed mood, anhedonia, fatigue, poor concentration, and disordered sleep. In the absence of disease, administration of inflammatory cytokines leads to depressed mood, increased somatic concern, cognitive impairment, and difficulties with flexible thinking. The effects are similar following physiological activation of the body's own cytokines; the experimental administration of bacterial

endotoxin results in activation of pro-inflammatory cytokines which leads to depressed mood, anxiety, and impaired performance on verbal and nonverbal memory functions.

Findings from experimental situations such as these can be extended to clinical contexts in which levels of pro-inflammatory cytokines are increased as the consequence of invasion by a pathogen. Replication of invading pathogens triggers a stereotypical immune response which is coordinated by inflammatory cytokines. Cytokines direct white blood cells to the site of infection, induce them to proliferate, differentiate, and activate mechanisms involved in pathogen destruction. The crucial cytokines to this process are IL-1b, IL-6, and tumor necrosis factor-a. Elimination of invading pathogens in this way results in a characteristic set of symptoms that are experienced as clinical illness. In addition to disease-specific symptoms that are dependent on the nature of the pathogen, infections are also associated with a host of nonspecific symptoms including fever, malaise, increased sleep, anorexia, anhedonia, reduced reproductive behavior, and social withdrawal. This coordinated behavioral response to infection has been termed "sickness behavior". The result of interactions between cytokines and the central nervous system, sickness behavior is considered an evolutionary strategy to maximize chances of survival after infection, and represents an attempt to conserve energy by limiting functions not essential to fighting the infection. Sickness behavior is coordinated by the brain with the cytokine IL-1 being the key molecule signaling between macrophages and the brain (Evans et al., 2000).

Behavioral Inhibition

Definition

Behavioral inhibition can be generally defined as an individual's ability to inhibit a desired behavior, or prepotent response. It belongs to a subset of "executive functions" which are the top-down self-regulatory functions that allow us to consciously control our actions afforded by the frontal cortex (Fuster, 1997).

Behavioral inhibition can be divided into three interrelated processes: (a) inhibition of an initial prepotent response to an event; (b) cessation of an ongoing response, which allows a delay in the decision to respond; and (c) the protection of this period of delay and the self-directed responses that occur within it from disruption by competing events and responses (interference control). Behavioral inhibition also involves overriding or inhibiting competing urges, and delaying gratification (Barkley, 1997; Muraven & Baumeister, 2000; Shallice & Burgess, 1993).

Characteristics

Refraining from performing an immediate desire often requires more effort than taking action, (for example, it is more difficult for a smoker to refrain from smoking, than to gratify their desire

to smoke) and involves more than just passive inaction. There are many situations where an individual may be required to use inhibition, where something is desired but not the right thing to do. Circumstances that involve temporal delays (i.e., delay of gratification), conflicts in temporally related consequences, or where there is a need to generate a novel response may rely heavily on behavioral inhibition. Consequently, inhibition is particularly relevant for addictive or impulsive behaviors for example drug use, smoking, or gambling, and health behaviors such as making healthy versus unhealthy food choices, exercising, etc. The Temporal Self-regulation Theory (Hall & Fong, 2007) is a relatively recent theory of behavior that includes behavioral inhibition and self-regulation as additional determinants of behavior. The theory predicts that the likelihood of performing a behavior is a function of both an individual's self-regulatory capacity (including behavioral inhibition), and the presence or absence of cues to that behavior in the environment.

Problems with behavioral inhibition are typically seen in children, individuals with attention deficit hyperactivity disorder (ADHD), or patients with frontal lobe damage/disorders (Barkley, 1997; Shallice & Burgess, 1991). Common symptoms of disinhibition in these groups of people include: acting out on impulses or desires, a strong inclination to seek immediate reinforcement or gratification, and difficulty inhibiting an action once it has begun. In normal children, behavioral inhibition (as well as other executive functions) improves with age, which coincides with the development and maturation of the frontal cortex (Russell, 1948).

Behavioral inhibition or self-control can be thought of as one of a subset of controlled or effortful cognitive processes (Hasher & Zacks, 1979). This is because the individual or self exerts control over its own responses rather than allowing them to proceed in their normal or automatic fashion (Muraven & Baumeister, 2000). In contrast, most behaviors occur automatically and do not require active participation or need the self to override the natural response and implement a different one (Bargh, 1994). The benefit of having automatic behaviors is that they are performed more efficiently; however, the disadvantage is that they are more rigid and difficult to change. Although controlled processes require more effort and resources, they are much more flexible.

Assessment of Behavioral Inhibition

Behavioral inhibition is assessed by performance on cognitive and behavioral tasks that require withholding of responding, delayed responding, cessation of ongoing responses, and resisting distraction or disruption by competing events. These include the Stroop color-word interference task, where the participant must override the prepotent response to read the word instead of say the color; and the stop-signal task where the participant is required to stop a just-begun or well-along-the-way motor response, and the delay of gratification paradigm where participants have a choice of a smaller immediate reward or a later, larger reward.

Behavioral Medicine

Definition

Behavioral medicine is an interdisciplinary field concerned with the development and integration of sociocultural, psychosocial, behavioral, and biomedical knowledge and techniques relevant to the understanding of health and illness and the application of this knowledge and these techniques to disease prevention, health promotion, etiology, diagnosis, treatment, and rehabilitation. The original definition of the field of behavioral medicine was developed at the Yale Conference on Behavioral Medicine and later published by Gary Schwartz and Stephen Weiss (1977). Since that time, there have been various refinements to the definition as reflected in the preceding definition.

Neal Miller (1909–2002), an American psychologist and recipient of the National Medal of Science (1964), is often credited as being the founder of behavioral medicine. He made significant contributions to our understanding of the relationship between reinforcement mechanisms and the control of autonomic behavior, and in pioneering the field of biofeedback, which is used successfully today to treat a variety of medical conditions.

Description

One of the earliest articles discussing issues that now fall within the discipline of behavioral medicine was published in 1956 in the *Journal of Medical Education*, and entitled "Premedical school education in the social and behavioral sciences" (Lidz & Pilot, 1956). The first book title to include the term was published in 1973 (Birk, 1973). The *Journal of Behavioral Medicine* was first published by Plenum in 1978 and is now published by Springer. A Medline search of the term behavioral medicine found over 27,000 references, clear evidence that the growth in this field has been enormous.

The discipline's first professional organization, the Society of Behavioral Medicine (SBM), was founded in 1979 and headquartered in the United States. In the following years, similar professional organizations were founded in Europe and Asia. The late 1980s saw the birth of the International Society of Behavioral Medicine (ISBM), which initially linked together six member societies. These organizations have grown substantially over the past two decades. The ISBM reports over 25 affiliated member societies, including those in Australia, Brazil, Chile, China, Denmark, Finland, Germany, Hungary,

Italy, Japan, Mexico, the Netherlands, Norway, Romania, Slovakia, South Africa, South Korea, Spain, Sweden, Thailand, the United Kingdom, and Venezuela. Additional societies are continuously being formed and joining the ISBM federation.

The SBM holds annual meetings, and the ISBM holds meetings every 2 years (the planning is considerably more complex given the very diverse membership and the international locations). The active participation by members in these meetings is reflected in the excellent attendance statistics. Approximately 1,300 attendees participate in the annual SBM meetings, with approximately 1,000 attendees participating in the ISBM's biannual International Congress of Behavioral Medicine. The first International Congress was held in Uppsala, Sweden, in 1990. Subsequent meetings have been held in Hamburg, Germany (1992); Amsterdam, the Netherlands (1994); Washington DC, USA (1996); Copenhagen, Denmark (1998); Brisbane, Australia (2000); Helsinki, Finland (2002); Mainz, Germany (2004); Bangkok, Thailand (2006); Tokyo, Japan (2008); and Washington DC, USA (2010).The 2012 meeting will be held in Budapest, Hungary.

Further evidence of the growth of the discipline of behavioral medicine is provided by the fact that training in this field can be found in universities around the world, ensuring that the next generation of researchers and practitioners will be trained by current experts. Before going on to specialize in behavioral medicine research or clinical practice, individuals often receive their terminal degrees in disciplines such as medicine, public health, nursing, and psychology.

In 2004, the Institute of Medicine's Committee on Behavioral and Social Sciences in Medical School Curricula (Institute of Medicine Report, 2004) issued the report "Improving Medical Education: Enhancing the Behavioral and Social Sciences Content of Medical School Curricula." This report identified six major domains of knowledge that should be represented in undergraduate medical education. They include: (1) mind-body interactions in health and disease, (2) patient behavior, (3) physician role and behavior, (4) physician-patient interactions, (5) social and cultural issues in health care, and (6) health policy and economics.

The Liaison Committee on Medical Education (LCME), the nationally recognized accrediting authority for medical education programs leading to the M.D. degree in United States and Canadian medical schools, now requires that the curriculum of a medical education program must include behavioral and socioeconomic topics in addition to basic science and clinical disciplines. Furthermore, the medical education program must demonstrate its ability to provide students with an understanding of the manner in which people of diverse cultures and belief systems perceive health and illness and respond to various symptoms, diseases, and treatments.

This diversity is a tremendous strength in this interdisciplinary field.

Basic Information

Behavioral science is an integral part of the United States (US) Centers for Disease Control and Prevention (CDC), an agency under the Department of Health and Human Services, which is the lead public health organization for the United States. The Communicable Disease Center, as it was first known, was a unit of the Public Health Service founded in Atlanta, Georgia, on July 1, 1946 (Centers for Disease Control and Prevention [CDC], 1996). Its mission was to fight communicable diseases, in particular malaria. The mandate to eradicate malaria by eliminating mosquitoes stemmed from the Malaria Control in Wartime Areas agency during the Second World War, and thus the agency originally employed more engineers and entomologists than public health doctors (Centers for Disease Control and Prevention [CDC], 2011a). The agency mission eventually grew beyond communicable diseases to include the prevention of disease, injury, and disability, promotion of good health, and preparation for new public health threats. As a result, the name was changed in 1970 to the Centers for Disease Control, with the words "and Prevention" added in 1992 (CDC, 1996).

Today the agency is responsible for public health planning, research, and prevention of infectious and chronic diseases, occupational health, health statistics, and the health component of national emergencies, from hurricanes to natural outbreaks to bioterrorism. CDC is comprised of the Center for Global Health, National Institute for Occupational Safety and Health, and 10 different offices (Centers for Disease Control and Prevention [CDC], 2011b). Within each office, there are national centers, divisions, branches, and programs, for example, the Office of Infectious Diseases houses the National Center for Emerging and Zoonotic Infectious Diseases, to which the Division of High-Consequence Pathogens and Pathology, and Chronic Viral Disease Branch belongs (CDC, 2011b). While both CDC and the US National Institutes of Health (NIH) fall under the U.S. Department of Health and Human Services, CDC engages in disease investigation and epidemiology, public health service – such as diagnostic reference services and compilation of reportable disease statistics – and applied prevention and response, as compared to the medical research agency objectives of the NIH. While CDC does provide extramural funding to health departments and service organizations, and some research funding to universities and other organizations, CDC extramural funding is markedly lower than that provided via NIH.

Behavioral scientists at the CDC work in a variety of public health areas such as health communication, HIV, autism, injury, chronic and infectious diseases, and birth defects (Centers for Disease Control and Prevention [CDC], 2006). Although the behavioral sciences were not formally incorporated at the CDC until the 1980s, this branch of science has become increasingly important to control and prevent both chronic and infectious diseases (CDC, 2006). In 1995, social and behavioral scientists at the CDC established the Behavioral and Social Sciences Working Group (BSSWG) to bring awareness to the fields in which the behavioral sciences contribute (CDC, 2006). Today, the group has approximately 700 members with oversight by the Office of the Associate Director for Science (CDC, 2006).

Behavioral scientists bring with them the research methods from psychology, sociology,

anthropology, and communications, which allow scientists to look at the intersecting impact of the environment, culture, and sociodemographic factors on public health problems. As noted in a 2006 article in CDC's Morbidity and Mortality Weekly Report, behavioral scientists use "qualitative, quantitative, or multiple methods to explore the effects of behavioral, social, and cultural factors on public health problems." Using a mixed research approach that includes qualitative and quantitative methods, behavioral science provides insight into the depth and breadth of public health problems.

CDC behavioral scientists bring experience in survey construction and implementation, often working collaboratively with epidemiologists and other staff. The Behavioral Risk Factor Surveillance System (BRFSS), which monitors behavioral risk factors that influence health outcomes, is a good example of behavioral science at work in the world of survey design (Centers for Disease Control and Prevention [CDC], 2011c). This annual survey, conducted by CDC, collects behavioral health data in all 50 states, the District of Columbia, Puerto Rico, the US Virgin Islands, and Guam. Analysis of BRFSS data informs health policy and prioritizes resources for public health problems. Many behavioral scientists also specialize in the field of evaluation, which allows CDC to critically evaluate whether programs are reaching the targets set and permits a process of continual refinement to meet the community and programmatic needs.

Behavioral scientists at CDC combine biomedical knowledge with systematically gathered information about communities to construct appropriate, effective interventions and health messages. Behavioral scientists can identify how best to implement interventions and evaluate outcomes to allow for sustainable and cost-effective programs. The role of behavioral scientists at CDC can be illustrated through the public health issues of the human immunodeficiency virus (HIV), vaccine safety, and chronic fatigue syndrome.

The importance of the role played by professionals who study human behavior and who suggest ways to intervene in human practices was exemplified by CDC's response to the epidemic of HIV, which involved engaging populations who were at risk for HIV infection in a process of behavior change. The fact that behaviors such as sexual activity and drug use were sensitive and often covert emphasized the need for qualitative and quantitative research and creative methodologies. For example, Semaan et al., in a meta-analysis looked at the effects of HIV prevention in drug users and found interventions with this population significantly reduced risky sexual behaviors (Semaan, Des Jarlais, et al., 2002; Semaan, Kay, et al., 2002).

Conducting needs assessments through focus groups and individual interviews within target communities are examples of how behavioral scientists get involved in the formative phase of interventions, such as in the area of vaccine safety. Outbreaks of measles and pertussis in the USA attest to the public health impact of lowered vaccination rates and yet there are population groups in which resistance to childhood vaccination is prominent (Feiken et al., 2000). In the case of childhood vaccination, members of the public are often challenged to interpret potentially frightening information, and health professionals are at a loss to comprehend why people would reject lifesaving tools. Behavioral medicine methodologies can work between these views, seeking ways to translate concerns, information, and perspectives of the community so policy makers and education experts can develop effective health communication interventions that meet the goals of public health and constituents.

An example of integrating behavioral science and epidemiology at the CDC is the chronic fatigue syndrome (CFS) program. This program has conducted several population-based studies as well as a general clinic research study to assess the prevalence and incidence of CFS, risk factors, and biological aspects associated with the condition. From the behavioral science perspective, the program was the first to publish research in the USA evaluating healthcare providers' perceptions, knowledge, attitudes, and beliefs on CFS. For example, one study measured how physicians and healthcare providers perceive CFS and how their perceptions may affect the diagnosis and management of the illness (Brimmer, Fridinger, Lin, & Reeves, 2010). A separate study examining continuing medical education showed that

when targeting healthcare providers at conferences, the conference size, theme, and mode of education courses may increase education efforts, which help direct resources for future initiatives (Brimmer, McCleary, Lupton, Faryna, & Reeves, 2009).

CDC has a rich history of using behavioral scientists and behavioral science methods to prevent, control, and conduct surveillance on infectious and chronic diseases. The advent of the BSSWG has further augmented the role of behavioral science within the CDC while increasing communication and strengthening agency objectives. Whether behavioral scientists work to prevent infectious disease or promote healthy lifestyles to reduce chronic disease morbidity, they use the fundamentals of evidence-based research, and quantitative and qualitative methods to meet public health goals.

Definition

The field of behavioral sleep medicine (BSM) is a burgeoning, multidisciplinary specialty that represents the integration of clinical sleep medicine and health psychology. Although the field of BSM was initiated by psychologists, individuals from other related disciplines, including nursing,

psychiatry, and general medicine, have also contributed to the growth and diversity of the field. In general, BSM specialists focus on the identification and treatment of the psychological or behavioral factors that contribute to the development and/or maintenance of sleep disorders, including factors that may influence adherence to prescribed sleep treatments. In particular, BSM techniques have been applied to the treatment of nightmares (i.e., Imagery Rehearsal Therapy; Hasler & Germain, 2009; Moore & Krakow, 2007), narcolepsy and idiopathic hypersomnias (Garma & Marchand, 1994; Mullington & Broughton, 1993), and adherence to continuous positive airway pressure treatment of obstructive sleep apnea (Aloia, Arnedt, Riggs, Hecht & Borrelli, 2004; Means & Edinger, 2007). This entry will focus on the principles of behavioral treatment of insomnia, as this is arguably the most well-known and rigorously tested application of BSM techniques.

Description

Cognitive behavioral therapy for insomnia (CBT-I) involves a diverse set of prescriptions designed to improve sleep consolidation and quality by modifying thoughts and behaviors that interfere with sleep. These treatments can be administered in individual or group formats, and typically range from 4 to 8 sessions in length. Evidence suggests that these treatments are preferred by patients and have consistent strong short-term and long-term efficacy (Irwin, Cole, & Nicassio, 2006; Morin et al., 2006) with few apparent side effects.

Techniques Utilized in CBT-I

Stimulus control therapy (Bootzin, Epstein, & Wood, 1991; Morin et al., 1999) aims to reinforce associations between sleepiness, sleep, and the sleep environment. The patient is instructed to go to bed only when feeling sleepy, and to use the bed and bedroom for sleep and sex only. If awake in bed for extended periods of time (e.g., 20 min or longer), the individual is instructed to get out of bed and leave the bedroom until feeling sleepy again.

Sleep restriction therapy is designed to increase sleep efficiency and consolidate sleep by restricting the time spent in bed, only to the amount of time the patient is actually sleeping (Spielman, Saskin, & Thorpy, 1983, 1987). Sleep restriction is often associated with slight-to-moderate sleep deprivation, which increases sleepiness, and enhances the ability to fall asleep and to maintain sleep. Given that sleep restriction may lead to increased daytime sleepiness (temporarily, usually), patients should be cautioned about operating machinery of performing duties that require high levels of alertness. This strategy is not a good option for patients that already report excessive daytime sleepiness symptoms, which may be due to untreated obstructive sleep apnea or other conditions, or patients that have a history of mania/hypomania.

Relaxation techniques aim to reduce physical and emotional tensions that are incompatible with sleep (Coursey, Frankel, Gaarder, & Mott, 1980; Hauri, 1991; Jacobs et al., 1993). Several specific relaxation techniques have been evaluated for insomnia, including autogenic training, progressive muscle relaxation, and biofeedback.

Cognitive therapy is based on the premise that maladaptive thoughts and beliefs about sleep and the consequences of sleep loss (e.g., I can't function without 8 h of sleep) increase tension and arousal, which perpetuates insomnia. In turn, cognitive techniques aim to help patients identify and correct these maladaptive thoughts and beliefs about sleep (Harvey, 2002; Harvey, Tang, & Browning, 2005).

Sleep hygiene refers to practices, habits, and environmental factors that facilitate getting good quality sleep. Exercising, having a pre-bedtime "wind-down" routine, avoiding stimulants and naps, and limiting alcohol intake are examples of behaviors that may enhance sleep quality. Sleep hygiene has limited efficacy as a stand-alone treatment for insomnia (Lacks & Morin, 1992); however, it is often useful in conjunction with other behavioral interventions.

Summary

Behavioral sleep medicine is a burgeoning, multidisciplinary field that has developed a diverse set

of psychological and behavioral treatments to treat sleep disorders. As a field, BSM has actively promoted the dissemination of empirically supported treatments, with the most solid evidence base in support of cognitive-behavioral interventions for insomnia. Challenges for this field will be to continue to train and accredit BSM providers, to ensure proper reimbursement for services, and to continue to develop empirical support for BSM techniques in diverse populations.

Definition

The term behavior therapy was suggested for the first time as the treatment concept that unified all behavior modification of whose foundation was an experiment based on a learning theory by Eysenk, H.J., in 1959. Plural studies and theories

were accumulated, and behavior therapy expanded to a treatment theory, technique, and its coverage afterward. The definition of behavior therapy has become largely extended. Behavior therapy is psychotherapy aimed at behavior modification where focus was assigned to an action, and to the understanding of the problem of the person in structure and the function of the action and form called the context. The characteristic of the behavior therapy is a point which the learning theory arrived at after identifying the problem and making the hypothesis through an experimental study.

Eileen, D.G., indicates that there are seven characteristics of behavior modification:

- Assessment and intervention informed by behavioral principles
- Emphasis on identification of current controlling conditions
- Deemphasize on labeling
- Emphasis on observable, countable responses
- Emphasis on positive, not punitive change method
- Emphasis on measurement of effects
- Rejection of special causative factors related to "problematic" behavior

Description

History

When learning a theory and its techniques, it is important to understand the history of behavior therapy because it is in behavior therapy where various psychological studies and knowledge of the clinical field were interlaced. It is difficult to express it by a word or single thought and theory.

The origin of behavior therapy dates back to behaviorism in the 1920s whose "heart" was on objectivity and scientific analyzes. Watson, J.B., has already applied the principle of respondent conditioning of Pavlov, I., to behavior disorder those days. In the early 1950s, Skinner, B.F., in the USA treated mental patients with operant conditioning and had already used the term behavior therapy. At the same time, Wolpe, J., in South Africa developed a technique called systematic desensitization from a study of neurosis and its cure. In the UK, Eysenk, H.J., performed a case study on neurosis and behavioral disorder using the techniques of experimental psychology. These knowledge and methodologies whose methods and objects are different were integrated to encompass the basic foundations of behavior therapy in the 1950s. Also, applied behavior analysis and neobehavioristic mediational S-R theory which were the representative theories of behavior therapy were also developed by this time. In addition, based on these theories, the techniques such as operant reinforcement, token economy, systematic desensitization method, and flooding were developed. There were only a few theories that could be compared with the theories and the resulting theory and technique of behavior therapy was clear and strong. In the early days, behavior therapy emphasized to put foundations on objectivity and in the scientific theory, and it accomplished remarkable development. Social learning theory was proposed after this, and the current cognitive-behavioral therapy led it. Most of neobehaviorists of that time performed theorization and the inspection through animal experiment, but Bandura, A., brought about the social learning theory that could explain the learning and the modification of social behavior among human beings. By this theory, he suggested observational learning and technique called modeling where there was more focus on cognition than was given the past learning theory. He considered expectation or self-efficacy to be a factor of reinforcement operation in behavior modification.In the 1960s, the rise of criticisms that human cognitive processes cannot be fully grasped through observed data only brought attention to cognition as a factor that effects treatment.

It was during this time that putting together various theories and techniques and every clinical object and purpose to develop a single technique package emerged. Treatment packages became more complicated when techniques were collected from a number of theories. Furthermore, in the USA, Ellis, A., produced rational-emotive therapy, and Beck, S.J., came up with cognitive therapy. They aimed at the intervention on the cognition domain and made remarkable effect on

the treatment of patients with depression. It attracted more attention when patients who went through behavior therapy but did not benefit from it showed remarkable change when introduced to cognitive therapy. Both Ellis and Beck started as therapists in the field of psychoanalysis, and they were both influenced by psychoanalysis, philosophy, behavior psychology, cognitive psychology, and personal construct psychology of Kelly, G.A. They emphasized the importance of the cognition of the patient. Both of them assumed the model that most disorders occur from wrong cognition or wrong process of cognition. Currently, among the models of behavior therapy and the models of the cognitive therapy, there is a difference in positioning of the cognition and action in the treatment. However, researchers and therapists called this using the general term "the cognitive-behavioral therapy," and this has increased popularity worldwide. A lot of these experimental studies are performed and attracted attention as a treatment based on the evidences gathered. In addition, with the increasing social needs, its coverage continues to spread.

Procedure for Treatment

Behavior therapy has many procedures for treatment. I will indicate the basic common features here. The process consists of four parts. The treatment goes on from 1 to 4, but it is necessary to go back to 1 or 2 when therapist gets new data or when treatment is not effective.

1. Assessment: Therapists assess client without labeling or categorizing them as "wimpy" or with "low self-esteem." They concretely collect data about the behavior, thought, feeling, environment, and so on. The goal of intervention is clearly stated between therapist and clients because of the data gathered.
2. Case formulation: Once enough interviews or observations or tests are conducted, the gathered data are analyzed, and relations or patterns are identified. Target behavior (or thought or environment) that has a tendency to change or to affects client's life or has profound influence on other problem is chosen. Case formulation is made with clients and shared.
3. Intervention: Intervention is conducted using appropriate technique.
4. Evaluation: Therapists or/and clients collect quantitative data to examine the effects of intervention. The frequency, magnitude, or duration of behavior, thought, or feeling before and intervention is compared.

Application

Initially, behavior therapy was intended for use in psychiatry or clinical psychology, but it later became useful also for education and other fields such as psychosomatic medicine, physical disease, preventive medicine, public health, and living environment. In the field of psychiatry, behavior therapy is used for the treatment of anxiety disorder (exposure) such as obsessive-compulsive disorder, space phobia and social phobia or the single phobia, and schizophrenia (token economy, Social Skills Training, family behavior therapy). In addition, it is also used in behavior medicine, such as for muscle-contraction headache and hypertensive treatment (biofeedback and various relaxation training) and corpulence (stimulation control, self-control).

Attitudes; Cognitions; Health beliefs

Definition

Beliefs refer to a conviction, or an attitude, that affirms something to be true. Belief involves a mental state of having a particular attitude, stance, or opinion about something. Belief can refer to expectations and assumptions about mundane matters concerning rules in the physical, social, and/or spiritual worlds (e.g., assuming that a chair can support your weight, that it is improper behavior to laugh during a eulogy, or that supernatural beings cause diseases), or they may also refer to existential, ethical, political, philosophical, theological, or scientific matters, among others as well. Many beliefs are the result of past experience (e.g., if I smile when I meet people, then they are more likely to be friendly toward me), cultural influence (e.g., it is wrong to eat pork), and from deliberate and critical reflection. Beliefs are often constructed by observing the behavior of others and by observing the consequences of others' actions. For example, individuals may acquire the belief that seatbelts are not that important if, while growing up, their parents did not wear seatbelts and were never injured in a car accident. Alternatively, if one's parents were seriously injured as a result of not wearing their seatbelt, then one might likely conclude that seatbelts are indeed important. Similarly, beliefs can be transmitted through explicit and implicit instruction from a variety of agents including family, friends, community members, educational and religious institutions, and various forms of media. Further, beliefs are often constructed through a dynamic interaction with other members of the same culture. Some beliefs may receive greater reinforcement, while others may receive greater discouragement or punishment.

Description

Beliefs can potentially have important influences on individuals, groups, and societies. Cognitive-behavioral theory highlights the importance of beliefs in how they may influence a person's mental and physical health. A variety of unhealthy beliefs have been associated with elements of mental health problems. For example, perfectionist beliefs are often associated with anxiety, depression, and anger. Treatment for many mental health-related problems typically involves identifying and challenging unhealthy beliefs and replacing them with healthier and more adaptive beliefs.

Beliefs can affect people's health-related behaviors which in turn affect their health (Wilkinson, Vasudevan, Honn, Spitz, & Chaberlain, 2009). According to the Health Belief Model, people are more likely to engage in health-promoting behaviors if they believe they are susceptible to a certain disease or condition and if they believe that the benefits of engaging in health-promoting behaviors outweigh the challenges to engaging in those behaviors (Rosenstock, Strecher, & Becker, 1988). Bandura (1977, 1986) suggested that individuals' health-related behaviors are influenced by their beliefs about self-efficacy (i.e., the degree to which people believe they are capable of performing a certain behavior or making health-promoting changes in behavior) and whether they expect the positive benefits to outweigh any negative

aspects. According to the Theory of Reasoned Action (Ajzen & Fishbein, 1980), health-related behaviors are primarily influenced by a person's intentions to engage in any particular health-related behavior. These intentions are shaped by attitudes and subjective norms. Attitudes are derived from an individual's beliefs about the consequences of certain health-related behaviors. Subjective norms are derived from individuals' beliefs about how important others think they should behave and their motivations to comply with such beliefs. In addition, according to the Theory of Planned Behavior (Ajzen, 1991), persons' intentions to engage in a particular health-related behavior are affected by their beliefs regarding the extent to which various factors may impede or facilitate performing the health-related behavior. Each theory underscores the impact of belief on health-related behaviors.

Health beliefs often include beliefs about illness, treatment, adherence, self-efficacy, locus of control, and perceptions of one's relationship with health-care providers. A recent meta-analysis (Gherman et al., 2011) examined the association between health beliefs related to diabetes and adherence to treatment for diabetes. Beliefs about self-efficacy, perceiving a positive relationship with health-care providers, and beliefs about the personal consequences of treatment adherence strongly predicted greater adherence to treatment for diabetes among patients. The more adherent patients tended to have greater levels of confidence in their ability to follow medical recommendations, and they expected more meaningfully positive consequences from adhering to treatment. They also viewed their relationships with health-care providers as more positive.

People's beliefs can also affect the likelihood that they will seek medical help when needed and engage in preventative behaviors (Fischer & Farina, 1995; Godin & Conner, 2008). For example, people may be less likely to seek out mental health treatment if they have negative attitudes about mental health services and cultural beliefs that view mental illness as shameful for the individual and the individual's family (Jang, Chiriboga, Herrera, Martinez Tyson, & Schonfeld, 2011). People who have fatalistic views about health (i.e., believe certain health conditions such as cancer cannot be prevented or cured) are less likely to engage in preventative behaviors, seek medical help early, and adhere to treatment recommendations (e.g., Monteros & Gallo, 2011). Certain religious beliefs may also influence help-seeking behavior. People who see health providers as "doing God's work" are more likely to seek help and adhere to treatment. People who see a conflict between medical science and their religious beliefs are sometimes less likely to seek early treatment and/or comply with medical recommendations (Exline & Rose, 2005; Miller and Kelley, 2005).

Sociodemographic variables appear to influence health-related beliefs and behaviors. Generally, people of higher socioeconomic status (SES) typically have more accurate health beliefs and are more likely to engage in healthy behaviors (Wilkinson et al., 2009). This may reflect a variety of the advantages that come with higher SES such as increased access to health care and higher levels of education. Also, compared to men, women tend to report more accurate health beliefs and engage in more health-promoting behaviors and less risky health behaviors. There also appear to be differences between racial and ethnic groups. To summarize the results of one study, European Americans tended to report healthier beliefs and greater medical compliance relative to Asian Americans, Hispanics, and African Americans (Courtenay, Mccreary, & Merighi, 2002). These findings may be related to SES and may partly reflect the advantages of higher SES.

Benefit Evaluation in Health Economic Studies

Definition

The rationale for economic evaluation of healthcare programs arises from the concepts of scarcity, choice, and opportunity cost. In the presence of scarcity, economic evaluation is about "...ensuring that the *value* of what is gained from an activity outweighs the *value* of what has to be sacrificed" (Williams, 1983).

Three techniques have been used for comparisons of consequences (what is gained) and costs (what is sacrificed) in economic evaluations of healthcare interventions: cost-benefit analysis (CBA), cost-effectiveness analysis (CEA), and cost-utility analysis (CUA). This entry describes

three outcome/consequences valuation techniques: quality-adjusted life-years (QALYs), Healthy-years equivalents (HYEs), and Willingness-to-pay (WTP). Comments on their appropriateness and validity from an economic perspective are provided.

Description

Economic Evaluation and Implications for Outcome Measurement

Where interest lies in solving resource allocation problems (i.e., *economic* evaluations) it is important that the methods used to measure consequences (what is gained) are consistent with the discipline of *economics*. The most commonly cited goal of economic evaluations is to maximize the health-related well-being of the population (i.e., the gains) from available resources. Thus, the methods used to measure health-related well-being must be consistent with the underlying welfare economic theory on which the analysis is based on. The "welfarist" approach is the one most commonly used. An extra-welfarist approach has been suggested, but there are many issues related to whether there is any "extra" in the extra-welfarist approach (Birch & Donaldson, 2003). The requirements of the measurement methods in order that these methods are valid ways of measuring outcomes for use in economic evaluations are briefly described. More details can be found in Gafni & Birch, 1995.

The Internal Structure of Preference Formulation

Under the welfarist approach to economics, an individual's preferences are embodied in that individual's utility function. Thus, for a measure of outcome to be consistent with the welfarist approach it must be consistent with a theory of utility. Users can choose between alternative theories based on how they would like individuals to behave (i.e., based on its normative appeal). Alternatively, they might choose to be guided by the approach that individuals are the best judges of their own welfare and hence choose a theory based on its accuracy in measuring the individual's true preferences, irrespective of how they feel about these preferences.

Attitudes Toward Risk

Preferences can be measured under conditions of certainty or uncertainty. When projects are approved from a societal perspective, it has been suggested that risk to the individual can be ignored and mean values can be used for a measure of outcome, but, health outcomes are intrinsic to individuals and cannot be redistributed among individuals. Hence, social decision-making concerning health outcomes should incorporate individuals' attitudes to risk if it is to reflect individuals' preferences (Ben-Zion & Gafni, 1983).

Aggregation of Individual Preferences

Different models exist for aggregating preferences, each of which is based on restrictions imposed on the set of preferences and/or the aggregation rules. The aggregation of individuals' utilities, necessarily involves attaching weights to the utilities of different individuals or groups (i.e., equity considerations are an intrinsic part of any social utility function). Hence, the calculation of a social utility function must reflect the equity criterion adopted in the analysis. If externalities (i.e., the effect of one person's health status on another person's utility) exist, they should be taken into account when constructing the social utility function.

The Meaning of Validity in Outcome Assessment

The basic concepts that are involved in determining the quality of a measurement are validity and reliability. In addition, measures should be tested to determine whether the measurement task is feasible and acceptable (e.g., clarity of the presentation, length of the interview, etc.). The difference between the "classical" psychometric approach and the economic approach is in the way that the validity of an instrument is determined. In economics, the validity of the instrument stems from the validity of the theory, which the instrument is derived from. It is often the case that researchers introduce additional assumptions, to those underlying the utility theory chosen (e.g., to simplify the measurement process). In this case, the validity of these additional assumptions should also be determined.

Quality-Adjusted Life-Years (QALYs)

The most commonly used measure of outcome in economic evaluations (CUA and CEA) is QALYs. QALYs are computed by adjusting each unit of time by a weight that reflects the quality of life in that unit of time and then discount it. By combining aspects of quality and quantity of life the QALY enables comparison of interventions that affect both of these dimensions. Moreover, it allows comparisons of effects on different dimensions of quality of life (e.g., pain versus hearing). In addition, the QALY is intuitively appealing to decision-makers as it can be "thought of as an equivalent number of years in full health – a number of quality adjusted life years" (Weinstein & Stason, 1977). It is presumably the lack of intuitive appeal that inhibited the use of the utility function directly (i.e., the meaning of a "util" (the unit of measurement) is not so easily understood by decision-makers). "The policy objective underlying the QALY literature is the maximization of the community's health. An individual's health is measured in terms of QALYs, and the community's health is measured as the sum of QALYs" (Wagstaff, 1991).

Although there is much agreement about the structure of the QALY measure (i.e., time durations weighted to reflect their quality of life and discounted), there is no agreement about the methods to be used to measure the weights. Unfortunately, different methods result in different numbers. This implies that the different methods cannot be measuring the same thing. The most commonly used approach is to assume that all individuals are expected utility maximizers (i.e., a theory of choice under uncertainty) and to use the standard gamble (SG) or time trade-off (TTO) approaches to measure these weights directly or indirectly (Drummond, Sculpher, Torrance, O'Brien, & Stoddart,, 2005). However, for QALYs to represent individuals' preferences for health requires additional conditions (i.e., in addition to those required by expected utility theory) to be satisfied (Gafni & Birch, 1995). Many studies have shown that expected utility is descriptively inaccurate and that people violate expected utility in systematic ways (Starmer, 2000). Furthermore, the additional conditions also lack empirical or normative support. Recognizing this fact, there are constant attempts in the literature to redefine QALYs (e.g., Weinstein, Torrance, & McGuire, 2009) or to use other utility theories as the foundation for the QALYs, which result in changing the way in which the weights should be measured (e.g., Bleichrodt & Pinto, 2006). Regardless of the recognition of the major problems associated with the QALY measure and some suggestions on how to deal with them, in empirical application it seems that nothing has changed. It might be that the ease of implementation might explain the lack of change. Researchers and practitioners seem to like simple solutions to complex problems (even if they might be wrong).

In terms of the implications for social preferences, as mentioned above, the health-related well-being of the community is calculated by summing individuals' QALY values. This implied the equity assumption that a QALY is a QALY regardless of who gains it and who loses it. This assumption has been widely criticized, and attempts are made to address this issue by developing a social weighing system (e.g., Dolan & Tsuchiya, 2006). The fact that the QALY metric is not likely to represent individuals' true preferences implies that a simple aggregation of QALYs is not likely to represent the community preference. A simple example is the case of a community of identical individuals. We need to ask only one individual for her preferences to know the community's preferences. But if the method used to measure the preferences does not represent the individual's true preferences, it cannot represent the community's preferences.

Healthy-Years Equivalent (HYE)

The HYE provides a user-friendly metric that is needed to improve communication as explained above. Unlike QALYs that mean different things to different people (and hence the need to distinguish the HYE from the QALY), the HYE means only one thing – it is a utility-based concept, derived from the individual's utility function by measuring the number of years in full health, holding other arguments in the utility function

constant, that produces the same level of utility to the individual as produced by the potential lifetime health profile following a given intervention (Gafni & Birch, 1997). The measurement of HYE requires that individuals be allowed to reveal their true preferences, which is consistent with the welfarist approach. It also seems reasonable when asking the public to assist in the determination of healthcare priorities, to choose measurement techniques that allow the public to reveal their true preferences. If not, why do we bother asking them at all?

Can an algorithm be developed to measure HYE that (a) does not require additional assumptions (i.e., in addition to the assumptions underlying the utility theory chosen) and (b) is feasible to use with the intended subjects (e.g., the number and complexity of questions asked is not too burdensome)? The concept of HYE does not require that an individual subscribe to expected utility theory. Any type of utility theory can be used as a basis for generating algorithms to measure HYE, and the choice of utility theory will determine the method of measurement. The only requirement is that preferences for health profiles are measured under uncertainty. For an individual who maximizes expected utility an algorithm that describes how to measure HYE without the additional assumptions of the QALY model is described in Johannesson (1995). In terms of feasibility of the HYE measure, "the jury is still out." Measuring HYE is likely to involve greater response burden, mainly in terms of the number of questions being asked. The need to simplify the assessment task (i.e., reduce the number of questions asked to generate HYE scores) is most evident in the case of large decision trees. This is because the number of different potential lifetime health profiles is likely to be large. Recently a method was suggested, which uses conjoint analysis that makes it feasible to generate the large number of HYE scores required (Johnson, Hauber, & Ozdemir, 2009).

Willingness-to-Pay (WTP)

The maximum amount that an individual is willing-to-pay is the measure typically used in cost-benefit analysis (CBA). WTP is appealing because it has its theoretical foundation in welfare economics and in particular, in the potential Pareto improvement criterion (Drummond et al., 2005). This criterion recognizes that often a policy, resulting in resource allocation, will create gainers and losers in welfare. But if the gainers could fully compensate the losers and remain better off themselves after the change, then society as a whole has benefited. Because compensation does not actually have to occur, it is called "potential" improvement. The measurement of benefit (gains) is the maximum that an individual is willing-to-pay for a good or service. The measurement of cost (losses) is the minimum amount that an individual is willing-to-accept (WTA) as compensation for the loss. A program is worth doing (i.e., cost beneficial) if the total WTP exceeds the total WTA.

Unlike CEA and CUA where the cost and consequences are measured using different units, in CBA the costs and consequences are measured using commensurate (typically monetary) units. This makes it easier to determine if a program is worth implementing or not. WTP is also appealing because it allows intersectoral comparisons, allows trade-offs between health and other goods, can capture externalities, the most sensitive outcome, and can be modified to capture the unique nature of health as a good (Gafni, 1997). The main objection to the WTP approach is that using a measure that is heavily influenced by ability to pay (i.e., WTP) will lead to evaluations favoring the rich. However, this objection was never tested empirically. Donaldson et al. (2002) show that the same income-distributional concerns apply to non-monetary valuations of health consequences, to measurement of costs, and to the decision rules of CUA/CEA. Hence, adopting CUA/CEA over CBA cannot be justified on the basis of avoiding distributional considerations.

A WTP instrument typically has two components: A description of the programs (or interventions) to be valued and a payment method to elicit an individual's WTP for the program in question. O'Brien and Gafni (1996) developed a set of questions to help researchers and practitioners

to determine how to design a proper WTP instrument for their evaluation. Examples of different approaches to elicit WTP values can be found in Gafni (1997), Drummond et al. (2005), and Donnaldson, Mason, and Shackley (2006).

Benefit Finding

Kristen Riley
Department of Psychology, University of Connecticut, Storrs, CT, USA

Synonyms

Adversarial growth; Posttraumatic growth; Stress-related growth

Definition

Benefit finding refers to a reported positive life change resulting from the struggle to cope with a challenging life event such as trauma, illness, or other negative experiences. The positive psychology movement has recently driven a shift toward an emphasis on the positive consequences of negative events. The discovery of benefits by individuals experiencing adversity is well documented and plays a prominent role in theories of cognitive adaptation to threatening circumstances and in emerging literature on posttraumatic growth and psychological thriving.

It is highly prevalent, has been studied in a variety of settings, has an association with personality and emotional well-being, and can predict health outcomes month and even years later. Benefit finding enhances emotional and physical adaptation in the face of adversity.

By definition, some view benefit finding as searching for benefits, that is, as a verb (Tennen & Affleck, 2009), while others measure it as a form of growth, as a noun. Additionally, benefit finding, the phenomenon of positive life changes that people report following their struggle to cope with negative life experiences, is often also referred to as stress-related growth, adversarial growth, or posttraumatic growth. While some have attempted to define these constructs as separate and distinct, others have used the terms interchangeably, and there is a consensus for the need to more narrowly define these terms for consistency across the field (Park, Lechner, Antoni, & Stanton, 2009).

Tennen and Affleck (2002) are careful to distinguish benefit finding from other terms as a perception of positive change rather than veridical change. Those who choose to view benefit finding as veridical change have measurement difficulties, as most measures used to assess growth are based on self-report, and therefore are inherently only perceptions of change.

Benefit finding manifests itself in a variety of ways. Individuals often report a newfound appreciation for their strength and resilience. Some benefit from negative experience in a social context, claiming that their relationships are stronger, that they feel more emotionally connected, and that they feel more compassionate or altruistic. Others emphasize developing the ability to recognize the important parts of life, redirecting priorities, and even openness to religion and spirituality. While there is a focus on positive psychological benefits, research suggests that benefit finding may also have a positive impact on physical health (Bower, Low, Moskowitz, Sepah, & Epel, 2008).

Benefit finding has also been conceptualized in myriad ways: as cognitive reappraisal, as a personality characteristic, and even as a coping mechanism. However, there has been an emphasis on the distinction between active efforts to recall benefits as a coping strategy during difficult times, deemed benefit reminding, and benefit finding (i.e., benefit-related cognitions as adaptive beliefs).

Benefit finding and stress-related growth have been studied mainly in the context of health and medical illness. Medical illness often induces feelings of uncertainty, fear, and loss. Growth and benefit finding is also widely reported as a result of illness. Research has proliferated from early studies on the impact of myocardial infarction to interest in the role of benefit finding and growth in cancer, HIV, lupus, infertility, arthritis, psoriasis, and other health problems. However, growth varies in the context of medical illness due to variation in symptom onset, etiology, threat to life, recovery trajectory, chronicity, permanence of change, and life context. Additional research is required to understand how benefit finding and growth function along these dimensions.

Benefit-Risk Estimation

J. Rick Turner
Cardiovascular Safety, Quintiles, Durham, NC, USA

Synonyms

Benefit-risk profile; Benefit-risk ratio; Risk-benefit assessment; Risk-benefit ratio

Definition

The benefit-risk estimate can be determined as follows:

$$\text{Benefit-risk estimate} = \frac{\text{Estimate (probability and degree) of benefit}}{\text{Estimate (probability and degree) of harm}}$$

In addition to the likelihood (probability) of benefit and of harm, the degree of both likely occurrences is important. For a given likelihood of a certain benefit, a 1 in 100 chance of a very mild adverse consequence (event) may be acceptable to a patient, but a 1 in 100 chance of a severe event might not.

The term "estimated" is used rather than calculated since, while a calculation (a division) is performed, the two values involved in the calculation are themselves estimates rather than precise quantitative statements (An analogous argument is used in the entry titled "▶ Sample Size Estimation.") The term "benefit-risk ratio" is commonly seen in the literature, but, following this argument, the term "ratio" can be seen to imply a degree of precision that is not (currently) possible in benefit-risk assessment.

The term "benefit-risk balance" is also meaningful. A favorable benefit-risk balance is one in which the estimate of benefit is sufficiently greater than the estimate of harm to make a decision to proceed with an intervention, and an unfavorable balance is one in which the estimate of benefit is not so. For a given intervention, the benefit-risk balance can differ for individual patients. While two patients may be considered likely to gain similar therapeutic benefit from the intervention, it is possible that concurrent illnesses, genetic susceptibility, and/or other factors present in one of them may increase the likelihood of harm to the point where the balance becomes unfavorable.

Benefit-risk assessments for an intervention are also potentially influenced by the availability of subsequent interventions. A new intervention may offer additional therapeutic benefit while maintaining a given level of safety. This would lessen the relative benefit-risk profile of the older intervention. The same would be true for a new intervention offering similar therapeutic benefit but doing so in such a way that the estimate of harm is decreased.

Definition

Physical activity is defined as body movement produced by skeletal muscle that results in energy expenditure above resting level and can be accumulated at any time, for example, during work, household, transportation, or during leisure time. Exercise is a subset of leisure-time physical activity that is usually structured, planned, repetitive, and has the purpose of providing recreation, improving or maintaining physical fitness, or enhancing other components of health or well-being (US Department of Health and Human Services, 1996). Physical fitness includes cardiorespiratory fitness, muscle strength, body composition, and flexibility (Thompson et al., 2003). Metabolic fitness is also increasingly recognized as an important component of fitness which is closely related to physical activity levels, as well as cardiovascular and musculoskeletal fitness (Hassinen et al., 2010).

Description

Physical activity recommendations were traditionally only focused on vigorous exercise to achieve fitness and health benefits (American College of Sports Medicine, 1978). However, in the following years, emerging evidence from clinical and epidemiological studies showed that moderate-intensity physical activity, such as walking, is also associated with significant health benefits (Dunn et al., 1999). This has led to a shift in the physical activity paradigm from a sole focus on fitness and performance to a broader public health perspective (Haskell, 2009). The current physical activity guidelines from major governmental and professional organizations state that health benefits can be gained through moderate physical activity, vigorous exercise, or a combination of both (Haskell et al., 2007; Nelson et al., 2007; US Department of Health and Human Services, 2008; World Health Organization, 2010).

These recommendations and guidelines are based on numerous epidemiological and clinical studies that have established the health benefits of regular physical activity and exercise (Bassuk & Manson, 2009; Lee & Paffenbarger, 1998; Lee, Sesso, Oguma, & Paffenbarger, 2003; Sesso, Paffenbarger, & Lee, 2000). There is a broad base of evidence that an active life-style reduces the risk of coronary heart disease, stroke, type 2 diabetes, some cancers, and osteoporosis; improves mental health and lipid profiles; lowers blood pressure; facilitates weight loss and maintenance; and increases longevity (Courneya & Friedenreich, 2011; Dishman, Washburn, & Heath, 2004; Haskell et al., 2007; US Department of Health and Human Services, 1996; Bouchard et al., 2012).

There are specific recommendations for physical activity and exercise for different age groups. Children and adolescents (5–17) should

engage in moderate- to vigorous-intensity physical activity for 60 min or more per day. On at least 3 days per week, this should include vigorous exercise with muscle- and bone-strengthening activities (US Department of Health and Human Services, 2008). Of particular relevance to children and adolescents is that physical activity and exercise promote a healthy growth and positively affect the social (Malina, Bouchard, & Bar-Or, 2004) and cognitive development (Sibley & Etnier, 2003).

Adults aged 18–65 should accumulate at least 150 min of moderate physical activity per week, such as walking, on at least five, preferably all, days of the week, or alternatively at least 75 min of vigorous exercise per week. For more significant health benefits, adults should engage in 300 min of moderate physical activity or 150 min of vigorous exercise per week. Additionally, twice a week, adults should engage in exercise that maintains or increases muscular strength or endurance (Haskell et al., 2007; US Department of Health and Human Services, 2008).

The recommendations for older adults (65+ years) are similar to those for adults with additional emphasis on exercise that improves flexibility and balance (Nelson et al., 2007). Of particular relevance to the elderly is that exercise reduces the risk of falls and associated injuries and has therapeutic benefits for various chronic diseases, such as coronary heart disease, hypertension, osteoarthritis, claudication, and chronic pulmonary disease. Furthermore, physical activity and exercise help in the treatment of depression and anxiety disorders, delay cognitive impairment and disability, and improve functional ability, mobility, and overall quality of life in the elderly. Maintaining a sufficient level of mobility is critical to independent living for older adults (Nelson et al., 2007). Therefore, physical activity and exercise can not only add years to life, but life to years.

Benson, Herbert

Stephanie Ann Hooker
Department of Psychology, University of Colorado Denver, Denver, CO, USA

Biographical Information

Dr. Herbert Benson

Herbert Benson was born in 1935 in Yonkers, New York. He graduated from Wesleyan University in 1957 with a B.A. in Biology and received his medical degree from the Harvard Medical School in 1961. He is currently the Director Emeritus of the Benson-Henry Institute (BHI) and the Mind/Body Medical Institute Associate Professor of Medicine at Harvard Medical School. In his career, spanning more than 40 years, Benson is considered to be the pioneer of mind/body medicine and to be one of the first Western physicians to integrate spirituality and healing into medicine (Massachusetts General Hospital, 2011a).

Major Accomplishments

Benson recognized that in contrast to the "fight-or-flight response" to stress, there must be an opposite physiological reaction to bring the body back to a state of homeostasis; this he defined as the relaxation response (Benson, 1975). This response is identified by marked decreases in respiration rate, metabolism, and heart rate and increases in alpha brain waves. Furthermore, Benson argued that this response could be mentally controlled and induced, similarly to biofeedback responses. Thus, he studied practitioners of Yoga, Zen, and Transcendental Meditation to fully understand this process. Interestingly, he found that individuals who were recently trained in the relaxation response had similar physiological responses during practice to highly trained experts in Yoga or Zen (Benson, 1975). Indeed, subsequent studies showed that these responses were not unique to Transcendental Meditation, but could be harnessed in a restful, hypometabolic state and, therefore, can be elicited through activities such as diaphragmatic breathing, knitting, chi gong, prayer, Yoga, jogging, Tai Chi, and progressive muscle relaxation. The key to eliciting the relaxation response is a repetitive thought, prayer, or movement and a casual return to that repetition if an intruding thought enters the mind (Massachusetts General Hospital, 2011b). Benson continues to teach and lecture about the beneficial effects of the relaxation response in counteracting stress. The revolutionary book, *The Relaxation Response*, was first published in 1975

and continues to be reprinted and translated into many different languages.

In addition to his work on the relaxation response, Benson advocates mind-body medicine through his work at the Benson-Henry Institute for Mind-Body Medicine at Massachusetts General Hospital. There, he supports a three-part system for treating patients: (1) pharmaceuticals, (2) surgery and procedures, and (3) "self-care" composed of mind/body interactions like nutrition, relaxation, exercise, and spirituality. He believes that this system is best because many patients are affected by stress-related conditions and need self-care to treat the person as a whole (Massachusetts General Hospital, 2011b).

Benson has authored more than 180 scientific publications and 12 books. More than five million copies of his books have been printed and translated into many languages. Many institutions have supported his research, including the National Institutes of Health, The John Templeton Foundation, and the Fetzer Institute. He has received numerous awards, including Fellow for the American College of Cardiology, a Presidential Citation from the American Psychological Association, and four honorary doctorates. Benson continues to lecture widely about mind/body medicine, striving to build awareness of the field and bridge the gap between Eastern and Western medicine.

Definition

Bereavement is the state of being deprived of something or someone, especially a loved one lost to death. Persons in a state of bereavement experience grief, as a normal emotional reaction to the major loss.

Beta Cells

Definition

Beta cells are cells contained within the islets of Langerhans (islets), which specifically produce and secrete insulin into the circulation, in response to a variety of stimuli, most notably blood glucose. Beta cells are part of the endocrine system and are essential in glucose regulation and homeostasis. They achieve this through a balance with counter regulatory hormones, such as glucagon, which is produced by the beta cell's neighbor in the islet, the alpha cell. When beta cells have difficulty in secreting insulin properly (type 2 diabetes) or are completely nonfunctional (type 1 diabetes), diabetes develops. The beta cells co-secrete with insulin a peptide called amylin, which is thought to also be important in metabolic regulation, by slowing gastric emptying, suppressing glucagon secretion, and increasing satiety. Beta cells can also be stimulated to release insulin by a number of antidiabetic medications such as sulfonylureas, glinides, GLP (glucagon-like peptide)-1 receptor agonists, and DPP (dipeptidyl peptidase)-4 inhibitors. Beta cells can also be used to reverse hyperglycemia when islet cells are isolated from cadaveric donors and transplanted into the liver of patients with type 1 diabetes.

Bias

Synonyms

Participation bias; Selection bias; Systematic bias

Definition

Bias is the difference between the true value of a particular quantity and an estimate of the quantity

obtained from scientific investigation. Randomization is a process designed to reduce bias as much as possible.

Description

Various influences can introduce error into the assessment of treatment effects: As an example, here systematic bias is discussed. If all of the subjects in one treatment group share a characteristic that is not present in any of the subjects in the other treatment group(s), it is not possible to ascribe differences between the groups to the influence of central interest in the study, i.e., the different treatments received by the groups. Putting all relatively tall subjects in one group and all relatively short subjects in another group would be an example of systematic bias. Another example would be putting all relatively heavy subjects in one group and all relatively less heavy subjects in the other. If the behavioral intervention (treatment) of interest was a putative means of reducing blood pressure, there is a certain degree of biological plausibility that the difference in body weights in the treatment groups could influence the results.

Participation bias (Volunteer bias): Participation bias refers to the differential likelihood of certain individuals accepting invitations to participate in a research investigation (often in a survey) and others not responding or declining to participate.

Recruitment of subjects for participation in various types of experimental methodologies has to acknowledge certain biases. Consider the randomized controlled clinical trial. Subjects are recruited before randomization to treatment groups occurs, and it is the intent that subjects complete their participation in the trial regardless of which treatment they were randomized to. (In the classic double-blind trial, they would not know to which treatment they had been randomized.) In contrast, consider mailed (or electronically mailed) invitations to participate in a research survey. If the survey addresses a disease that you have, or that close friends or family members have, there is a higher likelihood that you will agree to take part in the research study by answering the questions asked by the survey than there is for healthy subjects who have little knowledge of (and possibly little interest in) the disease or condition of research interest.

Selection bias: Selection bias occurs when study subjects are allowed to select into which treatment group in the study they would like to be placed.

Definition

The most widely used and accepted contemporary definition of the phrase "binge drinking" was published on February 5, 2004, by the NIAAA National Advisory Council. This definition for binge drinking put forth by a special task force assigned the responsibility of defining binge drinking and its differentiations from other patterns of alcohol use states that:

> A 'binge' is a pattern of drinking alcohol that brings blood alcohol concentration to 0.08 gram percent or above. For the typical adult, this pattern corresponds to consuming 5 or more drinks (male), or 4 or more drinks (female) in about 2 hours. Binge drinking is clearly dangerous for the drinker and for society (National Institute on Alcohol Abuse and Alcoholism, 2004).

This definition was released with the following caveats:

(a) A "drink" refers to half an ounce of alcohol (e.g., one 12 oz. beer, one 5 oz. glass of wine, or one 1.5 oz. shot of distilled spirits).
(b) Binge drinking is different from "risky drinking" (reaching a peak BAC of .05 g percent to .08 g percent) and a "bender" (2 or more days of sustained heavy drinking).
(c) For some individuals (e.g., older people or people taking other drugs or certain medications), the number of drinks needed to reach a binge-level BAC is lower than the "typical adult."
(d) People with risk factors for the development of alcoholism have increased risk with any level of consumptions.
(e) For pregnant women, any drinking presents risk to the fetus.
(f) Drinking by persons under the age of 21 is illegal.

Description

Multiple definitions of the term "binge drinking" have existed and been revised over time. Prior to 1991, a "binge" was often thought of to be an intense, multi-day or week long period of drinking that often done in a solitary fashion. The purpose of binge drinking was to become intoxicated, and a loss of control was a component of such a binge drinking episode. The binge was often accompanied by significant consequences such as blackouts, injuries and often ended in incarceration, alcohol poisoning, and/or inpatient treatment. Although a binge was occasionally referred to as a single event, the amounts of alcohol consumed were related to high levels of intoxication and related impairment over more than 1 day. Furthermore, binge drinking episodes, or binges, would often be separated by extended periods of sobriety.

In the United States, the meaning behind the phrase "binge drinking" underwent a drastic change after the term became widely used in the in research college student drinking in the early 1990s. Specifically, Dr. Henry Wechsler of the Harvard School of Public Health started to conduct large-scale surveys of college student alcohol use – the College Alcohol Survey (CAS). The CAS surveyed over 50,000 students at 140 colleges and universities in the United States. The first of these surveys was conducted in 1993, and subsequent surveys were conducted in 1997, 1999, and 2001 (Wechsler & Wuethrich, 2002). Originally defined as having 5 drinks per occasion, the definition was later amended to 5 drinks on one occasion for men and 4 drinks on one occasion for women. Furthermore, this definition lacked a time frame during which the drinks were consumed. Through the many research articles published from the CAS, as well as subsequent articles by other researchers that examined the phenomenon, "binge drinking" was conceptualized as the threshold for which alcohol-related harms became significantly more likely for the drinker. Furthermore, students who shared the environment with students engaging in binge drinking also experienced consequences such as having their sleep and studies disturbed, their property damaged, and even being assaulted. These "secondary effects" were also a source of concern for school administrators, and a commonly cited reason to increase prevention and intervention efforts on college campuses.

Dr. Wechsler's revised definition of the term binge was frequency used outside of research by the media to describe many high-profile alcohol-related fatalities and other related consequences. Thus, the revised definition of binge drinking was integrated into popular terminology.

During the 1990s and early 2000s, there was debate regarding the updated definition of "binge drinking" as Dr. Wechsler's definition of binge drinking was markedly different than the historical definition of a multi-day episode of heavy alcohol use. One concern about the Dr. Wechsler's definition is that it failed to differentiate between individuals who drank to the point of unconsciousness (e.g., BACs of .30 g/dL and higher) within individuals who met the binge drinking threshold but reached low levels of intoxication. In addition, the term binge drinking was often used in the media to describe sensational events related to high levels of intoxication. There was some concern that the use of binge drinking to primarily describe excessive levels of consumption would cause some individuals to falsely believe that the term binge drinking was synonymous to extreme intoxication. Furthermore, there was debate regarding whether the use of Dr. Wechsler's definition of binge drinking led to inaccurate beliefs about the actual occurrence of risky alcohol use at a time where a growing body of research indicated that overestimates about the frequency of alcohol use was positively related to increased personal use.

Synonyms of the term binge drinking were introduced to differentiate the historical and the current definition for binge drinking, and these synonyms included heavy episodic drinking, risky drinking episode, harmful drinking, dangerous drinking, excessive drinking, and problem drinking (Carey, 2001). In addition, NIAAA attempted to address limitations regarding Dr. Wechsler's definition of binge drinking by including level of intoxication as a criterion for whether a binge drinking episode occurred, as well as highlighting the importance of individual differences since some individuals may be at a heightened level of risk depending on their predisposition. Concurrent with the focus on binge drinking in the United States as a single, discrete drinking event researchers and policymakers around the world attempted to determine how many drinks needed to be consumed to constitute a binge drinking episode. Indeed, global cutoffs included a half bottle of spirits or two bottles of wine on one occasion (Sweden); double the daily recommended amount of alcohol – about 2–3 drinks (or 1 or 2 for women) (England); 6 bottles of beer (Finland) and 6 or more units of alcohol (women) and 8 or more units of alcohol for men (United Kingdom). However, to date, there is no worldwide consensus on the amount of alcohol that needs to be consumed to qualify as a binge drinking episode.

As with the term "binge drinking," there is a lack of consensus regarding how many binge drinking episodes one must experience in order to be classified as a "binge drinker." Researchers have used time frames used to capture binge drinking episodes have ranged from the past week to the past year. Overall, a 6-month time frame has been determined to be most informative in linking binge drinking to alcohol-related consequences. Dr. Wechsler and colleagues further differentiated between binge drinkers (one or two binge drinking episodes in the past 2 weeks) and frequent binge drinkers (two or more binge episodes in the past 2 weeks). However, this definition has not been universally accepted.

Because no stable definition of the term binge drinking or binge drinker exists, care must be taken to clearly define binge drinking when interpreting or disseminating research findings, especially when including different studies. As the definition of binge drinking has been clarified (defined in most studies as five or more drinks on one occasion for men and women) since 1991, research has implemented the construct into interviews and surveys with a variety of populations. That said, it is possible to identify some trends in the literature on binge drinking. Binge drinking typically peaks in adolescence and then decline as people get older, with the lowest rates found in individuals over 65 years old. Binge drinking is the most common style of drinking among adolescents, with over 90% of the alcohol consumed by high school students being imbibed while binge drinking. This is of concern as establishing this pattern of alcohol

use early in life may lead to continued binge drinking throughout the lifespan, as well as increase the risk for developing alcohol dependence. Research with adolescents and adults consistently indicates that binge drinking is related to injuries, violence, driving while intoxicated, unsafe sexual practices, and death. In addition, binge drinking in pregnant women can cause significant danger to the fetus such as fetal alcohol spectrum disorders. In the elderly, preliminary evidence suggests that binge drinking may be associated with the onset of dementia. The association of binge drinking with the concurrent use of other substances, such as tobacco, is also a public health concern.

Regarding gender and ethnic differences in binge drinking, men continue to binge drink more than women, accounting for as many as 81% of adult binge drinking episodes. Caucasians also report binge drink more than any other racial group, with African–Americans exhibiting the lowest rates of binge drinking.

Given the health implications, binge drinking has been the target of a variety of prevention and intervention efforts. In the college setting, the social norms marketing campaigns (SNM) became a widespread approach, with mixed results. In college students and other populations, individual brief motivational interventions (BMIs) have been administered in a wide variety of contexts, formats, and settings, and research indicates a consistent small to moderate effect on decreasing the frequency of binge drinking and related consequences. Interventions administered via the Internet have also demonstrated efficacy with college students and adults, and new approaches to screening and intervention through the web continue to be developed.

Binge Eating

Simon Sherry[1] and Skye Fitzpatrick[2]

Definition

Binge eating involves rapidly eating a very large amount of food in a relatively short period of time. Other key characteristics of binge eating include feeling out of control when eating, eating until uncomfortably full, eating apart from others, eating in the absence of hunger, and marked distress regarding overeating. Binge eating is distinguishable from other symptoms of disordered eating. Bulimia nervosa, for example, is a broader pattern of disordered eating including not only binge eating but also compensatory behaviors (e.g., dieting, purging, or exercising to avoid weight gain) and excessive concerns over body size, shape, and weight.

Description

Binge eating is usually conceptualized with reference to either a dimensional framework (with binge eating understood as lying along a continuum of severity ranging from mild to severe) or a categorical framework (with individuals suffering from severe binge eating understood as belonging to a qualitatively discrete diagnostic category). Binge Eating Disorder is a provisional diagnostic criteria set provided for further study in the *Diagnostic and Statistical Manual of Mental Disorders* (American Psychiatric Association, 2000). Binge Eating Disorder generally appears to represent a reliable and a valid diagnostic category. Subdiagnostic symptoms of binge eating are also important, as such symptoms negatively impact health and functioning and may herald the occurrence of more severe symptoms of disordered eating.

Epidemiological data suggest binge eating is a common and an impairing problem that most frequently occurs in wealthy, industrialized nations. The onset of binge eating is usually in late adolescence or in young adulthood. With a female-to-male ratio of 3-to-2, binge eating is the least gender-specific form of disordered eating. The prevalence of Binge Eating Disorder ranges from 1% to 4% in samples of community members and from 15% to 50% in samples from weight-control programs. An estimated 8% of individuals who are obese have Binge Eating Disorder. Binge eating is tied to health problems such as obesity, diabetes, and gastrointestinal dysfunction. Moreover, psychiatric difficulties and binge eating frequently co-occur, with mood, anxiety, substance use, and personality problems often accompanying binge eating. Binge eating is also associated with functional impairment in social, personal, familial, and occupational roles.

Several putative factors are involved in the onset and the maintenance of binge eating. Both personality traits (such as perfectionism) and Personality Disorders (such as Borderline Personality Disorder) are risk factors for binge eating. Negative affect is also implicated in binge eating, with binge eating conceptualized as a way of momentarily escaping negative affect. Evidence suggests unsatisfying interpersonal relationships (e.g., hostile interactions) and other interpersonal problems (e.g., evaluative fears) are related to binge eating. Cognitive biases such as strongly basing self-worth on control over eating are also tied to binge eating, and dietary restraint appears to play a key role in binge eating, with binge eating representing an attempt to compensate for caloric deprivation. Ultimately, no one single factor is responsible for binge eating and a confluence of the above factors appears to trigger and to maintain binge eating.

Binge eating is a treatable problem. Randomized controlled trials indicate cognitive behavioral therapy (Wilson & Fairburn, 2007) and interpersonal psychotherapy (Tanofsky-Kraff & Wilfley, 2010) are efficacious interventions for binge eating. Cognitive behavioral therapy focuses on establishing behavioral patterns that reduce binge eating (e.g., regular, moderate meals and snacks) and challenging dysfunctional cognitions that maintain binge eating (e.g., irrational cognitive distortions about dieting). Interpersonal psychotherapy focuses on identifying current interpersonal problem areas contributing to binge eating (e.g., marital disputes) and then improving those problem areas. Randomized trials also suggest antidepressants, especially selective serotonin reuptake inhibitors, are linked to short-term decreases in binge eating (Bodell & Devlin, 2010). Long-term effects of medications on binge eating are unknown. Combining psychotherapy and medication does not appear to result in greater reductions in binge eating.

Biobehavioral Mechanisms

Definition

Biobehavioral mechanisms within behavioral medicine refer to the interaction of biological, psychosocial, behavioral, and environmental factors that contribute to health-related outcomes and disease status. Biological processes are believed to mediate the influence of psychosocial, behavioral, and environmental factors on health and disease outcomes.

Description

Research concerned with biobehavioral mechanisms of health and disease has primarily focused on the impact of psychosocial, behavioral, and environmental factors on biological processes of the immune and endocrine systems. These factors can impact biological responses individually and/or synergistically and may include both acute and chronic effects. Psychological distress in response to stressors (i.e., negative life events, both acute and chronic) has been related to alterations in immune and endocrine functioning and much of this work has focused on the effects of stress on immunocompetence and inflammatory responses. Importantly, relationships among relevant biological, psychosocial, behavioral, and environmental factors are often bidirectional and synergistic in nature.

"Biobehavioral mechanism" is a term used to suggest biomarker research linked to psychological, behavioral, and sociocultural factors. Pioneering work first discovered the interrelationship between psychological stress and physiologic responses of the nervous, endocrine, and immune systems. Among the first researchers to evaluate these relationships were Walter Cannon and Hans Selye. It was Cannon (1939) who first identified the role of the autonomic nervous system (ANS) in the fight-or-flight stress response. Selye (1952, 1975) later demonstrated interactions of the hypothalamic-pituitary-adrenal (HPA) axis and the sympathetic nervous system (SNS) that lead to subsequent changes in immune functioning and the lymphoid organs in response to psychological stress. This led to a global immunosuppression model of stress and immunity. Over the years and with advancing technology, increasingly sophisticated methods for evaluating these relationships have been developed and our understanding of the mechanisms by which psychological and behavioral factors influence biological processes and health outcomes has advanced. Psychoneuroimmunology (PNI) has emerged as a field of study that is primarily concerned with interactions between the central nervous system, the endocrine system, and the immune system and the impact of these interactions on health and disease. The HPA axis and the sympathetic-adrenal medullary (SAM) axis are the primary pathways by which these systems interact. Much of this work has been concerned with the systemic effects of psychological stress on the regulatory processes of the HPA and SAM axes and the association between chronic inflammation and acute and/or chronic health conditions. Biomarkers are used to

objectively measure (ab)normal biological processes, pathogenic processes, disease progression, and response to treatment or intervention.

The HPA and SAM axes produce glucocorticoid hormones (e.g., cortisol) and catecholamines in response to stress. These neuroendocrine products bind to receptors on a number of immune cells, such as lymphocytes, monocytes, machrophages, and granulocytes, altering cellular activity and immune functioning (e.g., cell trafficking, proliferation, cytokine secretion, antibody production, and cytolytic activity; Padgett & Glaser, 2003; Rabin, 1999). Cytokines mediate and control inflammatory and immune responses. One of the effects of chronic activation of the stress response is downregulation of cortisol production and increases in the release of various pro-inflammatory cytokines such as C-reactive protein (CRP), interleukin-2 (IL-2), interleukin-6 (IL-6), and tumor necrosis factor-alpha (TNF-alpha). The nature and duration of stress (e.g., acute vs. chronic) has been identified as determining factors influencing the degree to which psychological stress leads to alterations in neuroendocrine functioning and immune dysregulation. Although both acute and chronic stress has been related to increased activation of inflammatory responses and alterations in immune function, longer-term or chronic stressors have been shown to have a more substantial impact.

"Biobehavioral mechanisms within behavioral medicine" is also a term that has been used to imply markers of disease activity. Both animal and human models have demonstrated that the interaction of the neuroendocrine and immune systems in response to stress influence a number of health-related outcomes. A lot of the emphasis looking at biobehavioral mechanisms has evaluated the interaction of stress and biomarker activity. Classic studies linking psychological and behavioral factors to biological mechanisms have demonstrated the negative effects of stress on immune functioning. Psychological stress has been shown to exacerbate viral and bacterial pathogenesis, increases susceptibility to viruses, slows wound healing, and alters autoimmune diseases (Black, 2003; Cohen et al., 1991; Kiecolt-Glaser et al., 1995; Padgett et al., 1998). Studies have demonstrated that subjects inoculated with a vaccine show poorer immunologic responses during times of stress (e.g., medical students during exams, caregiving for a spouse with dementia and Alzheimer's disease; Glaser et al., 1992, 2000, 2001; Jabaaij et al., 1996; Kiecolt-Glaser, Glaser, Gravenstein, Malarkey, & Sheridan, 1996; Vedhara et al., 1999) and this relationship has been shown to be dose dependent (Cohen et al., 1991). Furthermore, individuals who show delayed, weaker, or shorter-lived responses to vaccines are more likely to experience clinical illness and longer-lasting infections (Padgett & Glaser, 2003). Stress-induced alterations in neuroendocrine and immune responses have also been studied within a number of disease models including insulin resistance and type II diabetes (Black, 2003), cardiovascular health (e.g., atherosclerotic disease and hypertension; Black, 2003), cancer (Andersen, Kiecolt-Glaser, & Glaser, 1994; Andersen et al., 1998), human immunodeficiency virus (HIV; Antoni et al., 1990; Cruess et al., 2000), and multiple sclerosis (Ackerman, Martino, Heyman, Moyna, & Rabin, 1998).

Psychological stress may also impact biological processes indirectly through related effects on health behaviors. That is, efforts undertaken to manage the demands of stress or cope with an acute or ongoing stressor may lead to unhealthy behavior changes. For example, distressed individuals often have appetite and/or sleep disturbances and are more likely to self-medicate with alcohol and other drugs, including caffeine use and cigarette smoking. Likewise, health behaviors may have a direct effect on biological processes, independent of psychological stress. Immune functioning has been related to objective measures of sleep, nutrition, alcohol intake, and drug use. These factors may contribute independent effects and/or their interaction may lead to additive affects on neuroendocrine and immune functioning. For example, substance abuse has been directly related to immune dysfunction and indirectly through related effects on nutrition. Overall, poor health behaviors may interact with

psychological and biological processes in bidirectional ways, contributing to and exacerbating the effects of stress on health and disease.

Biofeedback

Biofeedback control; Biofeedback therapy

Definition

Biofeedback denotes the use of electronic methods to amplify or convert imperceptible bodily information and feed this information back to the person concerned in a perceptible form such as light, sound, vibration, numbers, or graphical representation for the purposes of improving health and performance. This feedback can be used in training aimed at developing self-control over physiological functions and autonomic responses that are difficult to treat using conventional methods. This kind of therapy is known as biofeedback therapy or biofeedback control.

Description

Research on biofeedback began around 1960. Biofeedback involves two basic processes – the perception of physiological functions and the control of those functions. The physiological function to be brought under control must be continuously monitored with sufficient sensitivity to detect in real time change, and the change in the physiological measure must be reflected immediately to the person attempting to control the process.

In learning theory terms, biofeedback involves the operant conditioning of neuromuscular and autonomic nervous activity. Bodily reactions such as changes in muscle tone or heart rate are operant behavior that can be controlled through feedback. This control is based on the principle that if a certain reaction results in a reward, and if that response is rewarded every time it occurs, it will occur with increasing frequency. As a form of applied psychophysiology, clinical biofeedback assists persons to alter their own behaviors through systematic feedback of such physiological responses.

Biofeedback therapy can be applied to a wide range of vital reactions, including blood pressure, heart rate, heart rate variability (HRV), skin temperature, skin potential reflex, sweat gland action potential, electrocardiogram (ECG), electrogastrogram, electromyogram (EMG), respiration, and electroencephalogram (EEG). Especially, biofeed back displaying real-time electroencephalography is also called neurofeedback. Biofeedback therapy methods can be divided into those that seek to directly control bodily reactions associated with a specific condition and those that seek to indirectly control the condition through full body relaxation.

Biofeedback has been applied to many different fields. In medical care, it is used mainly to treat or prevent psychosomatic conditions such as bronchial asthma, hypertension, arrhythmia, tension-type headache, migraine, writer's cramp, and spasmodic torticollis. It is also said to be effective in the field of sports psychology to manage and relax the body and mind of athletes prior to competing, with electromyogram and skin temperature biofeedback being the most frequently used. Biofeedback is also deemed to be effective for post-stroke rehabilitation. The final goal in gaining control over a reaction is to be able to control the

reaction with just one's own powers, without using a monitor.

Definition

1. A biomarker is a characteristic that is objectively measured and evaluated as an indicator of normal biological processes, pathogenic processes, or pharmacologic responses to a therapeutic intervention.
2. A biomolecule whose presence, absence, or abnormal concentration in blood, urine, saliva, or other body fluids, and/or tissues indicates normal or diseased processes in the body.

Description

The body's adaptive response to psychological and physical stressors produces detectable changes in multiple biochemical and physiological processes, and potentially, any of these alterations may be used as biomarkers. As measurable characteristics that reflect the biological underpinnings of health and disease, biomarkers are increasingly used to augment self-report measures of stress and to illuminate the interactions between social, environmental, and behavioral factors with health outcomes. The attractiveness of biomarkers in behavioral medicine stems from their potential to reduce the reliability and validity issues inherent to subjective self-report assessments. Of particular interest are readily obtained, quantifiable and reliable biological measures that reveal existing psychological states and serve as harbingers of future health disorders.

Most biomarkers used in behavioral medicine are selected for their ability to reflect activity in one or more of the three main stress response systems: the sympathetic-adrenal-medullary (SAM) axis, the hypothalamic-pituitary-adrenal (HPA) axis, and the immune system. Activation of the SAM axis is the body's immediate physiological response to acute stressors and the released catecholamines, epinephrine, and norepinephrine are commonly used as biomarkers to reflect SAM axis activity. HPA axis activation is a longer-term hormonal response that starts manifesting 15–20 min following stressor onset. Primary indicators of the HPA axis activation include cortisol, dehydroepiandrosterone (DHEA), its sulfated form (DHEA-S), and adrenocorticotropin hormone (ACTH).

Crosstalk with the neuroendocrine system also produces alterations in the immune system that vary according to stressor duration. For instance, short-term stressors provoke increases in the levels of the quick-acting, all-purpose immune cells such as the natural killer (NK) cells. Prolonged or chronic stressors produce more robust changes in immune biomarkers, including suppressed activity and proliferation of NK cells, and increases in inflammatory markers such as proinflammatory cytokines (e.g., IL-6, TNF-α) and C-reactive protein (CRP). Alternate expressions of stress-related immunosuppression include slower wound healing and weaker seroconversion rates following vaccination.

Utilized individually or as part of a panel representing the multiple response pathways, biomarkers can be used to identify the risk of developing disease (antecedent biomarkers), screen for subclinical disease (screening biomarkers), recognize overt disease (diagnostic biomarkers), categorize disease severity (staging biomarkers), or predict disease course and response to therapy (prognostic biomarkers). Recognizing that simple, univariate tactics (i.e., use of one biomarker) do not fully address the complex process of adjustment and adaptation to multiple recurring stressors, biobehavioral researchers are progressively transitioning to more comprehensive, multivariate approaches (i.e., use of multiple biomarkers). An illustrative example is the integration of hormonal mediators of the stress response, cortisol and epinephrine, with blood pressure and waist-hip ratio to operationalize the construct of allostatic load, the cumulative physiological toll exacted by the body's efforts to adapt to life experiences. By using an allostatic load index representing neuroendocrine, immune, metabolic, and cardiovascular system functioning, a variety of studies have demonstrated greater prediction of age-related health and cognitive declines over and beyond traditional methods employed in biopsychosocial investigations.

The intrinsic value of any biomarker derives from its measurement properties and as such, an ideal biomarker should be accurate (i.e., match the actual value of the health construct being measured), have high sensitivity and specificity for the outcome of interest, and explain a reasonable proportion of the outcome, independent of other established predictors. However, the desirable properties of a biomarker can vary with its intended use. Features such as low costs and high sensitivity, specificity, and predictive values are important for a screening biomarker. In contrast, features such as costs, sensitivity, and specificity are less important in prognostic biomarkers because only individuals with disease are tested and they serve as their own controls (i.e., baseline values are compared with follow-up values). The transition from putative biomarker to a known valid biomarker status occurs through a multistep confirmatory process. Although the biomarker literature frequently uses the term "biomarker validation" to describe the authentication process, it is important to distinguish between validation (assay or method validation) and qualification (or clinical validation or evaluation). Method validation refers to the process of assessing the assay or measurement performance characteristics (e.g., accuracy, precision, selectivity, sensitivity, and reproducibility). Biomarker qualification is the more appropriate term for describing the graded, evidentiary process for linking the biomarker with biological processes and clinical endpoints relevant to the intended application.

On a practical level, a biomarker can have clinical utility only if it can be extracted easily and unobtrusively, is reproducibly obtained in a standardized fashion, and the measurement is readily accessible and easy to interpret by the end-user. These practical considerations drive the concomitant development of robust, low-cost, and portable biosensors that will allow biomarkers to be detected and measured reliably in places as diverse as remote field environments, community hospitals, or even at home. The truncated biosampling-reporting cycle afforded by these point-of-care biosensors will eventually allow a time-sampling protocol that is sensitive to common sources of biomarker variability (e.g., diurnal variation, timing of collection relative to stressor) and enable time-series psychophysiological measurements in naturalistic settings. As advances in behavioral research and biomarker development converge with innovations in biosensing technology and systems biology, one can expect that the

ready access to accurate and reliable biomarker information will enable more precise, predictive, and personalized health care.

Biopsychosocial Model

Eleanor Miles
Department of Psychology, The University of Sheffield, Western Bank, Sheffield, UK

Definition

The view that illness and health can be best understood as a result of the interaction between physiological, psychological, and sociocultural factors.

Description

The biopsychosocial model, originally advanced by George L. Engel (1977), views disease and health as the product of physiological, psychological, and sociocultural variables. This viewpoint stands in contrast to the biomedical model, in which disease is viewed in terms of deviation from normal biological functioning, and where the experience and etiology of illness are understood solely in terms of biological factors, such as genetic predispositions or physiological dysfunctions. Engel argued that this model was too narrowly focused, and that a greater emphasis needed to be placed on the role of psychosocial factors.

The idea that psychological and sociocultural factors could have an influence upon illness had already been recognized (in the field of psychosomatic medicine, for example). For example, factors such as negative beliefs about an illness (e.g., helplessness) and avoidance behaviors may act to worsen symptoms, whereas the presence of active coping strategies and social support may have a positive effect on the course of an illness. A key aspect of the biopsychosocial model is the importance it places on the interconnections between the three domains of biological, psychological, and social functioning. For example, psychological factors can both influence biological functioning (e.g., alterations in autonomic nervous system function and hormone production), and can also be influenced by biological functioning (e.g., disease may cause cognitive impairments or contribute to depression and anxiety). The model holds that an illness can be best understood by considering its psychological and sociocultural effects as well as its biological ones, and that the cause and progression of an illness can also be influenced by all three of these factors, not just biological ones. In other words, the biopsychosocial model suggests that both the etiology and the expression or prognosis of illness are best understood as the result of an interaction between biological, psychological, and sociocultural variables.

The biopsychosocial model can help to explain why patients with the same disease or physical pathology may experience their illness,

and respond to treatment, in very different ways. In terms of clinical practice, the model encourages clinicians to consider all relevant psychological and social factors when making a diagnosis, and implies that treatment should address all of these factors rather than just the biological component of illness. More generally, the model has also been influential in encouraging researchers and clinicians to integrate knowledge from different domains in order to better understand illnesses and how they can be treated (see Borrell-Carrio, Suchman, & Epstein, 2004, for further discussion). The field of behavioral medicine can be seen as an application of the principles of the biopsychosocial model to medical practice and research. The recent growth in application of psychological theories to understanding and influencing health behavior (such as the theory of planned behavior) is also a reflection of the biopsychosocial model's influence. Numerous studies have validated this model by showing that psychosocial factors predict onset and progression of cardiac diseases, the common cold, recovery from surgery and cancer prognosis, independent of biomedical and demographic variables, and that psychological interventions may also improve the health outcomes of some of these conditions.

Birth Weight

Linda C. Baumann and Alyssa Karel
School of Nursing, University of Wisconsin-Madison, Madison, WI, USA

Definition

The birth weight of a newborn is an indicator of chance for survival and long-term development and can also reflect the health status of the birth

mother. Normal birth weight is classified as babies born between the 10th and 90th percentiles of all babies of the same gestational age. Low birth weight is a major problem of newborns worldwide. There are three categories of low birth weight: low birth weight (LBW) is less than 2,500 g or about 5.5 lb; very low birth weight (VLBW) is less than 1,500 g; and extremely low birth weight (ELBW) is less than 1,000 g. Low-birth-weight infants are either born small for their gestational age (SGA) or born prematurely. A preterm birth is a gestation of less than 37 weeks and is a major cause of LBW. Small for gestational age births are more common in developing countries.

High birth weight is far less common worldwide but can still have major consequences on the health of both the mother and the infant. High birth weight or large for gestational age (LGA) babies weigh greater than the 90th percentile of all babies of the same gestational age, which for full-term infants is about 4,000–4,500 g. Maternal diabetes is the most common cause of LGA babies. Maternal risks associated with LGA babies include increased vaginal delivery time, increased chance of a cesarean delivery, lacerations of the birth canal, and maternal hemorrhage. The newborn is at risk of problems related to glucose regulation and respiratory distress.

Low-birth-weight infants are at increased risk of mortality and morbidity throughout their lives. As infants, risks include an inability to maintain body temperature, infection, difficulty gaining weight, respiratory distress syndrome, neurological problems, and sudden infant death syndrome. Later in life they are at risk of for poor muscle development, cognitive disabilities and are more likely to remain below average on height and weight charts.

Demographic, medical, behavioral and environmental maternal risk factors for having a LBW infant include age <18 or >35, low socioeconomic status, low education level, and ethnicity (African Americans have increased risk of having LBW infants when compared to Latina American and Caucasian mothers). Risk factors include a previous LBW infant and a woman who was herself a LBW infant, infection, placental problems, poor weight gain/poor nutrition, or first or second trimester bleeding. Behavioral risk factors include smoking and use of drugs or alcohol during pregnancy. Environmental risk factors include poverty, maternal stress, and delayed or a lack of prenatal care.

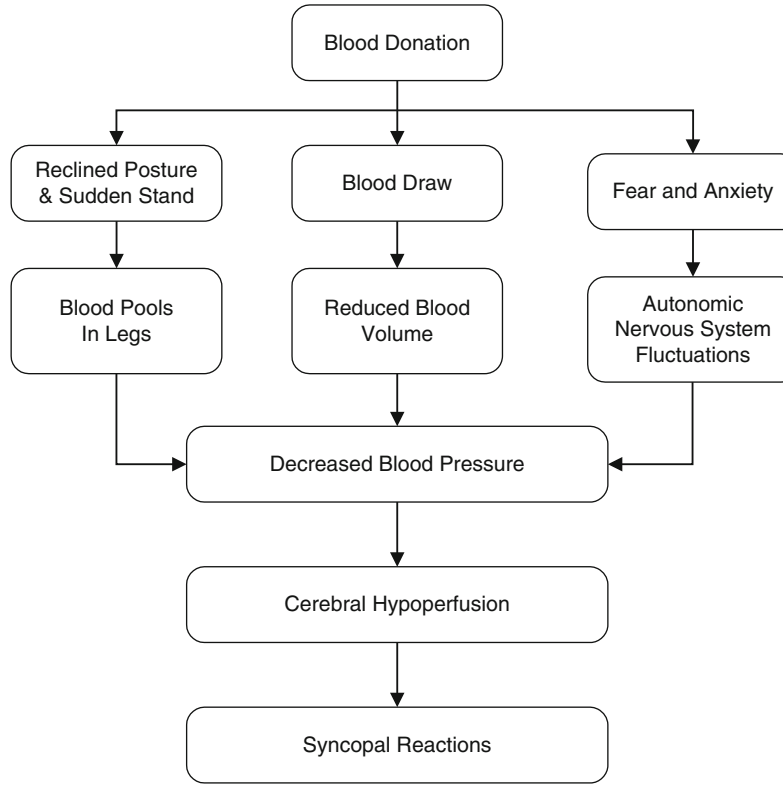
Blood Donation

Christopher France and Janis L. France
Department of Psychology, Ohio University, Athens, OH, USA

Description

The blood donation process places a unique set of physiological and psychological demands on the



Blood Donation, Fig. 1 Potential contributors to syncopal reactions in response to blood donation

donor. As shown in Fig. 1, these include postural challenge upon standing after a prolonged period of reclined seating, loss of blood volume, and potential fear and anxiety. These factors can combine to produce reductions in cerebral perfusion that, in turn, can result in a range of reactions from mild presyncopal (i.e., pre-faint) symptoms such as dizziness or lightheadedness to periods of syncope (i.e., fainting or loss of consciousness) that can last for a few seconds in mild cases to minutes in more severe cases.

Risk of Syncopal Reactions to Blood Donation

Overall, the risk for presyncopal and syncopal symptoms is low, with a recent study of over six million whole blood donors reporting presyncopal reactions in 2.5% of all donations and loss of consciousness in only 0.1% (Eder et al., 2008). However, in a related report, it was noted that 16–17-year-old donors had a presyncopal rate of 8.9% and a loss of consciousness rate of 0.3% (Eder, Hillyer, Dy, Notari, & Benjamin, 2008). These findings are consistent with other reports that presyncopal symptoms occur 2.6–9 times more often among first-time blood donors as compared to repeat donors. And young, female, first-time donors are at particularly high risk with on-site syncopal reactions rates as high as 16.1%. Importantly, additional reactions can occur after a donor leaves the blood collection site, and analysis of reported cases indicate that 10–15% of all syncopal episodes occur off-site (Kamel et al., 2010; Newman, 2004). These off-site reactions are particularly problematic as they are more likely to be associated with a fall and an injury to the head. It has been estimated that 1 in 9,300 donations results in a health-care visit due to syncopal reactions and that one third of such visits relate to an injury sustained during a fall (Newman, 2004).

Impact of Syncopal Reactions on Blood Donor Retention

Although a number of factors shape individual decisions to donate, retrospective studies of

existing blood donors demonstrate that the experience of adverse reactions is a particularly important barrier to retention. For example, in a retrospective survey of over 30,000 blood donors (Thomson et al., 1998), donors' perception of physical well-being during or after donation was the single strongest predictor of intent to donate again. Donors who rated their physical well-being during or after donation as "fair to poor" reported an anticipated attrition rate that was six times higher than those who rated their well-being as "good to excellent." Similarly, a comparison of current versus "lapsed" donors (i.e., previous donors who had not donated within the past 2 years) revealed that a positive donation experience was one of the most important determinants of return behavior (Germain et al., 2007). Similar findings have also been observed in prospective analyses of donor behavior. For example, a study of nearly 90,000 whole blood donors revealed that those who did not experience a presyncopal or syncopal reaction returned to donate at a rate of 64% in the following year as compared to a rate of 40% for donors who experienced a reaction (France, Rader, & Carlson, 2005).

Reducing the Risk of Syncopal Reactions

A number of intervention strategies have been adapted to the blood donation context to address the specific physiological and psychological demands illustrated in Fig. 1. These include applied muscle tensing techniques to enhance venous return, predonation water consumption to acutely increase total peripheral resistance and resting blood pressure, and distraction techniques to reduce fear and anxiety.

Using Applied Muscle Tension to Attenuate Venous Pooling. Repeated, rhythmic muscle contraction procedures have been used for decades to treat fainting reactions in individuals with blood and injury/injection phobia. For example, individuals with blood and injury phobia can learn to make voluntary muscular contractions when faced with feared stimuli, and these actions can increase blood flow to the brain and prevent faintness (Foulds, Wiedmann, Patterson, & Brooks, 1990). Because this technique has obvious practical implications for preventing blood donation reactions, they have also been attempted with volunteer blood donors. In a series of studies, donors were randomly assigned to either donation-as-usual or an applied muscle tension group that watched a brief predonation video on the use of applied muscle tension during donation (Ditto & France, 2006; Ditto, France, Albert, & Byrne, 2007; Ditto, France, Lavoie, Roussos, & Adler, 2003; Ditto, Wilkins, France, Lavoie, & Adler, 2003). On the whole, these studies demonstrated that compared to controls who did not watch the video, donors who learned the muscle tensing technique (1) reported lower levels of presyncopal symptoms, (2) were less likely to have their donation chair reclined by the phlebotomist, and (3) expressed greater confidence that they would donate blood again in the future. Interestingly, while the beneficial effects of muscle tensing have been demonstrated in both males and females (Ditto & France, 2006; Ditto et al., 2007; Ditto, Wilkins et al., 2003), in some studies, these effects have been restricted to female donors (Ditto, France et al., 2003). In part, more consistent findings for female donors may be related to the fact that they are, on average, at greater risk for reactions.

Using Water to Compensate for Blood Volume Reductions. Drinking water elicits acute increases in sympathetic nervous system activity and total peripheral resistance that may help maintain blood pressure during donation, and this simple intervention has been shown to significantly delay syncopal reactions to head-up tilt testing (Lu et al., 2003). Although water consumption immediately prior to donation will do little to restore blood volume reductions at the time of donation (due to delays in absorption time), the acute cardiovascular effects of drinking water may help to offset the reductions in blood pressure that can occur with the loss of approximately 500 ml of blood. Consistent with this notion, healthy young blood donors who drank 500 ml of bottled water approximately 30 min prior to donation reported reduced presyncopal symptoms as compared to donors who did not

drink water (Hanson & France, 2004). Further, there was no relationship between total body water levels at baseline and reported reactions, suggesting that the benefit of predonation water loading arises from acute rather than chronic hydration. The beneficial effects of predonation water consumption were subsequently replicated in a sample of nearly 9,000 high school donors, and findings from this study suggested that this intervention was most effective when the donor consumed the water closer to the time of the actual blood draw (Newman, Tommolino et al., 2007).

Using Distraction to Reduce Donation Anxiety. For many years, patients have been encouraged to divert their attention from stressful medical procedures as a means of reducing pain and distress. Empirical evidence suggests that many diversions such as music, videos, and reading can have significant benefits by reducing patient anxiety. In the blood donation context, donors who engage in coping strategies that involve either thinking about being elsewhere or explicitly trying to divert attention away from the donation procedures experience less distress (Kaloupek, White, & Wong, 1984; Kaloupek & Stoupakis, 1985). Conversely, those who do not engage in distraction report a decreased likelihood of making future donations (Kaloupek et al., 1984). More recently, audiovisual distraction was assessed as a potential method of reducing presyncopal reactions in first-time blood donors (Bonk, France, & Taylor, 2001). Results indicated that donors who preferred avoidant coping (e.g., turning away from the sight of the needle) were less likely to experience negative reactions when they watched a 3-D movie while giving blood. Those who preferred vigilant coping (e.g., attending to the donation process) were neither helped nor hurt by watching the movie (Bonk et al., 2001). Combined with other studies that did not observe a similar benefit of distraction (Ferguson, Singh, & Cunninham-Snell, 1997), these findings suggest that individual differences in coping style preferences, opportunities for choice, and perceptions of control may play an important role in reducing anxiety and risk for syncopal reactions.

Conclusion

Although the overall rate of syncopal and presyncopal reactions is low, they remain a safety concern and a deterrent to both initial and repeat donation attempts. Even a small reduction in the percentage of first-time donors who experience a syncopal reaction would have a major impact on the blood supply, as a positive initial donation experience can be the difference between a single unit of blood donated and a lifetime contribution of several hundred units. Further, failing to address the experience of such reactions may have a reverberating negative impact on donor recruitment; donors share their stories and in so doing may discourage others in their circle of friends and family from future donations. As described above, a number of strategies may help to reduce the risk for syncopal reactions; however, this is a relatively new area of research and additional studies are needed to address such questions as: (1) Who is most likely to benefit from these interventions? (2) What is the optimum timing for the application of individual strategies relative to the blood draw? (3) What procedures are most practical and effective in the blood donation context? (4) What methods of instruction will maximize donor adherence?

Definition

Blood glucose concentrations are maintained by tight regulation of glucose production and glucose utilization by insulin- and non-insulin-dependent tissues. Blood glucose levels are usually in the range of 70–99 mg/dL during fasting. Postprandial blood glucose levels might rise up to 140 mg/dl transiently. Blood glucose less than 70 mg/dL is considered hypoglycemia. Three main sources of glucose include gut absorption after ingestion of carbohydrates, endogenous glucose production from glycogenolysis (breakdown of glycogen), and gluconeogenesis (formation of glucose from amino acids, lactate, and glycerol). Only the liver and kidney provide the enzymes necessary for these two processes. The brain depends on continuous plasma glucose supply and cannot use free fatty acid as an energy source. Normoglycemia is essential to preserve cognitive functions, and long-term hypoglycemia or hyperglycemia can result in serious neurological sequela. Tissue-specific transport proteins are responsible for glucose transport from the extracellular to the intracellular space. GLUT-1 and GLUT-3 are glucose transporters that are non-insulin dependent but could be upregulated in prolonged hypoglycemia (Kronenber, Melmed, Polonsky, & Larsen, 2008; Lifshitz, 2007).

Hormones that Regulate Glucose

Insulin is the main glucose-lowering hormone and acts by suppressing glucose production and enhancing glucose use by insulin-dependent

tissues. Insulin secretion is tightly regulated by many factors including exogenous glucose, hormones, and the autonomic nervous system. Counter-regulatory hormones including glucagon, growth hormone, cortisol, and catecholamines increase glucose concentration by stimulating glycogenolysis and gluconeogenesis. Response to hypoglycemia involves a decrease in insulin levels, increase in glucagon levels stimulating glycogenolysis, and secretion of epinephrine that stimulates glucose production from liver and kidney and decreases glucose use. Growth hormone and cortisol stimulate glucose production and limit glucose use. Hormonal response to hypoglycemia occurs in a timely manner having acute lowering of insulin and increases in glucagon within minutes, and epinephrine being a critical hormone in a defect of glucagon. Growth hormone and cortisol are secreted in prolonged hypoglycemia, and their deficiency should be suspected in infants or children with persistent hypoglycemia (Lifshitz, 2007).

Blood Glucose Measurements

Blood glucose can be measured in plasma or in whole blood. Glucose concentration is lower in whole blood than in plasma. To convert whole blood glucose to plasma requires multiplication by 1.15. The majority of laboratories provide reports of plasma glucose. Blood glucose is reported in mg/dl in the United States, but other countries use international units. To convert to IU requires division of mg/dl by 18 and equals mmol/L (Kronenber, Melmed, Polonsky, & Larsen, 2008).

Definition

Blood pressure is the hydrostatic pressure exerted by circulating blood on the walls of a blood vessel; it is highest in the aorta and large systemic areas. Blood pressure is recorded by two values: systolic blood pressure, which is measured after the heart contracts, and diastolic blood pressure, which is measured before the heart contracts. Systolic blood pressure <120 mmHg and diastolic blood pressure <80 mmHg are considered within normal range. A person is considered to have hypertension when their systolic blood pressure is greater than 140 mmHg or their diastolic blood pressure is greater than 90 mmHg.

Definition

A blood pressure *response* is a change in blood pressure that occurs following exposure to a stimulus. In behavioral medicine, the term is reserved for responses to psychological stress. Blood pressure responses can be quantified as the arithmetic difference between blood pressure measured during a true resting state and that measured during exposure to a stressor. Blood pressure *reactivity* refers to an individual's characteristic pattern of blood pressure responses across time.

Description

Basis of the Blood Pressure Response to Stress

As cognitive stress is disruptive to a person's mental resting state, it is associated with visceral neurological changes in brain function caused by the contemplation, initiation, and maintenance of those activities required by the mental stress response. As a consequence, psychological stress can be expected to result in an investment of mental resources that precipitates observable physiological responses.

Specifically, responding to stressors involves immediate psychological processes relating to emotion, working memory, and decision-making, which in turn invoke neurological activity in the frontal cortex, as well as in the amygdala and the bed nuclei of the stria terminalis within the limbic system. This neurological activity establishes outflow beyond the prefrontal cortex via the brainstem and the hypothalamus, which is intrinsic to the person's psychological and behavioral response (Lovallo & Gerin, 2003). The hypothalamus is also responsible for moderating a number of the body's metabolic regulatory functions; as such, hypothalamic mediation of psychological responses to stress results in virtually simultaneous effects on autonomic and endocrinal outputs, including shifts in cardiovascular function. Indeed, parameters of cardiovascular function are known to be highly sensitive to mental stress, such that even small changes at the cognitive level (e.g., the shifting of attention from one visual stimulus to another) will be followed by measurable changes in many cardiovascular functions, including blood pressure.

Reactivity as a Stable Pattern of Responses

To date, a large body of research has examined the nature, extent, and consequences of blood pressure responding to psychological stress. Such research has established that, all other things being equal, cardiovascular responding is temporally stable within persons (i.e., that a person will tend to exhibit uniform levels of reactivity across tasks, relative to other people) and across time (i.e., that a person's characteristic

level of reactivity in early life will reflect their level of reactivity later in life).

A key feature of the way blood pressure responds to mental stress is that response patterns, while differing across individuals, appear to be stable within individuals. A number of empirical studies have suggested that the magnitude of a person's cardiovascular responses to stress can maintain consistency across very long periods of time, including weeks, years, and even decades (e.g., Hassellund, Flaa, Sandvik, Kjeldsen, & Rostrup 2010). Further indication of the biologically inherent nature of cardiovascular response patterns can be gleaned from the fact that similar patterns of long-term consistency have been observed across species (De Jonge, Bokkers, Schouten, & Helmond, 1996). An important implication of this phenomenon is that people can be classified with some reliability in terms of their dispositional response tendencies. It is this consistent and dispositional pattern of blood pressure responses that is generally referred to as blood pressure "reactivity."

Accordingly, while some stressors are associated with greater cardiovascular responses than others, people's dispositional patterns of blood pressure reactivity appear to maintain further consistency across contexts. A number of different studies have suggested that people's characteristic levels of blood pressure responding to cognitive stress tasks (i.e., whether people are consistently low or high reactors when compared with peers) generalize across different task domains, including mental arithmetic, public speaking, and reaction time testing.

The majority of studies into blood pressure responses to stress seek to elicit stress responses experimentally using standardized presentations of contrived cognitive stressors, usually in laboratory settings. Typically, researchers seek to present cognitive challenges that are novel to participants, in order to avoid the confounding of stress response data with the effects of participants' prior experience of performing particular tasks. This raises the question as to whether such laboratory-based measures validly reflect blood pressure responses to stress that occur in daily life surroundings. Studies that specifically assess laboratory-to-field comparability have confirmed that there is some similarity between artificial research tasks and naturalistic environmental stressors, although little such research has examined the generalizability of cardiovascular variables other than systolic blood pressure, diastolic blood pressure, and heart rate.

Etiological Significance

The usual function of a blood pressure reaction is to prepare the organism to respond behaviorally to a stressor by providing nutritional supply to the major organs needed for physical action. However, as pointed out by Cannon (1929) in his description of the fight-or-flight response, such physical readiness is of less relevance when the threats in the environment require psychological responses rather than physical ones. As such, it can be said that psychological stress provokes a degree of cardiovascular responding beyond that which is metabolically necessary. It has been demonstrated that the decrement between such elevated cardiovascular responses and metabolic needs is such that even relatively mild mental stress can exert an impact on the cardiovascular system equivalent to that of rigorous physical exercise. Further, the extent of this exaggeration appears to be greater among persons who have higher resting blood pressure (Balanos et al., 2010). The fact that blood pressure responses to stress are disproportionate to physiological demands is believed to contribute to the onset and progression of cardiovascular disease in individuals in whom such responses are particularly elevated (Obrist, 1981). This implication of elevated blood pressure responding in the etiology of cardiovascular disease is commonly referred to as the "cardiovascular reactivity hypothesis" (e.g., Krantz & Manuck, 1984; Obrist, 1981).

The reactivity hypothesis offers a number of possible explanations for the centuries-old observation that psychological stress can damage physical health. Several underlying mechanisms have been proposed. Due to their metabolic disproportionality to physical demands, blood pressure responses to psychological stress may serve to permanently disrupt physiological

homeostasis in ways that lead to the gradual resetting of blood pressure (Obrist, 1981). In addition, the repeated eliciting of responses may contribute to cardiac and vascular hypertrophy (Lovallo & Gerin, 2003). Elevated levels of blood pressure reactivity may enhance disease risk by increasing serum levels of low-density lipoproteins while lowering levels of high-density lipoproteins (Raitakari et al., 1997). Further, elevated reactivity may be part of the exaggerated sympathetic responding that leads to increased blood insulin concentrations, which themselves are known to increase hypertension risk (Nazzaro et al., 2002). Finally, elevated reactivity may contribute to atherosclerosis through raising serum concentrations of proinflammatory cytokines (Georgiades, 2007).

A number of empirical studies have corroborated such interpretations by linking heightened cardiovascular reactivity with future hypertension development (e.g., Carroll et al., 2001), atherosclerosis (e.g., Jennings et al., 2004), increased left ventricular mass (e.g., Murdison et al., 1998), and coronary heart disease morbidity and mortality (e.g., Treiber et al., 2003).

Most research has studied the adverse implications of blood pressure responses that are elevated. However, two important caveats have emerged. Firstly, while consistent elevations in blood pressure can be expected to precipitate adverse outcomes over protracted periods of time, they may be beneficial for health when elicited over the short term in response to acute stress. Previous research has suggested that acute stress can stimulate immune effectiveness and, crucially, that cardiovascular reactivity is positively associated with indices of enhanced immune responding (Phillips, Carroll, Burns, & Drayson, 2009). The detrimental cardiovascular impact of sustained elevations in blood pressure tends to be lessened by the fact that responses to stressors reduce over time due to processes of adaptation (Kelsey, Soderlund, & Arthur, 2004), an effect that is itself enhanced among psychologically healthy persons (Hughes, Howard, James, & Higgins, 2011). Secondly, blood pressure responses that are unusually *low* may also be detrimental to health. A number of cross-sectional screening studies have found significant associations between low acute responding and markers of poor health, including elevated levels of depression and obesity (Phillips, 2011). In summary, elevated blood pressure responses to stress may reflect advantageous processes in the short term (as suggested by the association between short-term response and immune strength), so long as such responses are not sustained in the longer term (as implied by associations between elevated reactivity [i.e., sustained responding] and cardiovascular disease end points). Correspondingly, suppressed blood pressure responses may reflect a maladaptive physiological pattern, associated with generally poor health.

Measurement Issues

Blood pressure responses to stress are typically investigated using orthodox measures of systolic and diastolic blood pressure, which collectively represent the impact of circulating blood on the walls of blood vessels. For many decades, these variables, along with heart rate, have comprised the most technically feasible and thus most studied indices of cardiovascular function in behavioral medicine research. Due to the fact that direct arterial assessment of blood pressure would be particularly invasive (and thus stressful), most studies of blood pressure responses to stress have utilized automated sphygmomanometry. Laboratory and field studies usually employ tabletop and ambulatory monitors, respectively. However, while much epidemiological data exists on systolic and diastolic blood pressure and their associated psychosomatic pathways, these variables lack granularity when compared to the multifaceted biodynamics underlying cardiovascular function as a whole, which although more informative are also more difficult to measure. In addition, conventional measurement of blood pressure tends to be noncontinuous and so does not facilitate real-time tracking. Instead, measures are based on episodic readings returned no more frequently than around once every 2 min.

Alternative technological approaches have been developed to enable real-time tracking of cardiovascular function by returning continuous

beat-to-beat measurement of systolic and diastolic blood pressure, as well as ready monitoring of a range of hemodynamic variables underlying these parameters. Such underlying variables may include specific dimensions of cardiac function (such as cardiac output, stroke volume, heart rate variability) and vascular function (such as total peripheral resistance, total arterial compliance, and aortic impedance), as well as neurological variables (such as baroreflex sensitivity). Measurement of such variables is facilitated by photoelectric plethysmography, typically via a finger cuff, which is suitably noninvasive (and thus nonstressful) for most psychological research.

Such devices facilitate the close monitoring of the components of blood pressure, which in turn enables the testing of hypotheses relating to these components. For example, blood pressure is influenced by both vascular and cardiac arousal. Vascular and cardiac arousal appear to be affected differently by independent changes in alpha- and beta-adrenergic nervous system activity. In turn, alpha- and beta-adrenergic responses are believed to reflect different types of psychological coping states (namely, vigilance- and attack-response postures) (Sherwood & Turner, 1992). Accordingly, analyses of hemodynamic response patterns based on independent changes in vascular and cardiac parameters allow researchers to drill down into the qualitative aspects of stress responding and its impact on cardiovascular health (Obrist, 1981).

Influencing Factors

Blood pressure responding to stressors is sensitive to a range of contextual and environmental cues and contingencies. For example, average levels of cardiovascular response are proportionate to the level of cognitive challenge present and can be increased or reduced by proximal factors such as task complexity, emotional comfort, and social context.

Among the main categories of factors that have been found to be relevant are the following: task-specific factors (aspects of stressors that influence the degree of cardiovascular impact, such as computational complexity, task feedback, emotional content, personal or social significance); environment factors (contextual aspects that influence the degree of cardiovascular impact, such as immediate physical environment, time of day, work or home location); physiological factors (aspects of personal biological function that influence the degree of cardiovascular impact, such as sleep levels, habitual and acute caffeine intake, habitual tobacco use, oral contraception use, body mass index, age); social factors (social or interpersonal variables that influence the degree of cardiovascular impact, such as social assistance during stressors, audiences during stressors, availability of social support, aspects of personal social network); and person-level psychological factors (psychological or emotional variables that influence the degree of cardiovascular impact, such as depression, anxiety, or other psychiatric symptoms, and personality types, subtypes, and traits).

Accumulating evidence of the associations between such variables and blood pressure responses to stress is important in two respects. Firstly, it enables researchers to adequately control extraneous influences on blood pressure responses when conducting studies examining disease-relevant physiological mechanisms. Secondly, it provides insight into the ways in which these variables themselves contribute to cardiovascular disease. For example, associations between particular personality traits and blood pressure reactivity may help explain why these same traits emerge as correlates of disease outcomes in epidemiological research.

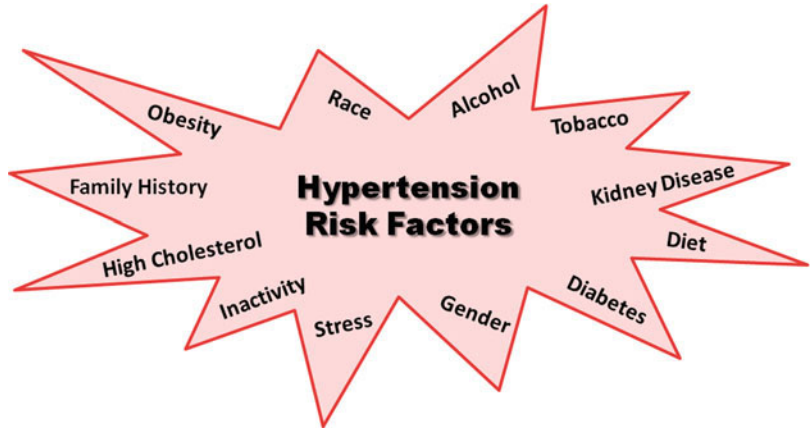
Definition

Hypertension (elevated blood pressure) refers to sustained high blood pressure in the arteries.



Blood Pressure, Elevated, Fig. 1 Risk factors for elevated blood pressure

A systolic blood pressure greater than 140 mmHg or a diastolic blood pressure higher than 90 mmHg (millimeters of mercury) is classified as hypertensive. The elevated arterial pressure requires the heart to use more energy to pump; this can eventually lead to myocardial infarction (heart attack) or heart failure. Individuals with hypertension are at an increased risk for cardiovascular disease and have a shorter life expectancy. Hypertension or high blood pressure cannot be attributed to any one identifiable cause. Some causes include diet, lack of exercise, stress, metabolic defects, and heredity factors. A more complete list is displayed in the figure below. Hypertension is more common in industrialized societies (Fig. 1).

Definition

Blood pressure is often measured using a noninvasive technique called a sphygmomanometer. Sphygmomanometer is derived from the Greek word sphygmos, meaning "pulse." A cuff is wrapped around the upper arm of the individual and inflated to a level which is much higher than the expected systolic blood pressure measurement. Then a stethoscope is placed over the brachial artery and when no sounds are picked up it means the artery has been collapsed by the pressure against the walls preventing blood from flowing. Systolic blood pressure is measured by slowly releasing the pressure in the cuff until it eventually reaches a point where tapping sounds are heard, which is caused by blood spurting with each pulse. This occurs during ventricular contraction. Diastolic blood pressure is measured by continuing to

let the air out of the cuff, and when sounds are no longer heard, a reading is taken; no sounds mean blood is continuously flowing through the artery. This occurs during ventricular relaxation.

Measuring blood pressure is a quick and non-invasive way to obtain a general index of cardiovascular function of individuals. It is also one of the most common physiological measures used in behavioral medicine research (Andreassi, 2006).

Body Composition

Anthropometrics; Body mass index; Fat mass; Fat-free mass

Definition

Body composition is the proportion of fat, muscle, and bone of an individual's body. It is most often expressed as percentage of body fat and percentage of lean body mass (LBM) or as a ratio of lean mass to fatty mass. Lean mass includes muscle, bone, skin, internal organs, and body water. Fatty mass consists primarily of body fat (subcutaneous fat) and internal essential fat surrounding organs (visceral or intra-abdominal fat). Two people of the same height and same body weight can appear completely different from each other due to different body compositions. Body composition can provide important information about an individual's possible risk for cardiovascular disease or diabetes.

The American Dietetic Association recommends that a healthy adult male's body should have between 8% and 17% fat and a female should have 10–21% (ADA, 2009). Levels significantly above these amounts may indicate excess body fat. Athletes, leaner individuals, and more muscular individuals will have a body fat percentage lower than these levels.

Body Composition Measurement

Body composition (particularly body fat percentage) can be measured in several ways. Anthropometric measurements usually include height, weight, body mass index (BMI), waist circumference, waist-to-hip ratio, and percentage of body fat. These measures are then compared to reference standards to assess weight status and the risk for various diseases. Anthropometric measurements require precise measuring techniques to be valid but are the simplest and least expensive way to measure body composition.

Body mass index (BMI) is defined as an individual's body weight divided by the square of his or her height (kg/m^2). It is used to estimate an individual's adiposity based on his/her height, assuming an average body composition. BMI is not a direct measure of percentage body fat, but because of the simplicity of measurement and calculation, it is the most widely used diagnostic tool to identify those who are underweight, normal, overweight, obese, or morbidly obese.

Waist Circumference. A high waist circumference (WC) is associated with an increased risk for type 2 diabetes, dyslipidemia, hypertension, and cardiovascular disease when BMI is between 25 and 34.9. (In adults, a BMI greater than 25 is considered overweight and a BMI greater than 30 is considered obese.) Changes in WC over time can indicate an increase or decrease in abdominal fat. Increased abdominal fat is associated with an increased risk of heart disease. WC is measured by locating the upper hip bone and placing a measuring tape around the abdomen (ensuring that the tape measure is horizontal).

Waist-to-Hip Ratio. The waist-to-hip ratio (WHR) has been used as an indicator of potential risk of developing serious health conditions. Research shows that people with "apple-shaped" bodies (with more weight around the waist) face more health risks than those with "pear-shaped" bodies who carry more weight around the hips. While the subject is standing, hip circumference is measured at the point yielding the maximum circumference over the buttocks using a tape measure to measure to the nearest 1 cm. The waist-hip ratio equals the waist circumference divided by the hip circumference.

Percent Body Fat. The most common method of measuring body fat is to assess skinfold thickness using a set of measurement calipers to measure the depth of subcutaneous fat in multiple places on the body. These measurements are then used to estimate total body fat with a margin of error of approximately 4% points. The measurement can use three to nine different standard anatomical sites around the body but typically include the abdominal area, the subscapular region, arms, buttocks, and thighs. The right side is usually only measured for consistency. The tester pinches the skin at the appropriate site to raise a double layer of skin and the underlying adipose tissue, but not the muscle. The calipers are then applied 1 cm below and at right angles to the pinch, and a reading in millimeters (mm) is taken 2 s later. The mean of two measurements should be taken. If the two measurements differ greatly, a third should then be done, then the median value taken.

Another common method of measuring body composition is bioelectrical impedance analysis (BIA), which uses the resistance of electrical flow through the body to estimate body fat. Partly because of a demand for faster and easier methods of evaluating body composition, BIA has become a widely used method of estimating percent body fat. The use of BIA is based on the principle that the conductivity of an electrical impulse is greater through fat-free tissue than it is through fatty tissue. Current-injector electrodes are placed just below the phalangeal-metacarpal joint in the middle of the dorsal side of the right hand and below the metatarsal arch on the superior side of the right foot. Detector electrodes are placed on the posterior side of the right wrist, midline to the pisiform bone on the medial (fifth phalangeal) side with the foot semiflexed.

Total body or estimated total body scans using dual energy x-ray absorptiometry (DEXA) give accurate and precise measurements of body composition, including bone mineral content (BMC), bone mineral density (BMD), lean tissue mass, fat tissue mass, and percent body fat results. The person lays on the whole body scanner, with the x-ray sources mounted beneath a table and a detector overhead. The person is scanned with photons that are generated by two low-dose x-rays at different energy levels. The body's absorption of the photons at the two levels is measured. The ratios can be then used to predict total body fat, fat-free mass, and total body bone mineral content. The procedure can take about 10–20 min. DEXA can also distinguish regional as well as whole body parameters of body composition. As such, it is considered a reference standard.

Body composition is also estimated using cross-sectional imaging methods like magnetic resonance imaging (MRI) and computed tomography (CT). Since MRI and CT give the most precise body composition measures to date, many pharmaceutical companies are very interested in these new procedures to estimate body composition measures before and after drug therapy, especially in drugs that might change body composition.

Definition

Body fat generally refers to adipose tissue, a complex connective tissue with specific roles in metabolism and endocrine function. While the terms "adipose tissue" and "body fat" can be used synonymously, body fat is most often used in the context of body composition, while adipose tissue is more often used when describing the physiological properties of fat. Fat consists of a variety of different cells including adipocytes (fat storage cells), connective tissue matrix (nonliving material to nourish the cells), nerve tissue, stromal vascular cells, and immune cells. Traditionally, adipose tissue was thought of as a passive storage depot of excess energy; however, recently, the specific roles of adipose tissue in endocrine function and metabolism have been identified.

Description

Body composition describes the proportion of lean and fat mass a person carries. Often, percent (%) body fat is used as a descriptor of body composition. Lohman, Houtkooper, and Going (1997) created recommended % body fat levels for children and physically active adults. They suggest average % body fat for healthy adults aged to be 18–35 is 13% for males and 28% for females or 18% for males and 32% for females aged 36–55. Severe excess of body fat, when compared to lean body mass, is known as obesity. An obese individual has a percentage of body fat greater than 22% in males and greater than 35% in females aged 18–35. For an older adult population (aged 36–55), obesity is defined as a body fat of greater than 25% for males and 38% for females (Lohman et al., 1997). The World Health Organization provides general classifications of overweight and obese individuals derived from population. These classifications are based on body mass index (BMI), one of the most common classifications of excessive body fat. BMI provides a ratio of a person's weight (in kg) to their height (in meters squared). Overweight individuals have BMI greater than 25.0 kg/m^2 and less than 29.9 kg/m^2 while individuals classified as obese have a BMI greater than 30 kg/m^2. Morbid obesity occurs in anyone with a BMI greater than 35 kg/m^2 (WHO, 2006). While BMI provides a quick and easy measure of body composition, it does not give any indication of % body fat. There are other methods available to provide a more complete description of body composition. These techniques, unlike weight and BMI, allow for the more precise measurement of body fat and fat-free mass (FFM) to better identify individuals who have excessive body fat.

Bioelectrical impedance analysis (BIA) crudely measures FFM and body fat. It measures body density based on the conduction of an electrical current applied to the organism. The intra- and extracellular fluids serve as electrical conductors for the current, while the cellular membranes act as electrical condensers. Lean body tissue contains a greater percentage of water (70–75%) while fat mass contains only 10–15% water (Kyle et al., 2004a). As such lean tissue conducts the current better than fat mass. BIA is based on the relationship between lean tissue's water concentration and conductance. BIA generates a resistance and reactance value that can then be used to calculated total body water, FFM,

and body fat. There are many different equations that have been developed to determine FFM and body fat from BIA measures and they range from generalized equations to population specific equations; it is up to the evaluator to choose the most appropriate equation. There are two excellent reviews that discuss the various equations for BIA analysis (see Kyle et al., 2004a and Kyle et al., 2004b). BIA is still a rather crude measure of body composition as it is based on many assumptions and the status of the participant, such as hydration level, fasting state, and caffeine ingestion, can significantly influence the results of BIA analysis. It, however, is easily accessible and does not require a trained technician to use.

Another method of body composition analysis that is often used in the field to measure body fat is the anthropometric measure of skinfold thickness. Skinfold thickness is often employed in combination with other anthropometric measures such as height, weight, and body circumference to create a general description of a participant's body composition. Also, skinfold measures are inexpensive and require little equipment, i.e., they can be easily used in a variety of settings. Skinfold measures are based on the premise that 30–70% of body fat is located subcutaneously, or just below the skin, and is proportional to visceral fat, or fat surrounding the internal organs and tissue. Calipers are then used to measure the thickness of subcutaneous fat (Heyward, 2006). From the skinfold measures, many equations have been developed to calculate the body density, percentage of body fat. Again these equations can be generalized to healthy or specific clinical populations. However, skinfold measures are still based on a variety of assumptions and requires skilled technicians for accurate measures. It is also a relatively insensitive measure of body fat and cannot detect differences over a short term.

Hydrostatic weight was at one time considered to be a gold standard of body composition analysis. It works by measuring the body volume of an individual submerged underwater. From body volume, body density is then calculated. One can then estimate body fat and fat-free mass from density values described in the literature. While hydrostatic weighing provides a reliable and valid measure of body density and body fat, it has a high subject burden (underwater submersion), it cannot differentiate between the different components of fat-free mass (muscle, organs, etc.) and relies on the assumed densities of FFM and body fat (Heyward, 2006).

Air displacement plethysmography (ADP) works on the same principle as hydrostatic weighing. However, body volume is determined via air displacement instead of water displacement. It has much less subject burden than hydrostatic weighing and is fast, noninvasive, and accessible to a wider range of body compositions. However, it also has the same limitations as hydrostatic weighing in that it cannot differentiate between the different components of fat mass and relies on the assumed densities of FFM and body fat (Heyward, 2006).

Dual-energy X-ray absorptiometry (DXA) uses very low dose radiation to differentiate between soft tissue and bone. Fat tissue is then estimated from the specific attenuation characteristics of soft tissue. DXA is able to distinguish between body fat, lean tissue, and bone, unlike any of the previously mentioned methods of body composition analysis. It is highly precise, and allows for the separation between different regions of the body. DXA, however, cannot differentiate between different compartments (i.e., visceral, subcutaneous, etc.) of fat and lean tissue (Heymsfield et al., 1997).

Computerized tomography (CT) uses X-ray attenuation to detect the different tissues and reconstruct an image of specific fat tissues (i.e., subcutaneous versus visceral), lean tissues (i.e., skeletal muscle, kidneys, liver), and bones. A trained technician can then use software to precisely quantify the amount of muscle and adipose tissue from just a single CT image. CT image analysis also allows differentiation between adipose tissue depots and individual muscle. CT imaging, however, exposes the participant to large doses of radiation, is very expensive, and requires highly skilled technicians to not only take the scan, but also to precisely quantify the amount of muscle and fat. It is still one of the most accurate methods to determine body composition at the tissue-organ level (Heymsfield, 2008).

Magnetic resonance imaging (MRI) is also one of the most accurate methods to determine

body composition. MRI involves the generation of a magnetic field where atomic protons behave like magnets and become aligned in the magnetic field. The protons are then activated by radio waves and absorb energy. A signal is then generated and is used to develop regional and cross-sectional images of the whole body. Fat, muscle, visceral organs, and bone are then precisely quantified (Heymsfield, 2008). MRI has the benefit of trivial radiation exposure, which lowers the risk for the participant. It is also the best method of body fat analysis as it can use multiple images and whole body or serial measures to get a precise measure of body fat and lean tissue. Again, it is very expensive, requires high technical skill, and the images can be affected by respiration.

Each of these methods can generate the amount of body fat and the % of body fat an individual possesses with varying degrees or accuracy and ease of use and cost. It is within the discretion of the individual to determine the most appropriate method.

Definition

Body image refers to how a person experiences or feels about his or her body size, weight, shape, or functionality. Body image is a broadly defined and measured construct. Some of the more commonly studied aspects are: body size satisfaction, body size estimation, weight appropriateness, self-perceived overweight, figure rating scale: current-ideal discrepancy, and appearance evaluation. Body image can influence weight-loss behaviors, emotional well-being, and health behaviors.

Description

Body image is a central component of emotional well-being and self-perception, involving the subjective experience and evaluations of the appearance of one's body. Body size satisfaction is the attitudinal component of body image, reflecting the feelings about one's own body, versus perceptual body image which describes one's estimated size. Media, peer, environmental, and personality characteristics can influence

a person's body image and satisfaction. Satisfaction with body image is a major factor which determines self-esteem and health-related behaviors, such as smoking, healthful nutrition patterns, and engaging in physical activity.

Approximately two-thirds of the US adult population is overweight (BMI $>=$ 25–29.9 kg/m^2) or obese (BMI $>=$ 30 kg/m^2) and excess weight is a known risk factor for diseases such as cardiovascular disease, type 2 diabetes, cancer, and mental illness. Concomitant with the increasing body size among the US population have been the counter-influences of national public health initiatives to reduce obesity and cultural preferences toward leaner figures. Obesity and overweight are also associated with decreased quality of life and poor body image. Poor or distorted body image can be a key factor in the etiology of eating disorders (anorexia and bulimia nervosa) and depression. Body Dysmorphic Disorder (BDD) is a newly recognized mental health condition characterized by an excessive concern with one's body image. While most of the body size satisfaction literature addresses weight concerns, it could also encompass feelings about one's height or specific body areas. Understanding the interrelationships between actual body size, perceived body size, and body image can be useful in determining motivation for weight loss, weight-control practices, and improving self-concept.

In studies of body image, women have consistently been found to view themselves as heavier than they actually are and desire a thinner figure. Research shows that African-American, Hispanic, and American Indian/Alaska native women all tend to display higher levels of satisfaction than white women. Many studies have also found the pattern of white women expressing greater body size dissatisfaction and at lower BMIs than their African-American or Hispanic peers. Women also show body size dissatisfaction at a lower BMI than men. National surveys have shown men to be more satisfied with their body size, even if they are overweight. Overall, men tend to show less awareness of being overweight and the necessity of losing weight if overweight or obese. Men appear to ascribe less importance to their body size than do women, which may account for these discrepancies in image and weight-control behaviors. Men who are dissatisfied with their size or weight tend to be split between wanting to gain muscle weight and wanting to lose excess fat, generally striving toward the muscular ideal male body type.

The associations between body size satisfaction and weight-loss practices are complex and depend on a variety of factors, such as actual or perceived body size, psychological factors, and health status, and they may differ by race and sex. In general, more people who report poor body image are likely to indicate that they are trying to lose weight, compared to those with low or no body image dissatisfaction. Traditionally, it has been reported that women who are dissatisfied with their body size or image tend to choose diet as a weight-loss strategy, while men dissatisfied with their bodies or body image focus more on exercise and diet in order to build muscle and lose weight. Dissatisfaction with body size and poor body image may lead women to avoid physical activity. Attempts to promote healthy weight loss, weight maintenance strategies, and positive body image may be best suited to encouraging appropriate physical activity, nutrition behaviors, and realistic body image and beauty expectations.

Definition

Body mass index (BMI) is defined as an individual's body weight divided by the square of his or her height (standard unit of measure is kg/m^2) (Table 1). It is used to estimate an individual's adiposity based on his/her height, assuming an average body composition. BMI is not a direct measure of percentage body fat, but because of the simplicity of its measurement and calculation, it is the most widely used diagnostic tool to identify those who are underweight, normal weight, overweight, obese, or morbidly obese. The most significant limitation of BMI is that the formula does not take into account phenotypical characteristics such as muscle mass (e.g., athletes who may be classified as "overweight" or "obese" according to their BMI, yet have a very low overall percent of body fat), bone mass, and frame size as well as varying proportions of fat, cartilage, and water weight. However, research has shown that BMI correlates well with direct measures of body fat, such as underwater weighing and dual energy x-ray absorptiometry (DEXA) (Mei et al., 2002; Garrow & Webster, 1985).

Since the early 1980s, the World Health Organization (WHO) has used BMI as the standard for recording obesity statistics worldwide (World Health Organization, 1995, 2000, 2004) (Table 2). In the United States, The Centers for Disease Control and Prevention (CDC) monitor BMI in both the pediatric and adult populations to generate prevalence estimates of underweight, normal weight, and overweight in the population (Ogden, Carroll, Curtin, Lamb, & Flegal, 2010). For adults 20 years old and older, BMI is interpreted using standard weight status categories that are the same for all ages and for both men and women.

For children and teens in the range of ages 2–20 years, the interpretation of BMI is both age and sex specific. While the BMI number is calculated the same way for children and adults, the criteria used to interpret the meaning of the BMI number for children and teens are different from those used for adults. For children and teens, BMI age- and sex-specific percentiles are used for two reasons: (1) the amount of body fat changes with age and (2) the amount of body fat

Body Mass Index, Table 1 How to calculate body mass index (BMI)

SI units	BMI = mass (kg)/(height (m))^2
	Note: Since height is commonly measured in centimeters, divide height in centimeters by 100 to obtain height in meters
Imperial/US customary units	BMI = mass (lb) × 703/(height (in))^2
	BMI = mass (lb) × 4.88/(height (ft))^2

differs by gender. Because of these factors, the interpretation of BMI is both age and sex specific for children and teens. Therefore, the CDC BMI-for-age growth charts take into account these differences and allow translation of a BMI number into a percentile for a child's sex and age. The percentiles fall into specific categories to define underweight, normal weight, overweight, and obese (Table 3).

For infants and children ages 0–24 months, the CDC recommends that health-care providers use the WHO growth standards to monitor growth via weight-for-length measurements that are sex specific to identify how children should grow when provided optimal conditions.

Body Mass Index, Table 3 Weight status categories for the calculated BMI-for-age percentile, United States pediatric population

Weight status category	Percentile range
Underweight	Less than the 5th percentile
Healthy weight	5th percentile to less than the 85th percentile
Overweight	85th to less than the 95th percentile
Obese	Equal to or greater than the 95th percentile
Morbidly obese	Equal to or greater than the 97th percentile

BMI is used as a screening tool to identify possible weight problems in both. However, BMI is not a diagnostic tool. For example, a person may have a high BMI, but to determine if excess weight is a health risk, a health-care provider would need to perform further assessments. These assessments might include skinfold thickness measurements; evaluations of diet, physical activity, and family history; and other appropriate health screenings and laboratory tests.

The Bogalusa Heart Study, originating in Bogalusa, Louisiana, has been focused on examining the early natural history of cardiovascular disease (CVD), coronary artery disease, and essential hypertension among a semirural community–based cohort of black and white children and young adults for over 30 years.

Description

The Bogalusa Heart Study, originating in Bogalusa, Louisiana, has been focused on examining the early natural history of cardiovascular disease (CVD), coronary artery disease, and essential hypertension among a semirural community–based cohort of black and white-children and young adults (Freedman et al., 2010; Voors, Foster, Frerichs, Webber, & Berenson, 1976). For over 30 years, study subjects identified in early childhood have been followed, and their anthropometrics, blood pressure, heart rate, blood cholesterol levels, as well as several other clinical end points that characterize CVD have been periodically measured (Voors, Webber, Frerichs, & Berenson, 1977). The investigators have described the incidence and prevalence of biologic and behavioral CVD risk factors in these children. Their population has enabled them to document differences not only between males and females but also between blacks and whites. The results from the Bogalusa Heart Study have clearly documented that atherosclerosis has its basis in childhood and that prevention can and must begin at the early ages and have resulted in hundreds of publications in the scientific literature (National Heart, Lung, and Blood Institute, http://clinicaltrials.gov/ct2/show/NCT00005129).

Design

The initial survey of over 3,500 children was initiated in 1973–1974 and was restricted to children from ages 2 ½ to 14 (Webber, Frank, Smoak, Freedman, & Berenson, 1987). A physical examination that included collecting anthropometric data, hemoglobin, blood pressure, serum lipids, and a health history was conducted. In 1976–1977, the second cross-sectional survey of over 4,000 children expanded the eligibility criteria to include children ages 5–17 years old. This

survey included information on salt intake, smoking, health beliefs, and attitudes, and for girls ages 8–17, menstrual history and oral contraceptive use. The third survey of over 3,500 children in 1978–1979 also collected skinfold thickness and two measurements of heart rate. The fourth survey of over 3,300 children in 1981–1982 added data on alcohol use, type A behavior, peer networks, and dieting habits.

The Bogalusa Heart Study continued to use a cross-sectional and longitudinal design with the general cross-sectional survey of approximately 3,700 Bogalusa children ages 5–17 in 1988–1989 in the sixth screen and additional longitudinal studies to recall children in defined subgroups for more intensive evaluation. Half of the 12,000 children screened since 1973 had been studied three or more times. There were several other cohort groups and studies. The Newborn-Infant Cohort Study was designed to describe distributions, interrelationships, and trends through time for blood pressure, serum lipid and lipoprotein concentrations, dietary intake patterns, and anthropometric measurements. Four hundred and forty infants born between January 1, 1974, and June 30, 1975, were examined at birth, at 6 months, and yearly at ages 1–4 and at 7, 10, and 13 years for cardiovascular risk factor variables. The Post-High School Study examined young adults ages 21–30 who previously were examined as children ages 5–14 in the first Bogalusa Heart Study screening in 1973–1974. The population included approximately 4,603 young adults originally screened and any other children or adolescents examined for the first time in any subsequent surveys.

The fifth screening began in 1988 and extended through December 1991. The Pediatric Pathology Risk Factor Program, which began in 1978, documented the relationship of cardiovascular disease risk factors to anatomic and pathologic changes. A local information system was established to obtain family or coroner's consent to autopsy any deceased resident between the ages of 3 and 26 in the Bogalusa area. Autopsy specimens were collected from over 100 deceased children and young adults, of whom approximately 40% had been previously examined in the Bogalusa Heart Study. Major activity during 1988–1991 involved 24-h dietary recall collections on all the 1963, 1966, and 1968 birth cohorts attending the Post-High School Study. A food frequency questionnaire was also self-administered to all the Post-High School Study participants. The use of these two dietary methodologies, 24-h dietary recall and food frequency questionnaire, provided data to assess the nutrient composition of diets of young adults, assess the weekly consumption of individual foods, compare nutrient composition data with food frequency data, and compare dietary intakes at the post-high school age with those of school age.

Several substudies were conducted using the Bogalusa Heart Study population. Among them were the impact of childhood obesity on risk factors, the relationship of apolipoproteins A-I and B in children to parental myocardial infarction, and the relationship between left ventricular size, as demonstrated by echocardiography and blood pressure distribution (Freedman et al., 2008). The study was renewed in Fiscal Year 1992 in order to follow up the previously examined young adults for development of abnormal levels of cardiovascular risk factors and clinical disease.

In 1997, the study was renewed and extended through June 2002 in order to study the impact of genetic factors on the evolution from childhood cardiovascular risk factors to subclinical and clinical morbidity in an adult population, ages 20–40, who had been followed over a long period of time. The study also seeks to study the association of risk factor phenotypes to anatomic changes in the cardiovascular system, as seen by necropsy. The population for genotype-phenotype studies includes approximately 1,400 siblings derived from 178 longitudinal birth cohorts. The cardiovascular phenotypes include obesity, blood pressure, lipids, lipoproteins, apoproteins, homocysteine, glucose-insulin, fibrinogen, plasminogen activator inhibitor-1, and von Willebrand factor. Environmental risk factors consist of sociodemographic characteristics, tobacco and alcohol use, oral contraception, physical activity, and diet. Subclinical morbidity includes echo-Doppler measurements of cardiac-carotid structure and function. Using robust sibling pair linkage

methods, a genome-wide search involving 391 markers with spacing of 10 cM is conducted for genes which influence quantitative traits. This is supplemented with 41 highly polymorphic markers located in or near candidate genes likely to be related to obesity, lipoprotein metabolism, blood pressure, insulin resistance, diabetes, atherogenesis, and thrombosis. The study is shifting from a population-based epidemiologic study to a family-based genetic epidemiologic study.

Over the past three decades, the Bogalusa Heart study has resulted in the following key scientific findings:

- Observations clearly show that the major etiologies of adult heart disease, atherosclerosis, coronary heart disease, and essential hypertension begin in childhood. Documented anatomic changes occur by 5–8 years of age.
- CVD risk factors can be identified in early life. Normative values from a large biracial (black-white) population (approximately 10,000 individuals) are available for comparison.
- The levels of risk factors in childhood are different than those in the adult years. Levels change with growth phases, i.e., in the first year of life, during puberty and adolescence, in the transition to young adulthood, and in adulthood.
- Autopsy studies show atherosclerotic lesions in the aorta and coronary vessels, and changes in the kidney vasculature relate strongly to clinical CVD risk factors, clearly indicating atherosclerosis and hypertension begin in early life.
- Gender and race contrasts are a major contribution to the research findings. It is well known that blacks have more hypertension and diabetes, white males have more early coronary artery disease, and women show a lag in the development of heart disease.
- Environmental factors are significant and influence dyslipidemia, hypertension, and obesity. Those that are controllable include diet, exercise, and cigarette smoking.
- Lifestyles and behaviors that influence CVD risk are learned and begin early in life. Healthy lifestyles should be adopted in childhood because they are critical to modulation of risk factors later in life. Primary care physicians, pediatricians, and cardiologists can play a major leadership role in the prevention of adult heart diseases beginning in childhood. Physicians are encouraged to obtain risk factor profiles on children, along with a family history of heart disease.

Definition

Brain damage causes physical damage to the brain that may range from microscopic neuronal damage to damage that extends over a large area of the brain. Although, technically, brain damage may result from a number of conditions including disease (e.g., dementias) and developmental conditions (e.g., autism, learning disabilities), the term "brain damage" is usually associated with brain injury. Brain injuries fall into two general categories related to mechanism of injury: traumatic and nontraumatic. Traumatic brain injuries (TBI) result from external forces and are often the result of falls, motor vehicle accidents, or being struck or assaulted. In wartime, blast injuries may also cause TBI. Nontraumatic brain injuries may result from a variety of events or infectious processes including, for example, cerebral vascular accidents (i.e., stroke), anoxia, tumor, seizures/epilepsy, or encephalitis. Brain damage typically results in impairment in brain functioning compared to previous or age-appropriate levels of functioning. The degree and pattern of behavioral change following brain damage is associated with the severity and location of injury.

Brain Tumor

Definition

Brain tumors (BT) are tumors which reside in the brain or spinal cord. They include abnormal cell proliferation of neurones or glia cells, in the cranial nervous, in the skull, in the limbic system, in the brain stem, or in the spinal cord. Metastasis may develop in the cortex. Severity of BT varies greatly, since this depends on their size, location, type, and stage of development upon detection. Those all are referred to as primary BT. Since often BT are hidden from the eye due to the skull, BT may be only detected via direct brain scans. Another type of BT are secondary BT, where peripheral tumors metastasize to the brain, mainly including lung, breast, colon cancers, and melanoma. Primary BT are among the ten most fatal cancers, with over 51,000 new cases diagnosed every year in the USA alone (Starkweather et al., 2011).

The most common type of BT is astrocytoma, where 75% of patients die within 5 years of diagnosis. Glioblastomas are one type of BT, with a median survival time of 14.6 months (Schneider, Mawrin, Scherlach, Skalej, & Firsching, 2010). Among the proven risk factors of BT are high-dose ionizing radiation, inherited genetic syndromes, and brain lymphomas associated with AIDS (Davis, 2007). The role of cellular phones in the etiology of BT is still under intense investigation. Often, psychological aspects are uniquely affected in BT, given the location of the tumor and its possible impact on mood, behavior, and cognition (Weitzner, 1999). Psychological factors such as depressive symptoms have been found to independently predict poor prognosis in BT (Starkweather et al., 2011). Furthermore, the latter authors reviewed studies and suggest that the neuroimmune interactions which are under control of astrocytes can in fact contribute to the depressive symptoms and the changes in tumor microenvironment seen in astrocytoma. Given the poor prognosis, observed psychological changes, and understood fear of having a BT, patients and close ones often require special psychological help for this tumor. Thus, BT are a clear example where behavior medicine can play a pivotal role in both research and treatment.

Definition

Brain waves are the physical representation of the brain's electrical charge and activity.

Electroencephalography (EEG) is the technique used to record electrical activity. EEG measures voltage fluctuations resulting from ionic current flows within the neurons of the brain. Brain wave activity is recorded from different standard sites on the scalp according to the international electrode placement system. Recording electrical activity requires measurement of voltage between two electrode sites. The electrical activity between electrode pairs is evaluated in terms of amplitude and frequency. Amplitude ranges from 5 to 200 μV. Frequency of EEG activity generally ranges from 0 to 100 Hz (American EEG Society, 1994; Niedermeyer and da Silva, 2004; Towle et al., 1993).

Brain wave activity can be recorded during wakefulness as well as sleep. With regards to sleep, stage N1 sleep or drowsiness is characterized by a fading of the alpha waves and increases in beta activity and a small increase in theta activity. As sleep deepens, high-voltage, single or complex theta or delta waves, which are called vertex sharp waves, appear. Stage N2 sleep is characterized by increased numbers of vertex sharp waves (K-complexes) and centrally predominant spindle waves, sinusoidal 12–14 Hz activity. Stage N3 sleep or slow wave sleep (SWS) is characterized by progressively higher amplitude and low-frequency delta waves (American EEG Society, 1994).

The frequencies are indicated by Greek letters:

- Delta – 0 to 4 Hz
- Theta – 4 to 8 Hz
- Alpha – 8 to 12 Hz
- Beta – 12 to 32 Hz
- Gamma – 3 to 100 Hz

Definition

The cerebral cortex is the outermost gray matter layer of the telencephalon or cerebrum of the brain.

Description

This entry describes the cerebral cortex in humans. Although there is a high degree of conservation across vertebrate species and especially in mammals, readers should refer elsewhere for phenotypic and functional details regarding other animals.

The cerebral cortex (Latin for "Brain" and "Bark" respectively) is the outermost layer of the cerebrum (also known as the telencephalon). The wrinkled or undulating appearance of the cortex is a result of folding that allows for greater surface area within the confines of the skull. The furrows are referred to as "sulci" (plural for sulcus and

Latin for "furrow") or "fissures" which are simply larger sulci that serve as important navigational landmarks. The rounded ridges between the sulci are the gyri (plural for "gyrus" and Latin from *gyre* meaning whirling or circular). There are individual differences in the patterning of the gyri and sulci, but the general pattern is highly correlated across individuals within species. The cerebral cortex consists of two hemispheres (right and left) that are connected by large bundles axons called commissures: the anterior, the posterior, and the corpus callosum. The largest of these white matter bundles is the corpus callosum and its fibers connect to corresponding regions of each hemisphere.

The surface of the cortex can be described in terms of the superolateral, medial, and inferior surfaces. The inferior surface can be further divided into the orbital and tentorial surfaces but it is commonly described according to the four of six visible lobes from anterior (front) to posterior (back) in a transverse or sagittal view: frontal cortex, temporal cortex, parietal cortex, and occipital cortex (there are also the insular and limbic subcortical lobes). These are named for the cranial bones they sit below and are demarcated by certain sulci and fissures and by hemisphere (i.e., right and left). The frontal and parietal lobes are divided by the central sulcus also known as the sulcus of Rolando. The temporal lobe is divided from the frontal and parietal lobes by the lateral sulcus also known as the Sylvian fissure. The occipital lobe is roughly delimited from the parietal and temporal lobes by the parieto-occipital sulcus converging with a line drawn upward from the preoccipital notch where the cerebellum meets the cerebral cortex.

The phylogenic history and evolution of the human brain is represented in the layers of the cortex. The outermost is the neocortex (Latin for "new bark") also known as the neopallium (Latin = "new mantel") or isocortex (Greek = "equal rind"). After the neocortex is the phylogenically older allocortex (Greek = "other cortex" also known as the archipallium). Next is the older still paleocortex or palepallium (Greek = "old cortex") and the oldest of all, the archaeocortex or archipallium.

In humans, the cerebral cortical surface area is on average between 2,200 and 2,850 cm^2. Typically, cortex is further organized by cell type in six layers or *laminae* that vary in total thickness from 5 mm at the precentral gyrus to 1.5 mm at the frontal and temporal poles with an average thickness of 3 mm. From the surface to the interior, the six layers of the cortex include: (1) molecular layer with mostly dendrites and long axons; (2) external granular layer with mostly small pyramidal cells; (3) pyramidal cell layer; (4) internal granular layer with small pyramidal and stellate cells; (5) inner pyramidal layer of large pyramidal cells; and, (6) the multiform or spindle-cell layer. The neurons of these layers number between 2.6 and 20 billion in the cortex with 0.6×10^9 synapses per mm^3. Regions of the cortex vary in terms of *laminae* thickness, in addition to cellular morphology, which involves the appearance of cells and their axons and dendrites.

There are a variety of other systems for mapping out the cortex including three-dimensional stereotactic coordinates or regions divided based on underlying cytoarchitectonic organization of the cortical tissue referred to as Brodmann's areas (BA). The cortex can also be classified by the general function associated with tissue within the region boundary but it should be noted that brain function requires coordination across and among a variety of brain regions.

For example, the primary visual cortex (also known as striate cortex; BA17) is part of the occipital lobe and is involved in processing visual information. Primary auditory cortex (BA41) is found on the lower surface of the lateral fissure that separates the temporal lobe from the frontal and parietal lobes. Somatosensory information processing occurs in the postcentral gyrus (also known as the primary somatosensory area; BA1,2,3) of the parietal lobe. Integration of visual and somatosensory information also occurs in the parietal lobe. Anterior to the somatosensory cortex are the primary (BA4) and secondary (BA6) motor cortices. Groups of cells within these regions can be quite specialized for a given perceptual or motor function.

Broadly, interpretation, planning, action, learning, and memory occur in the rest of the cerebral cortex in the association areas. The central sulcus serves to divide the adjacent anterior

and posterior cortical regions into the motor association cortex (also called the pre-motor cortex; BA6) and somatosensory association cortex respectively. The visual association cortex abuts the primary visual cortex in the most posterior part of the occipital lobes and the somatosensory association cortex in the parietal lobes, encompassing the lower half of the occipital and extending along the lateroventral temporal lobes.

The auditory association cortex encompasses roughly the upper temporal lobe. The language cortex is lateralized with the dominant hemisphere (commonly the left hemisphere) engaged in reception and production of language, and analogous areas in the non-dominant hemisphere (commonly the right hemisphere) that are involved in producing and understanding voice inflection and tone that provide information about the emotional content of speech. Within this region is a receptive language region known as Wernicke's area (BA22) that extends from the angular (BA39) and supramarginal (BA40) gyri. The expressive language area known as Broca's area (BA44 and 45) is located in the inferior fontal gyrus.

Particularly developed in humans is the most anterior part of the frontal cortex (often called the prefrontal cortex), which is rostral to the motor association cortex. The prefrontal cortex (PFC) is the slowest to mature and continues to develop well into young adulthood. The PFC is further divided into regions such as the orbitomedial (BA11 and 12) and dorsolateral (BA 9 and 10) PFC. These areas are associated with particular aspects of executive function such as impulse control, emotion regulation and reactivity, planning, judgment, working memory, and abstract reasoning.

Definition

Neuroimaging broadly refers to the relatively noninvasive technologies and techniques for localizing, measuring, and visualizing central nervous system function and structure. Common neuroimaging methodologies include magnetic resonance imaging (MRI), positron emission tomography (PET), and computerized tomography (CAT/CT).

Description

Neuroimaging refers to a collection of techniques used to noninvasively view structure and function of living brain tissue. The methods used to visualize brain tissue have evolved significantly over the last several decades from using x-ray technologies to the more recent and increasingly ubiquitous (nuclear) magnetic resonance imaging.

Contrast X-rays and Computerized Axial Tomography (CAT/CT)

X-ray photography creates images by passing x-rays through the body and onto a photographic plate by taking advantage of variation in x-ray radiation absorption of different tissues. Certain molecules and denser materials absorb more radiation and thus less reaches the photographic plate.

This method is excellent for seeing skeletal bones that appear on the photographic plate with a high degree of contrast compared to surrounding tissues. It is less useful for tissues that do not strongly differ in x-ray radiation absorption such as parts of the brain. One method to get around this is to introduce a radiopaque agent to increase contrast by differentially absorbing x-rays. This allows for the visualization of the cerebral ventricular and circulatory systems. Pneumoencephalography involves injecting air into the cerebral ventricular system to briefly displace cerebral spinal fluid (CSF), and cerebral angiography involves injecting a radiopaque dye into a cerebral artery. These methods are limited in the information they produce but can be used to examine general brain atrophy, damage, or displacement of blood vessels.

The next step in the evolution of x-ray imaging of the living brain was the introduction of computed tomography (CT) which is sometimes referred to as computerized axial tomography (CAT). However, CT is more appropriate, because "axial" merely refers to the plane of image acquisition, and images can just as easily be acquired in the coronal or sagittal planes. CT utilizes an x-ray detector rather than a photographic plate. The x-ray source and detector are mounted opposite one another on a rotating ring inside a tube that encircles the person being scanned. The CT scanner captures numerous images of the brain from several angles as the x-ray source and detector rotate around the head. These images are then reconstructed by a computer to make three-dimensional multi-slice images of the living brain. The brighter and darker areas of the images are described as "hyperdense" and "hypodense," respectively, with grayish components of the images as "isodense." Water and CSF appears almost black, white matter darker than gray matter, and skull as nearly white. Variation in image intensity is more carefully delineated in Hounsfield units (HU) with water having an HU of 0, CSF an HU between 8 and 18, gray matter and white matter HU = 37–41 and 30–34, respectively, and bone HU = 600–2,000. CT scans have the benefit of being relatively inexpensive and having very fast acquisition times making them particularly valuable tools for detecting recent brain trauma and intracranial lesions in emergency situations. Limitations of CT scanning include poorer contrast between brain tissue types and the number of CT scan any one person can have at a given time is limited because of safety requirements to limit exposure to x-ray radiation. Furthermore, while CT can be used to visualize brain structure, it is not useful for measuring brain function while engaging in a process or activity. Other methods allowing for accurate localization of brain function include positron emission tomography (PET) and functional magnetic resonance imaging (fMRI). Imaging equipment that combine CT and PET technologies in one package are now commonly available and increase information yield and utility with the practical benefit of taking up less space than dedicated CT and PET scanners.

Single Photon/Positron Emission Tomography (SPECT/PET)

Positron emission tomography (PET) and single photon emission computerized tomography (SPECT) are used to image brain activity. This method also uses radiation and radiation detectors but rather than shooting an x-ray through the material to be imaged, PET utilizes radiolabeled tracers in the form of chemicals that have specific actions within the brain. For example, fluorine-18-labeled 2-fluoro-2-deoxy-D-glucose (18F-FDG) is a commonly used radiotracer. When 18F-FDG is injected into the carotid artery, it is rapidly taken up by metabolically active neurons during an experimental task as it very similar to glucose. However, it cannot be metabolized like glucose and thus accumulates in active brain regions where it slowly breaks down. The radioactive label (or ligand) gives off photons (i.e., S*P*ECT) as a result of a nuclear process where a proton in the nucleus is converted into a neutron, neutrino, and a positron (i.e., *P*ET). Both the neutrino and the positron are then ejected from the nucleus. The kinetic energy of the ejected positron both varies and declines at a rate that depends on the nature of the surrounding material. When an ejected positron meets an

electron, it creates an annihilation reaction where the electron and the positron turn into two photons that travel in opposite directions (180°) of each other. These photons are measured as a line by two of a series of scintillation detectors mounted in opposition from one another. The images created by the PET scanner are not images of the brain itself; rather, they are images created from the relative distributions of detected amounts of radioactivity in brain regions of interest.

PET is powerful methodology that can be used to study hemodynamics, drug action localization, receptor function, metabolism, and even molecular processes including DNA synthesis. PET is particularly valuable in detecting disease processes that may be evident as metabolic variation but are not yet manifested as anatomical abnormality that could be detected using CT or MRI. However, PET images can be effectively combined with CT or MRI images providing accurate localization of accumulated radioactivity. PET is also advantageous in that radiation exposure is relatively limited. The primary limitation of PET is the necessity for local access to a cyclotron to produce radiotracers. The radiotracers have a very short half-life and thus must be made in close physical proximity to the PET scanner and utilized quickly. The limitations of PET and CT have led to a significant increase in application of methods that do not utilize hard radiation like x-rays or radiolabels that are expensive to produce. Structural and functional magnetic resonance imaging (sMRI and fMRI, respectively) and the recent emergence of near infrared spectroscopic imaging (NIRSI) allow for detailed analyses of both brain structure and function in the living brain.

Magnetic Resonance Imaging (MRI)/ Functional Magnetic Resonance Imaging (fMRI)

Magnetic resonance imaging (MRI) methods produce images of the brain and other bodily regions that are high in both contrast and resolution. Although some MRI methods utilize contrast agents, MRI does not expose patients or study participants to ionizing radiation. Rather, this technique utilizes a very powerful homogeneous and stable electromagnetic field.

This brief description of how MRI works is limited to "classical"/Newtonian physics, but quantum mechanical descriptions are available elsewhere. Protons are found in all of the nuclei of the atoms that make up the body, but conventional MRI utilizes hydrogen protons. Hydrogen protons spin randomly with their magnetic moments "pointing" in random directions until they are in the influence of the strong magnetic field of the MRI scanner where they all align in parallel with the direction (z-axis) of the external field generated by the electromagnet. Application of a radiofrequency (RF) pulse is applied to the z-axis aligned hydrogen protons with an excitation/receiver coil. As a result of absorbed energy from the RF pulse, the hydrogen protons move or "flip" into a higher energy state that is antiparallel to the z-axis toward the x-y plane. With the removal of the RF pulse, the hydrogen protons "relax" or move back into alignment with the external electromagnetic field along the z-axis and release the absorbed energy form the RF pulse as electromagnetic waves that are detected by the excitation/receiver coil and other magnetic gradient coils in three dimensions.

Static contrast methodologies are used to generate anatomical images of the brain. Depending on the type of RF pulse applied, the images highlight different types of tissue or fluids. Static contrast between tissue types is achieved by three properties of protons in tissues: (1) the proton density (i.e., how many hydrogen protons are in the region), (2) proton relaxation times along the z-axis (i.e., the longitudinal relaxation time or T1), and (3) proton relaxation times along the x-y plane (i.e., the transverse relaxation time or T2). Motion contrasts detect dynamic properties of protons in tissues and fluids to generate images of blood flow, capillary irrigation, perfusion, and diffusion of water.

Functional MRI (fMRI) refers to MRI methodologies that estimate brain activity. Brain slices are repeatedly imaged over time allowing for statistical contrast of experimental manipulations. The most common is blood oxygen level–dependant (BOLD) fMRI. BOLD fMRI methods exploit changes in levels of oxygen in the blood that result from the metabolic demands of brain tissue during

neural activity. Active brain tissue utilizes oxygen and the change from an oxygenated state to a deoxygenated state can be detected because deoxygenated blood is paramagnetic. Other methods include perfusion or dynamic-contrast MRI, which measures changes in blood volume using an injected paramagnetic contrast agent such as gadolinium, or magnetic resonance spectroscopy (MRS) which measures localized levels of brain metabolites. There is also diffusion MRI that measures diffusion coefficients of water in brain tissue. Diffusion tensor imaging (DTI) examines the water diffusion coefficients in neighboring voxels to estimate the shapes and directions of white matter tracts.

MRI possesses advantages over CT and PET including very high-resolution images that can be acquired without ionizing radiation. In most MRI procedures, no contrast agent is needed and the procedures are completely noninvasive. MRI still requires significant safety procedures though. The magnet is always active, and any objects that are susceptible to magnetism can become dangerous projectiles within the boundaries of the field. Furthermore, patients and study participants must be screened for metallic objects or medical devices such as pacemakers in and on their bodies.

Diffuse Optical Imaging or Tomography (DOI/DOT) and Near Infrared Spectroscopy (NIRS)

Diffuse optical imaging (DOI) and near infrared spectroscopy (NIRS) are relatively new applications for measuring relative changes in blood volume and oxygenation via hemoglobin levels as a proxy for cellular metabolism. These methods exploit changes in the properties of near IR light projected through tissue in the absorptive spectra and light scattering properties of water, oxygenated hemoglobin, and deoxygenated hemoglobin. Like BOLD fMRI, DOI measures the hemodynamic response as blood flows to the active tissue supplying oxygen to satisfy the metabolic needs of neurons in the active region. Changes in the way that light moves through brain tissue from the IR source to the IR detector can be computationally modeled and blood flow to particular brain regions can be examined based on the placement of the IR source and detectors.

Modeling how light moves through the various tissues of the head is a complex process that contributes to DOI and NIRS limitations. One method of simplifying the model is to assume the brain region being scanned is essentially "flat" and that the tissues do not differ in their optical properties. However, anatomical MRI can be combined with DOI/NIRS to provide a better model of absorption and scattering of light with bone and other head tissues. Advantages of this technology include a high degree of portability, rapid data acquisition, relative low cost, and complete noninvasiveness. The primary disadvantages result from the lack of robust spatial resolution and that imaging is limited to surface and near-surface brain tissue.

Definition

A brain injury refers to any damage that occurs to the brain. Brain injuries can be classified in various ways: specific types of injury, primary and secondary, focal and diffuse.

Description

Types of Injury

Brain injuries can be developmental in origin while others are acquired through trauma, stroke, or neurodegenerative processes such as Alzheimer disease. The focus here will be on brain injury acquired through trauma. Regardless of etiology, brain injury can have primary and secondary as well as focal and diffuse effects (Jallo, & Loftus, 2009; Weber, & Maas, 2007).

Primary Versus Secondary Injury

A primary injury arises during the initial blow to the brain. At the moment of trauma, the physical structures of the brain are displaced. This displacement results in a contusion or bruise to the brain, damage to blood vessels, and stretching or tearing of axons. The blood–brain barrier and the tissues covering the brain called the meninges may also be damaged. As well the cells in the brain may be damaged and die. Different tissues in the brain have varying thresholds of deformation or response to mechanical loading and so vary in their potential for injury. Depending on the location and intensity of the forces during the initial traumatic event, some tissues in the brain may experience greater forces and so may be more affected than others.

There are two principal mechanisms of primary injury. One involves actual trauma to the brain arising from the brain coming in contact with the inside of the skull. The point of initial contact results in what is called the coup injury. Depending on the forces involved in the trauma, the brain may in a sense bounce off the coup location inside the skull and move in the opposite direction. The point at which the brain contacts the skull results in the contrecoup injury. Depending on the force of the trauma, there can be a bleeding or hemorrhaging in the brain. This bleeding can be epidural or extradural meaning outside the dura mater, the outer most of three membranes or meninges covering the brain. There may also be subdural bleeding. This bleeding can lead to an epidural or subdural contusion or hematoma.

The other mechanism of primary injury arises from the whiplash effect with the head rotating on the neck due to the acceleration and deceleration forces present in some traumatic accidents such as in motor vehicle accidents. These acceleration-deceleration forces result in shearing strains which may cause tearing of blood vessels deep in the brain resulting in petechial hemorrhages. These strains also causing tearing of the axons or diffuse axonal injury.

The primary injuries lead to secondary injuries which result from processes precipitated by the trauma. Secondary injury begins within hours of the primary injury and plays an important role in the eventual outcome. While most people who suffer a traumatic brain injury recover to varying degrees, about 40% deteriorate due this secondary damage. Secondary injury results from complications associated with the primary injury which include cerebral hypoxia (low oxygen levels in the brain), hypotension (low blood pressure), cerebral edema (brain swelling), and increased intracranial pressure (pressure within the skull). Large increases in intracranial pressure can lead to pushing the brain (herniation) through the hole in the base of the skull called the foramen magnum.

Other secondary damage includes meningitis, acidosis (high acid levels in the blood), and

hypercapnia (high levels of carbon dioxide in the blood). Secondary injury can also be caused by release and imbalances in brain chemicals called neurotransmitters. One effect is called excitotoxicity which can cause neurodegeneration through the action of free radicals. Cerebral autoregulation is another type of secondary injury which affects the regulation of blood flow to the brain. Breakdown in the blood–brain barrier as well as cerebral ischemia are also secondary changes in brain function following injury.

Focal and Diffuse Injury

Focal injury refers to injury which occurs in a specific location in the brain. Diffuse injuries involve damage over a more widespread region. Focal injuries arise from a blow to the head which affects the underlying brain area. Diffuse injuries most often arise from acceleration-deceleration forces rather than a blow to the head. It is common for these types of injury to occur at the same time. Focal and diffuse injuries can occur in the context of trauma but also from other forms of brain injury such as stroke.

In the context of trauma, a focal injury arises from direct forces such as when the head strikes the inside of the windshield in a motor vehicle accident or the ice surface in a hockey game. These types of focal injury involve the skull remaining intact. Other focal injuries involve penetration of the skull such as in gunshot wounds to the head. Focal injuries are associated with symptoms arising from damage to the affected brain area such as the loss of hand function on one side of the body due to damage in the motor area on the opposite side of the brain.

Diffuse injury involves damage to the brain over a more widespread area. Diffuse may be a misnomer for this type of injury since the damage often involves multiple focal injuries spread over wide areas in the brain. In the context of trauma, such injuries arise from shearing forces associated with acceleration-deceleration forces resulting in diffuse axonal injuries and tearing of blood vessels. In the context of stroke, diffuse injury arises from multiple strokes occurring around the same time in different brain areas.

Diffuse axonal injury is most often seen in traumatic brain injury and refers to damage to the white matter tracts arising from rotational shearing forces associated most often with deceleration forces in assaults or motor vehicle accidents. The major source of injury is to the axons, the part of the neuron that affords communication between the neurons. The axon appears white due to the myelination and so is called white matter and collectively these axons form white matter tracts. When the brain is decelerated, parts which vary in their densities and distances from the point of rotation slide over one another and so create shearing forces which serve to tear these tracts. The most common locations for diffuse axonal injuries include white matter tracts of the cerebral cortex, basal ganglia, thalamus, and the deep hemispheric nuclei. Diffuse axonal injury involves axonal separation at the point of the stretch with the part of the axon distal to this tear degrading. It was thought that the major reason for the axonal injury was due to the mechanical forces present at the moment of trauma (the primary injury). Now, it is believed that there are a series of biochemical changes which occur in response to the primary injury hours to days after the primary injury due to shearing forces.

Definition

Neural or brain tissue is specialized for communication through the transmission of electrical signals. The majority (approximately 98%) of neural tissue is found within the brain and the spinal cord. It is composed of two basic classes of cells: nerve cells (or neurons), which transmit communication signals, and glial cells, which act to support both the structure and function of neurons (Carlson, 2004).

Neurons

The basic functional unit of the brain is the neuron. Its functional role is to send and receive the electrical impulses that communicate messages about sensory, motor, and cognitive events throughout the brain. The average brain contains roughly 100 billion neurons. Although there are upwards of 1,000 different types of neurons, they all have the same basic structure and function.

Each neuron has a soma, or cell body, that performs all the basic metabolic functions required to keep the cell alive and functioning. At one end of the cell body are the dendrites; these are fine processes or branches that receive incoming information from other neurons. Together the cell bodies and dendrites of neurons compose the gray matter of the brain, so named for its pinkish-gray coloration. At the other end of the cell body is the axon, a long cylindrical projection that conducts signals from the cell body for transmission to other neurons. Most axons are surrounded by a fatty layer of tissue, called the myelin sheath, which helps speed the conduction of electrical signals along the axon. White matter is composed mostly of axons and is so named for the whitish appearance created by the myelin sheath (Nolte, 2009).

Information is transferred from one cell to another at communication sites called synapses. Individual neurons are not physically connected to one another; rather between two communicating cells is a tiny gap called the synaptic cleft. The electrical signals transmitted along the axon of the sending (presynaptic) cell trigger the release of specific chemicals (neurotransmitters) which travel across the synaptic cleft and bind to receptor sites on the receiving (postsynaptic) cell (Conners, 2005).

Glial Cells

Greek for "nerve glue," neuroglia, or glial cells, are the support cells of the brain. Outnumbering neurons at a ratio of approximately 10:1, glial cells make up over half of the volume of the brain (Pinel, 2006). Glia were traditionally thought to physically hold neurons together. However, it is now known that glial cells provide structure and support for neurons by surrounding the cell bodies and processes of neurons (Kandel, 1991). Although not directly responsible for information processing and transmission, glial cells do play a variety of essential roles in maintaining and supporting the function of neurons:

Glial cells act to support neurons and, in doing so, provide the overall physical structure for the brain.

Specialized glial cells (oligodendrocytes in the central nervous system, Schwann cells in the peripheral nervous system) produce and maintain the myelin sheath that insulates axons.

Glial cells act as a supply system providing oxygen and nutrients to neurons.

Some glia (e.g., astrocytes and microglia) perform important cleaning and protective roles, removing excess neurotransmitters, pathogens, and cellular debris left following cell death.

During the process of development, specialized glia (radial glial cells) act to guide the migration of neurons to their specific locations in the brain and to direct the path of axon growth.

Cell type	Function
Astrocyte	Structural support, regulation of ion concentrations in the extracellular fluid, provide nutrients to neurons, and clean up debris following neuronal death (phagocytosis)
Oligodendrocytes	Produce the myelin sheath around axons
Radial glia	Specialized astrocyte, directs the path of migrating neurons and guides axon growth during development
Ependymal glia	Create the wall of ventricles and secrete cerebrospinal fluid (CSF)
Microglia	Phagocytosis and immune function protecting the brain from microorganisms; also produce the inflammatory response following brain injury

BRCA1 and BRCA2

Definition

BRCA1 and BRCA2 are breast and ovarian cancer susceptibility genes first identified in the mid-1990s (Miki et al., 1994; Wooster et al., 1995). Mutations in BRCA1 and BRCA2 (BRCA1/2) are associated with significantly increased risks of breast and ovarian cancer among women and smaller increases in breast and prostate cancer among men. The development of predictive genetic testing for BRCA1/2 mutations was accompanied by concerns about psychological and behavioral consequences of learning one's test results (Lerman, Croyle, Tercyak, & Hamann, 2002). However, a meta-analysis by Hamilton, Lobel, and Moyer (2009) concluded that although general and cancer-specific psychological distress may rise immediately after testing for mutation carriers, it tends to return to baseline

levels over time. Mutation noncarriers tend to report short-term decreases in anxiety and long-term decreases in cancer-specific distress. Despite these overall findings, there is a need to more fully understand the social context associated with BRCA1/2 testing; for example, Hamann and colleagues (2008) found that siblings who had different genetic test results experienced more negative interpersonal responses than siblings who shared the same test result.

In addition to investigations of psychological reactions to BRCA1/2 testing, increased attention has been paid to the behavioral consequences of testing. Among mutation carriers, prophylactic breast and ovarian surgeries dramatically reduce associated cancer risks (Domchek et al., 2010). Although the evidence for risk reduction is less clear, BRCA carriers may also receive recommendations for intensive breast (e.g., mammogram, breast MRI) and ovarian (e.g., CA125, transvaginal ultrasound) surveillance. Of note is a recent study of long-term behavioral outcomes which reported that over 80% of female mutation carriers had obtained risk-reducing breast or ovarian surgeries, compared to much lower levels among women with uninformative or negative results (Schwartz et al., 2011). Rates of mammography were generally high for all tested women (66–92%); ovarian screening was less well utilized, but still higher among mutation carriers. In general, results indicate that BRCA testing has favorable effects on behaviors associated with cancer risk reduction.

Despite the accumulated data on BRCA1/2 testing, there is a continued need for outcome assessment among understudied groups, including racial and ethnic minorities and underinsured populations. A more complete picture of the psychosocial and behavioral correlates of BRCA testing will emerge with studies that include more diverse populations.

Breast Cancer

Definition

Breast cancer is a disease that involves uncontrolled division of abnormal cells in breast tissues, typically the ducts (tubes that carry milk to the nipple) and lobules (glands that make milk). Several different forms of breast cancer

exist, which have implications for distinct medical treatments. Breast cancer cells can spread through the blood and lymph systems to other parts of the body.

Description

In the United States, breast cancer is the most common form of cancer in women and their second leading cause of cancer death (after lung cancer). It is estimated that more than 230,000 women and 2,000 men will be diagnosed with breast cancer in 2011, and nearly 40,000 adults will die of the disease (Siegel, Ward, Brawley, & Jemal, 2011). Approximately one in eight women will be diagnosed with breast cancer in her lifetime. Incidence and mortality rates for breast cancer have decreased in the past decade. Health disparities exist, however; for example, African American women are less likely to be diagnosed with breast cancer than are white women, but more likely to die from the disease. In addition, women with no greater than a high school education are more likely to die from breast cancer than are more educated women. Worldwide, breast cancer is the most common cancer in women, with increasing incidence and much lower survival rates in developing and low-income countries.

Researchers and clinicians in behavioral medicine, health psychology, and related fields are contributing to understanding and improving the lives of women with breast cancer in at least four ways. First, researchers have focused on understanding and promoting early detection of breast cancer, which contributes to enhanced survival. Barriers to obtaining mammograms to detect breast cancer are well characterized, including contextual factors such as having no regular physician and no physician's recommendation for mammography, language barriers, lack of health insurance and access to screening, low education, and low social support for screening. Individual factors including lack of knowledge regarding breast cancer screening, low perceived risk of and worry about breast cancer, embarrassment about screening, and fatalistic beliefs that cancer is incurable also serve as barriers to early detection. Provision of reminders (e.g., letter, phone) for screening, video and print materials, and one-on-one education to overcome barriers are effective methods for increasing mammogram use (Baron et al., 2008). Although mammography rates have risen dramatically in the past three decades, a minority of eligible women have never had a mammogram, and many more do not receive mammograms on the recommended schedule. Effective interventions targeted to these groups are needed.

Researchers in behavioral medicine and health psychology also are investigating biobehavioral factors that might contribute to breast cancer initiation and progression. Behavioral factors that play a role in poorer breast cancer prognosis include lack of physical activity, weight gain/obesity, alcohol use, and nonadherence to breast cancer treatments (e.g., McTiernan, Irwin, & Vongruenigen, 2010). It is crucial to note that no psychological factor has been demonstrated to promote the initiation of breast cancer. Plausible models through which psychosocial and environmental factors might promote disease progression exist, however, and experimental research with nonhuman animals suggests that chronically stressful environments might contribute to the spread of breast cancer once it has developed (Antoni et al., 2006). Application of these findings to humans must proceed only through very carefully conducted research.

Characterizing processes of psychological and physical adjustment to breast cancer and its treatment and delineating factors that help and hinder women as they confront the disease represent another important area of research in behavioral medicine and health psychology. Clearly, diagnosis of and treatments for breast cancer often constitute profound stressors for women (e.g., Stanton, 2006). Best demonstrated in prospective research (i.e., studies in which psychological and physical health indicators are assessed prior to and after breast cancer diagnosis), women who are diagnosed with breast cancer evidence significant declines in physical, emotional, and social functioning/roles relative to women who are not diagnosed with breast cancer. Women are most

prone to distress and life disruption during particular phases of the cancer trajectory (e.g., diagnosis and treatment, medical treatment completion, cancer recurrence). For most women, psychological and physical adjustment improves such that overall quality of life is positive and indistinguishable from that of the general population by approximately 2 years after diagnosis. Specific problems can persist for some women, however, such as fatigue/sleep problems, cognitive disruption during and after chemotherapy (e.g., memory problems), depression, fear of cancer recurrence, and sexual problems (e.g., Bower, 2008). Intimate partners and other loved ones also face challenges as they go through the breast cancer experience (Andersen, 2009; Manne & Badr, 2008).

Longitudinal studies reveal contextual and individual factors that predict psychological adjustment in women who confront breast cancer diagnosis and treatment. For example, low education, social isolation or lack of interpersonal support, lack of satisfaction with the medical team, and holding negative expectancies about general and cancer-specific outcomes can contribute to an increase in distress in women with breast cancer. Coping through attempting to avoid thoughts and feelings related to breast cancer also predicts decrements in adjustment, whereas engagement in approach-oriented coping strategies (e.g., problem-focused coping, seeking social support, emotional expression, positive reappraisal) often is associated with more favorable psychological status across time. Treatment-related alterations in biological systems also may contribute to negative side effects of breast cancer, such as cancer-related fatigue. Theories of adjustment and associated research demonstrate that multiple aspects of the environment and the individual influence women's psychological and physical health during and after the breast cancer experience.

Finally, researchers and clinicians have developed and tested the efficacy of psychosocial and behavioral interventions to promote well-being and health in women with breast cancer. Although findings are not completely consistent, reviews of this literature suggest that such approaches as cognitive-behavioral interventions, relaxation techniques, and psychoeducational strategies are effective in improving psychological status (e.g., distress, depressive symptoms, anxiety), fatigue, and pain (e.g., Duijts, Faber, Oldenburg, van Beurden, & Aaronson, 2011; Tatrow & Montgomery, 2006; Zimmerman, Heinrich, & Baucom, 2007). Interventions to promote physical activity also appear effective in improving fatigue, body image, depressive symptoms, quality of life, and physical functioning in women with breast cancer (e.g., Duijts et al., 2011; McNeely et al., 2006). Psychosocial interventions also can affect physiological parameters, although the question of whether they can affect important health outcomes in women with breast cancer is far more controversial (McGregor & Antoni, 2009).

In sum, theory and research in behavioral medicine, health psychology, and associated fields have promoted early detection of breast cancer, contributed to delineation of biobehavioral factors relevant to disease progression, advanced the understanding of women's experience of breast cancer, and offered effective interventions to enhance quality of life and health in breast cancer survivors. Ongoing and future research promises to extend these findings to underserved groups (e.g., women with advanced breast cancer, low educational resources, diverse ethnicities) and to create maximally effective and efficient interventions for women and loved ones who confront the disease.

Brief Multidimensional Measure of Religiousness/Spirituality (BMMRS)

Multidimensional measure of religiousness/spirituality

Definition

The Brief Multidimensional Measure of Religiousness/Spirituality (BMMRS) is a paper-pencil, self-report measure of different dimensions or facets of religiousness and spirituality (R/S) that was developed in 1999 a US national working group of experts supported by the Fetzer Institute in collaboration with the US

National Institute on Aging (NIA), part of the National Institutes of Health. The group's primary mission was to develop items for assessing health-relevant domains of religiousness and spirituality. Thus, the measure was specifically designed for use in health outcomes and other health research. It contains 38 items across 11 dimensions with two additional meaning dimension items in an appendix.

Description

Research into the relations between religiousness and spirituality (R/S) and health outcomes has increased in recent years. Scholars from many different disciplines including psychology, medicine, epidemiology, public health, sociology, nursing, anthropology, and other fields have launched empirical investigations not only to determine if there is a relation between R/S and health but also to ascertain the direction and strength of that relation and, more importantly for present purposes, its precise nature. That is, scholars recognize that both R/S and health are complex multidimensional constructs. Thus, questions at the global level (e.g., "Does R/S predict health?") are necessarily limited. More precise questions of the type "what aspects of R/S predict what dimensions or measures of health?" are likely to produce stronger and more consistent empirical findings.

It is in this context that the BMMRS was conceptualized and developed. Idler and colleagues (2003) describe specific procedures regarding delineation of domains as well as development and selection of items. An excellent summary may be found in Piedmont, Mapa, and Williams (2007). Briefly, the BMMRS was designed to provide a single-source measure of what are considered important domains of R/S that are likely to be significant for health outcomes research. Further, the instrument was to include both religiousness and spirituality. It was understood that though these terms are related, many investigators view them as distinguishable from one another. Thus, the authors of the BMMRS concluded that spirituality is generally concerned with the transcendent, addressing ultimate questions about life's meaning with the guiding belief that there is more to life than only what is seen or understood. Religiousness, on the other hand, is often the path to development of spirituality, but it also includes specific behavioral, social, doctrinal, and denominational characteristics that may or may not promote spiritual development. According to this formulation, it is possible to be religious and not spiritual, spiritual and not religious, or both spiritual and religious. Measures of both spirituality and religiousness were included in the BMMRS.

The specific dimensions assessed by the BMMRS include daily spiritual experiences (six items), values/beliefs (two items), forgiveness (three items), private religious practices (five items), religious and spiritual coping (seven items), religious support (four items), religious/spiritual history (three items), commitment (three items), organizational religiousness (two items), religious preference (one item), and overall self-ranking of religiousness and spirituality (two items). An appendix consists of two items assessing meaning. As intended, the BMMRS (or subscales) has begun to receive attention and use by investigators analyzing R/S and health outcomes. Recently, four studies (Masters et al., 2009; Neff, 2006; Piedmont et al., 2007; Stewart & Koeske, 2006) investigated the psychometric properties of versions of the scale (including both the longer scale and the BMMRS). Generally, these studies provide empirical support for the multidimensional construction of the scale, though it is also clear that these dimensions are considerably correlated with one another. This led Piedmont et al. (2007) to suggest that perhaps the scale should be considered multifaceted rather than multidimensional, a characterization that Masters and colleagues (2009) supported.

Brief Symptom Inventory

Suzana Drobnjak
Department of Psychology, University of Zurich, Binzmuehlestrasse, Switzerland

Definition

The Brief Symptom Inventory (BSI) is a 53-item-self-report instrument. It is a short alternative to the complete Symptom Checklist-90-Revised (SCL-90-R). The BSI was designed to assess psychological symptoms during the last 7 days in medical patients, non-patients, and subjects for experimental studies. It can be used in both cross-sectional and longitudinal studies, and it can measure chronological sequences as well as pre- and post-ratings.

The BSI is composed of nine primary symptom dimensions (somatization, obsessive-compulsive, interpersonal sensitivity, depression, anxiety, hostility, phobic anxiety, paranoid ideation, and psychoticism). It includes three global indices of distress (Global Severity Index, Positive Symptom Distress Index, and Positive Symptom Total), which measure the overall psychological distress level, the intensity of symptoms, and the number of self-reported symptoms. Each item of individual psychological stress can be answered on a 5-point scale, ranging from 0 = "not at all" to 4 = "extremely." It takes 8–10 min to answer all items.

The interpretation of the BSI is carried out in three steps. First, the three global indices of overall distress are used. Second, each primary symptom dimension is considered in order to determine the specific areas of psychopathology. Third, individual items are focused on discrete symptoms. The optimal interpretation is dependent on the integration of information from all three source levels. The test scores are reported in terms of standardized area T-scores.

For the evaluation of the BSI, different normative data for different samples were consulted. Among these were adult non-patients, adult psychiatric outpatients, adult psychiatric inpatients, and adolescent non-patients.

Based on a sample of 719 psychiatric outpatients, reliability coefficients were established. Internal consistency (Cronbach's alpha: 0.71 for psychoticism to 0.85 for depression) and test-retest reliabilities (Cronbach's alpha: 0.68 for somatization to 0.91 for phobic anxiety) show a high reliability. The Global Severity Index also revealed an excellent stability coefficient of 0.90. All primary symptom dimensions of the BSI also correlate highly with the comparable dimensions of the SCL-90-R, which makes the BSI a particularly apt shorter inventory. Moreover, the BSI has a high convergent, discriminant, and construct validity.

The BSI is used by professionals like psychologists, psychiatrists, physicians, nurses, and other healthcare professionals. It helps them to assess the psychological problems of their patients, to find an adequate support for care management decisions, and to measure and monitor patient

progress during and after treatment. Furthermore, by providing aggregated patient information, the BSI is an effective tool to measure the outcome of treatment programs. The BSI is used worldwide and therefore has been translated into two dozen languages, such as Spanish, French, and Italian.

More recently, the BSI-18 has been developed. The BSI-18 is a brief 18-item-srcreening inventory designed to screen for psychiatric disorder in medical and community populations. The items are selected from the anxiety, depression, and somatization dimensions of the SCL-90-R and BSI.

Bronchitis

Linda C. Baumann and Alyssa Karel
School of Nursing, University of Wisconsin-Madison, Madison, WI, USA

Definition

Bronchitis is a respiratory condition in which there is inflammation of the bronchi and excess mucus secretion in the airway. This excess secretion of mucus often causes a partial obstruction of the bronchi. Bronchitis can either be short lived and self-limiting (acute) or present with a recurrent productive cough (chronic).

Description

Most cases of acute bronchitis are preceded by an acute viral infection of the upper respiratory tract, but bacterial causes are also not uncommon. The most common symptom is a persistent cough accompanied by excessive production of mucus. Other symptoms include headache, chest discomfort, and shortness of breath, which is often made worse with exertion. Because acute bronchitis is generally self-limiting and will subside within 7–10 days, treatment is often supportive and antibiotic treatment is not recommended. Supportive treatment consists of fluids, rest, anti-inflammatory medications such as aspirin or acetaminophen, the use of a humidifier, and occasionally bronchodilators and cough suppressants.

Chronic bronchitis is characterized by persistent cough with excessive sputum production for at least 3 months for two consecutive years. Along with emphysema, a disease characterized by enlargement of alveoli distal to the terminal bronchiole, chronic bronchitis is one of the two major forms of chronic obstructive pulmonary disease (COPD). The conditions most often coexist and COPD is usually discussed as one disease state.

Chronic bronchitis is characterized by chronic inflammation of the airway, lung parenchyma, and vasculature. The inflamed airways result in hypertrophy of mucous glands causing excessive mucus in the airway and occlusion of small bronchi. Cycles of injury and repair of small airways cause narrowing and fibrosis. Changes in lung parenchyma results in emphysema and destruction of the lungs over time. Typically patients have problems with hypoxemia, airflow limitation, and hyperinflation of the lungs, gas exchange abnormalities, and pulmonary hypertension.

COPD is a major cause of death in the USA and worldwide. Smoking tobacco is the major behavioral risk factor for developing COPD. Although there has been a decrease in cigarette

smoking in the USA, there has been a marked increase in developing countries. Other risk factors in the development of COPD are exposure to occupational chemicals and dust, air pollution, infections and deficiency of the a_1-antitrypsin is a genetic risk factor.

COPD has both physiological and psychological consequences. Persons with COPD, when compared to the general population, experience higher rates of depression and anxiety, which can further complicate respiratory symptoms. Anxiety and depression negatively impact the quality of life of persons with COPD.

Non-pharmacological treatment modalities for COPD include cognitive behavioral therapy and pulmonary rehabilitation. Through progressive exercise, training of respiratory function, breathing exercises, education about medications, smoking cessation and physical activity, persons with COPD are often able to achieve an increased tolerance for exercise, decreased shortness of breath, and an improved quality of life.

Pharmacological interventions include tricyclic antidepressants and selective serotonin reuptake inhibitors (SSRIs). Benzodiazepines can also be used but the possibility of respiratory depression can be a serious side affect and therefore they should not be a first-line medication. Although presently no drug can reduce decline in lung function associated with COPD, bronchodilators can be used to improve ventilation. Commonly used bronchodilators include b_2-adrenergic agonists, anticholinergic agents, and methylxanthines. Oxygen therapy is also often used in treatment by raising partial pressure of O_2 in inspired air. Long-term O_2 therapy can improve survival, exercise capacity, and cognitive performance.

Brownell, Kelly D. (1951–)

Lara LaCaille
Department of Psychology, University of Minnesota Duluth, Duluth, MN, USA

Biographical Information

Kelly D. Brownell was born in 1951. He completed his undergraduate education at Purdue University and earned his Ph.D. in clinical psychology at Rutgers University in 1977. He then joined the faculty in the Department of Psychiatry at the University of Pennsylvania School of Medicine where he worked for 13 years. Since 1991, Brownell has been on the faculty at Yale University where he has served in a number of leadership roles including Master of Silliman College and Chair of the Department of Psychology.

Brownell is a professor, scientist, and internationally known expert on obesity. He is the co-founder and director of the Rudd Center for Food Policy and Obesity, the director of the Yale Center for Eating and Weight Disorders, and professor of psychology, epidemiology, and public health; institute for social and policy studies; and forestry and environmental studies at Yale University.

Major Accomplishments

Brownell's early research focused predominantly on the treatment of obesity. His "Learn Program for Weight Management" (Brownell, 2004), a treatment manual for patients, was first published in 1987 and has become the gold standard for behavioral weight loss interventions. Over the past decade, Brownell's emphasis has shifted to examining the deleterious effects of the "toxic food environment," the importance of obesity prevention, and the role of public policy in fighting the obesity epidemic. In particular, he has advocated for prohibiting fast foods and soft drinks in schools, restructuring school lunch programs, regulating food advertising aimed at children, taxing foods with poor nutritional value, and subsidizing the sale of healthy foods. His leadership in these efforts has been highly regarded. Time magazine identified Brownell as one of the "World's 100 Most Influential People" and referred to him as an "Obesity Warrior" due to his extensive efforts to translate science into public policy.

Brownell has published 14 books and over 300 scientific articles and chapters. His paper on "Understanding and Preventing Relapse" (Brownell, Marlatt, Lichtenstein, & Wilson, 1986), published in the American Psychologist, was listed as one of the most frequently cited papers in psychology. He has been the recipient of numerous prestigious awards including the James McKeen Cattell Award from the New York Academy of Sciences, the award for Outstanding Contribution to Health Psychology from the American Psychological Association, the Lifetime Achievement Award from Rutgers University, and the Distinguished Alumni Award from Purdue University. In addition, Brownell has served as president of many national and international organizations, including the Society for Behavioral Medicine, the Society for Advancement of Behavior Therapy, and the Division of Health Psychology of the American Psychological Association. He was elected to membership in the Institute of Medicine in 2006.

Physical environment

Definition

The widely accepted definition for the built environment was provided by the Transportation Research Board and Institute of Medicine (2005). Broadly defined, the built environment refers to "land use patterns, the transportation system, and design features that together provide opportunities for travel and physical activity" (Transportation Research Board and Institute of Medicine, 2005). Specifically, land use patterns refer to "spatial distribution of human activities," such as land use for residential, business, and recreational purposes. The transportation system refers to the "physical infrastructure and services that provide the spatial links or connectivity among activities." Examples of the transportation system include roads, public transit, sidewalks, and bike lanes. Design refers to the "aesthetic, physical and functional qualities of the built environment." Design features are related to both land use and the transportation system, such as greeneries, architectural design, and streetscape. The field of built environment is drawn upon interdisciplinary collaboration from urban planning, architecture, design, engineering, policy, economics, and many other areas.

Description

There has been increasing recognition in recent years about the link between the built environment and public health. Research in this area has been guided by ecological models (Berrigan & McKinnon, 2008), which emphasize multi-level environmental influences on behaviors (Hovell, Wahlgren, & Adams, 2009; Sallis, Owen, & Fisher, 2008). Built environment attributes of neighborhoods, such as land use, zoning, layout, design, recreation facilities, and transportation infrastructures, are associated with a series of health behaviors and outcomes (Renalds, Smith, & Hale, 2010). The most frequently examined health outcome is obesity, as behaviors related to both energy consumption (e.g., dietary behaviors) and energy expenditure (e.g., physical activity) are influenced by the built environment (Papas et al., 2007; Sallis & Glanz, 2009).

Dietary Behaviors

Food can be accessed from stores, markets, and restaurants. The number, type, location, and accessibility of food outlets are directly associated with individuals' food choices (Glanz, Sallis, Saelens, & Frank, 2005). Studies consistently found that individuals living in neighborhoods with better access to healthy food outlets (e.g., grocery stores) have healthier dietary behaviors and weight outcomes (Morland, Diez Roux, & Wing, 2006; Morland, Wing, & Roux, 2002). Conversely, individuals living in neighborhoods with little or no access to healthy food options (i.e., "food deserts"(Smith & Morton, 2009)) or with concentrated fast-food restaurants have poorer diets and worse weight outcomes (Li, Harmer, Cardinal, Bosworth, & Johnson-Shelton, 2009; Moore, Diez Roux, Nettleton, Jacobs, & Franco, 2009).

Physical Activity

The association between the built environment and physical activity is complex due to the multidimensionality of both built environment and physical activity (Sallis, Adams, & Ding, 2011). Built environment attributes related to physical activity are usually categorized as neighborhood design, transportation infrastructures, and recreation facilities.

Walkable neighborhoods (sometimes synonymous with "traditional neighborhoods" or "smart growth" neighborhoods), characterized by high residential density, good street connectivity, and mixed land use, support physical activity, especially active transport (e.g., walking, biking for transport purpose). These types of neighborhoods provide destinations within close proximity and direct routes for walking and biking (Owen, Humpel, Leslie, Bauman, & Sallis, 2004; Saelens & Handy, 2008; Saelens, Sallis, & Frank, 2003). Access to and quality of transportation infrastructures such as sidewalks, bike lanes, and public transit systems provide opportunities for transport physical activity (Saelens et al., 2003; Sallis et al., 2009). Recreational facilities such as public parks and neighborhood streets provide locations for leisure-time physical activity (Sallis et al., 2011). On a "micro" scale, features,

conditions, and amenities within parks and streetscapes such as aesthetics, cleanliness, and vegetation are related to individuals' physical activity in these locations (Ellaway, Macintyre, & Bonnefoy, 2005; Kaczynski, Potwarka, & Saelens, 2008).

Environmental Quality

Unsustainable planning and development bring hazards and threats to the natural environment, which, in turn, affect public health (Dearry, 2004; Frumkin, Frank, & Jackson, 2004). Current patterns of land use and development have led to environmental consequences such as natural habitat loss, fragmentation, and water shortage (Environmental Protection Agency, 2001). Urban sprawl and increasing automobile travels contribute to air and water pollutions (Dearry, 2004; Frumkin et al., 2004). Auto-dependent neighborhoods encourage driving, which accounts for a large proportion of greenhouse gasses emission, a major cause of global climate change (Intergovernmental Panel on Climate Change, 2007).

In addition to the evidence from the above areas, other studies have found associations between the built environment and other aspects of public health, such as mental health, social capital, and alcohol abuse (Renalds et al., 2010). With emerging evidence supporting the link between the built environment and public health, better policies and planning are needed to engineer health-promoting and environmentally sustainable neighborhoods.

Bulimia

Anna Maria Patino-Fernandez
Department of Pediatrics, University of Miami, Miami, FL, USA

Definition

The Diagnostic and Statistical Manual of Mental Disorders, fourth edition, Text Revision (APA, 2000), includes as the essential features of bulimia nervosa: (1) recurrent episodes of binge eating, characterized by eating in a discrete period of time an amount of food that would be considered excessive and a sense of lack of control over eating during the episode; (2) at least two binge/purge cycles a week, on average, for at least 3 months; (3) recurrent compensatory behaviors in order to prevent weight gain, such as vomiting, fasting, excessive exercise, and/or misuse of laxatives, diuretics, enemas, or other medications; and (4) self-evaluation is unduly influenced by body shape and weight. There are more women than men affected by this disorder which is often accompanied by depression and substance abuse.

Warning signs for bulimia nervosa (NIMH, 2011) include the following:
(a) Preoccupation with food
(b) Binge eating, usually in secret
(c) Vomiting after bingeing
(d) Abuse of laxatives, diuretics, and diet pills
(e) Denial of hunger or drugs to induce vomiting
(f) Compulsive exercise
(g) Swollen parotid glands
(h) Broken blood vessels in the eyes

Treatment of Bulimia Nervosa

Unless malnutrition is severe, the goal of treatment is to reduce or eliminate the person's binge eating and purging behavior. Psychotherapy has proven effective in helping to prevent the eating disorder from recurring and in addressing issues that led to the disorder (le Grange, Crosby, Rathouz, & Leventhal, 2007). As with anorexia, family therapy is recommended. Cognitive behavioral therapy (CBT) has also proven effective. Research has found that family-based treatment for adolescent bulimia nervosa is more effective and shows faster treatment effects than individual-based supportive psychotherapy (le Grange et al., 2007). CBT is an effective intervention for the purging and eating behaviors and associated symptoms of depression that often accompany bulimia nervosa (Agras, Walsh, Fairburn, Wilson, & Kraemer, 2000). CBT for this disorder includes psychoeducation, self-monitoring (e.g., keeping a food diary as a way of becoming more aware of the types of situations that trigger bingeing), eliminating rigid dieting, strategies to reduce bingeing and purging, and application of behavioral strategies to establish more regular eating habits (e.g., self-reward for three meals plus two snacks at regular times of the day). CBT may also involve addressing cognitive distortions (e.g., certain foods are good or bad) and using exposure techniques for avoided food or anxiety-evoking situations. CBT is often combined with nutritional counseling and/or antidepressant medications. Reviews of antidepressant trials in adults have found short-term improvements in bulimic

symptoms and a small improvement in depressive symptoms (Romano, Halmi, Sarkar, Koke, & Lee, 2002). No studies with antidepressants have been conducted in children with bulimia.

Definition

Bupropion is a medication that is currently approved in the United States for the treatment of major depressive disorder, seasonal affective disorder, and to assist in smoking cessation (Product Information, 2010a, 2010b). Although its mechanism of action is not clear, it (or its metabolite) appears to inhibit the reuptake of norepinephrine and dopamine with little effect on serotonin reuptake (Baldessarini, 2006; Product Information, 2010a). Bupropion is available in three formulations: immediate release (usually taken three times daily), sustained release (usually taken twice daily), and extended release (taken once daily) (Teter, Kando, Wells, & Hayes, 2008). When used for smoking cessation, it is recommended that bupropion be initiated 1 to 2 weeks prior to the day that the patient is planning to quit smoking and treatment should be continued for 7 to 12 weeks, with longer therapy considered to prevent relapse for those who successfully quit during initial therapy (Fiore et al., 2008; Product Information, 2010b). When used to treat depression, the full therapeutic effects of bupropion may not occur for up to 8 weeks after treatment initiation, although some symptoms may start to improve sooner (American Psychiatric Association, 2010; Finley, 2009). The length of treatment depends on patient characteristics such as severity of the episode of depression and number of previous episodes. Clinicians should consult the latest clinical practice guidelines for the treatment of depression for specific recommendations regarding the length of time patients should be maintained on antidepressant treatment, but depending on patient characteristics the recommendations currently range from 4 months of therapy (from the time of symptom improvement) to indefinite maintenance of therapy (American Psychiatric Association, 2010; Finley, 2009). Due to bupropion's activity as both an antidepressant and a drug that increases smoking cessation rates, this medication may be a good choice for patients being treated for depression who would also like to quit smoking (American Psychiatric Association, 2010).

Side effects commonly associated with the use of bupropion include dry mouth, insomnia, agitation, jitteriness, skin reactions, and gastrointestinal complaints (such as nausea and vomiting) (American Psychiatric Association, 2010; Teter et al., 2008). Bupropion can increase the risk of seizures and is contraindicated in patients with seizure disorders or who may be at increased seizure risk (e.g., someone with a history of eating disorder or head injury, someone who may be withdrawing from alcohol or sedative hypnotic drugs) (Product Information, 2010a). Risk of seizures when using bupropion can be minimized by avoiding high doses, avoiding rapid titration, and being sure to split the total daily dose as recommended in the product labeling (e.g., three times daily and twice daily dosing for the immediate and sustained release formulations, respectively) (American Psychiatric Association, 2010; Product Information, 2010a). As with all antidepressants, bupropion carries a warning regarding increased suicidality, particularly in children and young adults during the initial stages of therapy (Product Information, 2010a). Bupropion can also be involved in drug-drug interactions since it is a potent inhibitor of the cytochrome P450 (CYP450) 2D6 isoenzyme which is responsible for metabolizing a large number of medications (Finley, 2009). Therefore, the potential for drug interactions should be considered prior to initiating or discontinuing therapy and managed as appropriate.

Bypass Surgery

School of Nursing, University of Maryland, Baltimore, MD, USA

Coronary artery bypass graft (CABG); Heart bypass surgery

Definition

Coronary artery bypass grafting (CABG) is a revascularization procedure used to treat the advanced manifestations of coronary artery disease (CAD). In this type of heart surgery, healthy arteries or veins from elsewhere in the body are grafted to coronary arteries to increase blood flow and oxygen supply to the myocardium (heart muscle). Grafts are placed to bypass

coronary arteries significantly narrowed (stenosed) by arteriosclerosis.

Description

Coronary artery bypass surgery is one of the most common operations performed in the world. The goals of CABG are to prolong survival or to relieve symptoms of myocardial ischemia (e.g., angina). Other symptoms that may be improved following CABG include dyspnea, exercise tolerance, and quality of life. First introduced in the 1950s, today's conventional CABG procedure uses cardiopulmonary bypass (a heart-lung machine) and cardioplegia (intentional paralysis of the heart). Newer alternatives in CABG include off-pump (i.e., without cardiopulmonary bypass support), beating heart, and minimally invasive endoscopic approaches. A combination of approaches may be used during a single CABG procedure depending on the assessment of patient risks and benefits and provider preference and experience. Rapid evolution of new technologies in CABG as well as in the alternative therapies available to treat CAD has resulted in conflicting evidence from disparate clinical trials and registries. Consequently, consensus is lacking about the superiority of one approach over another (Eagle et al., 2004; Morrison, 2008).

Indications

The risks of CABG should be balanced against the expected symptom relief and survival benefit. CABG does not treat CAD pathophysiology. Vessel restenosis and graft blockage is common within 10–12 years following CABG (Eagle et al., 2005). Angina relieved by CABG typically recurs within 5–10 years (Bravata et al., 2007).

Ideally, a patient under consideration for CABG has developed medically refractory myocardial ischemia in the setting of optimal drug therapy. Indications for CABG outlined by the American College of Cardiology/American Heart Association guidelines for patients with stable angina, unstable angina, or myocardial infarction (MI) are based on the extent of CAD and left ventricular function (Eagle et al., 2004). Criteria include >70% narrowing of three, and in some cases two major coronary arteries, >50% narrowing of the left main coronary artery, or left ventricular ejection fraction < 0.55. The risk factors associated with mortality following CABG are the priority of the operation (emergent, urgent, or elective), advanced age, prior CABG, female gender, left ventricular ejection fraction < 0.40, number of major coronary arteries with significant stenoses, and percent stenosis of the left main coronary artery. While CABG continues to be the standard of care for patients with left main and three-vessel disease (Lee, Hillis, & Nabel, 2009), the evidence supporting this is being challenged by newer, alternative therapies (below).

Surgery

Prior to surgery, a coronary angiogram is conducted to estimate the extent of vessel blockage. Patients may have additional functional stress testing and perfusion imaging studies to evaluate the degree of inducible ischemia and myocardial viability.

Surgery begins with graft preparation. Internal mammary artery (IMA) grafts are preferred over other grafts because they demonstrate superior long-term patency (Umakanthan, Solenkova, Leacche, Byrne, & Ahmad, 2010). When feasible to preserve its native blood flow, an IMA graft is left in situ (connected) to the subclavian artery and its peripheral end anastomosed to the coronary artery beyond the area of stenosis. Saphenous veins harvested endoscopically with small incisions at the groin and knee may be used for multiple grafts.

The number of bypasses in a single operation may range from one to six. In conventional CABG, the chest is opened via a median sternotomy. Venous blood, which must be anticoagulated and kept warm, is rerouted to a cardiopulmonary bypass machine where it is oxygenated and then redirected back to the systemic arterial circulation. To stabilize the myocardium during graft placement, the heart is temporarily stopped using a potassium solution. Risks associated with use of cardiopulmonary bypass (e.g., thrombosis, emboli, bleeding, fluid

shifts, and temporary organ dysfunction) limit the length of CABG with cardiopulmonary bypass to less than 4 h, after which time the heart is restarted with controlled electrical shocks and the sternum wired closed (Gravlee, Davis, Stammers, & Ungerleider, 2008). The usual length of hospitalization following a conventional procedure is 4–6 days. For adequate wound healing, patients must avoid activities that put strain on the sternal incision for 12 weeks. Benefits of endoscopic CABG are smaller incisions, faster wound healing, shorter recovery times, and cost savings (Bravata et al., 2007). However, use of robotic devices, beating heart grafting, and limited visualization with endoscopic CABG procedures demand a high level of surgical skill and are more likely to result in incomplete revascularization. Recommended resources describing CABG approaches are Gomez and Gibson webcast (2007), Kuss, von Salviati, and Börgermann (2010), Sellke et al. (2005), and Umakanthan et al. (2010).

Complications

People undergoing CABG are at risk for the same complications as any surgery, plus some adverse events more common with or unique to CABG. The major complications associated with CABG are related to procedural success and durability. These include death, MI, stroke, neurocognitive impairment, renal dysfunction, mediastinitis, non-closure of the sternum, and need for revascularization. Myocardial infarction and stoke can occur due to emboli. Neurological abnormalities range from deterioration of intellectual function or memory to stupor or coma and may arise from hypoxia, emboli, hemorrhage, and metabolic abnormalities experienced during CABG (Knipp et al., 2004; Pepper, 2005). Mediastinitis and non-closure of the wound may arise with use of IMA grafts, which alter blood flow in the chest. Restenosis and graft blockage requiring revascularization can occur within months to years. Adverse events related to CABG surgery may be classified as perioperative or short-term (within 30 days of surgery), early (within the first year), and late effects (after the first year).

Alternative Therapy

Alternative therapies for CAD are risk factor modification, medical management, and percutaneous coronary intervention (PCI). Behavioral risk factor modification is a powerful tool that is often underemphasized in the treatment of CAD. Smoking cessation, diet modification, exercise, weight loss, and tight glycemic control in diabetics limit the progression of arteriosclerosis and prolong survival. Medical therapy for CAD includes aspirin, lipid-lowering agents (especially statins), beta-blockers, and angiotensin-converting enzyme inhibitors and/or angiotensin receptor blockers. Each of these drugs increases survival and has relatively few adverse outcomes (Morrison, 2006). Percutaneous coronary intervention is a group of catheter-based approaches that includes balloon angioplasty, bare metal stents, and drug-eluding stents. Percutaneous methods are revascularization alternatives to CABG surgery that are less costly, less invasive, performed more rapidly, and have shorter recovery times.

Whether to manage patients medically and whether to revascularize using CABG or PCI are current controversies. Revascularization is recommended for unstable angina and evolving MI; however, it is less clear how to best manage patients with stable angina. A recent study found that medical therapy plus CABG improved long-term outcomes over medical therapy alone in the management of asymptomatic patients with severe left ventricular dysfunction (Velazquez et al., 2011). In general, the incidence of restenosis is greater in PCI compared to CABG, while CABG has greater risks of mortality, stroke, and neurological complications. Percutaneous intervention is generally indicated over CABG in the setting of an acute MI or with comorbidities other than diabetes (Morrison, 2008). The newest PCI technology is drug-eluding stents which are designed to minimize restenosis in stented vessels, a common complication of bare metal stents. Drug eluding stents challenge the superiority of CABG to PCI and comparative study is currently underway. Overall, the decision to use CABG or PCI appears to be evolving to one that focuses on the complexity of coronary anatomy, patient

preferences, and potential risk and benefits depending on patients' medical states and their comorbidities (Lee et al., 2009).

Cachexia (Wasting Syndrome)

Definition

Cachexia is a syndrome characterized by the loss of lean body tissue, often including involuntary weight loss, accompanied by increased metabolic and proinflammatory cytokine activity. It is distinct from mere weight loss due to anorexia and from sarcopenia, which is characterized by the loss of lean body tissue replaced by fat mass with little or no resulting weight loss. Cachexia occurs in patients with chronic illnesses such as cancer, HIV/AIDS, chronic kidney disease, chronic heart failure, and chronic obstructive pulmonary disease.

Description

Etiology

The etiology of cachexia is multifactorial. Increased inflammatory processes in the form of cytokine production lead to metabolic dysregulation, such as increased resting energy expenditure, and may contribute to heightened protein degradation accompanied by decreased protein synthesis. Many patients with cachexia will also experience anorexia (i.e., a loss of appetite) and decreased nutrient absorption in the gastrointestinal tract, which accounts for concomitant weight loss. However, the overall loss of lean body tissue observed in patients with cachexia occurs independent of nutrient uptake.

Diagnosis

The multifactorial etiology and absence of a consensus definition for cachexia presents challenges to diagnostic uniformity. Most current diagnostic systems for cachexia assess at least some of the following: (1) percentage of unintentional body weight lost in a specific time frame (e.g., the past 12 months); (2) proportion of lean body mass to fat mass; (3) body mass index; (4) the presence of clinical symptoms such as

M.D. Gellman & J.R. Turner (eds.), *Encyclopedia of Behavioral Medicine*,
DOI 10.1007/978-1-4419-1005-9,

decreased muscle strength, fatigue, and decreased appetite; and (5) abnormal biochemistry such as increased inflammatory markers.

Treatment

Treatments for cachexia aim to restore lean body mass and improve quality of life. Pharmacological treatments have focused on (1) increasing appetite and caloric intake through the use of appetite stimulants; (2) maintaining and/or restoring lean body mass with testosterone, anabolic steroids, or human growth hormone; and (3) downregulating cytokine activity through the use of systemic anti-inflammatory medications. Non-pharmacological treatments include resistance training for muscle retention, nutritional counseling and supplementation to ensure adequate macro- and micronutrient intake, and targeted amelioration of conditions that may exacerbate cachexia such as opportunistic infections in those with compromised immune systems.

Psychosocial Impact of Wasting

Although cachexia has a gradual onset, its clinical manifestation occurs somewhat rapidly and often during advanced disease stages. Considerable reductions in physical activity, coupled with decreased appetite and metabolic changes, have a significant impact on patients' quality of life. Many patients with cachexia feel shame or embarrassment about their bodily changes and distance themselves from loved ones. Decreased libido may have deleterious effects on individuals' romantic partnerships.

The Role of Behavioral Medicine

Behavioral medicine plays a key role in the treatment of patients with cachexia. Behavioral medicine professionals can provide patient education regarding cachexia treatment options, deliver interventions to improve medication adherence, and offer counseling and instruction for tailored nutrition and exercise programs. The provision of psychotherapy that addresses acute psychiatric conditions, adjustment to chronic illness, and couples issues pertaining to sexuality can help to improve overall quality of life for persons diagnosed with cachexia.

Definition

Caloric intake is defined as the amount of energy consumed via food and beverage. A calorie is

a unit of energy that is defined as the amount of heat energy required to raise 1 g of water by 1°C. Calories are units that measure the energy in food as well as the energy produced, stored, and utilized by living organisms.

Daily caloric intake needs are determined by a variety of factors such as age, gender, height, weight, activity level, and genetics. Three well-documented formulas are used to calculate daily caloric needs: the Harris-Benedict equation (1919), the Mifflin-St Jeor equation (1990), and the Institute of Medicine's Dietary Reference Intake equation (2002). These equations determine the resting metabolic rate (RMR), which represents the minimum energy needed to maintain vital body functions. While the terms RMR and basal metabolic rate (BMR) are often used interchangeably, the BMR requires more stringent testing conditions and factor in calories needed based on the individual's activity level. The HHS/USDA 2005 recommendations for daily caloric intake requirements for healthy weight maintenance and prevention of obesity according to age, gender, and activity level are available at http://www.nhlbi.nih.gov/health/public/heart/obesity/wecan/downloads/calreqtips.pdf.

Caloric intake can be measured using objective and subjective methods. Common objective methods are calorimetry and the doubly labeled water technique, while common subjective methods are 24-h dietary recall interviews and food diaries. Objective measurements are highly accurate but costly to implement, while subjective measurements are less expensive but subject to greater error. In fact, subjective estimates can be off by as many as 800 kcal (Beasly, Riley, & Jean-Mary, 2004).

One pound of body weight is equal to approximately 3,500 cal. When caloric intake is equal to caloric expenditure, an energy balance is achieved and body weight is maintained. Weight loss occurs when caloric expenditure is greater than caloric intake. Conversely, weight gain is the result of greater caloric intake than caloric expenditure. Caloric imbalances in either extreme have multiple health risk implications, including obesity and eating disorders and their associated medical comorbidities.

Definition

A field in which the relationship between cancer and diet is examined from the interdisciplinary

perspectives of basic medicine, clinical epidemiology, preventive medicine, and behavioral medicine.

Description

The relationship between diet and cancer has recently been recognized as an area of scientific interest. Dietary factors are thought to be involved in 30% of cases of cancer in developed countries and in 20% in developing countries (Marian, 2010).

In 2004, the American Society of Clinical Oncology (ASCO) announced a goal of achieving prophylactic intervention for cancer prevention, with a focus placed on reduction of tobacco use, control of obesity, cancer-causing infections, and environmental carcinogens (Lippman & Bernard, 2004).

A WHO report (http://www.who.int/gho/en/) showed that 35% of adults aged ≥20 years old worldwide were overweight (body mass index [BMI]: ≥25 kg/m^2) and 12% were obese (BMI: ≥30 kg/m^2) in 2008. The rate of obesity has more than doubled since 1980.

Previous studies have suggested that unhealthy eating and lack of physical activity can affect the development and prognosis of some cancers, including breast cancer, colon cancer, and prostate cancer.

Research into the details of the association of diet with development of cancer is limited. However, a report by the International Agency for Research on Cancer (IARC) in 2002 showed that being overweight or obese is associated with an increased risk of cancer in both men and women (International Agency for Research on Cancer (IARC), 2002).

Based on these data, the American Cancer Society (ACS) guidelines (American Cancer Society guidelines on nutrition and physical activity for cancer prevention http://caonline.amcancersoc.org/content/vol56/issue5/) recommend:

1. Maintenance of a healthy weight throughout life
2. Adoption of a physically active lifestyle
3. Consumption of a healthy diet, with an emphasis on plant sources
4. Limited consumption of alcoholic beverages

Further research is required to examine the relationship between single dietary factors and development or progression of cancer and between health behaviors, including dietary lifestyle, and cancer.

A field in which the relationship between cancer and physical activity is examined from the

interdisciplinary perspectives of basic medicine, clinical epidemiology, preventive medicine, rehabilitation, and behavioral medicine.

Description

The relationship between physical activity and cancer has recently been recognized as an area of scientific interest. The role of physical activity in preventing cancer has been examined in several epidemiological studies and several reviews of publications. An appropriate physical activity may reduce cancer risk and improve the quality of life of cancer patients (Marian, 2010).

Epidemiological evidence suggests that physical activity is associated with a reduced risk of colon and breast cancers. Some studies have also reported the link between physical activity and a reduced risk of endometrial (uterus), lung, and prostate cancers. More good news – physically active lifestyle helps you reduce your risk of heart disease, diabetes, and osteoporosis (American Cancer Society guidelines on nutrition and physical activity for cancer prevention http://www.cancer.org/acs/groups/cid/documents/webcontent/002577).

Based on several publications such as the American Cancer Society (ACS) guidelines (American Cancer Society guidelines on nutrition and physical activity for cancer prevention http://www.cancer.org/acs/groups/cid/documents/webcontent/002577), the Centers for Disease Control and Prevention (CDC) (State indicator report on physical activity, 2010) and the American Institute for Cancer Research (AICR) (http://www.aicr.org/reduce-your-cancer-risk/recommendations-for-cancer-prevention/recommendations_02_activity.html) recommend at least 30 min of moderate to vigorous physical activity, above usual activities, 5 or more days a week, and they say 45–60 min of intentional physical activity is more beneficial.

Further research is required to examine the role of physical activity in cancer survivorship and its correlation with quality of life and reduced cancer risk. The National Cancer Institute (NCI)-funded studies are exploring the ways in which physical activity may improve the prognosis and quality of life of cancer patients and survivors (National Cancer Institute fact, sheet, physical activity and cancer).

Cancer and Smoking

Cancer and cigarette smoking; Cancer and tobacco smoking; Lung cancer and smoking

Definition

A cancer diagnosis represents a heterogeneous class of diseases characterized by uncontrolled

growth of malignant cells in the body. These cells form a tumor that starts in the epithelium, invades organs of the body and nearby tissue, has the capacity to metastasize to other sites through the bloodstream or lymph nodes, and may recur after surgical removal. The development of cancer may be influenced by hereditary and/or environmental factors.

Tobacco smoking is defined as the practice of burning and inhaling tobacco. The combustion from the burning allows the nicotine, tar, and other chemicals and toxins to be absorbed through the lungs. Cigarette smoking is the most prevalent form of consuming tobacco. Most national surveys define a current smoker as having smoked at least 100 (five packs) cigarettes in their lifetime and currently smokes on at least some days.

Description

Over 46 years of scientific research, including 29 reports from the US Surgeon General, has led to the unequivocal conclusion that cigarette smoking causes cancer. But, Dr. John Hill, first deduced that snuff (smokeless tobacco) might be cancerous in "Cautions Against the Immoderate Use of Snuff," written in 1761 (U.S. Department of Health and Human Services [USDHHS], 1982). The earliest scientific investigations on the positive association between smoking and cancer were published in the 1920s and 1930s (USDHHS, 1982). In 1950, four retrospective studies examining the smoking histories of lung cancer patients compared to controls were published, all indicating a positive link between smoking and cancer. The first Surgeon General's report with sufficient evidence to declare that smoking causes lung cancer was published in 1964 (U.S. Department of Health, Education, and Welfare [USDEW], 1964). At that time, smoking was causally linked to lung cancer among men, but there was insufficient evidence among women. Early on, the most prevalent lung cancers, squamous cell and epidermoid, were specifically associated with smoking. It was also found that the frequency of oat-cell and adenocarcinoma was greater among smokers compared to nonsmokers. In 1968, the Surgeon General's report concluded that smoking also caused lung cancer in women (USDHEW, 1968). Lung cancer remains the most common form of cancer among men and women.

Cigarette smoking is responsible for the majority of deaths due to cancer. Between 1995 and 1999, over 70% of cancer deaths among US males were attributable to smoking (USDHHS, 2004). During the same years, over 50% of cancer deaths among women were due to smoking. This corresponds to almost 1.5 million years of potential life lost among men, and almost 1 million years among women (USDHHS).

Some have questioned how a causal relationship could be determined between cigarette smoking and cancer. This is largely because random assignment and a control group are necessary preconditions to conclude that a cause-and-effect connection exists. However, the accumulation of robust associations over a long period of time can also be used to establish causality. The criteria used by the Surgeon General's report included the following: (1) the consistency of association; (2) the robustness of association; (3) the specificity of association; (4) the temporal nature of association; (5) the rationality of association; and (6) experimental and clinical autopsy-based evidence (USDHEW, 1967). Using these criteria, there is no doubt that cancer is caused by smoking.

Since the finding that smoking definitively causes cancer, the prevalence of cigarette smoking has declined. In 1965, the overall smoking prevalence was 42%, which decreased to 33% by 1971 (USDHEW, 1971). The rates of smoking sharply declined in the USA, although there was no change in the absolute number of smokers (53 million) over the 20-year period between 1951 and 1971. Since 2004, smoking rates have leveled off at about 20%. In 2010, 19.3% of adults (45 million) were current smokers (Centers for Disease Control and Prevention, 2011). The past decade witnessed an overall decline in the prevalence of cancer in the USA, which is directly related to declines in smoking.

With each Surgeon General's report, the evidence explicating the types of cancers caused by

smoking have increased. It is now well established that smoking damages almost every organ in the human body and causes at least 15 types of cancer (Table 1). There is a dose–response relationship between cancer mortality and the number of cigarettes smoked per day (USDHHS, 1982). Smoking a greater number of daily cigarettes leads to increased exposure to the 7,000 chemicals and toxins contained in each cigarette (USDHHS, 2010). Although addictive, the nicotine in cigarettes is not the source of cancer development. Rather, it likely results from the effects of the 69 carcinogens contained in cigarettes (USDHHS, 2010). There are several key chemicals in cigarettes that are known to be cancer causing in humans (Table 2). Among these dangerous chemicals are formaldehyde and arsenic.

The mechanisms that explain the causal relationship between smoking and cancer are complex. Genetic predisposition and polymorphisms are related to cancer risk among smokers and nonsmokers (USDHHS, 2010). Inhalation of the chemicals and toxins in cigarette smoke initiates genetic and cellular processes that lead to malignant tumor development. To date, the unique contribution of the carcinogens found in cigarettes to cancer is not fully known. But the evidence suggests that cigarette smoking leads to DNA damage. Repeated exposure to cancer-causing agents alters major cellular pathways through genetic mutation and the growth of DNA adducts. DNA adducts (i.e., DNA pieces that are chemically bonded to a carcinogen) are formed by cytochrome P-450 enzymes, which metabolize the carcinogens in cigarette smoke. Smokers with polymorphisms in the GSTM1 and CYP1A1 genes appear to have greater frequencies of DNA adducts compared to those without these polymorphisms. These processes facilitate unconstrained cell increases and inhibit the immune system's ability to reduce their progression and range.

Cigarette smoking is the single most important avoidable cancer risk behavior. Smoking cessation is the only method for stopping the pathogenic processes that ultimately lead to cancer. Thus, quitting smoking reduces the likelihood of a cancer diagnosis. A former smoker's chance of developing cancer declines gradually over time and depends on the extent of exposure to cigarette smoke. With the increasing duration of cessation, the overall rate of cancer mortality approaches that of nonsmokers (USDHHS, 1982). Ex-smokers of 15 years or more have lung cancer rates only two times greater than never-smokers.

The prevalence of smoking among people diagnosed with cancer approximates the national average. Many people erroneously believe that once a person has been diagnosed with cancer, the damage is already done; thus, there is no benefit of smoking cessation (USDHHS, 1990). However, the evidence indicates that continued smoking among cancer patients negatively affects their prognosis. Specifically, smoking is associated with increased risks of recurrence,

a second cancer, and decreased efficacy of cancer treatment. Thus, smoking cessation is also important for cancer patients and survivors.

In summary, cigarette smoking causes cancer. Indeed, smoking is the leading preventable cause of multiple cancers, including lung cancer. There is a dose–response relationship between daily smoking intensity and cancer mortality, but there is no safe level of smoking. The prevalence of smoking has declined since the first Surgeon General's report directly linking smoking to cancer, but about 20% of the US population continues to smoke. All of the biological mechanisms by which smoking leads to cancer are not yet elucidated; but it is known that smoking leads to DNA damage and reduces the immune system's ability to rid the body of cell overgrowth. Smoking cessation is the best way to reduce the risk of cancer and is beneficial even after a cancer diagnosis.

Screening

Definition

Despite the development of modern medicine, cancer is a leading cause of death and disability. Since the development of cancer is associated with many genetic and environmental factors, efforts to prevent cancer by decreasing environmental factors have been made.

There are three levels in the cancer prevention strategy. The primary prevention is to reduce exposures to risk factors contributing to develop cancer. It includes smoking cessation, treatment of viral infections including papillomavirus, hepatitis B and C virus, diet, physical activity, reducing exposures to sunshine, ionizing radiation, or some harmful material such as aniline dyes, benzenes, and asbestos. Currently, at least one-third of all cancer cases are thought to be preventable via avoiding these risk factors.

The secondary prevention intends to promote early detection and early treatment and, therefore, reduces significant morbidity or mortality by cancer. Screening cancers is the main attempt but has been proven effective for relatively few types of cancer, with a few exceptions. The U.S. Preventive Services Task Force currently recommends cervical cytology testing for cervical cancer screening, mammography for screening breast cancer, and fecal occult blood testing, sigmoidoscopy, or colonoscopy for screening colorectal cancer.

Tertiary prevention involves activities to minimize the negative impact or outcome of cancer and maximizing the quality of life after developing cancer. Some risk factors for the development of cancer may accelerate the advance of cancer and result in early recurrence or shorter survival. Examples include negative effects of continued smoking after development of lung cancer on survival and high fat consumption in promoting breast cancer recurrence. This level also includes rehabilitation programs and patient support programs.

Cancer Risk Perceptions

Definition

Risk is the likelihood that something will happen.

Risk is a combined function of the probability of loss and the consequences of loss

(e.g., severity of loss in the physical, psychological, social, and economic realms).

Risk is a population-based measure, the chance of something happening, as determined by its occurrence among a large group of people over time. An individual's risk varies considerably within a given numerical boundary of a population's risk, due to variations in personal, genetic, environmental, and behavioral factors.

Risk communication is the communication with individuals (not necessarily face to face) which addresses knowledge, perceptions, attitudes, and behavior related to risk.

Cancer risk perception is the judgment, based on cognitive and affective factors, of the chances that a given individual will develop cancer over a certain period of time. It can be significantly influenced by the way in which an individual's risk is communicated to him or her. Both "thinking" and "feeling" are critical components of risk perception in general and cancer risk perception in particular.

Description

The issue of risk perception and communication in the cancer arena has received increasing attention over the past decade (Klein & Stefanek, 2007; Peters, McCaul, Stefanek, & Nelson, 2006; Rothman and Kivniemi, 1999). This is due in large part to the increasing awareness that the judgment that people make about their likelihood of developing cancer has important implications. At the level of the individual, risk perceptions guide protective action, such as not smoking, exercise and dieting behavior, and undergoing screening tests for early detection of cancer. If the perception of risk is underestimated, such protective action may not occur. If the perception exceeds the objective risk, such perception may cause anxiety, depression, stress, or may even result in excessive screening behaviors or indulgence in "alternative" health practices that have no evidence base. At the community level, risk perceptions may guide responses by communities concerned about "cancer clusters" in their immediate environment, what might be causing such excess cancers, and what is needed to fix the problem. At the policy level, risk perceptions may influence funding for cancer research and the development of guidelines for screening to detect cancer early or genetic tests to identify individuals who may inherit a higher risk of developing cancer.

Risk Perceptions and Health Behavior

Arguably the most critical issue determining the importance of risk perceptions is determining if such perceptions promote healthy behavior. Outside of the cancer realm, a recent meta-analysis of vaccination behaviors did indeed find a consistent relationship between risk perceptions and behavior, supporting the role of risk perceptions as a core concept in health behavior theories (Brewer et al., 2007). Reviewing the link between risk perception and behavior in cancer, the relationship is present, but appears modest. A solid summary of this data is provided by McCaul, Magnan and Dillard (2009) and a systematic review by Edwards et al. (2006) focusing upon personalized risk communication for informed decision making related to screening tests. These summaries note a generally positive relationship in areas such as mammography screening and smoking cessation, but also report that such relationships may have any number of mediators or moderators involved in this risk perception – health behavior link, including worry, barriers to change, or the presence of a family history of cancer. Given the modest relationship between risk perceptions and health behaviors linked to cancer prevention or early detection, it is not surprising that direct evidence that changing risk perceptions will cause subsequent changes in behavior is less available. However, there is indirect evidence that such changes may occur. McClure (2002) reviewed a series of studies of interventions that have provided biomarker data (carbon monoxide feedback to smokers) and supported the role of changes in risk perception in smoking cessation. There is also some evidence that using "teachable moments" such as the diagnosis of cancer to support smoking cessation may be productive,

linked perhaps to a new appreciation of one's risk of death (McBride & Ostroff, 2003).

In sum, risk perception is but one of a number of variables impacting health behaviors most critical to cancer control such as healthy eating, physical activity, tobacco use, excessive alcohol intake, excessive sun exposure, and appropriate utilization of cancer screening tests.

Given the data to date that supports the role of risk perception in cancer control, it is important to have an understanding of the processes involved in how people develop their perception of risk, how it is measured, and future research needed to develop our understanding of cancer risk perceptions.

Risk Perception: The Role of Affect and Cognition

How do people think about risk? It is now recognized that our perceptions of risk are influenced by a host of cognitive and affective variables. In addition, "how" risk is communicated impacts how our perception of the risk of cancer may be formed. These processes often lead to biases and misperceptions that influence both laypeople and health-care providers. There are a host of such processes to consider, many reviewed by Klein and Stefanek (2007), Peters et al. (2006), and McCaul et al. (2009) in the context of cancer control and well explained by Slovic (2010) in a more general overview of risk and risk communication. A number of such cognitive processes involve mental "shortcuts" or "heuristics." Very briefly, these heuristics can be thought of as "rules of thumb" that are used often automatically to influence the perception of risk. These include the availability heuristic, representativeness heuristic, the anchoring heuristic, and the affect heuristic. As one example, the availability heuristic refers to the common practice of making judgments about the frequency of an event based upon the information that is most readily available. If such information is unrepresentative or incomplete, the subsequent judgment will be inaccurate. For instance, if someone is in the process of scheduling a flight and is exposed to several stories of airline crashes, this may make the person feel relatively more at risk than driving to his or her destination. Likewise, when someone hears a story of celebrities developing cancer, perhaps by repeated media exposure, he or she may overestimate the risk of developing similar cancers. While such "heuristics" may indeed be helpful and accurate, they hold the potential for very inaccurate estimates of risk.

In addition to cognitive influences, there is a growing appreciation of the role of "affect" or emotion in risk perception (Slovic, 2010). It has become clearer that people process information through two distinct modes: deliberative and experiential (Slovic, 2010), following what has become known as the "dual process" theory of thinking, with the "deliberative" system being logical, analytical, slower, and the "experiential" system being more affective, intuitive, and fast. While it is assumed that these systems interact in forming risk perceptions, much work is needed to determine how this process plays out in forming risk perceptions. The role of the "experiential" system may be even more contributory in the area of cancer risk perception, given the fear and anxiety that accompanies the image of cancer development and treatment.

Finally, how risk is presented may significantly influence the perception of risk. Risk estimates can be provided in ways that differ only in format. For instance, relative risk (RR) is most commonly used (e.g., the risk of cancer is 25% higher in group A than in group B) in medical journals and the media. Another approach is to provide the number needed to treat (NNT) (e.g., 300 people need to take medicine A in order to save 1 life). Finally, the information can be presented as an absolute frequency (1,000 people took medicine A and 3 developed cancer; 1,000 people did not take medicine A and 4 developed cancer). Formats for conveying risk are critical since individuals are not mathematically fluent, nor do they have stable opinions about the magnitude of any given risk (Lipkus, 2007). This issue of presentation format becomes key, given the recognition over the past several years of the influence of numeracy in risk communication.

Conveying Risk Estimates

Whether perceptions of risk impact decisions and behavior relies on how messages of risk

magnitudes are conveyed. It is important to emphasize that communicating risk is not equivalent to communicating numbers. In fact, there is some controversy in the field of risk perception about the degree to which presenting risk in numerical format is critical to an individual's understanding of risk over time and links to behavior change. That is, what may be key is not specific numerical reasoning, but simply whether an individual has an understanding of the risk in a general fashion, whether she or he understands the "gist" of the risk (Reyna, 2004). Presenting risk verbally (e.g., "you have a somewhat higher than average risk") provides an overall sense of risk, but may fail to communicate the exact magnitude of risk, and is not helpful in making direct comparisons of risk across individuals. Numbers may be more precise than verbal representations of risk and provide a bit of scientific credibility to the risk communication, and most people express a preference for numbers. However, they do not address "gut" reactions or intuition well and do not provide clear information to individuals who may struggle with numerical competency. This latter issue of "innumeracy" is a critical one since increasing evidence indicates that a large proportion of individuals, even highly educated ones, struggle with numbers (Lipkus, Samsa, & Rimer, 2001; Schwartz, Woloshin, Black, & Welch, 1997). In fact, Schwartz et al. (1997) found that numeracy was strongly linked to being able to accurately use information about the benefit of mammography and called for more effective formats to present risks and benefits of mammography. Overall, there are few "best practices" cleanly established, although the call to present information both numerically and visually (graphs, tables) has been proposed (Lipkus, 2007).

Summary and Future Directions

It is clear that cancer risk perceptions are but one of many influences on health behavior related to cancer control. However, there is growing evidence that risk perception generally and cancer risk perception specifically can impact health behavior. In addition to cognitive influences on risk perception, it is essential to acknowledge the role of affect in the perception of risk. This includes not only incident affect (emotional state when risk information is communicated) but also "integral" affect (i.e., affect specifically related to the risk in question). It is not in the too distant past that cancer was viewed as a death sentence, with disfiguring and toxic treatments. Thus, the image of or beliefs surrounding cancer can clearly "link" to negative affect, which may then influence the perception of risk. Another key issue is how best to convey risk information. In addition, numeracy impacts the perception of risk. Many people have problems dealing with frequencies, percentages, or fractions, which impacts accurate risk representations, and the use of verbal labeling to transmit risk information risks being less than specific and perhaps quite different in meaning than the communicator(s) of such risk meant to transmit.

Continuing research is needed to determine how best to present risk while also utilizing what we do know about presenting such information in as "transparent" a manner as possible (Kutz-Micke, Gigerenzer, & Martignon, 2008). We must also continue to explore cultural differences in risk perception and how such influences may impact both perceptions and risk communication in order to intervene most effectively to enhance cancer control behaviors.

Definition

Cancer screening is the use of diagnostic tests and procedures to detect the presence of cancerous tissue before it is symptomatic. There are recommended routine screening tests for some of the more prevalent cancers. The parameters (such as age, time intervals) set for screening recommendations increase the likelihood that tests may detect the disease rather than the disease presenting itself symptomatically.

Description

According to the President's Cancer Panel, 41% of Americans will develop cancer in their lifetime (Reuben, 2010); however, data from the National Health Interview Survey indicates that only 75% of the US population adheres to recommended routine colorectal, breast, cervical, and prostate cancer screenings (National Health Interview Survey [NHIS], 1997–2010). Screening is important because it increases the probability of finding a cancerous growth in its early stage, despite the lack of any noticeable symptoms. Finding a cancerous growth in its earliest stage (i.e., during its period of *sojourn*), or in some cases before it becomes *palpable*, increases the likelihood of successfully treating the disease before it spreads. Additionally, there must be sufficient evidence that treatment initiated earlier as a result of screening will lead to an improved outcome (National Cancer Institute [NCI], 2011).

Cancer screening may reveal no tumor or the presence of a cancerous growth, which is then classified by stage. The concept of *staging* as a general classification of localized, regional, and distant disease was developed in the 1940s (NCI, 2011). Staging describes the severity of a person's cancer based on the extent of the primary tumor. One of the more detailed and more widely used staging systems is the *Tumor, Node, Metastasis (TNM) system*. In the TNM system, the tumor size, the status of the lymph nodes, as well as the status of distant metastases (spreading to other parts of the body) are also categorized (NCI, 2011). The statuses of these

core elements are aggregated into stages 0 through 4 and are associated with the likelihood of disease survival. Adherence to recommended routine screenings usually leads to discovery of tumors in their earliest stage. This includes *in situ*, where any abnormal cells present are only in the layer of cells in which they developed, or *localized*, wherein the cancer is limited to the organ in which it originated, and has not spread.

There are several recommended routine cancer screenings, most of which are age specific, some of which are gender specific (Table 1). Recommendations to patients are usually made by primary care physicians, but most screening tests are performed by physicians or technicians specializing in that particular field. Adherence to recommended routine cancer screening has led to the discovery of early stage tumors and has prevented the development of advance stage cancers. This has in turn resulted in an increase in quality adjusted life years and saves thousands of dollars in medical expenditure. There are several cancer registries in the USA which maintain records of reported tumors and that work closely with hospitals, cancer research centers, and agencies responsible for cancer surveillance. The continued surveillance of screening behavior within the population, the chronicling of cancer staging in addition to monitoring associated morbidity and mortality rates provide valuable information treatment and survival.

Cancer surveillance and screening are carried out by several agencies and responsible programs such as the Surveillance, Epidemiology, and End Results (SEER) Program of the National Cancer Institute (NCI), and the Center for Disease Control's National Program of Cancer Registries-Cancer Surveillance System (NPCR-CSS). Cancer surveillance involves the measurement and monitoring of cancer incidence, survival, morbidity, and mortality for persons with cancer. Surveillance also assesses of genetic predisposition of a population, environmental risks in addition to population cancer health and risk behavior (NCI, 2010a).

Cancer screening is not without controversy, and there are ongoing debates regarding whether the harms associated with some tests outweigh their benefits. Screening tests may present unnecessary physical and psychological risks for persons being tested. Some screening procedures have been known to cause bleeding, while others have resulted in perforation of the lining of sensitive organs (Morbidity and Mortality Weekly Report [MMWR], 2010) (see Table 1). The risks of screening tests may be further increased as the test results may not always be valid (i.e., a test may fail to detect a cancerous growth, and this kind of *false-negative* result can lead to a delay in treatment and/or removal of the cancer). Contrarily, sometimes a test may detect a cancer when there is none present. This *false-positive* test result causes undue stress and anxiety and usually leads to the patient being submitted to further tests, which may also have risks (Levin et al., 2008).

The ability of a screening test to detect cancer in a person who truly has the disease (*sensitivity*) or failure to find cancer in a person who is truly negative for the disease (*specificity*) is of outmost importance in determining the gold standard for screening tests. A reliable screening test should have both high sensitivity and high specificity.

History of Screening

While cancers were being surgically removed as early as the 1700s, screening for the disease did not begin until the late nineteenth century. This was as a result of an insightful discovery by a mid-nineteenth century, German pathologist named Rudolf Virchow. Virchow discovered that cancerous tumors were the result of abnormal growth of normal cells (McNeely, 2002), which laid the foundation for early detection.

Cancer screening has evolved since its institution in the early 1900s, and advances in detection techniques have resulted in the early discovery of cancerous cell growth. This is attributed to the highly sophisticated screening tools used for various tests and procedures. The most common types of screening tests are imaging and laboratory tests. Imagining tests include x-ray mammograms for breast cancer screening and computed tomography (CT) scans used to detect or confirm the presence of brain, lung, and bone cancers, among others. Papanicolaou (Pap) tests for

Cancer Screening/Detection/Surveillance, Table 1 Advantages and disadvantages of some common cancer screening tests

Screening exam		Current recommendations	Benefits/advantages	Risks/disadvantages
Breast cancer screening	Mammography (a digital or film x-ray picture of the breast)	Women ≥40 years should have mammograms every 1–2 years	Only proven reliable method of detection of small abnormal tissue growths confined to the milk ducts (ductal carcinoma in situ)	False positive- which may lead to unnecessary additional testing
		Women who are at higher than average risk of breast cancer should talk with their health care providers regarding frequency of screening and age at which to start	Detects all types of breast cancers, including invasive ductal and lobular cancers	Over diagnosis may lead to the treatment of clinically insignificant cancers. This may result in breast deformity, thromboembolic events, lymphedema, development of new cancers, or toxicities due to chemotherapy
	Clinical breast exam	Every 3 years for women in their 20s and 30s and every year for women ≥40 years	Lead to a decrease in breast cancer cause specific mortality among women 50 –69 years	False-negatives lead to a false sense of security and a delay in cancer diagnosis
Cervical cancer screening	Pap test	Recommended for women at least 3 years after having first vaginal intercourse, but no later than 21 years old	Reduces mortality from cervical cancer by finding cancers when they are most treatable	Regular Pap tests lead to additional diagnostic procedures (e.g., colposcopy) and treatment for low-grade squamous intraepithelial lesions (LSIL), with long-term consequences for fertility and pregnancy
		Regular Pap test every 1 year or newer liquid-based Pap test every 2 years		
		Women ≥30 who have had 3 consecutive normal Pap test results may get screened every 2–3 years. Women ≥30 years may also get screened every 3 years with either the conventional or liquid-based Pap test, in addition to the human papilloma virus (HPV) test		
		Women ≥70 years with 3 or more consecutive normal Pap tests in and no abnormal Pap test results in the last 10 years may choose to stop having Pap tests		
		Women who have had a total hysterectomy for non-cancer related reasons may stop having Pap-tests

Screening exam		Current recommendations	Benefits/advantages	Risks/disadvantages
Colorectal screening	Flexible sigmoidoscopy	Men and women ≥50 years	Allows the doctor to view the rectum and the entire colon	Examines only the rectum and the lower part of the colon. Any polyps in the upper part of the colon will be missed
		Every 5 years[a], or	Doctor can perform a biopsy and remove polyps or other abnormal tissue during the test, as needed	
	Colonoscopy	Every 10 years, or		Requires thorough cleansing of the colon before the test. Some form of sedation is used in most cases
	CT colonography (virtual colonoscopy)	Every 5 years[a]		Risks tearing or perforation of the lining of the colon
	Double-contrast barium enema	Every 5 years[a], or		cannot perform a biopsy or remove polyps during the test
	Fecal occult blood test (gFOBT)	Annually[b], or	Not an invasive procedure, hence complications are rare	Additional procedures are necessary if the test indicates an abnormality
	Fecal immunochemical test (iFOBT/FIT)	Annually[b], or	No sedation is necessary	Fecal tests fail to detect most polyps and some cancers
			No cleansing of the colon is necessary	Dietary changes recommended a few days prior to gFOBT but not iFOBT
			FOBT does not cause bleeding, tearing or perforation of the lining of the colon	Colonoscopy required if the test indicates an abnormality
Digital rectal exam (DRE)	Annually	Interval uncertain (possibly 3–5 years)[b]	No cleansing of the colon is necessary	Only detects abnormalities in the lower part of the rectum
Stool DNA test (sDNA)	Interval uncertain (possibly every 3–5 years)			
Prostate cancer screening	Prostate specific antigen (PSA) blood test	Discuss with physician the pros and cons of receiving a baseline PSA and if conducted, when another test would be necessary	Detects the disease in its early stage among high risk men	Detects small non life threatening cancers that leads to over diagnosis and complications from unnecessary treatment
	PSA velocity test (How PSA measures rise over time)			Causes unnecessary anxiety
	PSA density test (Ratio of PSA level to size of prostate gland)	Men at higher than normal risk (Blacks, men whose father, brother or son have been diagnosed with prostate cancer)		Elevated PSA levels may be due to other noncancerous conditions such as benign prostatic hyperplasia and prostatitis
	Percent-free PSA (Ratio of unattached PSA in blood to total PSA)	Discuss screening with physician at 45 years

[b]The multiple stool take-home tests should be used. One test done by the doctor in the office is not adequate for testing. A colonoscopy should be done if the test is positive

cervical cancer screening and prostate-specific antigen (PSA) tests for prostate cancer screening are typically confirmed by laboratory tests. Other screening tools include ultrasound, magnetic resonance imaging (MRI), and fine-needle biopsy. Additionally, proteomics have been used to diagnose and identify the best treatment for specific individuals, and genetic testing has been used to confirm whether women tested may have an increased probability of developing a certain type of cancer (NCI, 2011).

The use of vaginal smears (Pap test) for cervical cancer screening was established in the late 1930s by George Papanicolaou (Papanicolaou and Traut, 1941). Colorectal screening began in the 1940s and was conducted with a rigid proctoscope until the introduction of the flexible sigmoidoscope in the 1980s (Grossman, 1998). Breast cancer screening was implemented in the 1960s (Fletcher, 2011), while PSA serum test was approved for prostate cancer screening by the Food and Drug Administration in the early 1990s (NCI, 2010b).

Recommending Authorities

Several authorities on cancer issues periodically update screening guidelines. Some of the more prominent agencies which make screening recommendations include the following: the American Cancer Society (ACS), the American College of Radiology (ACR), the American College of Obstetricians and Gynecologists (ACOG), and the National Cancer Institute (NCI). The ACS, the ACR, and the NCI issue guidelines for all cancer types considered amenable to screening, while the ACOG makes recommendations for female gender–related cancers such as breast and cervical cancer screening (American Cancer Society [ACS], 2011b; American College of Obstetrics and Gynecologists [ACOG], 2009, 2011; NCI, 2011). The United States Preventive Services Task Force (USPSTF) is another organization that makes screening recommendations. They are a small independent panel of nongovernment medical experts who have a strong foundation in preventive and evidence-based medicine (United States Preventive Services Task Force [USPSTF], 2011). The panel usually comprises of general doctors (such as family physicians, internists, physician specialists, pediatricians, nurses, and health behavior specialists). There is some amount of disagreement regarding some screening guidelines among these different groups, especially with reference to the recent controversial changes in breast cancer screening.

The USPSTF assigns one of five letter grades to each of its recommendations; a level of certainty regarding net benefits accompanies each letter grade (USPSTF, 2011). The USPSTF also uses an I-statement/grade when there is insufficient evidence to assess the balance of benefits and harms of the recommended service. These recommendation processes and methods are outlined in a procedure manual and are based on evidence-based medicine (USPSTF).

Controversial Recommendations

In 2009, the USPSTF recommended changing the breast cancer screening guidelines for women from annual mammograms beginning at age 40 to every other year beginning at age 50 after determining that the benefits of annual mammograms beginning at age 40 did not outweigh the potential risks (Pickert, 2011). They argued that increased mammography screenings would lead to a greater likelihood of false positives, psychological stress, depression, overexposure to radiation, and unnecessary surgery.

The scientific panel supporting the USPSTF's decision strongly believes that much of the abnormal cell growth detected in women in their 40s could be detected in their 50s with no adverse effects from the delay. However, there have been numerous studies, including that by Anders et al. (2008), which show aggressive fast-growing cancers in younger women, which would in fact contradict the USPSTF. The ACS, ACR, ACOG, and the NCI still recommend annual screenings, beginning at age 40 (ACOG, 2011; ACR, 2008; ACS, 2011a; NCI, 2011).

Prostate cancer screening is equally contentious and is notorious for detecting false positives and false negatives. PSA testing does not distinguish tumors that would cause no harm from clinically significant tumors, which results in overdiagnosis and overtreatment (Pickert, 2011). In October 2011, the USPSTF issued a 'D' grade for PSA screening, thus recalling previous recommendations of annual screenings for men who do not have an increased risk of getting the disease. The USPSTF has determined that there is a moderate or high certainty that PSA screening offers no net benefit and that the harms from associated tests and exams outweigh the benefits of the screening.

As agencies try to improve on screening recommendations and clinical practice, careful consideration must be made with regard to the public health message being communicated to the general population. New scientific discoveries, frequent changes in recommendations, and disagreements between recommending authorities cast doubts among the general public and dissuade persons from adhering to recommended screenings. In an effort to increase the number of early detections and reduce the incidence of avoidable cancers within the population, it is important to resolve existing controversies and reduce the frequency of changes in recommendations. These inconsistencies may result in confusion, mistrust, and a negative attitude and behavior toward recommended cancer screenings.

Surveillance

Public health officials often consider the proportion of the population that must participate in a screening program for one death to be prevented within a defined time interval. This proportion is dependent on the disease characteristics as well as other population parameters. Epidemiologists and population scientists often investigate the measures of risks within a particular population; this translates to the implementation of public health policy and screening guidelines as well as helps dictate the actions taken by medical practitioners.

Ongoing surveillance conducted by the aforementioned recommending authorities has identified disproportionately lower screening behavior among certain subsets of the US population. African American and Hispanics are less likely to seek recommended cancer screening compared to their non-Hispanic White counterparts (Vidal et al., 2009). Uninsured Americans and those living below the poverty income level are less likely to report having a routine place of care and thus less likely to get recommended screening advice from a medical professional. Blue-collar workers and workers in the service industry are less likely to adhere to recommended screenings when compared to persons employed in the white-collar job sector (Vidal et al.). In the United States, this information (on the noninstitutionalized civilian population) is collected and stored in several population health databases. As such, epidemiologists and behavioral scientists are able to assess the adherence to screening in conjunction with some of the more common social determinants of health and demographic information. With this information, we are also able to correctly identify groups of persons that are at a higher risk and therefore require more frequent

screening. These analyses lead to reports which further drive policies and influence research and investigations into current recommendations and screening practices. It is of utmost importance to not only recommend cancer screening but also provide the public with information on the associated harms and benefits to early detection and encourage persons to take a more active role in managing cancer-related and other preventive health behavior.

The information in the table below has been adopted from the American Cancer Society and the National Cancer Institute. It provides an overview of general screening recommendations and their associated advantages and disadvantages.

Definition

Cancer survivorship, as a construct, is a recognition of the large number of individuals living with cancer and its aftermath. The term represents an expanded emphasis placing quality of life on a par with efforts to prolong and lengthen survival. Although there is general agreement that "cancer survivorship" represents a distinct concept within the cancer experience trajectory, the definition of *who* is a survivor and *when* one transitions from patient to survivor status is less clear and depends more on sociological and political considerations than empirical data. The most common definition and that preferred by the Office of Cancer Survivorship at the National Cancer Institute is that cancer survivorship starts at "the time of diagnosis" and continues "through the balance of (the survivor's) life. Family members, friends, and caregivers are also impacted by the survivorship experience and are therefore included in this definition."

Description

Origin

Cancer survivorship is a relatively new area of study. Only since the 1970s could more than half of those adults diagnosed with cancer expect to live at least 5 years. "Cancer survivorship," as a construct, was introduced in the mid-1980s by the National Coalition for Cancer Survivorship. The definition introduced by the founder of that organization defines an individual as a cancer survivor from diagnosis throughout the remainder of his or her life and includes family, friends, and informal caregivers. Thus, survivorship was broadly defined and inclusive of those with whom the patient interacted intimately and from whom the patient received support. The impetus for this definition appears to be a desire to shift the focus away from the concept of the "cancer victim" to one in which individuals were seen as actively coping with the range of physical, psychological, and social sequelae that occur throughout the cancer experience from diagnosis to end of life.

Although this is the most common view of when cancer survivorship begins, other views exist, as well. Historically, the medical field has endorsed a more circumscribed definition of a cancer survivor as an individual who has completed active cancer treatment and experienced a period of at least 5 years of disease-free status. Thus, survivorship is more or less equated with "cure" of primary disease, and the focus is clearly on the aftereffects of cancer and its treatment. Others have defined a cancer survivor as "someone who has completed initial treatment and has no apparent evidence of active disease, or is living with progressive disease and may be receiving treatment but is not in the terminal phase of illness, or someone who has had cancer in the past." Again, this focuses away from the immediate effects of cancer and treatment and toward issues of posttreatment well-being.

Characteristics of Cancer Survivors

As of 2008, there were approximately 11,900,000 cancer survivors in the United States, representing about 4% of the population. As can be seen in Table 1, cancer is disproportionately a disease of older adults, and almost 60% of cancer survivors are aged 65 and older, although these individuals represent only about 12% of the total population, while less than 1% of cancer survivors are aged 19 or younger. Thus, issues of cancer survivorship occur most commonly in the context of physical comorbidities that are frequent among older adults.

The number of cancer survivors is growing in the USA, due to earlier detection of breast,

Cancer Survivorship, Table 1 Cancer survivorship in USA by age group (2008)

prostate, and colorectal cancer and, to a lesser extent, improved treatments. Currently, more than 66% of adults diagnosed with cancer can expect to live at least 5 years and 75% of children can expect to live at least 10 years following a cancer diagnosis. The total number of survivors is expected to increase at even a faster pace as the number of individuals aged 60 and older increases due to population growth and the aging of the "baby boomer" population. Simultaneously, the number of individuals who have survived cancer for a long period of time is expected to increase. Currently, more than 15% of cancer survivors have lived 20 or more years from initial diagnosis.

In terms of specific cancer sites, female breast cancer survivors represent the plurality of survivors (22%), followed by prostate cancer survivors (20%), colorectal cancer survivors (9%), gynecological cancer survivors (8%), hematological cancer survivors (8%), urinary tract cancer survivors (7%), and melanoma survivors (7%).

Racial and ethnic minorities are somewhat underrepresented among cancer survivors, particularly African Americans who represent approximately 13% of the total population but only 8% of cancer survivors. Considering all cancers, African Americans are more likely than other racial groups to die following a cancer diagnosis and less likely to survive for extended periods (e.g., $\geq$10 years). The precise reasons for this disparity are presently unknown, but likely include a complex interplay of social, cultural, and economic factors, with access to adequate medical care and poverty playing key roles. What is clear is that following diagnosis, racial and ethnic minorities experience relatively worse outcomes including greater chance of cancer recurrence, increased mortality, and decreased overall survival times.

Seasons of Cancer Survival

In 1985, Mullen described the "seasons" of survival, each of which is centered around a different stage of disease and treatment, and each of which focuses on a specific set of concerns. These seasons, acute, extended, and permanent survival, are described in Table 2.

Long-Term and Late Effects of Cancer and Its Treatment

As noted, long-term survival is now the norm for most cancer patients. This increased survival time has come with a cost; cancer and its treatment can and often do lead to decreased quality of life. Some of these effects are caused directly by tumor burden itself, while others are related to treatment exposures. That is, they are the unintended consequences of exposure to surgery, toxic chemotherapy, and ionizing radiation, among other treatments. The side effects of cancer and its treatment can occur in physical, psychological, or social domains and are often conceptualized in terms of long-term or late effects.

Long-term effects are those side effects that arise during cancer treatment and persist following the treatment period. These effects can last for months or years following cancer treatment, but may resolve over time. For example, many people treated with certain chemotherapies develop peripheral nerve damage during treatment that can affect hearing, balance, or touch for years afterward. *Late effects* on the other hand, are those symptoms or toxicities that are either undetected or absent during active treatment but arise only afterward. In many cases, late effects may not be recognized for years following cancer treatment. Research into the long-term and late effects of cancer and its treatment is ongoing, better understood in cases of pediatric cancer than adult-onset cancer, and not well-developed in terms of prevalence estimates or an understanding of when they might arise or how long they might last before resolving. Although many long-term and late effects of treatment are

Cancer Survivorship, Table 2 Seasons of survival (Mullen 1985)

Season	Disease and treatment stage	Physical concerns	Psychosocial concerns
Acute survival	Diagnosis, primary treatment	Pain control, side effects	Mortality issues, fear, distress, coping with treatment
Extended survival	Remission, completion of primary treatment	Physical limitations, treatment effects, loss of strength, fatigue	Fear of recurrence, body image
Permanent survival	Cure of disease	Long-term and late effects of treatment, second tumors, reproductive health	Employment, insurance, coping with diminished health

specific to particular cancer sites or treatment regimens, there are a number of common symptoms and experiences.

Physical Effects of Cancer and Its Treatment

The most common physical symptom reported by cancer patients regardless of cancer site or treatment is fatigue, with more than 50% of cancer patients reporting fatigue at some point in the survivorship trajectory. Pain is also a common long-term effect of cancer treatment, with more than 40% of cancer patients reporting pain at some point and more than one-fifth reporting pain as long as 2 years after diagnosis, most commonly resulting from surgical intervention. Other physical effects that can arise from cancer, surgery, radiation, chemotherapy, or hormonal exposures include second cancers, bone difficulties such as osteoporosis, cardiovascular and coronary dysfunction, fertility difficulties, hormonal deficiencies, sexual dysfunction, hematological problems, immunosuppression, lymphedema, pulmonary difficulties, and problems with renal function.

Psychosocial Effects of Cancer and Its Treatment

The term "distress" has been used to describe the emotional experience of cancer survivors in a nonpathologizing and nonstigmatizing manner. The most commonly used conceptualization of distress, from the National Comprehensive Cancer Network, defines it as "a multifactorial unpleasant emotional experience of a psychological (cognitive, behavioral, emotional), social, and/or spiritual nature that may interfere with the ability to cope effectively with cancer, its physical symptoms and its treatment. Distress extends along a continuum, ranging from common normal feelings of vulnerability, sadness, and fears to problems that can become disabling, such as depression, anxiety, panic, social isolation, and existential and spiritual crisis." Thus, distress encompasses a broad range of emotional experiences that range from normative feelings of sadness and fear about the future to more chronic and interfering experiences such as depression and anxiety.

Psychosocial difficulties such as distress appear to be fairly common among early cancer survivors, although many of these difficulties are mild in severity and tend to decrease over time from diagnosis. One exception to this appears to be an increase in negative emotional experience among individuals nearing end of life or entering into palliative care.

Essentials of Survivorship Care

To improve the outcomes achieved by the ever increasing number of cancer survivors, the Institute of Medicine has outlined four components essential to quality survivorship care. First, survivorship care should focus on *prevention* of new and recurrent cancers, as well as other late effects of treatment. Second, there should be an emphasis on *surveillance* for new, recurrent, or spread of cancer as well as medical and psychosocial late effects. Third, there is a need for *intervention* to assist survivors in dealing with the consequences of cancer and its treatment. Fourth, given the complex medical environments in which cancer survivors find themselves, *coordination of care*, particularly between specialty and primary providers, is essential to ensuring that survivors' needs are met.

Definition

Medical intervention in cancer commonly involves multiple modalities including surgery, systemic chemotherapy, and radiation therapy. For patients newly diagnosed with cancer, surgery is typically the first of these methods as it is commonly used to confirm a diagnosis, determine the severity of the disease (i.e., stage and grade), and in some cases, for "tumor debulking." Radiation therapy is used in more than half of all patients with cancer, either as a definitive treatment, or in combination with surgical interventions and/or chemotherapy. Finally, chemotherapy involves the use of drugs to target and destroy rapidly dividing cancer cells. As a treatment, its effectiveness is dependent upon the type and severity of disease, but it can be used to shrink tumors, control the spread of disease, or cure cancer (i.e., remission).

Description

Cancer patients are at an increased risk for psychological and physiological distress throughout the treatment and management of their disease. The most common types of treatment, as previously discussed, impact the body physically, mentally, and emotionally. Behavioral and psychosocial strategies can not only be used to supplement these medical treatments but also reduce the physical and psychological side effects of cancer treatment and management. The primary symptom of concern and of focus in the psychosocial treatment of individuals with cancer is *distress*. The National Comprehensive Cancer Network (NCCN), an organization that has composed widely used guidelines for distress management, posits that the term "distress" is more acceptable in its use because it carries a less stigmatizing connotation. NCCN defines distress in cancer as "A multifactorial unpleasant emotional experience of a psychological (cognitive, behavioral, emotional), social, and/or spiritual nature that may interfere with the ability to cope effectively with cancer, its physical symptoms and its treatment."

Patients are at an increased risk for distress if they have a history of a psychiatric disorder or substance abuse, are cognitively impaired, have language, literacy, or physical barriers to communication, have severe comorbid illness, experience uncontrolled physical symptoms, have spiritual/religious concerns, have inadequate social support, or have additional stressors including family conflict, financial stressors, dependent children, limited access to healthcare, or have a history of abuse. Providers participating in the care of cancer patients should assess for these risks and also be aware of times associated with increased vulnerability for distress. Periods of increased vulnerability are often marked by times of change or novelty in a patient's cancer experience or feelings of uncertainty. For example, awaiting diagnosis and/or treatment, altering treatment modality, transitioning into survivorship, recurrence, and end of life are often circumstances under which distress may be more likely to manifest.

In addition, distress is associated with physical side effects of disease and/or cancer treatment including pain, fatigue, nausea, and insomnia. These symptoms are very common in cancer patients and often result from psychological distress and physiological effects of cancer treatment. As such, there is a bidirectional relationship among these symptoms and distress such that unpleasant physical side effects may prompt distress while the experience of emotional distress may also exacerbate and maintain these physical symptoms.

Psychosocial cancer management and treatment must first begin with a brief distress screening. It is optimal that these be completed earlier in a patient's cancer experience (i.e., upon diagnosis). NCCN provides a brief, validated distress screening tool that measures recent distress and the presence of factors (i.e., practical, family, emotion, spiritual, or physical problems) that may contribute to distress. Patients who endorse clinically significant levels of distress should then be referred to the appropriate service(s), depending on their individual needs. Cancer patients experiencing distress may benefit from assistance from a mental health professional, social worker, and/or chaplain.

Patients referred to a mental health professional should undergo a more comprehensive evaluation in order to further understand the difficulties they are having and to inform treatment decisions. These evaluations will commonly assess for suicidality, mood or anxiety disorders, adjustment disorders, substance-abuse disorders, personality disorders, and cognitive impairments secondary to disease and/or cancer treatment. Sleep disorders are assessed through a thorough sleep and medical history and objective evaluations such as polysomnography. Results from these evaluations are disseminated to all other providers involved in the patient's care in order to ensure that their comprehensive treatment plan is tailored to their individual needs.

Treatment for distress and its associated symptoms secondary to cancer is multifaceted in nature. While psychotherapy is indicated in patients with mild to severe distress, antidepressants and anxiolytics can be used to supplement psychotherapy in individuals with moderate to severe distress. Psychological interventions including cognitive-behavioral therapy (CBT), supportive psychotherapy, and family or couples therapy have been shown to help cancer patients manage distress and improve quality of life. Cognitive-behavioral treatments in cancer often focus on increasing problem solving skills and addressing maladaptive thought patterns that promote feelings of depression, anxiety, and/or guilt. Behavioral management strategies are also used with cancer patients to decrease the psychosomatic manifestation of distress. Fatigue in cancer can be managed through the practice of relaxation, distraction, exercising to increase energy, improving sleep, and emotional support. Individuals with insomnia benefit from behavioral treatments that place focus on creating a comfortable sleep environment that promotes sleep (i.e., stimulus control), avoiding behaviors that contribute to poor sleep such as drinking caffeine and napping, and addressing any emotional concerns that may contribute to poor sleep. Behavioral techniques can also be used in addition to anti-nausea/vomiting medications and analgesics to help patients relax and feel more in control of nausea and/or pain following cancer treatment. Guided imagery allows the patient to mentally transition to a more pleasant, safe place, and to distract oneself from the nausea and/or pain. Likewise, cancer patients can utilize hypnosis or learn self-hypnosis in order to block physical discomfort and pain during and after treatment procedures. Lastly, progressive muscle relaxation and biofeedback can also be used to help patients increase awareness of tension, anxiety, and other bodily changes in order to achieve relaxation and prevent nausea, pain, or insomnia.

The initial screening, comprehensive evaluation, and treatment are essential to ensuring that cancer patients navigate their experiences effectively; however, it is also important to conduct assessments of distress at further points along the cancer experience. As previously mentioned, there are periods of time in which patients may have an increased vulnerability to distress and it is during these transitional periods in which their distress should be reassessed and treated as necessary.

Given its complex nature, physical and psychological distress throughout the process of cancer treatment should be assessed and managed through comprehensive involvement by all providers in the patient's healthcare team. This requires that the patient's healthcare team function in an environment in which interdisciplinary work is promoted and in which there is regular, open communication among all providers involved in the patient's care and management of their disease.

Definition

Bladder cancer research has almost exclusively employed epidemiological or clinical research approaches, leaving it understudied from a behavioral medicine perspective. Yet, research provides many opportunities for clinicians and researchers to develop targeted bladder cancer prevention and survivorship interventions for mental health, diet and exercise, fatigue, smoking cessation, and other areas.

Description

Bladder Anatomy and Histopathology

Bladder cancer originates in the urinary bladder, a hollow, muscular organ that collects urine from the kidneys via the ureters and excretes it via the urethra (Konety & Carroll, 2007; Pashos, Botteman, Laskin, & Redaelli, 2002). Before excretion, urine is stored in the lumen, which is surrounded by several cell layers comprising the bladder wall. The innermost layer, or urothelium (epithelium), directly contacts urine in the lumen.

The second layer, or lamina propria, consists of subepithelial connective tissue. The third layer, the muscularis propria, contains smooth muscle. The final layer contains perivesical fat tissue.

Approximately 70–80% of newly diagnosed US bladder cancers are confined to the urothelium or lamina propria (i.e., Ta, Tis, T1; also called superficial or nonmuscle invasive [NMIBC]; Sexton et al., 2010). Remaining diagnoses are classified as muscle invasive (MIBC), where the tumor has invaded the muscularis propria (i.e., T2, T3). Once a bladder tumor begins invading surrounding organs, it becomes T4 (Jacobs, Lee, & Montie, 2010; Konety & Carroll, 2007; Pashos et al., 2002). Most US bladder cancer patients (90%) have transitional cell carcinoma; the remaining have squamous cell carcinomas (5%), adenocarcinomas (1–2%), primary small cell carcinoma, or other tumor histologies (Sexton et al., 2010).

Bladder Cancer Epidemiology and Risk Factors

Bladder cancer incidence, morbidity, and mortality vary by country (Botteman, Pashos, Redaelli, Laskin, & Hauser, 2003). It is the fifth most common cancer in the United States and the second most commonly diagnosed urologic cancer (Altekruse et al., 2010). From 1988 to 2008, the number of US diagnoses increased by more than 50% (Shariat et al., 2009). The United States had an estimated 70,530 new bladder cancer diagnoses and 14,680 deaths in 2010 (Jacobs et al., 2010).

While many cases contain no explicit ties to carcinogenic exposure, bladder cancer has several well-established biological, sociodemographic, and environmental risk factors (Pashos et al., 2002). Men are three to four times more likely to receive a diagnosis than women. While men have higher lifetime risk for developing bladder cancer, women tend to present with later-stage disease and worse prognosis for 5-year survival, even controlling for tumor stage and grade (Jacobs et al., 2010; Pashos et al., 2002; Shariat et al., 2009). Bladder cancer diagnoses among adolescents and young adults remain relatively rare (Sexton et al., 2010). Over three quarters of cases occur in individuals 60 years and over. Race/ethnicity is also important. Caucasian Americans are twice as likely to develop bladder cancer as African Americans. Despite lower incidence, African Americans are diagnosed at advanced-stage disease and have higher mortality rates, even after controlling for tumor characteristics (Konety & Carroll, 2007; Pashos et al., 2002; Sexton et al., 2010).

Environmental risk factors for developing bladder cancer include behavioral risk factors and occupational or chemical exposures (Pashos et al., 2002; Sexton et al., 2010). Less than 10% of individuals diagnosed with bladder cancer report a positive family health history. Smoking is the primary environmental risk factor (Jacobs et al., 2010; Pashos et al., 2002; Sexton et al., 2010). Additional behavioral risk factors include diet/nutrition, specific herbal supplements, chronic urinary tract infection or inflammation, parasitic infection, arsenic-contaminated water, and pelvic radiation. Chemicals linked to increased bladder cancer risk include aniline dyes, aromatic amines, cyclophosphamide, and specific analgesics. At-risk occupations include autoworkers; metalworkers; hairdressers; painters; and paper, leather, dye, and rubber plant workers (Jacobs et al., 2010; Sexton et al., 2010).

Bladder Cancer Symptoms and Detection

Approximately 80–90% of patients diagnosed with bladder cancer present with gross or microscopic amounts of blood in the urine (hematuria; Pashos et al., 2002). As there is a small latent period between bladder cancer development and symptom onset, hematuria is considered the most important symptom (Pashos et al.; Sexton et al., 2010). Twenty percent of patients report other symptoms, including flank pain, painful urination (dysuria), increased urgency or frequency of urination, and inability to urinate (Pashos et al., 2002). Many bladder cancer symptoms, particularly hematuria, are also symptomatic of urinary tract infections, benign prostatic hyperplasia, and other benign conditions. Women may inadvertently be misdiagnosed with gynecological conditions or chronic urinary tract infections in lieu of bladder cancer, contributing to delayed diagnosis (Jacobs et al., 2010).

Physicians suspecting bladder cancer as a potential explanation for these symptoms perform a physical exam and health-history assessment, including smoking history/status and chemical/occupational exposures (Pashos et al., 2002). Clinicians may use intravenous or retrograde pyelography, ultrasound, computed tomography, positron emission tomography, or magnetic resonance imaging to check for urinary tract tumors (Sexton et al., 2010). More commonly, physicians rely on cystoscopy, involving insertion of a camera attached to flexible tubing into the bladder via the urethra while the patient is under local anesthetic (Pashos et al., 2002; Sexton et al., 2010). This procedure is considered the "gold standard" for detecting bladder cancer and allows direct visualization of the urethra and urothelium for tumors (Sexton et al.). Urine cytology, or a bladder wash, is often performed adjunctive to cystoscopy to check for hematuria and bladder cancer cells pretreatment and during posttreatment surveillance (Pashos et al., 2002; Sexton et al., 2010; see below). Early detection of cancer recurrence is linked to reduced morbidity and mortality, although only 40% of bladder cancer survivors are adherent with surveillance (Schrag et al., 2003). Behavioral medicine interventions are warranted in this particular area of cancer control.

Nonmuscle-Invasive Bladder Cancer (NMIBC) Treatment

Transurethral resection of the bladder tumor (TURBT) is a first-line treatment for NMIBC. TURBT may be performed under anesthesia and serves diagnostic, prognostic, and therapeutic functions. Individuals with low risk for progression (i.e., those with low-grade Ta tumors) may be treated using TURBT alone. A repeat TURBT may be performed to restage individuals with high risk for progression (e.g., high-grade T1) within the first month of initial diagnosis (Jacobs et al., 2010; Konety & Carroll, 2007; Sexton et al., 2010). Intravesical chemotherapies such as mitomycin C and immunotherapies such as bacillus Calmette-Guérin (BCG) may be used immediately post-TURBT or as maintenance therapy to treat persistent microscopic tumors, prevent reimplantation or tumor formation, and reduce the chance of stage/grade progression (Jacobs et al., 2010; Konety & Carroll, 2007; Sexton et al., 2010). Common side effects of TURBT include bleeding and infection, whereas intravesical therapies are associated with dysuria, fever, chills, and increased frequency of urination (Pashos et al., 2002; Shariat et al., 2009). BCG intravesical therapy is linked to erectile difficulties; there may also be treatment-related female sexual issues. Patients who have recurrent, high-grade NMIBC unresponsive to intravesical therapy may eventually undergo partial or radical cystectomy (Pashos et al., 2002; Sexton et al., 2010; see below).

Muscle-Invasive Bladder Cancer (MIBC) Treatment

Individuals with MIBC may require more intensive treatment. A "curative" treatment involves radical cystectomy, in which the entire bladder is removed and some adjacent lymph nodes and organs. Male patients may have the prostate and seminal vesicles removed, while women may have their uterus, fallopian tubes, ovaries, and anterior vagina wall removed (Konety & Carroll, 2007). Patients then receive some form of urinary diversion so that they can continue to collect and excrete urine. Options include ileal conduit (i.e., urine is stored in a small portion of intestine and drained through a stoma in the abdomen into an ostomy bag), neobladder (i.e., urine is collected in a section of small intestine connected to the urethra, allowing "normal" urination), and continent cutaneous pouch (i.e., urine is stored in a small portion of the intestine and drained through a stoma via catheter; Jacobs et al., 2010; Konety & Carroll, 2007; Pashos et al., 2002).

Postoperative complication rates and side effects vary by diversion type. Daytime and nighttime incontinence, urinary retention, internal bleeding, infection, wasting syndrome, diarrhea, renal failure, and vitamin deficiencies are some short- and long-term effects (Pashos et al., 2002). Additional side effects include sexual dysfunction and infertility. While cystectomy is considered the gold standard for MIBC treatment, there are bladder-preservation alternatives

for poor surgical candidates due to age, health status, or other factors, or whose beliefs and values preclude surgery. Alternatives include TURBT alone or in combination with external-beam radiation therapy and/or systemic chemotherapy; however, survival rates are generally lower than those from radical cystectomy (Konety & Carroll, 2007).

Bladder Cancer Surveillance

The risk for bladder cancer recurrence is higher than for any other cancer but varies by tumor grade. For example, the 3-year recurrence rates for Ta- and T1-stage tumors are 40–70% and 50–80%, respectively (Schrag et al., 2003). Therefore, surveillance is an important disease-management strategy.

Bladder cancer is also the most expensive cancer in terms of cost per patient per year and lifetime costs per patient. Current estimates place total patient costs at almost $3 billion US dollars per year, of which an estimated 60% goes to monitoring and treatment of recurrence. NMIBC treatment and monitoring represents a substantial portion of these costs (Botteman, Pashos, Redaelli, et al., 2003).

Physicians vary in terms of their surveillance protocols. American Urological Association guidelines recommend intensive follow-up consisting of cystoscopy and cytology every 3 months in years 1 and 2, semiannual cystoscopy and cytology in years 3 and 4, and annual cystoscopy and cytology in years 5–10 or for life (American Urological Association, 2007). Given that cystoscopic examinations are time-consuming and invasive, current adherence rates to bladder surveillance are estimated at about 40% (Schrag et al., 2003). Individuals who are older, non-Caucasian, less-educated, and living in urban geographic locales or low-income areas are significantly more likely to be nonadherent with surveillance (Schrag et al.).

Issues in Bladder Cancer Survivorship

More than 500,000 bladder cancer survivors currently live in the United States (Altekruse et al., 2010), yet little is known about their survivorship needs, particularly those stemming from gender and race/ethnic disparities or psychosocial factors (e.g., fear of recurrence, social constraint and support, psychological distress, and anxiety) (Botteman, Pashos, Hauser, Laskin, & Redaelli, 2003). Given the chronic nature of this disease and related symptoms, bladder cancer survivors may benefit from targeted, culture- and literacy-appropriate patient health education interventions that impact lifestyle/behavior change, symptom management, health-related quality of life, and treatment/surveillance adherence. Limited patient education materials are available from The American Cancer Society (www.cancer.org), Bladder Cancer Advocacy Network (www.bcan.org), and National Cancer Institute (www.cancer.gov). There are few research-tested bladder cancer interventions; however, interventions designed for prostate cancer may be helpful to survivors.

Definition

Cervical cancer is a slow-growing cancer that develops in the lower portion of the uterus, known as the cervix. Approximately 1 in every 145 women will develop invasive cervical cancer in her lifetime. In 2010, an estimated 12,200 women were diagnosed with cervical cancer (ACS, 2010). Significant racial/ethnic disparities exist in cervical cancer incidence rates, with African American and Hispanic/Latino women having elevated rates compared to White, Asian American/Pacific Islander, and American Indian/Alaska Native women (NCI, 2011).

Cervical cancer typically begins as a precancerous condition, known as cervical intraepithelial neoplasia (CIN; (ACS, 2011)). Patients who do not undergo regular pelvic exams and Pap tests are likely to develop one of the two main types of cervical cancer: squamous cell cervical carcinoma or cervical adenocarcinoma. The majority of cases, approximately 80–90%, are squamous cell carcinomas of the cervix (ACS). Persistent infection with human papillomaviruses (HPVs) has been identified as the cause of cervical cancer in the majority of cases. There are over 150 types of HPV, including 40 types that are transmitted sexually (NCI). HPV types 16 and 18 are considered to be carcinogenic (cancer-causing) to humans and have been classified as Group 1 carcinogens by the International Agency for Research on Cancer/World Health Organization. Accordingly, cervical infection with HPV types 16 and 18 confers high risk for the transformation of CIN to cervical cancer and causes over 70% of all cervical cancers (ACS). In contrast, HPV types 6 and 11 have been classified as possibly carcinogenic to humans (Class 2B carcinogens) and are mostly implicated in the development of anogenital condylomata (genital warts; (ACS)). Women who are sexually active at a young age or have many sexually partners are at a greater risk for HPV infection. As of 2011, the Federal Drug Administration (FDA) has approved the use of two vaccines for the prevention of the most common types of HPV infection (ACS; NCI). One vaccine prevents four HPV types (6, 11, 16, and 18) and is indicated for use in females and males 9–26 years of age. A second vaccine protects against two HPV types (16 and 18) and is indicated for use only in females 10–25 years of age (NCI). Additional risk factors for cervical cancer include smoking cigarettes and exposure to secondhand smoke, a high number of full-term pregnancies, long-term use of oral contraceptives, and immunosuppression (ACS).

Screening for cervical cancer includes regular pelvic exams and a Papanicolaou (Pap) test to screen for precancerous or malignant changes in cervical cells (ACS). If the Pap test detects abnormal cells, an HPV DNA test is conducted to determine whether HPV infection is present (NCI). Furthermore, a colposcopic examination can be performed to identify abnormal areas on the cervix visually and allow for a biopsy of cervical tissue (ACS). If invasive cancer is identified, additional imaging studies may be conducted to determine if the cancer has metastasized (spread) to distant organs and facilitate staging. Women who have early-stage cervical cancer often do not experience any symptoms; however, once the cancer has progressed and spread to proximal tissues, women may experience abnormal vaginal bleeding, unusual discharge, and pain during intercourse (ACS).

Treatment of cervical cancer can include surgery, chemotherapy, and radiation therapy. As with all cancers, the appropriate treatment choice depends largely on the stage of disease. Surgical methods for treating cervical cancer include cryosurgery, laser surgery, conization, hysterectomy, and trachelectomy (NCI). Pelvic exenteration or lymph node dissection may be performed when there has been spread or recurrence of cervical cancer (ACS; NCI). The most common types of chemotherapy that target cervical cancer include cisplatin, paclitaxel, topotecan, ifosfamide, and 5-fluorouracil (5-FU; ACS)). Six to seven weeks of radiation treatment may also be used to treat cervical cancer (ACS). Certain stages of cervical cancer may require a combination of chemotherapy and radiation, known as chemoradiation.

The 5-year survival rate of cervical cancer is 71% (ACS). While the number of deaths due to cervical cancer has decreased across the last several decades, mortality rates have remained steady since approximately 2003. African American women have the highest cervical cancer mortality rates compared to all other racial/ethnic groups, which may be partly due to the fact that African American women are less likely to be diagnosed with early-stage cervical cancer than White women (ACS).

Colorectal cancer

Definition

Colorectal cancer (CRC) is the third most frequently diagnosed cancer in men and women in the United States. Patients with localized colon cancer have a 90% five-year survival rate (Jemal et al., 2009).

Colorectal cancer mortality can be reduced by early diagnosis and by cancer prevention through polypectomy. Therefore, the goal of CRC screening (CRCS) is to detect cancer at an early, curable stage as well as to detect and remove clinically significant adenomas (Levin et al., 2008).

Screening tests that can detect both early cancer and adenomatous polyps are encouraged. Current technology falls into two broad categories: structural tests and stool/fecal-based tests. Regular screening with the fecal occult blood test (FOBT) or sigmoidoscopy facilitates earlier detection of CRC and lowers mortality. Screening colonoscopy may decrease CRC incidence through early detection and removal of precancerous polyps. Reported interventions to promote the FOBT have included patient reminders through use of personal media, approaches that reduce structural barriers such as mailing of FOBT kits, and use of provider assessment and feedback (Baron et al., 2008; Hardcastle et al., 1996; Kronborg, Fenger, Olsen, Jorgensen, & Sondergaard, 1996; Mandel et al., 1993; Selby, Friedman, Quesenberry, & Weiss, 1992; Shapiro et al., 2008; Winawer et al., 1993).

Other preventive health behaviors are positively associated with CRCS, including a recent mammogram or Pap test for women, a recent prostate-specific antigen (PSA) test for men, a cholesterol test, dental visit, seat belt use, fruit and vegetable consumption, and physical activity (See ff et al., 2004).

CRC is predominantly a disease of Westernized countries, indicating that components of the Western lifestyle may contribute to the risk. A large body of evidence has implicated modifiable lifestyle factors as causes of colorectal cancer, including smoking, lack of physical activity, body composition, alcohol intake, and diet (Shapiro, See ff, & Nadel, 2001).

Aspirin taken for several years at doses of at least 75 mg daily reduced long-term incidence and mortality due to colorectal cancer. Benefit was greatest for cancers of the proximal colon, which are not otherwise prevented effectively by screening with sigmoidoscopy or colonoscopy (Rothwell et al., 2010).

Type C has emerged as a behavioral pattern, coping style, or personality type that predisposes people to or is a risk factor for the onset and progression of cancer. Type C has been described as a personality that is overcooperative, stoical, unassertive, patient, avoiding conflict, compliant with external authorities, unexpressive through suppression or denial of negative emotions, self-sacrificing, and predisposed to experiencing hopelessness and depression. There is evidence of connections among personality, stress and cancer, as well as among personality, stress, and the autonomic, endocrinological, and immune systems. These psychological characteristics can be considered as cancer risk factors. Nevertheless, a type C or cancer-prone personality should be understood in terms of its synergic interactions with genetic, biological, and environmental factors (Eysenck, 1994).

Significant barriers to advanced cancer patients receiving mental health treatment for distress have been reported in the literature. Monthly monitoring of distress in older patients using telephone monitoring and educational materials, along with referral for appropriate help, has been found to be efficient means of reducing anxiety and depression, compared with patients who received only educational materials (Kornblith et al., 2006).

Acupuncture, transcutaneous electrical nerve stimulation, supportive group therapy, self-hypnosis, and massage therapy may provide cancer pain relief in dying patients (Pan, Morrison, Ness, Fugh-Berman, & Leipzig, 2000).

Definition

Lymphatic cancer is a cancer of the lymphatic system, which is a part of the immune system. It is also called lymphoma. Although lymphoma commonly affects lymph node, it also affects other organs such as spleen.

The new World Health Organization classification (Swerdlow et al., 2008) is usually used to classify lymphoma, and lymphoma is divided into Hodgkin lymphoma and non-Hodgkin lymphoma (B cell and T/NK cell). Staging is basically based on distribution of the lesions. Non-Hodgkin lymphoma is clinically classified into indolent, aggressive, and highly aggressive.

Symptoms and signs of lymphoma are lymphadenopathy which is without tenderness and mobile, fever, fatigue, nocturnal sweating, weight loss, bloating sensation, etc.

In Hodgkin lymphoma, radiotherapy with or without chemotherapy is used for a limited stage and chemotherapy is the first choice for an advanced stage. High-dose chemotherapy with autologous hematopoietic stem cell transplantation is considered for recurrent or refractory cases.

In non-Hodgkin lymphoma, treatment is selected depending on the pathological classification and the grade of malignancy. In B cell indolent lymphoma, radiotherapy or surgical therapy is used for a limited stage and chemotherapy or careful follow-up without any therapy is selected for an advanced stage. Monoclonal

antibody called rituximab is also used. In aggressive B cell lymphoma, chemotherapy combined with rituximab is generally used and radiotherapy is combined for a limited stage. High-dose chemotherapy with autologous peripheral blood stem cell transplantation is conducted at first remission in a high-risk group. In highly aggressive B cell lymphoma, treatment which is used for acute lymphoblastic leukemia is applied. Although no standard therapy is established for T cell lymphoma, chemotherapy is often applied. Eradication of *Helicobacter pylori* is used for gastric mucosa-associated lymphoid tissue (MALT) lymphoma.

Ovarian carcinoma; Ovarian neoplasm

Definition

Ovarian cancer is a malignancy of the tissue of the ovary and most commonly consists of either an epithelial cell tumor, arising from cells on the surface of the ovary, or a germ cell tumor, in which the cancer forms in the egg cells. Approximately 22,000 new cases of ovarian cancer were reported in the United States in 2010, and ovarian cancer ranks as the fifth most common cause of death among women with cancer (American Cancer Society [ACS], 2010). Because ovarian cancer is difficult to detect during the early stages, women are often diagnosed with advanced disease that has spread to the lymph nodes or metastasized to other organs. The overall 5-year survival rate for women diagnosed with ovarian cancer is 46% (ACS, 2010). The course of treatment varies by tumor type and stage but may include chemotherapy, radiation therapy, and/or surgery to remove the tumor and/or one or both ovaries (oophorectomy).

Description

A diagnosis of ovarian cancer and its corresponding treatment has been associated with significant decrements in emotional, physical, and functional quality of life (Arriba, Fader, Frasure, & von Gruenigen, 2010). Women with ovarian cancer often report pervasive fatigue, disrupted sleep, and limitations in their ability to be active. Moreover, younger women typically experience loss of fertility, and many survivors report sexual concerns that persist well beyond the period of physical recovery. Not surprisingly, emotional distress is common, including symptoms of depression and anxiety. Distress can persist well after treatment ends, with survivors commonly reporting fear of a cancer recurrence and significant anxiety around follow-up clinic visits and diagnostic tests (Arriba et al., 2010).

Research is also beginning to delineate biobehavioral mechanisms by which behavioral factors may alter physiological pathways associated with ovarian tumor growth and development, including effects on immunosuppression, inflammation, and angiogenesis (growth of new blood vessels to nourish the tumor) (Costanzo, Sood, & Lutgendorf, 2011). For example, ovarian cancer patients who report greater distress and have

more limited social support show poorer NK cell activity in peripheral blood and tumor infiltrating lymphocytes as compared to women with lower distress and better support (Lutgendorf et al., 2005). Greater depressive symptoms and less social support have also been associated with elevated levels of pro-angiogenic cytokines including interleukin-6 and vascular endothelial growth factor (VEGF) (Costanzo et al., 2011). Moreover, ovarian cancer patients who report more depressive symptoms show higher and less variable levels of nocturnal cortisol (Lutgendorf et al., 2008). Stress hormones, including norepinephrine and epinephrine, have been shown to increase VEGF production and the in vitro invasiveness of ovarian tumor cells (Lutgendorf et al., 2003; Sood et al., 2006). These findings suggest that behavioral factors may play an important role not only in quality of life, but also in ovarian cancer outcomes.

Definition

Prostate cancer originates in the prostate, a walnut-shaped gland in the male reproductive system. Fluid secreted by the prostate nourishes and transports sperm. Over 95% of cancers of the prostate are adenocarcinomas, originating in glandular tissue. The prostate is made up of three distinct zones of glandular tissue. Approximately 70% of cancers develop in the peripheral zone, 10–20% in the transition zone, and 5–10% in the central zone. Most prostate cancers are slow growing, and survival rates are high, particularly for men with localized disease.

Description

Prostate Cancer Epidemiology

Aside from skin cancer, prostate cancer is the most common malignancy and the second most common cause of cancer death among men in the United States. Roughly 1 in 6 men will be diagnosed with prostate cancer in their lifetime. In 2010, an estimated 220,000 incident cases of prostate cancer were diagnosed in America, mostly among men over age 70. Additionally, more than 30,000 prostate cancer deaths were projected, second only to lung cancer for cancer deaths among American men.

The etiology of prostate cancer is not well understood. However, the male sex hormone testosterone, particularly at high levels, can accelerate the reproduction and growth of existing cancer cells in the prostate. Increasing age is the most important risk factor for prostate cancer. A positive family history is also associated with increased risk. Additionally, African American men have higher incidence and mortality rates than Whites. Since 1975, incidence rates in the United States have fluctuated, slightly decreasing since 2000. Substantial changes can be traced to the introduction of the prostate-specific antigen (PSA) screening test in the 1980s.

Prostate Cancer Screening

Screening for prostate cancer includes serum PSA testing and digital rectal examination. Due to the widespread implementation of PSA testing, over 90% of prostate cancers are detected at early stages, when the disease is localized to the prostate and easiest to treat. However, PSA testing is not without controversy, and guidelines for screening differ. Please see *Prostate-Specific Antigen* for additional information.

Prostate Cancer Diagnosis

Prostate cancer may be suspected if the PSA level is greater than 4 ng per mL. When prostate cancer is suspected, a core needle biopsy is performed for tissue analysis. If the tissue biopsy confirms the presence of cancer, further testing (e.g., computed tomography or magnetic resonance imaging) may be completed to determine whether the cancer has spread to other parts of the body. A Gleason score (range: 2–10) is also calculated to evaluate the growth rate of the cancer, dependent on the appearance of tumor cells under microscope. A high Gleason score indicates advanced disease. Together, tumor stage and Gleason score are used to determine prognosis and to direct treatment decisions. Today, nearly all prostate cancers are detected when tumors are confined to the prostate (i.e., Gleason score 6 or 7).

Prostate Cancer Treatment

Many treatment options are available to men diagnosed with localized prostate cancer (e.g., active surveillance, radiotherapy, and surgery). However, there is currently no consensus regarding optimal treatment. Each treatment impacts quality of life differently – ranging from urinary, sexual, and bowel dysfunction to more systemic concerns, such as weight gain, bone loss, hot flashes, and depression. Therefore, individuals must make decisions based upon their own personal preferences, clinical characteristics, and a variety of external factors, including provider recommendations. Most men experience decreased sexual potency, regardless of treatment. However, men undergoing radical prostatectomy suffer most from urinary problems, while radiotherapy is associated with poor bowel function. The physical side effects associated with prostate cancer treatment can severely affect a man's quality of life. Additionally, the emotional and psychological distress associated with symptoms, as well as complications in spouse or partner relationships, can further diminish quality of life. Given the slow-growing nature of most prostate cancers, some individuals may consider deferring treatment to maintain better quality of life. Active surveillance involves routine monitoring of patients diagnosed with early-stage, low-grade prostate cancer, in lieu of definitive treatment. However, this option carries its own burden, primarily the uncertainty and anxiety associated with having an "untreated" cancer. For men with advanced stages of disease, additional treatment options are available (e.g., hormonal therapy, chemotherapy).

Current Medical Research and Interventions in Prostate Cancer

A major concentration in current prostate cancer research focuses on the evaluation of potential factors affecting the observed racial disparity. Several projects are attempting to identify genetic and other variants that may increase incidence and mortality in African American men. Furthermore, there is an emphasis on identifying additional biomarkers to improve detection and prognostic accuracy. Studies are also being conducted to compare the effectiveness of active surveillance for disease management with immediate treatment. Finally, for men with advanced hormone-refractory disease, improved chemotherapy regimens are being evaluated (e.g., docetaxel and cabazitaxel).

Current Behavioral Medicine Research and Interventions in Prostate Cancer

Given the array of treatment options available to men and the lack of consensus concerning best practices, decision-making tools are essential to assist in determining which treatment option is most in congruence with their values and lifestyle preferences. In a review of treatment decision-aid studies, aids were found to decrease distress, increase knowledge, and support shared decision making.

Additionally, only a limited number of evidence-based behavioral medicine interventions have been developed to address quality-of-life concerns in this population. The first of these interventions was developed from work done in breast cancer and shown to be effective in improving quality of life. Unfortunately, the results have been more mixed in interventions focusing on improving psychosocial distress. Reductions in distress have generally been modest and of short duration. However, other research suggests that men adjust to changes in functional status and symptom distress improves over time.

Developing these materials and programs should be an immediate priority for behavioral medicine researchers. Promising results have been shown in adapting cognitive behavioral stress-management programs, peer-support, nurse-led, and telephone-based interventions. Less work has been done with subgroups among prostate cancer patients and survivors. Only one intervention has been developed to provide psychosocial support for men on active surveillance. Little data exist on gay and bisexual men with prostate cancer. No interventions have focused on the particular needs of single men, for whom treating erectile dysfunction related to prostate cancer may be particularly challenging.

Definition

Testicular cancer is a type of cancer that forms in the tissue of one or both testicles, the male reproductive glands located in the scrotum. There are several different types of testicular cancer but most cases originate in germ cells (cells that make sperm) and are called testicular germ cell tumors. Testicular germ cell tumors may be further categorized into seminomas and nonseminomas. Seminoma tumors are a slower growing and less aggressive form of testicular cancer. They are usually isolated to the testicle or testes and are particularly sensitive to radiation treatment. Nonseminoma tumors are faster growing and more aggressive. This form of testicular cancer tends to occur in younger men.

Description

Testicular cancer is not common and accounts for only 1% of all cancers in men. There are an estimated 8,290 new diagnoses and about 350 deaths due to testicular cancer each year. It is most common in young and middle-aged men such that about 9 out of 10 testicular cancers occur in men between the ages of 20 and 54. Treatment is very successful and the risk of dying from testicular cancer is low.

Factors that may increase the risk for developing testicular cancer include abnormal testicle development, such as Klinefelter's syndrome, undescended testicle (cryptorchidism), personal or family history of testicular cancer, age, and ethnicity. Non-Hispanic white men are more likely than African-American and Asian-American men to develop testicular cancer. The risk of Hispanic/Latino men developing this type of cancer is between that of Asians and non-Hispanic whites.

Signs and symptoms of testicular cancer include a lump or enlargement in either testicle; a feeling of heaviness in the scrotum; a sudden collection of fluid in the scrotum; pain or discomfort in a testicle, scrotum, abdomen, or lower back; and enlargement or tenderness of the breasts. However, many men do not experience symptoms, even when the cancer has spread to other organs.

Diagnosis and Treatment

Initial diagnosis generally involves an ultrasound or biopsy. To determine whether the cancer has spread outside of the testicle, a computerized tomography (CT) scan to look for signs of cancer in the abdominal lymph nodes or blood tests to look for elevated tumor markers may be used. The staging of the cancer will depend on the results of these tests. There are three stages of testicular cancer: Stage I cancer is limited to the testicle (localized); Stage II cancer has spread to the lymph nodes in the abdomen (regional); and Stage III cancer has spread to other parts of the body and most commonly includes the lungs, liver, bones, and/or brain (distant).

Definition

Cancer is a term used for a disease in which abnormal cells divide uncontrollably and invade other tissues.

Cancer includes many forms of disease, and there are more than 100 different types of cancer. Most cancers are named for the organ or type of cell from which they originate. Cancer types can also be grouped into broader categories.

The main categories of cancer include:

Carcinoma – cancer that begins in the skin or in tissue that lines or covers internal organs

Sarcoma – cancer that arises from bone, cartilage, fat, muscle, blood vessels, or other connective or supportive tissue

Leukemia – cancer that starts in blood-forming tissue such as the bone marrow

Lymphoma and myeloma – cancers that begin in the cells of the immune system

Central nervous system cancers – cancers that begin in the tissue of the brain or spinal cord

The cancers that are diagnosed with the greatest frequency in the United States are bladder cancer, breast cancer, colorectal cancer, endometrial cancer, kidney cancer, leukemia, lung cancer, melanoma, non-Hodgkin lymphoma, pancreatic cancer, prostate cancer, and thyroid cancer.

Some behavioral factors have been reported to have an association with the incidences of cancer, cancer screening, cancer recurrence, and cancer mortality. For example, cigarette smoking contributes significantly to mortality rates for lung cancer, oral cancer, and cancers of the esophagus, larynx, bladder, stomach, pancreas, kidney, and cervix.

Each type of cancer has characteristic-associated behavioral factors (see the section on a particular cancer for more information).

Definition

Psychosocial treatment in oncology covers a broad range of effective therapies that have yet to become the standard of care for most cancer patients. Psychosocial therapies help cancer patients and their families emotionally adjust to diagnosis and treatment, cope with treatment-related side effects (e.g., fatigue, pain, nausea), improve adherence to chemotherapy regimens, and improve health behaviors. Therapies can include cognitive behavioral therapy, hypnosis and guided imagery, mindfulness-based therapies, cognitive behavioral stress management, couple- and family-based therapy, play therapy for children, and motivational interviewing for behavior change. Psychosocial therapy is typically administered by clinical psychologists, psychiatrists, social workers, nurses, and more recently, via web-based interventions and telephone counseling. This therapy can be administered in both individual and group settings at multiple points along the cancer continuum, from before diagnosis among people at elevated risk for cancer, to many years after active treatment has completed. Psychosocial therapies have been shown in numerous studies to improve not only psychological (e.g., reduce distress) and quality of life outcomes, but also physical outcomes (e.g., improve immune function and physical functioning) among cancer survivors in need of therapy.

Description

Natural History

A cancer diagnosis can be considered an existential crisis in the lives of many of those affected and can result in increased distress, changes in emotional roles, social roles, physical functioning, and quality of life for most people who are diagnosed. Cancer patients have higher rates of clinically significant psychological disorders than their non-diagnosed age-matched peers. Several factors tend to influence the extent of psychological distress in response to a cancer diagnosis. These include younger age at diagnosis, history of mental illness and premorbid psychological functioning, stage at diagnosis and prognosis, and social support or other resources available (e.g., health insurance). As they do with other major life events, individuals with a cancer diagnosis rely on a variety of strategies to cope with the changes their diagnosis and treatment bring. Notably, most patients do not experience clinically significant symptoms of distress or dysfunction and, over time, typically 1–2 years, most patients will weather the crisis and return to baseline levels of functioning. However, for a significant number of individuals, full emotional and physical recovery can take much longer. Psychosocial intervention can facilitate emotional and physical adjustment to and recovery from cancer diagnosis and treatment.

Indications and Assessment

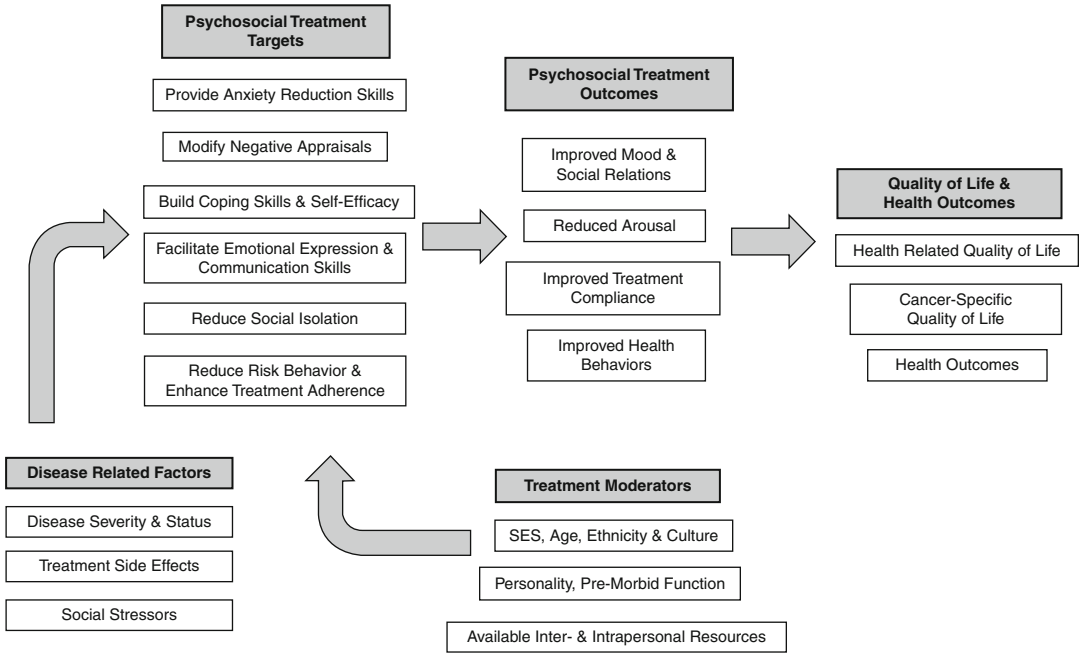
Psychosocial intervention is indicated not only when the patient is reporting elevated levels of distress, depression, or anxiety (which should be

assessed regularly during cancer treatment and posttreatment follow-up visits, see below), but also when a patient reports difficulty with pain management, fatigue, cognitive complaints, or problems with sexual functioning. Assessment and patient education regarding available psychosocial interventions is warranted at routine intervals during cancer treatment and care, as many patients who might benefit from intervention may not be reporting symptoms at the time and early intervention can be effective prophylaxis against later symptom development. Commonly used instruments to assess psychosocial and physical well-being include a distress thermometer or validated measures of mood and affect, such as the Hospital Anxiety and Depression Scale (HADS). To address concerns regarding changes in cognitive functioning, neuropsychological testing may be warranted. For those who experience severe levels of distress and/or meet clinical criteria for a mental health disorder, evaluation for pharmacologic treatment may be warranted.

Psychosocial Treatment Modalities

Several psychosocial intervention models in cancer have shown success in reducing distress, improving quality of life, and facilitating the overall posttreatment adjustment period. Psychosocial treatment approaches have ranged from open support groups and psychoeducational programs that are based on information provision, to supportive group therapy approaches and individual treatments that are structured to provide a nurturing environment to express concerns over the multiple challenges associated with cancer survivorship. Both individual and group-based interventions based on cognitive behavioral intervention models that blend a variety of therapeutic techniques (e.g., cognitive restructuring, relaxation training) have shown success in improving health-related quality of life across multiple cancer populations. Other intervention approaches include mindfulness-based stress reduction, emotional expression, symptom management, health behavior change, and motivational interviewing. A significant amount of research has shown that effective therapy components in multimodal intervention efforts include techniques such as relaxation training (e.g., guided imagery) to lower arousal, disease information and management, an emotionally supportive environment where participants can address fears and anxieties, behavioral and cognitive coping strategies, and social support skills training. Therapeutic processes by which participants benefit from intervention include giving and receiving information, sharing experiences, reducing social isolation, and providing patients with coping skills that facilitate self-efficacy and sense of control over the cancer experience. Some evidence suggests that cancer patients may benefit more from structured interventions than purely supportive ones; this may be due to learning skills with which they can more effectively cope with cancer-related changes after the intervention has ended (e.g., stress management). Interventions may also be couple or family based, depending on the goals of therapy and targeted outcomes, and may be administered at all phases of the cancer continuum, from post-diagnosis and treatment decision making to end of life or long-term survivorship time periods. Such interventions can be delivered via several modalities including face-to-face and technology-based individual and group-based formats.

The model in Fig. 1 proposes that cancer patients and survivors may benefit from psychosocial interventions that target multiple components. For example, teaching anxiety reduction skills can provide a way to reduce anxiety, tension, and other forms of stress responses and, thus, help the survivor achieve a sense of mastery over disease-related and general stressors. The use of cognitive restructuring techniques can help patients identify links between thoughts, emotions, and bodily changes, and increase their ability to identify commonly used distorted thoughts and understanding of how these thoughts can interfere with emotional well-being, effective management of the disease, and multiple domains of quality of life. Participants in these interventions can also benefit from techniques that challenge cognitive, behavioral, and interpersonal coping strategies by increasing awareness of the use of maladaptive coping strategies to deal with



Cancer: Psychosocial Treatment, Fig. 1 Conceptual model of psychosocial treatment interventions

stress and disease-related challenges. Therefore, attention is given to replacing inefficient and indirect ways of dealing with stressors and promotes both emotion and problem-focused strategies while increasing patients' ability to adaptively express both positive and negative emotions. These intervention models also promote identifying and utilizing beneficial sources of social support, as well as providing self-management skills to engage in positive lifestyle changes and behaviors. Communication skills are also targeted, particularly those specific to interacting with health care professionals and communicating concerns about functional limitations and treatment-related side effects with the spouse/partner, family, and friends.

Within the intervention model, disease-related factors provide several considerations for psychosocial treatment approaches. Disease severity (localized vs. advanced disease) and status (disease free survival vs. recurrent disease) significantly influences the experience of the cancer patient and survivor. For example, advanced and recurrent diseases are characterized by greater psychosocial compromises such as greater levels of anxiety, depression, and interpersonal disruption, as well as existential concerns regarding the end of life. Similarly, treatment type and timing within the cancer survivorship continuum will pose varying psychosocial and physical responses that need to be considered. Some treatments are characterized by immediate functional limitations with a slow recovery that invariably does not reach baseline functioning over 1–2 years posttreatment. In contrast, other treatments have a more insidious side effect trajectory with the greatest consequences surfacing up to 1 year posttreatment. Therefore, an awareness and knowledge of the trajectories of treatment-related side effects must be considered as these symptoms will vary by treatment type. It is also critical to understand ongoing stressors not specifically related to cancer such as financial burdens or other major life events that may be impacting quality of life as these will also influence the efficacy of psychosocial treatments. Furthermore, a series of possible treatment moderators need to be considered. Older patients will be more likely to have multiple comorbidities and functional limitations

that will impact health-related quality of life outcomes. Socioeconomic status can play a significant role in treatment adjustment as it has been consistently associated with health-related quality of life outcomes via its influence on treatment compliance and follow-up. It is also critical to have a good understanding of pretreatment psychological functioning. Cancer patients with prior histories of psychological dysfunction such as depression, anxiety, or interpersonal difficulties seem to have greater difficulties in adjusting to the multiple challenges faced posttreatment. Similarly, low levels of education and a lack of interpersonal resources have also been shown to significantly impact adjustment. Therefore, any intervention approach needs to consider multiple disease-related characteristics and possible treatment moderators as these will likely interact with intervention efficacy and influence psychosocial treatment outcomes.

Psychosocial Effects of Intervention

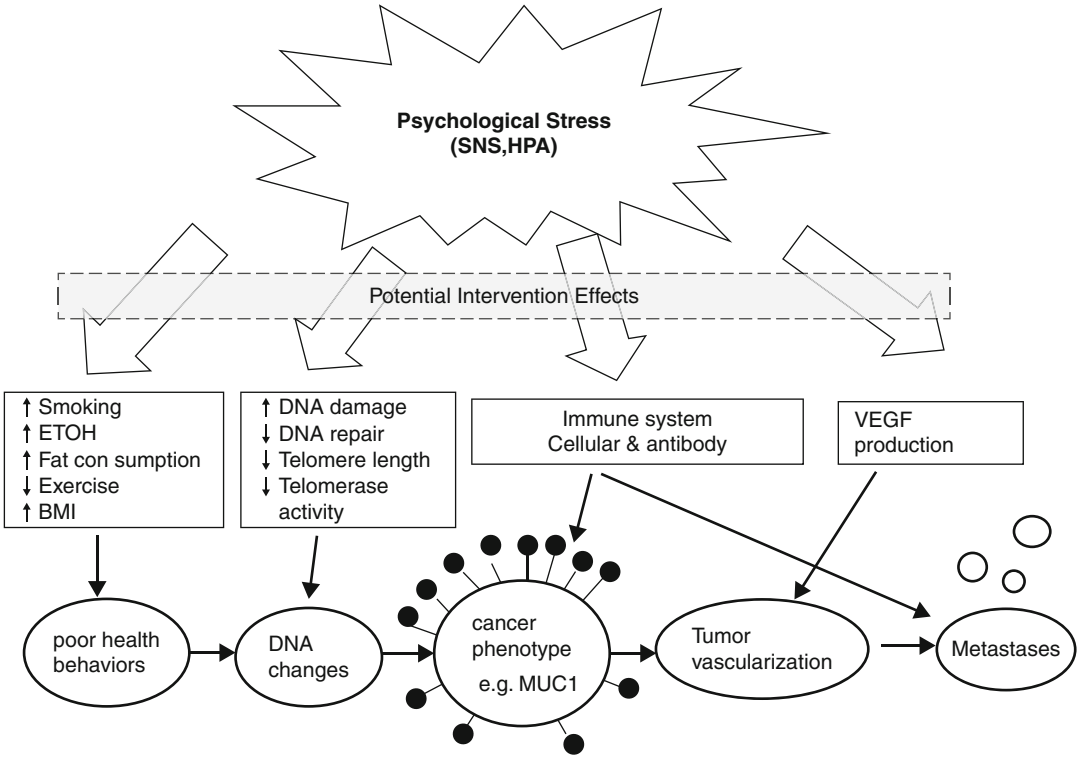
There is a large literature documenting the effectiveness of psychosocial intervention with cancer patients. Interventions have demonstrated positive effects across a range of psychosocial and physical outcomes, including symptoms of depression and anxiety, and cancer-related fear, social functioning, and disease- and treatment-related symptoms (e.g., fatigue, nausea, pain). Although findings have been mixed with reports of nonsignificant effects as well, several reviews of the literature have concluded that the majority of psychotherapeutic interventions among cancer patients demonstrate some improvement in psychosocial adjustment. Notably, sociodemographic factors (e.g., age, education, and socioeconomic status), premorbid psychological and physical functioning, social support, coping styles, and certain personality traits (e.g., neuroticism, interpersonal sensitivity, and social inhibition) have been associated with increased risk of adjustment difficulties following cancer diagnosis and treatment, suggesting that there may also be considerable variability in baseline functioning and response to intervention efforts.

Biological Effects of Intervention

Psychological distress can influence tumor progression via many different pathways (e.g., genetic changes, immune surveillance, pro-angiogenic processes). For example, there are data to suggest that psychological intervention can influence important neuroendocrine (e.g., cortisol) and immune function pathways, especially lymphocyte proliferation and TH1 cytokine production. One landmark study showed that women with metastatic breast cancer who participated in an expressive supportive group therapy intervention lived about twice as long as women in the comparison condition. This effect has been partially replicated in a subset of women with estrogen-receptor-negative tumors. While some groups have attempted to replicate survival findings, and with only limited success, other teams conducted studies focusing on neuroendocrine and immune mechanisms to explain the putative health effects of psychosocial intervention in breast cancer patients. One recent longitudinal study, which started with the intent of evaluating the intervention effect on not only psychological distress, but also immune function and survival, did show a survival advantage for intervention participants compared to comparison group participants. There is evidence now that psychological stress, via the HPA axis and SNS, can influence the course of tumor progression at almost every phase of the cancer continuum, from health behaviors to metastases. However, more systematic studies with large sample sizes and long-term follow-up effects are needed to provide conclusive evidence of any survival effects of these interventions. Potential psychosocial effects on biological mechanisms are depicted in Fig. 2.

Stepped Care Model of Psychosocial Intervention

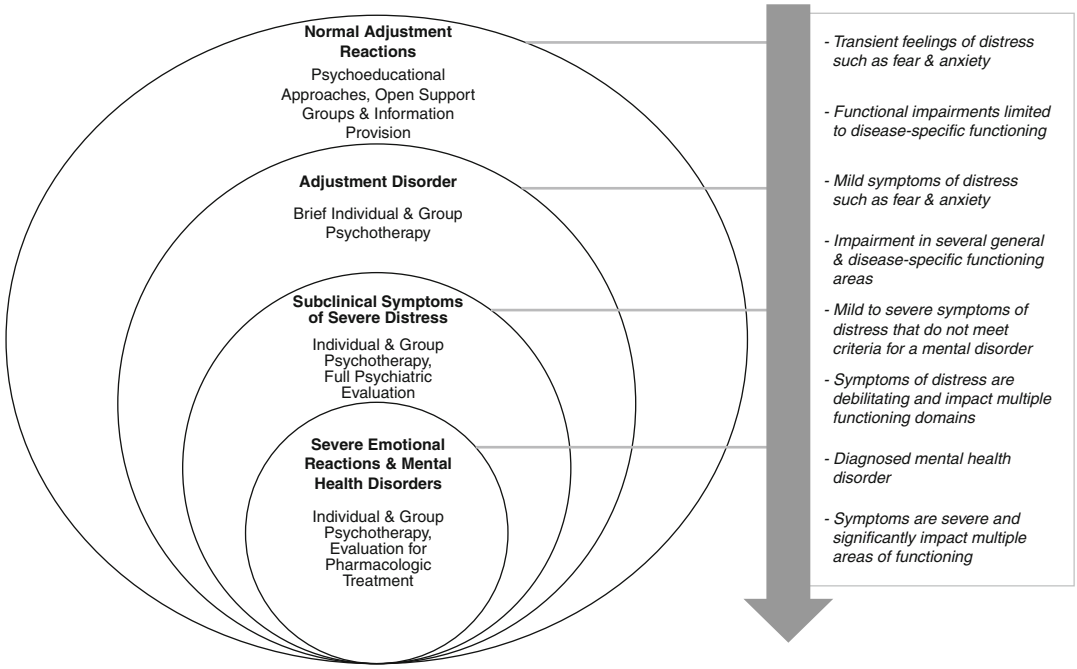
Several psychosocial treatments among cancer patients have shown promise in improving emotional well-being, and both general and disease-specific quality of life. Most intervention approaches involved group therapy interventions following cognitive behavioral, stress and coping, stress management, and supportive



Cancer: Psychosocial Treatment, Fig. 2 Development and progression of cancer and how/where psychological stress and interventions might influence the process

group environment theories and models. Some work has also provided psychoeducational interventions, engaged spouses/partners, or provided phone-based delivery of the interventions. Regardless of the intervention approach, it is important to consider the distress continuum among cancer patients to determine the most optimal level of care based on their needs (see Fig. 3).

Psychosocial intervention is not necessary for all patients and a stepped care model of intervention delivery is recommended. This involves a collaborative care approach to intervention efforts in which patients are involved in treatment planning and therapeutic resources are utilized based on systematic assessment and monitoring of patients' psychosocial well-being. Stepped care approaches require that treatments of different intensity are provided depending on the need of the individual. Treatments are initially implemented that are of minimal intensity but still likely to provide benefit and progress to more intensive interventions only if patients do not demonstrate improvement from simpler approaches or for those who can be reliably predicted to not likely benefit. An important feature of the stepped care model is that progress and decisions regarding intervention efforts are systematically monitored and changes in outcomes of interest are carefully assessed. A "step up" to a more comprehensive therapy is made only when there are no significant gains in the targeted outcomes. Stepped care may involve increasing intensity of a single therapeutic approach, transition to a different therapeutic approach, or using several therapeutic approaches additively. Likewise, different interventions may be applied to address different aspects of a patient's problem. Psychosocial needs also change as patients move from through their cancer experience and either transition to survivorship or face advanced disease and



Cancer: Psychosocial Treatment, Fig. 3 Psychological interventions' stepped approaches as a function of emotional reactions across the cancer distress continuum

end-of-life concerns. Utilizing a stepped care approach to promote adjustment and well-being at all phases of the cancer continuum may enhance intervention efficacy through more stringent assessment methods and appropriateness of intervention techniques, while also using the least amount of therapeutic resources.

The model in Fig. 3. proposes that treatment planning and intervention efforts must consider the distress continuum among cancer patients to determine the most optimal level of care based on their needs. Most cancer patients adjust relatively well to the cancer diagnosis and treatment. The majority of individuals experience some transient levels of distress characterized by mild symptoms of anxiety and depression, fear, and interpersonal disruption specific to disease-related functioning (e.g., sexual dysfunction). Because their emotional reactions are transient and significantly below clinical levels, these patients are likely to benefit from information provision or psychoeducational approaches that offer information on what to expect from prostate cancer treatment, the recovery process, available options for coping with treatment-related side effects (e.g., sexual aids), and communication skills to effectively navigate the medical system or voice concerns with the spouse/partner and family and friends.

A minority but yet significant number of cancer patients may experience emotional reactions that warrant a more structured approach at psychological care. Those lacking in social resources, presenting with high levels of perceived stress and enduring longstanding interpersonal dysfunction – likely driven by deficits in interpersonal skills and personality traits – are more likely to benefit from such interventions. Similarly, individuals with premorbid psychopathology and physical limitations, greater treatment-related functioning limitations, and recurrent disease are more likely to experience greater levels of distress and benefit the most from psychosocial interventions. Those who meet criteria for a mental health disorder are likely to be experiencing an adjustment disorder which is characterized by clinically significant symptoms of distress. In such cases, brief individual and group psychotherapeutic approaches can be useful in ameliorating

persistent symptoms of distress that among prostate cancer survivors are commonly related to treatment-related dysfunction. If untreated, these symptoms can interfere with multiple domains of health-related quality of life. Cancer patients who experience subclinical manifestations of mental health disorders such as anxiety, depression, and PTSD (i.e., experience severe symptomatology but not meeting diagnostic criteria) may benefit from a full psychiatric evaluation to determine the most appropriate level of care. For these survivors, individual and group psychotherapeutic approaches can positively impact mental health and health-related quality of life outcomes. Among the small number of patients who experience severe emotional reactions and are diagnosed with a mental health disorder, evaluation for pharmacologic treatment, in addition to individual and group psychotherapeutic approaches, is warranted.

Canonical Correlation

Stephanie Ann Hooker
Department of Psychology, University of Colorado, Denver, CO, USA

Definition

Canonical correlation is a multivariate statistical technique that specifies relationships between

two sets of variables. Researchers interested in understanding how two multidimensional constructs are related may find this technique useful. For example, someone interested in further understanding the relationships between the multidimensional constructs of personality and a healthy behavioral lifestyle might identify two sets of variables that measure those constructs. In the personality set, one might include factors like conscientiousness, openness to experience, and neuroticism, whereas in the healthy behavior set, one might include physical activity, healthy eating, sleep, or dental hygiene.

To use this technique, the researcher should identify two sets of measured variables. The variables selected for a set should measure different dimensions of the same construct (e.g., conscientiousness, openness to experience, and neuroticism would all be different facets of personality). Similar to exploratory factor analysis, canonical correlation identifies latent variables within each set. The canonical correlation (R^c) is the statistic that identifies the strength and directionality of the relationship between two latent variables (one from each set). Only statistically significant canonical correlations should be interpreted. The R^c is interpreted like the Pearson correlation coefficient, ranging from −1.0 to 1.0. A positive R^c indicates a positive relationship between the two latent variables and a negative R^c indicates a negative relationship between the two latent variables. R^c values closer to 1.0 (or −1.0) indicate stronger relationships.

Latent variables are interpreted using two statistics: standardized coefficients and canonical variate-variable correlations. Standardized coefficients indicate the extent to which each measured variable contributes to the latent variable. Canonical variate-variable correlations indicate the strength and directionality of the relationship between the measured variable and the latent variable. Stevens (2009) suggests examining both the standardized coefficients and the canonical variate-variable correlations to include the measured variable in the interpretation of the latent variable. Many of the measured variables may correlate highly with the latent variable, but the standardized coefficient identifies which variables may be redundant in the interpretation. Once the researcher determines which measured variables contribute to each latent variable, he or she names the latent factor and interprets the meaning of the canonical correlation.

Capsaicin

Barbara Resnick
School of Nursing, University of Maryland, Baltimore, MD, USA

Synonyms

Pepper

Definition

Capsaicin is the ingredient found in different types of hot peppers, such as cayenne peppers, that makes the peppers spicy hot. You can eat it raw or as a dried powder placed in food. It is also available as a dietary supplement, topical cream, or via a high dose dermal patch (trade name Qutenza). Capsaicin, in any of these forms, is used to relieve the pain of peripheral neuropathy

from postherpetic neuraligia caused by shingles and for temporary musculoskeletal pain and has been used to treat psoriasis (to decrease itching and inflammation). Capsaicin works by first stimulating and then decreasing the intensity of pain signals in the body. Capsaicin stimulates the release of a compound believed to be involved in communicating pain between the nerves in the spinal cord and other parts of the body. To be effective, the cream needs to be used four to five times a day. At the time of use, the skin may burn or itch, although these sensations decrease over time. It is important to wash your hands thoroughly after each use and to avoid getting the cream in your eyes or places in which there are moist mucous membranes such as the mouth or vaginal or rectal areas. Contact with these areas will cause burning. The cream should also not be used on areas of broken skin.

Capsaicin has also be used as a supplement to improve digestion, eliminate infections, prevent heart disease by lowering blood cholesterol levels and blood pressure, and prevent clotting and atherosclerosis. Theoretically, capsaicin acts as an antioxidant and protects the cells of the body from the damage of free radicals. In so doing, health benefits can be derived. Lastly, capsaicin makes mucus thinner and thus may improve pulmonary function among those with chronic obstructive pulmonary disease or chronic bronchitis.

Capsaicin is generally considered safe when taken orally or used as a cream. As noted, it can cause some unpleasant effects. If this occurs, the best way to alleviate further pain is to remove the exposure via removing clothing if it has been contaminated and washing off the skin with soap, shampoo, or other types of detergents. Water, vinegar, and bleach are all ineffective at removing capsaicin. Applications of cool compresses may help with the burning sensations experienced with capsaicin.

An allergic reaction to capsaicin is possible. If you are just beginning to use capsaicin, either as fresh or prepared food or in powder form, start with small amounts. If you use a topical cream, you should first apply it to a small area of skin to test for an allergic reaction.

Definition

A carbohydrate is an organic compound, or in other words, a compound containing a carbon atom. In addition to carbon, all carbohydrates also comprise the atoms hydrogen and oxygen, and share the common formula

$$C_nH_{2n}O_n$$

where n is any whole number.

The name "carbohydrate" is derived from the bonding of a water molecule to a carbon atom, thus carbohydrates are hydrates of carbon.

Carbohydrates can be classified into several categories. Monosaccharides are the most basic units, and when two monosaccharides are chemically bonded, a disaccharide carbohydrate is formed. Oligosaccharides are generally considered to be carbohydrates with three to ten

monosaccharides, and polysaccharides are carbohydrates with more than ten of these basic units. In nutrition, carbohydrates are often categorized into "simple" and "complex" forms. Simple carbohydrates include monosaccharides and disaccharides (sugars) whereas complex carbohydrates are oligosaccharides and polysaccharides (starches). Carbohydrates, despite being nonessential dietary constituents, function primarily as a source of energy, and are a particularly important fuel for high-intensity exercise.

Substances that cause cancer

Description

It is well established that cancer initiation and progression occurs through complex genetic and environmental interactions (Pfeifer & Hainaut, 2011). Completely genetically induced tumors are rare (Pfeifer & Hainaut, 2011). Most malignancies occur as a result of exposure to internal or environmental agents that cause genetic damage (Pfeifer & Hainaut, 2011). However, susceptibility to these environmentally induced mutations can be inherited (Pfeifer & Hainaut, 2011). Environmental factors in a very broad sense can include physical and chemical agents, dietary factors, behavioral exposures such as tobacco and alcohol and microenvironmental factors such as infection and inflammation. Any such factor that causes cancer is a carcinogen.

Sir Percivall Pott was the first to report that a malignancy could be caused by an environmental carcinogen when he described "the chimney-sweepers" cancer in 1775 (Cogliano, 2010; Stone, 2003). This work concluded that scrotal cancer was caused by soot that became wedged in the scrotum and also marks the first time that an occupational cancer was linked to a specific cause (Cogliano, 2010; Stone, 2003). As a result of this type of work, it is now understood that tobacco, including that found in second-hand smoke, causes lung cancer (Stone, 2003). It is also known that mesothelioma, frequent in shipyard workers, is due to asbestos exposure (Cogliano, 2010; Pfeifer & Hainaut, 2011; Siemiatycki et al., 2004; Stone, 2003), and leukemia, frequent in the shoe-production industry, is related to benzene (Cogliano, 2010; Siemiatycki et al., 2004). Similarly nickel refining, smelting, and welding are associated with cancers of the lung, nasal cavity, and sinuses and ionizing radiation is associated with bone, leukemia, lung, liver, and many other types of cancer (Siemiatycki et al., 2004). Certain viruses such as human papillomavirus (HPV) and hepatitis C virus are also carcinogenic (Stone, 2003).

Following Pott's example, public health agencies such as the United States National Toxicology Program and International Agency for Research on Cancer (IARC) have worked to identify and educate the public about additional carcinogens (Cogliano, 2010; Siemiatycki et al., 2004). In the case of the IARC, agents, mixtures,

or exposure circumstances are selected for evaluation if humans are known to be exposed and there is reason to suspect they may cause cancer (Siemiatycki et al., 2004). At regular intervals, the IARC meets as a working group consisting of 15–30 experts from related fields (Siemiatycki et al., 2004). These experts identify a concerning agent and review the epidemiological, animal, and other laboratory studies to help determine whether a substance of interest is carcinogenic (Siemiatycki et al., 2004). Epidemiologic evidence is generally considered the most important determinant (Siemiatycki et al., 2004). This evidence stems from associations between suspected causal agents and presence or absence of cancer in populations. The second most important determinant is the direct laboratory animal evidence of carcinogenicity (Siemiatycki et al., 2004). Other laboratory evidence such as genotoxicity, mutagenicity, metabolism, cytotoxicology, or mechanisms are also considered important (Siemiatycki et al., 2004). Based on the combination of these different types of data, the IARC develops a consensus and then classifies the substance as carcinogenic, probably carcinogenic, possibly carcinogenic, not classifiable, or probably not carcinogenic (Siemiatycki et al., 2004). Results of the working group meetings are published in the IARC monographs which provide important information for determining research priorities and preventing cancer (Siemiatycki et al., 2004).

Despite Pott's work, incidence of scrotal cancer in England did not decrease until the 1950s when counteractive measures such as improved chimney-cleaning, alternative heating methods, and protective clothing were put in place (Cogliano, 2010). Even today, exposure to many of the hundreds of common and suspected carcinogens occurs in industry (Cogliano, 2010). Further education and preventive measures are needed to fully educate and protect the public.

Malignant neoplastic disease

Definition

Carcinoma includes malignancies that begin in the lining or covering of organs.

Description

According to the National Cancer Institute (National Cancer Institute [NCI], 2011), carcinoma is the most common category of cancer and includes malignancies that begin in the lining or covering of organs. Other cancer categories include sarcomas that begin in connective or supportive tissue such as muscle and bone, leukemias which start in blood-forming tissues, lymphoma and myelomas which originate in the immune system, and central nervous system tumors which include malignancies that start in the brain and spinal cord (NCI, 2011). Nonmelanoma skin cancer, including basal cell and squamous cell, are the most common carcinomas in the United States with more 1,000,000 diagnosed annually (NCI, 2011). Other

carcinomas involving the prostate, breast, lung, and colon are the next most common (NCI, 2011).

Carcinoma, like any cancer, is characterized by dysregulated growth and uncontrolled dissemination of abnormal cells which, left unchecked, can result in death (American Cancer Society [ACS], 2011). Exposure to environmental factors such as tobacco, viruses, chemicals, and radiation can cause cancer and such agents are known as carcinogens (ACS, 2011; NCI, 2011). Internal factors such as inherited mutations, immunodeficiency, and mutations arising from metabolic dysfunction can also give rise to cancer (ACS, 2011). Because most malignancies initiate and progress through a combination of environmental and internal factors, only about 5% of cancers are felt to be familial (ACS, 2011). Decades can pass between exposure to external factors and detectable cancer (ACS, 2011). Some individuals who are exposed to known carcinogens, such as tobacco, for many years may never develop cancer (ACS, 2011). Individual factors such as ability to repair DNA damage, remove carcinogens, and destroy abnormal cells all play a role in determining who will go on to develop cancer (NCI, 2011).

Depending on site, stage, and specific pathology of the carcinoma, treatment includes combinations of surgery, radiation, and chemotherapy (ACS, 2011; NCI, 2011). Other therapies such as hormone therapy, biological therapy, and targeted therapy may also be used (NCI, 2011). Treatment can be very toxic, resulting in long-term morbidity especially for late stage disease which is primarily determined by its size and whether it has spread to lymph nodes or other areas of the body (NCI, 2011). Even with the most aggressive therapy, sometimes cure cannot be attained. For these reasons, programs to prevent and detect cancers early are imperative.

The American cancer Society (ACS) recommends regular screening for breast, colorectal, and cervical cancer as screening programs have resulted in decreased mortality for these cancers (Smith et al., 2011). Though evidence in favor of prostate cancer screening is increasing, there is still some controversy whether risks outweigh benefits (Smith et al.). The ACS recommends that men aged 50 or over and with at least a 10-year life expectancy should have an opportunity to make an informed decision with their health care provider about prostate cancer screening after receiving counseling as to the risks, benefits, and uncertainties associated with such screening (Smith et al.).

Prevention of carcinoma focuses on decreasing tobacco use, increasing nutritional awareness, and limiting exposure to known carcinogens. Tobacco use is leading risk factor for carcinoma and the most preventable cause of death worldwide, responsible for the deaths of half of long-term users (ACS, 2011). Furthermore, it has also been estimated that one-third of cancer deaths in the United States each year are due to poor nutrition, physical inactivity, and excess weight (ACS). In addition, environmental exposures other than tobacco use can increase risk of carcinoma. These exposures include infectious agents, excessive sun exposure, and exposures to carcinogens that exist in air, food, water, and soil (ACS). The United States' National Toxicology Program and the International Agency for Research on Cancer work to identify carcinogens and provide information to the public and other regulatory agencies in an effort to decrease the burden of human cancer (ACS, 2011).

Sudden cardiac death

Definition

Cardiac death is defined as occurring when the rhythmic contractions of the heart cease and do not return spontaneously. Generally speaking, cardiac death may occur suddenly or non-suddenly. Sudden cardiac death is defined by death within 1 h of the onset of symptoms, in the absence of preceding evidence of severe heart failure. This definition is usually used to capture death due to cardiac arrhythmia. Non-sudden cardiac death generally encompasses death due to pump failure (Hinkle & Thaler, 1982).

Cardiac Events

Synonyms

Coronary event; Major adverse cardiac and cerebrovascular event (MACCE); Major adverse cardiac event (MACE); Major adverse cardiovascular event (MACE)

Definition

The term cardiac event is used to denote the composite of a variety of adverse events related to the cardiovascular system.

Description

The exact definition for cardiac events often varies depending on the specific study. At the narrowest, it is synonymous with coronary event, which refers to adverse events caused by disease processes affecting the coronary arteries. These may include what are termed "hard" events such as deaths that are attributed to coronary artery disease and nonfatal myocardial infarctions but also occasionally "soft" events such as angina or revascularizations for progressive coronary artery disease (Kip, Hollabaugh, Marroquin, & Williams, 2008). More broadly, the term cardiac event is often used interchangeably with another loosely defined term, major adverse cardiac event or MACE. Common definitions of MACE include death (either all-cause or cardiac), nonfatal myocardial infarction, and revascularization (with optional additional specification of target vessel or lesion, i.e., if the revascularization occurred at the site of a previously identified diseased coronary vessel or atherosclerotic lesion, respectively); occasionally, stroke is also incorporated into MACE, and

the term is alternatively defined as major adverse cardiovascular event or major adverse cardiac and cerebrovascular event (MAACE). Finally, in some circumstances, nonfatal heart failure events (i.e., hospitalization for heart failure) are also considered cardiac events, though this is infrequent and occurs mainly in studies that focus on the prognosis and treatment of heart failure (Skali, Pfeffer, Lubsen, & Solomon, 2006).

Since cardiac events and the other related terms described above are composites of clinical events of varying significance, there remains considerable debate on what should constitute the most appropriate component endpoints and how to define them. Furthermore, it has been increasingly recognized that the wide variability in these definitions may significantly influence the results and impact of clinical trials and other studies. For instance, many have noted that less consequential but more frequently occurring endpoints such as revascularizations or heart failure exacerbations are often what drive the statistical significance or the lack there of for the results of many trials (DeMets & Califf, 2002; Lim, Brown, Helmy, Mussa, & Altman, 2008). Different component endpoints may also trend in opposing directions, rendering the interpretation and generalization of the primary result problematic (Wilcox, Kupfer, & Erdmann, 2008). These considerations have induced recent attempts to standardize the definitions of events that have the most clinical relevance, and guidelines such as the 2001 ACC Clinical Data Standards and the 2007 Joint ESC/ACCF/AHA/WHF Task Force for the Redefinition of Myocardial Infarction Expert Consensus Document have outlined explicit definitions for terms such as cardiovascular death and myocardial infarction, with emphasis placed on objective findings that include ECG changes and the typical rise and fall of biomarkers such as cardiac troponins. In addition, most contemporary studies have begun routinely disclosing the results of individual endpoints as well as those of alternative composite measures. It is hoped that with these and other future efforts, the methodological challenges inherent in the use of composite endpoints such as cardiac events will finally be adequately addressed.

Cardiac Output

Simon Bacon
Department of Exercise Science, Concordia University, Montreal Behavioral Medicine Centre, Montreal, QC, Canada

Definition

Cardiac output (Q) is the volume of blood pumped out of the heart (specifically from the

right and left ventricles) per minute. It is generally calculated as a function of heart rate and stroke volume (cardiac output = heart rate × stroke volume). Average resting cardiac output is about 5 L/min (normal range 4–8 L/min) and tends to be slightly higher in men versus women. During acute exercise and mental stress, cardiac output increases. This increase can be as high as 35 L/min for exercise (in elite athletes) and 15 L/min for mental stress.

There are many methods of measuring cardiac output, which range from intracardiac catheterization (invasive) to arterial pulse tonometry (noninvasive). The Fick principle, which uses the measurement of oxygen consumption and the oxygen content of the arterial and venous blood, is considered the most accurate method of assessing cardiac output, though it is an invasive technique, which limits its utility. Great effort has been placed into finding accurate reliable noninvasive methods of assessing cardiac output, such as, dye dilution, ultrasound-based techniques, impedance cardiography, and, more recently, magnetic resonance imaging. Each one of these comes with both positives and negatives and the selection of one method over another needs to be made given the individual requirement for cardiac output measurement.

As cardiac output is driven by heart rate and stroke volume, the factors that control changes in these parameters also influence cardiac output. Specifically, parasympathetic and sympathetic activity and venous return influence cardiac output.

Secondary prevention programs

Definition

Cardiac rehabilitation is a multidisciplinary program of secondary prevention measures that assist cardiovascular disease patients in their comprehensive recovery to previous functioning.

Description

Introduction

Cardiac rehabilitation is a comprehensive platform of pharmacologic, psychosocial, and behavioral secondary prevention measures that is typically provided to patients with a history of cardiovascular disease. Cardiac rehabilitation is designed with a multidisciplinary approach to patient care and requires a cohesive plan of various therapies and practitioners. Cardiac rehabilitation has been shown to improve outcomes and initiate a type of "re-conditioning" process for many patients (Clark et al. 2005). Targeted patient populations for cardiac rehabilitation include those individuals who have recently had an acute cardiovascular event (i.e., myocardial infarction or unstable angina), post-cardiac bypass patients, and those who have stable angina, heart failure, or other patients with cardiac disease who have become deconditioned for any reason.

History of Cardiac Rehabilitation Programs

In the 1930s, patients who had suffered a myocardial infarction were instructed to

observe strict bed rest, often up to 6 weeks in duration. Gradually, increasing levels of physical activity were added to the post-event regimen. In addition to the salutatory effects of cardiac rehabilitation for recovery of previous functional status, it was eventually recognized that there were significant benefits in avoiding the hazards of bed rest which included deconditioning, deep venous thrombosis, and even limb atrophy and contractures. Today, post-acute coronary syndrome patients are encouraged to return to physical activity soon after the event. Early intervention with physical therapy is now a hallmark of contemporary cardiovascular care.

Typical Components of Cardiac Rehabilitation

The United States Public Health Service (USPHS) defines cardiac rehabilitation programs as comprehensive, multidisciplinary efforts with the following components (Hamm et al. 2011). These are the broad categories that encompass both short- and long-term goals. Newly admitted cardiac rehabilitation patients must undergo risk stratification to identify their needs for supervision and particular exercise plan.

1. Medical evaluation
2. Exercise training
3. Secondary prevention efforts and risk factor reduction
4. Patient education and counseling

Evidence Supporting Cardiac Rehabilitation

There are several trials that have compared the efficacy of cardiac rehabilitation programs that focus primarily on risk factor reduction versus an approach that favors increasing exercise tolerance. An integrated approach is the most favorable for reducing morbidity and mortality after a cardiovascular event. Modification of depressive symptoms is an important target for a cohesive rehabilitation program (Milani et al. 2007). Other less-quantifiable benefits include the socialization and support that comes from working with a variety of clinicians and peer groups.

A growing body of evidence in the literature supports exercise-training programs for cardiac rehabilitation (Antman et al. 2008). All enrolled patients should undergo a thorough medical evaluation prior to initiating any program of physical exertion. This is particularly relevant for those who are survivors of an acute coronary syndrome or symptomatic heart failure. While there used to be a prevalent belief in the medical community that prolonged bed rest was the only safe activity level after a cardiac event, numerous studies have demonstrated the safety of medically supervised exercise programs (Franklin, 1998). These exercise programs not only improve the quality of life for cardiac patients but have actually been shown to increase life expectancy in some cases. Specifically, most individualized exercise programs should encompass aerobic activities for at least 2 days per week.

Guidelines for Cardiac Rehabilitation

The American Society of Cardiovascular and Pulmonary Rehabilitation have published guidelines outlining ten core competencies that practitioners must have to provide the highest standard of evidence-based care for patients. Briefly, the ten areas are patient assessment, nutritional counseling, weight management, blood pressure management, lipid management, diabetes management, tobacco cessation, psychosocial management, physical activity counseling, and exercise training evaluation. The guidelines encompass an array of skills that transcend the abilities of any single provider. Instead, they assume a collaborative and comprehensive approach to cardiac rehabilitation. The competencies are divided into discrete "knowledge" points and then "skills" without specific reference to the particular type of provider who will provide the services. To coordinate the broad variety of necessary services, they suggest a case management model for individual patients. In the position statement enunciating the ten core competencies, the Society emphasizes the extent to which individual providers need not be proficient in all facets of secondary prevention but rather be willing and able to identify particular patient needs. The focus on multidisciplinary care involves the participation of physicians, nurses, physical therapists, clinical nutritionists, social workers, and psychologists.

Of particular interest is the core competency of psychosocial management. The knowledge piece requires cardiac rehabilitation providers to become aware with the literature on the impact of psychological factors on the pathophysiology of cardiovascular event onset and the impediments that can prevent recovery. In particular, the competency requires specific attention to developing familiarity with the effect of major depression on adverse cardiovascular outcomes and worse adherence to treatments (Prochanska & DiClemente, 1983). This references the current research question of whether poorer outcomes among depressed post-heart attack patients are due to their non-adherence of rehabilitative therapies or rather a distinct pathophysiologic state.

Definition

Cardiac surgery is the subset of operative procedures focused on the heart and vasculature. Common examples of cardiac surgery include coronary artery bypass grafting (CABG), valvular repair, and the correction of congenital cardiac malformations. Cardiac surgery is a subspecialty of general surgery that requires additional training beyond a traditional 5-year residency. Advancements in anesthesiology have been critical to the development of cardiac surgery. For example,

the widespread use of heart-lung bypass machines since the 1990s have extended the possible duration and complexity of these procedures.

Surgeries on the heart and great vessels (e.g., aorta and vena cavae) are generally performed on seriously ill patients who have either tried or been deemed ineligible for less invasive measures such as medication-based or percutaneous interventions (Lie, Bunch, Smeby, Arnesen, & Hamilton, 2012). Increased rates of mood disorder such as depression or cognitive impairment have been noted in post-CABG patients, suggesting a possibly important role for behavioral therapies (Katon, Ludman, & Simon, 2008). To date, however, it is unknown whether depression treatment in post-CABG patients improves cardiovascular outcomes.

Definition

A cardiologist is a physician who has specialty training in the area of cardiology. Cardiologists are often MD trained, and typically had general training in internal medicine (or pediatrics if a pediatric cardiologist) prior to the completion of cardiology fellowship. Cardiologists are often confused with cardiac or cardiothoracic surgeons, who primarily perform operations on the heart. A "board-certified cardiologist" is a physician who trained in cardiology, met minimum training requirements, and also passed the cardiology board exams. After cardiology fellowship, physicians can choose to undergo additional training in a subspecialty of cardiology (e.g., echocardiography, nuclear cardiology, intervention, etc).

Definition

Cardiology is a medical specialty of the structure, function, and disorders of the heart.

Traditionally, cardiology has mainly focused on the heart; however, more recently, the field of cardiology has expanded into the study and disorders of the arteries and veins, as well as other organs such as the brain (i.e., stroke or transient ischemia attack) or kidney (i.e., cardiorenal syndrome). This is probably due to a common underlying pathophysiology of disease. As such, cardiology has recently involved areas of medicine typically associated with other specialties (such as neurologists, nephrologists, etc.).

Definition

Cardiovascular disease is a group of chronic diseases (e.g., myocardial infarction, chronic heart disease, stroke) of the heart and blood vessels. Cardiovascular disease prevention is composed of the various early actions taken to thwart the onset of cardiovascular disease.

Description

Cardiovascular diseases (CVD) claim the lives of thousands of individuals every year. In 2007, the top cause of death in the United States was heart disease (616,067 deaths), second was cancer (562,875 deaths), and third was stroke (or cerebrovascular disease, in many cases a form of cardiovascular illness; 135,952 deaths) (U.S. Centers for Disease Control and Prevention [CDC], 2010). Although there is a general inheritability for CVD, the formation of these diseases is seen as largely preventable. In a unique interpretation of the causes of death in the year 2000, Mokdad and colleagues (Mokdad, Marks, Stroup, & Gerberding, 2004) found that the top three actual causes of death were due to three modifiable behavioral risk factors: (1) smoking (435,000 deaths; 18.1% of total deaths in the year

2000); (2) poor diet and physical inactivity (400,000 deaths; 16.6%); and (3) alcohol consumption (85,000 deaths; 3.5%). All three of these behaviors are risk factors for CVD and are considered preventable.

Primary prevention of CVD, like other chronic, noncommunicable diseases, is seen as more cost-effective than treatment of the disease, which is usually long term and expensive (Probst-Hensch, Tanner, Kessler, Burri, & Künzli, 2011). Practitioners of behavioral medicine can encourage their patients and the community at large to make lifestyle modifications to prevent the onset of CVD. These can include behavioral changes such as (1) getting regular health screenings; (2) limiting tobacco exposure; (3) engaging in regular physical activity; (4) eating a heart-healthy diet; (5) maintaining a healthy weight; (6) limiting alcohol use; and (7) reducing stress and negative emotionality. These seven behavioral changes are described in detail below.

Get Regular Health Screenings

Beginning at age 20, adults should get screenings for CVD risk factors at least every 2 years. These include blood pressure, body weight, waist circumference, and pulse (as a screen for atrial fibrillation). At least every 5 years (or less if at higher risk), blood lipids (either fasting serum lipoproteins or total and high-density lipoproteins [HDL] if fasting unavailable) and fasting blood glucose should be recorded to monitor risk for hyperlipidemia and diabetes (Pearson et al., 2002).

Blood pressure should be maintained at a level below 140/90 mmHg for the average individual whereas those with diabetes should maintain their blood pressure below 130/80 mmHg (Pearson et al., 2002). Individuals with hypertension can make behavioral modifications (e.g., limit salt intake, increase physical activity, and reduce alcohol intake). Blood pressure medications are recommended for individuals who have attempted lifestyle modifications but have not succeeded in controlling blood pressure.

Limit Tobacco Exposure

Individuals should avoid exposure to tobacco smoke as much as possible. Thus, they should not smoke cigarettes or other forms of tobacco, and those who do should quit. Exposure to secondhand smoke should be limited as well (Pearson et al., 2002). Tobacco use accounted for 18.1% of all deaths in the United States in the year 2000 and was the top behavioral risk factor for death (Mokdad et al., 2004). Cigarette smoking is one of the main risk factors for coronary heart disease, and women who smoke have a 25% greater risk of coronary heart disease than men after controlling for other risk factors (Huxley & Woodward, 2011).

Engage in Regular Physical Activity

The American Heart Association recommends that individuals engage in at least 30 min of moderate-intensity exercise most days of the week (Pearson et al., 2002). Exercise treats many CVD risk factors, including elevated blood pressure, insulin resistance, glucose intolerance, obesity, elevated triglycerides, and low HDL cholesterol (Thompson et al., 2003). Exercise also has short-term effects of reducing serum triglycerides for up to 72 h, introducing a spike in HDL, reducing systolic blood pressure for up to 12 h, and helping stabilize glucose levels (Thompson et al., 2003). Physical activity might also help individuals make other preferable behavior changes, including helping with smoking cessation (Ussher, Taylor, & Faulkner, 2008).

Eat a Heart-Healthy Diet

Individuals should eat a "heart-healthy" diet. This is a diet that is low in fat (saturated fat $<10\%$ of calories), cholesterol (<300 mg/day), and trans-fats (limit as much as possible), and salt (<6 g/day) and that is rich in assorted fruits, vegetables, whole grains, and low-fat dairy. Energy intake should match energy expenditure, i.e., intake should not exceed what is needed, and if necessary, intake should be reduced for weight loss (Pearson et al., 2002). Although there has been a major focus on *how much* individuals consume, there is evidence that *what* individuals eat is important to reduce CVD risk. In a meta-analysis of randomized clinical trials of dietary interventions in which patients were advised to

either (1) reduce total fat intake, (2) reduce saturated fat intake, (3) reduce dietary cholesterol, or (4) shift from saturated to unsaturated fat, modification in dietary fat intake reduced risk for cardiovascular mortality by 9% and reduced risk for subsequent cardiac events by 16% (Hooper et al., 2001).

Maintain a Healthy Weight

Body mass index (BMI; weight (kg)/height $(m)^2$) should be maintained in the normal range (18.5–24.9 kg/m^2) (Pearson et al., 2002). Waist circumference should be maintained at less than 40 in. in diameter for men and less than 35 in. in diameter for women (Pearson et al., 2002). In a meta-analysis of over 80,000 individuals, greater waist-to-hip ratio and waist circumference were associated with greater risk of CVD-related mortality, after controlling for other relevant CVD risk factors, over an average 98.7-month follow-up (Czernichow, Kengne, Stamatakis, Hamer & Batty 2011). However, BMI, the most commonly used measure of obesity, was not related to CVD-related mortality after controlling for other risk factors, suggesting that some (if not all) of the risk that higher BMI contributes to CVD mortality is subsumed by the other related risk factors (e.g., blood pressure, cholesterol).

Limit Alcohol Use

Alcohol use should be limited to $\leq$2 drinks/day for men ($\leq$14 drinks/week) and $\leq$1 drink a day for women ($\leq$7 drinks/week) (Pearson et al., 2002). In a meta-analysis of prospective cohort studies linking alcohol use to cardiovascular outcomes, including mortality and cardiovascular event morbidity, moderate consumption of alcohol (about 1 drink/day) was associated with a 14–25% reduced risk of all cardiovascular outcomes when compared to abstainers (Ronksley, Brien, Turner, Mukamal, & Ghali 2011). Conversely, consuming higher amounts of alcohol (>1 drink/day) was associated with higher probability of CVD-specific mortality and cardiac events.

Reduce Stress and Negative Emotionality

Individuals should limit their exposure to stress and promote positive rather than negative emotions. There is evidence that negative emotions (i.e., depression, anxiety, and anger) are related to the development of CVD. Multiple pathways have been proposed to explain the relation between negative affect and CVD risk, and these include engagement in more adverse health behaviors, greater stress exposure, greater physiological reactivity, lower heart rate variability, and greater inflammation (cf., Suls & Bunde, 2005, for a review). In particular, type D personality, a personality type comprised of negative emotionality and social inhibition, is positively related to cardiac events. A recent meta-analysis by O'Dell, Masters, Spielmans, and Maisto (2011) revealed that patients with type D personalities were three times more likely to experience myocardial infarction, coronary artery bypass grafting, percutaneous cardiac intervention, or cardiac mortality than non-type D individuals. Conversely, there is preliminary evidence that some psychosocial resources may provide a protective buffer against cardiovascular risk. Roepke and Grant (2011) reviewed 32 studies of personal mastery (i.e., the belief that one has some control over future life circumstances) and cardiometabolic health and revealed that the overwhelming majority of studies found that higher mastery was associated with a reduced risk for cardiovascular outcomes.

Conclusions

Cardiovascular disease is largely preventable when individuals practice a healthy lifestyle. This includes practicing health-promoting behaviors like engaging in regular physical activity, eating a heart-healthy diet, maintaining a healthy weight, and getting regular health screenings and avoiding health-compromising behaviors like risky alcohol use and tobacco use. Additionally, individuals can make attempts to reduce their experiences of stress and negative emotions and promote positive emotional experiences. The combination of these behaviors will help reduce the risk of CVD and promote longer, healthier lives.

Cardiovascular Recovery

William Gerin
The College of Health and Human Development, University Park, PA, USA

Definition

Cardiovascular recovery refers to the extent to which elevations in blood pressure (BP) or heart rate (HR) due to a stressor persist after the stressor is no longer present.

Description

Recovery of cardiovascular prestress resting levels following a stressor has been of interest to researchers for many years, going back to the original cardiovascular reactivity studies by Hines and Brown (1936), who noted that not only did hypertensive patients show greater responses to the cold pressor than normotensive controls but also recovered more slowly. Since then, evidence from several studies suggests that recovery may provide prognostic information concerning the development of cardiovascular diseases, such as hypertension and coronary heart disease (CHD) (Fredrickson & Matthews, 1990).

Cardiovascular reactivity (the magnitude of the acute BP or HR response to a stressor) has been implicated as a risk factor in the development of cardiovascular-related diseases (i.e., the "reactivity hypothesis"). However, this measure does not take into account the duration of the response (i.e., recovery; the time BP or HR takes to return to prestress baseline levels from elevations due to a stressor that is no longer present). There is strong evidence that sustained elevation of BP is a cause of target organ damage, e.g., left ventricular hypertrophy, and, over time, of essential hypertension (HTN) (Fredrickson & Matthews, 1990). To the extent that we may regard slow recovery periods, observed in the laboratory, as analogous to sustained elevated BP in the natural environment, this measure provides information over and above that of the magnitude of the response. However, there is not nearly the body of evidence examining the causes and effects of recovery as there is for reactivity.

Much of the evidence that does exist for recovery comes from cross-sectional comparisons, examining variables that are related to the development of cardiovascular diseases and including comparisons based on normotensive-hypertensive status; family history of hypertension; and ethnicity. For example, children of normotensive parents show more rapid recovery than children of hypertensives (Linden, Earle, Gerin, & Christenfeld, 1997). It is noteworthy that in this review, differences in *reactivity* were *not* observed among the groups. Hines & Brown (1936) found that hypertensive subjects showed longer recovery times than normotensives. Finally, studies examining race have found that Black women and men had slower recovery rates than White women and men (Linden et al., 1997).

Thus, several important risk factors for hypertension and CHD appear to influence BP and HR return to prestress levels following a stressor. The recovery data are important, especially given findings showing that in a sample of borderline hypertensives, a strong predictor of future stable hypertension was the recovery of diastolic BP following a mental arithmetic task (Borghi, Costa, Bocshi, Mussi, & Ambrosioni, 1986). In fact, these researchers found recovery a more useful predictor than reactivity.

There are in theory many reasons why recovery should be poorer in one individual than in another. In general, the mechanisms could be central or peripheral. An example of the former would be a persistence of the autonomic arousal, or an inability to "unwind" following exposure to a stressor. A second mechanism could be an impairment of baroreflex sensitivity. The function of the baroreflex is to buffer acute changes of blood pressure, and an insensitive reflex would result in an enhanced and protracted pressor response to a stimulus. A third, and peripheral, mechanism is changes in the vasculature, such as hypertrophy and remodeling, which could result in delayed relaxation of vascular smooth muscle following exposure to a vasoconstrictor stimulus.

There is evidence that recovery and reactivity represent independent dimensions. For example, in one review paper, reactivity changes were weakly correlated with recovery scores (Linden et al., 1997). In addition, Haynes, Gannon, Orimoto, O'Brien, and Brandt (1991) reported that, across a total of 65 studies, of the 81 statistical analyses (out of 180) that indicated *nonsignificant stressor effects* (i.e., reactivity) for a variable (e.g., between group, between phases), significant effects *were* found during the *recovery* phase for 74% of the same variables. Conversely, of the 74 statistical analyses that indicated *significant* stressor effects for a variable, nonsignificant effects were found during the *recovery*

phase for 42% of those same variables. This is important because it suggests that the physiological mechanisms underlying the two processes of reactivity and recovery must be considered separately and that the information contained in *both* measures may provide greater insight into the cardiovascular mechanisms underlying the stress response than either measure alone. These considerations have led a number of researchers to suggest that causal explanations of biobehavioral disorders and the design of clinical interventions may be well served by studying psychophysiological recovery.

Early Theories of Stress and Recovery

As early as the 1930s, the seminal theories of stress, and the optimal ways to respond to stress, were proposed. For example, Seyle (1936) proposed that stress has three phases: activation, resistance, and exhaustion. When the body is initially challenged by a stressor, it responds with physiological activation of a defense system to deal with the immediate stressor, what is often referred to as the fight-or-flight response. A resistance (or coping) phase follows during which the body begins to suffer from the effects of heightened activity, but continues to function to ward off the stress-inducing stimuli. If the resolution of stress is unsuccessful the body may experience exhaustion. Activation that endures beyond the resistance stage (i.e., does not lead to swift resolution) is presumed to contribute to disease. At about the same time, Freeman (1939) posited that psychological recovery from experimental loads may be useful in estimating an individual's ability to withstand conflict in ordinary life situations. Such early suggestions that quick recovery from stress-induced arousal reflects particularly effective coping laid the foundation for later theories of the stress-disease linkage.

Subsequent work has thus refined these theories, and posited biological mechanisms for how stress impacts the body and contributes to disease. Important to refinement was the altering of Seyle's notion from a ubiquitous, "whole-system" response to challenge, to one that distinguished at least two axes of physiological responding. The sympatho-adrenal axis reflects activation due to motor and cognitive effort, including rises in epinephrine, norepinephrine, muscle tension, plasma free fatty acid levels, and blood pressure due to cardiac output. This activation when accompanied by adrenocortical hormone suppression has also been described as a "positive stress reaction" because it is short-lived and permits adaptive responding with maximal strength (De La Torre, 1994). In contrast, the hypothalamic-pituitary axis (HPA) is thought to reflect affective distress and be the result of chronic, unresolved strain (De La Torre), and may be the most indicative bodily response during delayed recovery. HPA axis activity is associated with increased release of free fatty acid into circulation, suppression of immune function, increased glucose and urea production, and increased blood pressure due to vasoconstriction (i.e., total peripheral resistance); HPA activation is inferred from the measurement of cortisol and its precursor adrenocorticotropic hormone (ACTH).

Cognitive-Affective Determinants of Poorer Recovery

A fundamental question that arises concerns how acute stressors can have lasting effects for some but not others, or put another way, why some individuals have poorer recovery than others. Brosschot, Gerin, and Thayer (2005) have proposed that the tendency to relive stressors in one's mind (i.e., ruminate and worry) causes repeated HPA activation and results in negative health outcomes, such as sustained hypertension. In other words, people do not need an external stressor to be present to experience stress. Rather, stress can have longer durations and impacts on the body, simply through thinking about and remembering negative emotions and having persistent thoughts about the negative experiences. Furthermore, it is those individuals who continually experience the mental representation of stress that have poor recovery and ultimately poor health. This focus on the cognitive-affective determinants of poorer recovery has begun to be seen as an important area of study, augmenting reactivity models.

Conclusion

In sum, the duration of time it takes for an individual's cardiovascular system to return to resting levels is a key determinant of that person's health. Furthermore, the duration of experienced stress (i.e., recovery) is an independent and often more important predictor of future health than the magnitude of the stress response (i.e., reactivity). Current models of hypertension and cardiovascular disease are beginning to focus on delayed recovery as an essential variable to consider. This work, and future explorations, will need to consider the role that perseverative cognitions, such as rumination, play in delaying cardiovascular recovery. While the effects of the arrangement of stress in one's environment cannot be ignored, how stress is arranged in one's mind appears to be as important a factor to determining one's health.

Definition

A cardiovascular risk factor is a predictor of one or more diseases of the heart or circulation.

Description

A "risk factor" is a variable that bears an empirical association with one or more diseases or other

medical conditions. "Cardiovascular disease" and "heart disease" refer to a set of specific disorders that affect the heart and circulation. Therefore, a cardiovascular risk factor is a correlate of one or more cardiovascular diseases. A distinction is sometimes made between risk and protective factors as a way to capture the direction of the relationship. For example, elevated cholesterol is a risk factor, whereas social integration has been studied for its possible protective effects.

The identification of risk factors for medical conditions is a major goal of the field of epidemiology. The term "risk factor" was introduced in the context of cardiovascular epidemiology, a field that underwent great expansion during the twentieth century. Certain acute infectious conditions that had been the major sources of death in the early 1900s came under control as a result of advances in the fields of public health and biomedicine. As a consequence, several multiply determined chronic disorders became more prevalent. Chronic illnesses, and diseases of the heart and blood vessels in particular, became the leading sources of death in the United States and in other industrialized nations. This continues to be the case despite reductions in cardiovascular death over the past several decades. Many risk factors for cardiovascular disorders have been identified. They may be categorized in a number of different ways, for example, in terms of the particular form(s) of cardiovascular disease with which they are related or on the basis of characteristics of the risk factors themselves.

Major Cardiovascular Disorders

Among the various forms of cardiovascular disease (CVD), coronary heart disease (CHD) is a major contributor to cardiovascular morbidity and mortality. Also referred to as ischemic heart disease, CHD occurs when the heart is inadequately supplied with oxygenated blood. It has several clinical manifestations including angina pectoris (a syndrome involving chest pain and other symptoms), myocardial infarction (MI) or "heart attack" (death of a portion of the myocardium), and sudden cardiac death (death within minutes of symptom onset). Coronary heart disease can promote other cardiovascular disorders, such as when damage due to myocardial infarction leads to congestive heart failure, a condition in which the pumping action of the heart cannot adequately meet the demands of the body for oxygen and nutrition. Atrial fibrillation is one of several forms of CVD that involve a disturbance in heart rhythm and may be a consequence of MI or heart failure.

Clinical CHD is usually a consequence of coronary atherosclerosis, or coronary artery disease (CAD). Coronary atherosclerosis involves the accumulation of plaque, comprising fatty substances and other materials, which forms on the inner lining of the coronary arteries, the vessels that supply oxygenated blood to heart muscle. The buildup of atherosclerotic plaque, which reflects a number of metabolic, hemodynamic, inflammatory, and hematologic processes, culminates in CHD when blood vessel openings become narrowed to the point at which blood flow to the heart muscle is obstructed and can no longer meet its metabolic demands. The triggering event in CHD is often thrombosis (clot formation) leading to occlusion of an already narrowed coronary artery. The atherosclerotic process also may affect blood vessels of the brain, leading to cerebrovascular incidents commonly referred to as "stroke."

Still another form of cardiovascular disease is essential hypertension, a condition defined by sustained high blood pressure levels with no identifiable cause. Hypertension is often associated with vascular inelasticity, referred to as arteriosclerosis. Hypertension increases risk for CHD as well as for stroke, retinopathy, heart failure, and kidney disease.

Risk factors differ somewhat for different forms of CVD. For example, cigarette smoking is a well-established risk factor for MI and other forms of CHD, but its role in the development of essential hypertension is less clear. On the other hand, dietary intake of salt, a possible risk factor for essential hypertension in some segments of the population, has a less well-established relationship with other types of heart disease. Similarly, certain kinds of heart valve problems

more clearly operate as predisposing factors for heart rhythm disturbances than for other cardiovascular conditions.

Taken together, the multifaceted nature of cardiovascular diseases, complexities in interrelationships among its various forms, and their overlapping but nonidentical determinants complicate the description and classification of cardiovascular risk factors. However, clinical manifestations of CHD and other major forms of CVD reflect a common substrate, atherosclerosis and, in the aggregate, account for considerable morbidity and mortality. This provides an important focus for much research in this area. Moreover, although genetic and other biological risk factors may be in play from the time of birth, much of the burden of cardiovascular diseases reflects the operation of multiple aspects of lifestyle, as will be discussed further below. This raises the possibility that programs of primary prevention may bring about significant reductions in the burden of cardiovascular disease.

Attributes of Risk Factors

Risk factor status, by itself, does not imply causality. The case for a causal role requires several forms of evidence. For example, there should be an association with disease in well-designed studies that is consistent, strong, prospective (rather than merely cross-sectional), and independent of other possible risk factors. The putative risk factor also should show a dose–response relationship with disease outcomes and should plausibly be related to disease etiology and pathophysiology, and its removal should reduce the risk of disease. Although causal analysis often follows after a variable is identified empirically as a risk factor, in other cases a variable is examined as a possible risk factor only after a role in disease causation is first suggested in mechanistic research.

The strength of the relationship between a risk factor and disease is often expressed in terms of relative risk. Relative risk is the ratio of the probability of disease occurrence with and without the risk factor in question. For example, a relative risk of 2.0 would indicate that individuals with the risk factor are twice as likely (or, equivalently, 100% more likely) to develop the condition by comparison with those without the risk factor. Major risk factors for one or more cardiovascular conditions are those for which a significant relative risk is well established. Variables for which the evidence is less clear are sometimes referred to as contributing risk factors. The more risk factors that are present, and the higher the level of each one, the greater the risk for CVD.

In addition to its relative risk, attributes of a cardiovascular risk factor that determine its overall importance from a public health standpoint include its prevalence, the degree to which it can be readily modified, and the impact of its modification on CVD outcomes. Several risk factors, such as resting blood pressure and cholesterol level, can be modified, and their modification is associated with reductions in cardiovascular morbidity and mortality. In other cases, including that of many suspected psychosocial variables, there are questions either about the effects of interventions on the risk factor or about the impact of risk factor modification on CVD outcomes. Still other risk factors, such as gender and age, are clearly not modifiable, though it remains possible that some of the pathways through which they exert their effects are amenable to intervention.

Risk Factor Categories

In addition to distinctions in terms of the CVD outcomes with which they are associated, CVD risk factors may be distinguished on the basis of their intrinsic characteristics. One rather broad distinction is that between states or conditions of the person and those that describe the environment. Person factors include variables such as resting blood pressure, gender, and personality. Environmental factors may be defined geographically, in terms of regions, such as the Southeastern United States (where CVD is highly prevalent), or with respect to variables such as the average socioeconomic status of individuals residing in a particular community (which is inversely associated with CVD risk).

Risk factors also may be categorized in terms of the time point and chronicity of their influence on the natural history of CVD. The hypothesized pathogenic effect may be to promote progression of CAD, as in the case of variables related to blood cholesterol or sugar levels. Alternatively, a risk factor may be suspected of playing a role in the manifestation of clinical CHD, as where an acute stressor triggers an ischemic event in the context of previously asymptomatic CAD. Within these major disease phases, risk factors may exert their influence gradually, over the course of months and years, or more rapidly, within days, hours, or even minutes.

Risk factors also may be described at several levels of analysis. Many are biological, ranging from the molecular, for example, specific genetic polymorphisms and proinflammatory factors, to systemic physiological conditions such as high resting blood pressure. Some risk factors are behavioral, including cigarette smoking, physical inactivity, and various dietary practices, and some are psychological, including personality attributes like cynical hostility and mood and anxiety disorders like major depression and posttraumatic stress disorder. Still others are described at a social level of analysis, including social network characteristics and socioeconomic status.

Risk Factor Interactions

Risk factors for CVD do not operate in isolation from one another. Individual variables may share causal antecedents, influence one another directly, and exert additive or synergistic effects in the etiology and pathogenesis of disease. For example, CVD risk factors such as poor diet and exercise habits combine to promote obesity and high cholesterol levels, which are themselves CVD risk factors. Functional relationships among a set of multiple determinants of a single outcome suggest that it may be useful to consider them in combination. A case in point is cardiometabolic syndrome, a biological CVD risk factor defined as a cluster consisting of central obesity, hypertension, and dysregulation in glucose and fat metabolism. The disease-promoting effects of certain risk factors are thought to amplify those of others. In particular, cigarette smoking has been examined for its possibly interactive effects with other variables including genes, high blood pressure, and oral contraceptive use.

Traditional and Psychosocial Risk Factors

Historically, those risk factors that were identified early on or that fit within the original paradigm for understanding cardiovascular diseases have been referred to as "traditional" or "biomedical." Variables that exemplify this tradition and that are recognized by contemporary epidemiologists include cigarette smoking, resting blood pressure, cholesterol levels, diabetes, older age, male gender, specific genetic markers, and family history; also implicated are obesity, physical inactivity, a high fat, high carbohydrate diet, low levels of high-density lipoprotein cholesterol, high levels of triglycerides, and high levels of C-reactive protein and other inflammatory markers.

Beginning in the middle of the twentieth century and continuing today, a very large body of research has sought to identify additional types of risk factors for CVD, including a number of social and psychological variables. These efforts were stimulated by limitations in the predictive power of the more traditional risk factors, theoretical and empirical work concerning the effects of psychological stress and emotion on cardiovascular physiology, and informal observations by clinicians and empirical research findings that were suggestive of psychosocial influences on CVD. Many of the more recently identified risk factors (some of which are discussed below) are characteristics of the person and social context that are referred to as "psychosocial." Recognition of the potential importance of psychosocial CVD risk factors contributed significantly to the emergence and growth of the fields of health psychology, behavioral medicine, and behavioral cardiology.

Lifestyle as the Major Determinant of CVD

The designation of many of the traditional CVD risk factors as "biomedical" is something of a misnomer. For example, four major

cardiovascular risk factors identified in early epidemiological work, and still the target of considerable research, are cigarette smoking, resting blood pressure, cholesterol levels, and blood sugar problems including diabetes. Cigarette smoking is, of course, a behavior pattern, and although it is maintained, in part, by physiological processes of nicotine addiction, its initiation and natural history also reflect social and psychological influences. Similarly, blood pressure, cholesterol, and blood sugar are to some extent regulated by specific behaviors such as diet and exercise and also may reflect psychosocial influences such as stress and emotion.

Given that most forms of CVD take decades to develop, recognition that many of the traditional risk factors reflect aspects of lifestyle has important public health implications. One is that efforts to prevent CVD should begin early in life. Behavior patterns such as cigarette smoking and those involved in weight regulation and nutrition begin during or even before adolescence. Tobacco use has a devastating effect on health, including cancer and respiratory consequences as well as CVD, and recent trends involving the earlier emergence of obesity and, relatedly, diabetes mellitus, are alarming in light of their projected impact on trends in the prevalence of heart disease. When combined with possible psychosocial determinants of CVD, which in many cases also may begin to emerge in the earlier years of life, the need for a life span perspective on CVD risk reduction becomes quite clear. The promotion and maintenance of a healthy lifestyle in young people has the greatest potential for reducing the lifetime burden of cardiovascular diseases.

Stress and Emotional Dispositions

Several promising psychosocial risk factors for CVD involve the concept of psychological stress. Psychological stress entails (a) stressors, or environmental events and conditions that place demands and constraints on a person's adaptive resources; (b) psychological responses to stressors, including perceptual-evaluative (appraisal) processes that initiate stress and emotion processes, and cognitive and behavioral responses, including coping activity, that may counteract or exacerbate stressors and their impact; and (c) biological responses, including neuroendocrine, autonomic, cardiovascular, and immunological/inflammatory perturbations that are potentially damaging to cardiovascular health. Among stressors that have been linked empirically to CVD outcomes are major life events, occupational stress, and marital conflict.

Psychosocial factors that in some way interact with psychological stress also have received attention as possible CVD risk factors. One such construct, the type A behavior pattern (TABP), formed the foundation for contemporary work on psychosocial factors in CVD. Type A refers to a set of behaviors that include competitiveness and achievement striving, impatience and time urgency, hostility and anger, and vigorous speech and motor characteristics (Friedman & Rosenman, 1974). Type B refers to a more relaxed, less impatient, and less irritable pattern of behavior. Type A was conceptualized as the outcome of a person-situation interaction in which its defining features are displayed in response to stressful and challenging events and conditions in susceptible individuals. The TABP construct initially attracted considerable attention for a prospective association with CHD that was independent of traditional risk factors such as cholesterol levels, resting blood pressure, and cigarette smoking (Rosenman et al., 1975). Subsequent research did not fully confirm these findings, resulting in diminished interest in the TABP (Matthews, 1988).

About this time, evidence began to emerge to suggest that hostility and anger form the risk-enhancing components of the TABP. Prospective studies of hostility and anger constructs and different forms of anger expression have yielded promising findings (Kent & Shapiro, 2009). Much of this research has relied on the Ho Scale first described by Cook and Medley (1954). It appears that hostility, characterized by cynicism and interpersonal mistrust, may be related to CAD-related outcomes, although negative findings have been reported as well (Kent & Shapiro, 2009).

More recently, depression has been identified as a potentially potent independent predictor of

CHD in healthy populations and as a factor that may contribute to both the manifestation and worsening of CHD among coronary patients. In addition, depression is associated with several major cardiac risk factors (e.g., hypertension, physical inactivity). Various forms, severity levels, and symptoms of depression have been examined in this regard. Findings indicate that depressive symptoms and major depression are associated with increased cardiovascular morbidity and mortality, even after controlling for other risk factors (Kent & Shapiro, 2009). Further, major depression is associated more strongly with adverse cardiac events than is the presence of subclinical depressive symptoms (Rozanski, Blumenthal, Davidson, Saab, & Kubzansky, 2005).

In addition, depressed individuals are more likely than nondepressed individuals to have more than one risk factor for CVD, which may indicate that the association between depression and CVD is due, in part, to the combination of risk factors rather than to each risk factor considered independently (Joynt, Whellan, & O'Connor, 2003). As with hostility, there are some inconsistencies in this research. Nonetheless, the sheer volume of findings that support depression as a CHD risk factor builds a strong case in its favor (Kent & Shapiro, 2009).

A third emotional disposition that has been implicated as a possible CVD risk factor is anxiety. Research has revealed a link between anxiety and the development of CVD in physically healthy populations, but evidence for this association has been mixed (Suls & Bunde, 2005). Studies of populations with known CHD have also yielded inconsistent findings, with some reporting null effects and others finding an inverse relationship (Suls & Bunde). To assess anxiety, some researchers use diagnostic interviews and clinical criteria, whereas others use self-report measures. Generally, results supporting anxiety as a CVD risk factor are more consistent in samples of initially healthy individuals than in CVD patients. This may signify that negative emotions constitute a greater risk for the development of CVD than for its progression. Inconsistencies in the findings also may reflect difficulty in assessing anxiety in the context of a medical condition and hospitalization, and in differentiating a temporary state of anxiety from chronic anxiety (Suls & Bunde). As with depression, anxiety has been examined both as a subclinical dimension of individual differences and in terms of clinical conditions such as posttraumatic stress disorder.

Still another emotional disposition that may operate as a CVD risk factor, neuroticism, refers to individual differences in irritability, anger, sadness, anxiety, worry, hostility, self-consciousness, and vulnerability in response to threat, frustration, or loss. Initially, neuroticism was not thought to play a causal role in CVD. Instead, the association with CAD was thought to reflect effects on somatic complaints and health-care-seeking behaviors (Costa & McCrae, 1987). However, an expanding body of evidence implicates neuroticism as a possible causal agent in multiple mental and physical disorders, including CVD (Lahey, 2009). Neuroticism is thought to contribute to health risk through the experience of more stressors, less social support, and greater likelihood to engage in risky behaviors. Given that neuroticism incorporates anger, sadness, and anxiety, and in light of positive associations among these emotional dispositions when measured separately, questions have been raised about the independence of these variables and their possible interactions, especially since few studies have examined two or more of them simultaneously (Suls & Bunde, 2005).

Social Factors

In addition to these dispositional constructs, some CVD risk factors are present in an individual's social environment. One example is low social support (Krantz & McCeney, 2002). Social support refers to the availability of a variety of social contacts from whom to derive benefits. Such benefits include emotional support, tangible aid, feelings of belonging, and informational support. Social support is associated with other factors that are related to health such as socioeconomic status and medication compliance. Prospective studies have found an association between low social support and risk of CVD.

Particular emphasis has been placed on stress as a mechanism underlying the association between low social support and CVD, although relevant investigations have yielded divergent findings (Uchino, Cacioppo, & Kiecolt-Glaser, 1996). It appears social networks may be cardioprotective as a result of their stress-buffering effects, but they also may operate independently of stress, for example, by promoting healthy behaviors and discouraging unhealthy ones.

Another social contextual factor that has been identified as a CVD risk factor is low socioeconomic status (SES). SES has been defined in terms of a person's occupation, economic resources, social standing, and education. There is considerable support for the existence of an SES health gradient that affects many diseases, including CVD. Higher SES is associated with better general health, less chronic illness, and decreased mortality. That this association is evident throughout the SES spectrum suggests that its effects cannot be completely explained by the effects of poverty on access to affordable health care. Relevant mechanisms may include cognitive and emotional processes, as well as psychosocial factors including social support (Marmot et al., 1991).

Identification of possible psychosocial risk factors for CVD gave rise to research on explanatory mechanisms. These may be described in terms of three major categories, namely, stress-related physiological activity; behaviors that may promote CVD in initially healthy individuals, including other CVD risk factors such as cigarette smoking, sedentary lifestyle, and poor diet; and cognitive and affective responses to illness and its treatment once CVD has developed, including processes culminating in delay in health-care seeking and treatment noncompliance.

Of the many theoretical and empirical contributions to emerge from mechanism-focused work on psychosocial CVD risk factors, perhaps the most significant development was formulation of the reactivity hypothesis. Reactivity refers to changes in physiologic activity associated with psychological stress, including alterations in neuroendocrine, autonomic, hemodynamic, hematologic, and immunological/inflammatory processes. Beginning with research on TABP, findings began to emerge in which emotional attributes and social-contextual factors moderated the effects of psychological stress on one or more physiological response measures. In addition, accumulating evidence suggested that physiologic reactivity represents a dimension of individual differences that is consistent across different psychological stressors and stable over time. It appears related to or may even constitute a form of emotional volatility that runs through emotion constructs discussed above including anger/hostility, depression, anxiety, and neuroticism. These findings, in turn, have led to the hypothesis that physiological reactivity might operate as an independent CVD risk factor and to empirical observations linking reactivity to CVD outcomes including the development of CHD and essential hypertension and the precipitation of acute episodes of myocardial ischemia and other cardiac events.

Conclusion

Although the risk and protective factors described above have received considerable attention, they are not exhaustive of the constructs that have been examined as potential causes of CVD. Many other variables have been investigated, including macrosocial factors such as culture, political systems, and migration; additional forms of stress, such as racism; emotional dispositions such as Type D behavior (negative emotions accompanied by social inhibition); social and personal forms of religion and spirituality; specific behaviors such as alcohol consumption; and various infectious conditions and biomarkers. These efforts are fueled by the need to identify additional risk factors to account more completely for new cases of CVD and to improve the public health benefits of risk factor modification for this multiply determined set of chronic lifestyle disorders.

Definition

One who receives care; an individual with a medical condition or who requires support with activities of daily living and is in a relationship with a caregiver, such as a doctor, nurse, friend, or family member, who provides treatment,

assistance, or comfort (National Alliance for Caregiving & AARP. Caregiving in the U.S, 2009). Care recipients are not necessarily passive; action often must be taken to access, secure, and personalize care. This may involve navigation of the health-care and insurance system; decision making based on personal, family, or cultural values and beliefs; selecting, managing, and adhering to the treatment regime; emotional responses to and coping with the potential stress of receiving care; and managing communication with care providers (Holman & Lorig, 2000).

Definition

Caregiving affects the quality of life of millions of individuals and is frequently associated with physical and psychological distress. Caregiving burden has been linked to decreased preventative health behaviors and perception of quality of life, which ultimately negatively impacts the care recipient. Additionally, the chronic stress of caregiving has been found to decrease immune functioning of the caregiver in general, including decrements in cellular immunity, higher risk for infectious disease, and slower wound healing. Multicomponent interventions have been helpful in coping both cognitively and behaviorally.

Description

Caregiving has become an issue of national public health. Due to advances in medicine and technology, a shortage of nurses and other health-care workers, and a movement since the 1960s away from institutionalization, caregiving, especially family caregiving, has become a necessity that affects the quality of life of millions of individuals (Family Caregiver Alliance, 2011). Caregiving is a diverse endeavor because the demands of caregiving differ with regard to age, developmental level, mental health needs, and physical health needs of both the caregiver and the care recipient. Those in the caregiving role become a critical agent between the recipient and a multitude of environments, including biological, psychological, social, cultural, physical, and

political (Perkins & Haley, 2010). Although the core of successful caregiving revolves around the caregiver's own physical and mental health, it is a situation that has been described as one filled with heartache, pain, and loss (George & Gwyther, 1986; Poulshock & Diemling, 1984).

Thrust into a role devoid of formal training, choice, or compensation, many family caregivers suffer physical and psychological distress related to their experiences. In an effort to provide care for their ill relatives, caregivers often neglect their own health. Some caregivers believe they are not entitled to time to themselves or time away from the recipient, which ultimately leaves them feeling fearful and guilty (Bedini & Guinan, 1996). Those who do participate in noncaring activities, such as socializing or discovering hobbies, may derive less positive experiences due to the spillover effect of distress resulting from care. As a result, subjective well-being, including positive affect, life satisfaction, and perceived quality of life, may be affected (Gilleard, et al., 1984; Kosberg & Cairl, 1986). Compared to matched controls, caregivers, especially spousal caregivers, have demonstrated uniformly negative changes in immune function due to chronic stress, including decrements in cellular immunity, higher vulnerability to infectious disease, and slower wound healing. These immunological consequences often persist at measurable levels even after cessation of caregiving tasks and may be the cause of morbidity and mortality in the elderly (Kiecolt-Glaser, Dura, Speicher, Trask & Glaser, 1991; Kiecolt-Glaser, 1999). Additionally, individuals who report strain are less likely to engage in preventative health behaviors such as getting enough sleep, taking time to recuperate, exercising, eating regular meals, and keeping medical appointments (Burton et al., 1997; Talley & Crews, 2007). Consequently, caregivers are at significant risk for experiencing health problems, depression, anxiety, and social isolation.

Risk for physical and mental health difficulties can be predicted to some extent by qualities present in both the caregiver and the care recipient. The dependency needs of the recipient, such as the number of hours of care needed or the degree to which activities of daily living can be completed independently, play an important role in caregiver burden. Those in the care position with the heaviest burden are more likely to report their health as fair or poor and are more likely to report physical strain as well as significant emotional strain (Caregiving in the US, 2004). Burden has also been linked to caregiver mood, caregiver's perceptions of the degree of recipient disability, and negative affectivity. Negative affectivity is the extent to which a person experiences negative mood states, including upset, anger, worry, guilt, fear, and disgust. Caregivers who rate high in negative affectivity often report distress, discomfort, and dissatisfaction over time, regardless of the situation (Blake et al., 2000). Higher negative affectivity has also been linked to less adaptive coping strategies and is a vulnerability factor in the development of anxiety and depression (Gunthert et al., 1999). Relationship with the recipient prior to illness or disability and availability of social support also play important roles in the extent to which the caregiver experiences strain.

Research on the differences between male and female caregivers has been mixed. Although men and women do not differ greatly in aspects of providing care, male caregivers report experiencing less burden and demonstrate more problem-focused coping strategies than female caregivers (Tiegs et al., 2006). One explanation is that women's involvement in the caregiving role tends to be more intensive and affective in nature than their male counterparts. Additionally, it has been suggested that women are more likely to carry out household tasks while caring for a family member (Miller & Cafasso, 1992; Parks & Pilisuk, 1991). Other research has shown no gender differences when controlling for protective factors, such as personality and social support.

Due to the associated risks, individuals caring for loved ones benefit from the development of a repertoire of both cognitive and behavioral strategies that enable them to defend against distress while continuing to provide effective care. Research to date on caregiver interventions has focused primarily on reducing depression and

strain via an emphasis on the following six intervention approaches: psychoeducational, supportive, respite/adult care, psychotherapy, improvements in care receiver competence, and multicomponent interventions (Sorenson et al., 2002). Intervention outcomes include the family caregiver's well-being, psychologic morbidity (stress, depression, perceived burden), beliefs (self-efficacy, control), cognitive behaviors and positive psychological outcomes (rewards, gains), and care recipient's function, behavior, and ability to avoid institutionalization (Gitlin et al., 2003). The most effective caregiver interventions to date have been multicomponent interventions that utilize a combination of cognitive behavioral approaches to reducing caregiver stress. Behaviorally, exercise and the utilization of social support have been the most valuable techniques in relieving stress associated with caregiving. Available social support and perceived social support can buffer caregiver vulnerability to stress and provide physical assistance when needed (Dean & Lin, 1977; O'Brien, 1993). Cognitively, the utilization of logical analysis and problem solving has been associated with higher levels of life satisfaction, better health, and lower depression in caregivers. A realistic appraisal and acceptance of the difficult situation is healthy and allows the caregiver to live his or her own life while accommodating the needs of the recipient. Less effective cognitive coping styles include avoidant-evasive, regressive, and an increased use of wishfulness and fantasizing by the caregiver, all of which have been related to higher levels of care burden (Hayley et al., 1987; Quayhagen & Quayhagen, 1988).

Despite the reality of care strain and its resulting physical and mental health risks, many caregivers persist for years in their roles and are able to report positive and reciprocal caregiving experiences (Pinquart & Sorenson, 2004). Long-term caregiving may result in the acquisition of skills and a sense of self-efficacy within the care role. Some individuals found that caregiving provided a sense of usefulness during a time in which they felt a loss of control. This sense of usefulness and improved self-esteem based on perceived abilities to handle difficult situation may provide some symptom relief from depression and anxiety (Konstam et al., 2003). Finding meaning through caregiving allows the caregiver to hold positive beliefs about one's self and one's caregiving experience.

Carpal Tunnel Syndrome

Daniel Gorrin
Department of Physical Therapy, University of Delaware, Newark, DE, USA

Definition

The carpal tunnel refers to the area of the wrist between the carpal bones and the overlaying fibrous band of connective tissue called the transverse carpal ligament or the flexor retinaculum. The median nerve passes through the carpal tunnel along with nine tendons of muscles providing finger and wrist flexion (flexor digitorum profundus, flexor digitorum superficialis, and flexor pollicis longus).

Carpal tunnel syndrome refers to an entrapment or compression of the median nerve at the wrist. The median nerve can become compressed under the flexor retinaculum. The etiology is unknown in most cases; however, carpal tunnel syndrome can result from a trauma such as a fracture or dislocation of the carpal bones at the wrist. Such trauma can lead to direct injury of the nerve and increased pressure within the carpal tunnel. Other potential causes of the condition include rheumatoid arthritis, renal disease, hypothyroidism, lupus, obesity, pregnancy, alcoholism, diabetes, and certain collagen diseases. If the underlying cause of the condition can determined and treated, the median nerve dysfunction could be resolved.

Symptoms of carpal tunnel syndrome include burning, numbness, and tingling in the region of the hand supplied by the median nerve (thumb, index finger, middle finger, and medial side of the ring finger) which can be exacerbated at night.

Increased symptoms at night can likely be attributed to the patient favoring wrist flexion during sleep. This position narrows the space within the carpal tunnel causing increased pressure on the nerve. In more severe cases, the patient may experience weakness and atrophy of the musculature controlling the thumb.

Electrodiagnostic tests and electromyographic studies can be used in conjunction with patient history and physical examination in order to diagnose carpal tunnel syndrome. Initially, treatment is intended to control inflammation and decrease stress on the nerve. Conservative treatment includes activity modification, splinting to decrease wrist flexion and pressure on the median nerve, and steroid injections to decrease inflammation within the tunnel. If the patient does not respond to conservative management, a surgical decompression of the median nerve may be indicated.

Definition

A case report is a descriptive study that provides a detailed description of a case of a disease that is unusual, and therefore noteworthy, for some particular reason. It is usually written by a doctor, or perhaps by a group of doctors who have all become familiar with the case with each having something unique to contribute to the report. An extension of the case report is a case series, where the first report sparks interest and leads to reports on similar cases.

In the discipline of epidemiology, a more substantive investigative process often begins with a case report or case series (Webb, Bain, & Pirozzo, 2005). These reports provide detailed descriptions of an individual, or a small group of individuals, who share salient characteristics. The disease might not have been seen before, been noted in the literature before, or rarely been seen in that form before. Also, it may be noteworthy that a known disease occurred in a patient who would not normally be expected to have the disease, or in a geographic location where the disease is particularly rare.

Such reports are by nature selective: Doctors may or may not write a case report which may or may not be published and reach a large readership of other doctors. Additionally, they are not able to provide evidence of causality, and they cannot provide much evidence on the patterns of disease occurrence. For these reasons, they tend to appear toward the bottom of the "Hierarchy of Evidence," a tabular representation of the relative strengths of various investigational methodologies. Nonetheless, they can be very informative as the starting point for more extensive investigation.

Provocative case reports can certainly lead to important findings. A report of a series of five cases of *Pneumocystis carinii* pneumonia that occurred in young, previously healthy, homosexual men in three Los Angeles hospitals in a 6-month period during 1980–1981 is noteworthy (Webb et al., 2005). In this case, the disease had been seen before, but virtually always in patient populations with different characteristics: the elderly, patients who were severely

malnourished (and hence compromised when combating infection), and patients receiving chemotherapy for cancer who had developed compromised immune systems. The clustering of cases in the population of young homosexual men suggested a different disease. While the case reports, as noted previously, were not able to address causality or causal biological pathways, they did suggest the possibility of a relationship with the patients' sexual behavior. You may recognize that this disease is now known as HIV/AIDS (which is certainly not limited to young homosexual men).

Case-Control Studies

Jane Monaco
Department of Biostatistics, The University of North Carolina at Chapel Hill, Chapel Hill, NC, USA

Synonyms

Observational designs; Observational studies; Observational study

Definition

A case-control study is a study in which subjects are selected based on their outcome status, such as with disease or disease-free. Investigators select cases (subjects with the outcome of interest) and controls (subjects without the outcome of interest) and then compare the exposure (or risk factor) status in the two groups.

Description

Case-control studies are a very common observational study design within behavioral medicine research. Because the participants are selected based on their outcome status (commonly disease status), this study design is well suited for an outcome that is rare. For diseases with long latency periods (for example, melanoma or coronary heart disease), case-control studies can also be time efficient because the outcome has already occurred at the initiation of the study. When the exposure (or risk factor) is rare, a case- control study is often not practical.

Case-control studies determine the subjects' exposure retrospectively, commonly through historical records or self-report conducted after the exposure has occurred. Limitations of using retrospective data contribute to results from case-control studies being considered weaker than results from experimental designs that examine similar associations. Recall bias can occur when case subjects remember exposure differentially compared to controls. For example, a mother whose infant was born with a birth defect may differentially recall her use of medication during pregnancy compared to a mother of an infant without a birth defect (Rockenbauer, Olsen, Czeizel, Pedersen, & Sørensen 2001). The use of retrospective data, however, may facilitate study approval by ethical review boards, particularly, when the risk factor is illegal or known to be harmful, such as illicit drug use or tobacco use.

The selection of control subjects is critical in the design of a case-control study. Subjects chosen as controls should be as similar as possible to the case subjects except, potentially, with respect

to the exposure. Specifically, cases and controls should have had equal chance to be exposed to the risk factor. For this reason, cases and controls are often matched with respect to age, gender, ethnicity, and other factors.

In many case-control studies, the groups are compared by evaluating the odds ratio which is defined as the odds of exposure among the cases divided by the odds of exposure among the controls. In general, investigators cannot determine incidence rates of the disease since the subjects are selected based on disease (outcome) status. Thus, computing a relative risk directly is not possible. However, the relative risk can be approximated by the odds ratio when the outcome of interest is relatively rare.

In a typical behavioral medicine case-control example, Brent et al. (1993) investigated the association between adolescent suicide and multiple psychiatric risk factors. Sixty-seven adolescent suicide victims (cases) were matched to 67 controls with respect to age, gender, socioeconomic status, and county of residence. Investigators obtained information about the suicide victims through a "psychological autopsy protocol" in which parents, siblings, and friends were interviewed concerning the victim's risk factors. The controls' risk factor information was obtained from the participant and at least one parent. The study found that the suicide victims had significantly higher odds of major depression and substance abuse compared to the controls.

Some characteristics of case-control studies:

- Usually less expensive and less time consuming than cohort designs or experimental designs
- Often used when the outcome of interest is rare or has a long latency period
- Not practical when exposure is rare
- Sample size requirement is usually smaller than cohort or experimental designs
- Often used in initial investigations of an association due to logistical ease and relative lower cost
- May be used when exposure of participants to risk factor would be considered unethical in an experimental design
- Appropriate when studying multiple risk factors
- Usually can only address a single outcome (disease)
- Susceptible to recall bias (since exposure and outcome are determined retrospectively) and selection bias (which can occur when the controls are selected in such a way that they did not have same risk of exposure as the cases)
- Often considered weaker study design compared to cohort studies or randomized trials that study analogous associations

Case-Crossover Studies

J. Rick Turner
Cardiovascular Safety, Quintiles, Durham, NC, USA

Definition

The innovative case-crossover study design is a hybrid design. Hybrid designs are those that combine the elements of two or more basic designs, or extend the strategy of one basic design through repetition (Kleinbaum, Sullivan, & Barker, 2007).

The case-crossover design represents an attempt to achieve the ideal, but unattainable, design of studying a group of subjects exposed to a particular event, activity, or influence, and also studying exactly the same subjects during the same period when not exposed to it. The design utilizes each subject as his or her own control. Exposure to the event in a defined (and likely fairly short) time period before the onset of disease is compared with typical exposure to it in a much longer period before disease onset, defined as the normal exposure.

Only a limited set of research topics are amenable to the employment of the case-crossover design (Rothman, Greenland, & Lash, 2008). The exposure must vary over time within individuals, rather than stay constant, and the exposure must have a short induction time and a transient effect. A classic example is the study reported by Maclure (1991), which used this design to study the effect of sexual activity on incident myocardial infarction. Several aspects make this design appropriate and informative in this case. First, the exposure to the factor of interest, sexual activity, is intermittent and presumed to have a short induction period for the hypothesized effect. Second, any increase in risk for myocardial infarction caused by sexual activity is presumed to be confined to a short time interval following the activity. Third, since myocardial infarctions are thought to be triggered by events close in time, this outcome is well suited to this type of study (Rothman et al., 2008).

CAT Scan

Department of Psychology, Drexel University, Philadelphia, PA, USA

Synonyms

Computed transaxial tomography; Computerized axial tomography; CT scan; X-ray computed tomography

Definition

A CAT scan is a structural imaging method based on the x-ray principle but is more sensitive to bone, tissue, and fluid density differences and employs a narrower beam, allowing for the segmentation of the imaged area into multiple transaxial images from many different angles. These images can be combined via computer technology to provide either 2D or 3D images. Enhanced CAT scans can reveal even greater contrast through injection of an intravenous dye. CAT scans are useful for imaging bones, soft tissue, blood vessels, and internal organs and particularly useful in imaging size and location of tumors and their relationship to normal tissue. CAT scans are also useful in imaging injuries to skeletal structures in relation to the surrounding tissue and the detection of vascular disorders in the body and brain. CAT scans are particularly useful in the identification of emboli (blood clots)

and aneurysms. Scans of the brain cannot reveal microscopic brain changes (e.g., axonal injury) but are useful in identifying lesions, tumors, and stroke (infarct) and particularly for differentiating hemorrhagic from nonhemorrhagic stroke. CAT scans are generally cheaper than magnetic resonance imaging (MRI) but provide poorer resolution. In relation to the brain, CAT scans also do not show the functioning of the brain as would be revealed with functional imaging methods such as (functional MRI (fMRI) or positron emission tomography (PET)).

Catastrophizing/Catastrophic Thinking

Lara Traeger
Behavioral Medicine Service, Massachusetts General Hospital/Harvard Medical School, Boston, MA, USA

Synonyms

Arbitrary inference

Definition

Catastrophizing refers to the anticipation without evidence of extreme and terrible consequences or outcomes of an event. Catastrophizing is a characteristic type of cognitive distortion or error that may underlie a negative and inaccurate thought (Beck, Rush, Shaw, & Emery, 1979; Clark, Beck, & Alford, 1999). It can have negative health consequences for individuals who are managing a chronic illness. For example, a recent cancer survivor may interpret his fatigue as meaning that he will never recover his usual energy level and that he will have to give up all of his meaningful activities. This type of thinking can maintain negative emotions such as depression and lead to adverse or unhelpful behaviors such as poor medical adherence.

Catecholamines

George J. Trachte
Academic Health Center,
School of Medicine-Duluth Campus,
University of Minnesota, Duluth, MN, USA

Synonyms

Adrenaline; Epinephrine; Norepinephrine/Noradrenaline

Definition

Catecholamines are derivatives of the chemical dihroxyphenyl (catechol) ethylamine. They are found in the sympathetic nervous system, adrenal

medulla, and selected brain regions. The prominent naturally occurring catecholamines in humans are dopamine, norepinephrine, and epinephrine. These agents are intrinsic neurotransmitters of the sympathetic nervous system and mediate the "fight or flight" reactions to stressful situations. Examples of sympathetic responses include tachycardia, hypertension, pupillary dilation, sweating, and liberation of fuel sources. They also are prominent neurotransmitters in specific regions of the brain, typically being associated with pleasure, excitement, and movement.

Catecholamine synthesis involves conversion of the amino acid, tyrosine, to dihydroxyphenylalanine (DOPA) by adding a hydroxyl group. DOPA is converted to dopamine by removal of a carboxyl group. Dopamine is a neurotransmitter in the brain and in peripheral nerves. Dopamine also is a precursor of norepinephrine, requiring a conversion by dopamine ß hydroxylase. Norepinephrine is the major neurotransmitter of the sympathetic nervous system and also is a major neurotransmitter in the central nervous system. Norepinephrine can be converted to epinephrine by phenylethanolamine-N-methyl transferase, primarily in the adrenal medulla but also in the brain. Epinephrine is considered to be a neurotransmitter of the sympathetic nervous system although it functions more as an endocrine agent, circulating in the blood to promote various stress-related effects.

The physiological relevance of norepinephrine and epinephrine in the periphery is quite obvious because these agents mediate most of the responses to stressful situations. They have the following effects: activation of ß1 receptors on the heart to increase heart rate, force of contraction, and blood pressure; activation of α1 receptors on vascular smooth muscle, the eye, and sweat glands to raise blood pressure, dilate pupils, and promote sweating; and activation of α1, ß2, and ß3 receptors to liberate fuel stores for energy. Central actions of dopamine and norepinephrine are equally obvious. Dopamine is critically involved in movement, reward, emotion, memory, and cognition. Conditions related to dopamine deficiencies include Parkinson's disease. Conditions related to excessive stimulation of dopamine receptors include addiction, schizophrenia, psychoses, and learning deficits. Norepinephrine also is a critical central neurotransmitter. Augmentation of norepinephrine concentrations in nerve synapses is a frequent mechanism of action of antidepressants.

The synthesis of catecholamines is regulated primarily at the tyrosine to DOPA step. The release of catecholamines is regulated by activity of the sympathetic nervous system, involving acetylcholine as a neurotransmitter, or by activation of specific brain regions.

Dopamine is recognized as a critical neurotransmitter influencing movement, memory, cognition, emotion, and reward. As such, it influences movement and its absence is most easily noted in the symptoms of Parkinson's disease. Dopamine also is involved in a variety of psychological abnormalities such as addiction, schizophrenia, psychoses, and learning deficits. It also inhibits prolactin release, potentially indirectly elevating mood.

Norepinephrine has mood-elevating effects and a variety of antidepressants increase the concentrations of norepinephrine in neuronal synapses of the brain. The variety of antidepressants elevating norepinephrine concentrations includes monamine oxidase inhibitors, tricyclic antidepressants, and norepinephrine reuptake inhibitors.

Definition

A causal diagram is a more modern form of causal pathway models that have been used to summarize visually hypothetical relationships between variables of interest to the researcher. They represent a merger of graphical probability theory with path diagrams. This theory confers a powerful means of deducing the statistical associations implied by causal relations.

Once the rules for reading statistical associations from causal diagrams are mastered, they facilitate many tasks. These include understanding confounding and selection bias, choosing covariates for adjustment and for regression analyses, and understanding analyses of direct effects and instrumental-variable analyses (Glymour & Greenland, 2008).

Cellular Theory of Aging

Emil C. Toescu
Division of Medical Sciences, The University of Birmingham, Edgbaston, Birmingham, UK

Definition

Cellular theories explain the aging process as originating in individual cells, either at the level of the genetic information or through changes in metabolism.

Description

The quest for understanding the process of aging is probably as long as human history, and its resolution is still far from clear or even assured. A major factor for this state of affairs is that aging is a complex, multifactorial process that develops during ontogeny gradually, at multiple levels, involving a certain degree of stochastic randomness. At a certain time (early 1990s), more than 300 various hypotheses were circulating for explaining aging, and, responding to a need for organizing such a vast catalogue, these

hypotheses were classified as *cellular theories* that explain the aging process as originating in individual cells, either at the level of the genetic information or through changes in metabolism; *system theories*, that propose that aging, while expressed at the level of individual cells, results from dysfunction in one or another of the general system that maintain overall body homeostasis (e.g., *the neuroendocrine theory of aging*); and *evolutionary theories*, that address the fundamental biological puzzle that aging, as a fundamentally deleterious process, should have been gradually eliminated during evolution since evolution aims to improve the adaptation of individuals and species to their environment.

Within the group of cellular theories, the various hypotheses can be further separated into those that invoke (a) changes in the genetic makeup (genome) of cells or (b) alterations and dysfunction in various metabolic pathways (overall, the "wear and tear" theories).

The *genome-related theories of aging* start from the fundamental fact that the whole of the genetic information that controls the identity, development, and status of a cell is contained within the DNA. Like anything else in nature, this molecule can be damaged either by random, stochastic agents or by specific factors or processes. Amongst other features, one of the unique properties of the DNA is that it is the only biological molecule that relies for maintenance on the repair of the same existing molecule, without the possibility of remanufacture. Apart from the implications for the importance and reliability of the DNA repair mechanisms, this fact also leads to the conclusion that DNA molecules accumulate damage over a lifetime since an error in DNA sequence information, once made during replication or recombination, becomes irreversible, due to the loss of the reference template. DNA integrity can be affected by several mechanisms. One is endogenous, represented by the cellular metabolism; activity in all cells will generate continuously reactive oxygen and nitrogen species (free radicals) that either directly, or secondarily, through generation of lipid peroxidation products, alkylating agents or protein carbonyl species, will damage DNA by inducing single-strand breaks and oxidation of various bases. The other category of damaging agents is exogenous, represented by chemical or physical (e.g., UV and other types of ionizing radiations) factors. It has been shown that DNA mutations/alterations and chromosomal abnormalities increase with age both in animals (e.g., rodents) and humans. In addition, the role of genetic mutation in inducing the aging phenotype is demonstrated by a number of syndromes of accelerated aging (progeria). Amongst them, the best known is the Werner's syndrome which is determined by an autosomal recessive mutation in a gene, WRN, that encodes for a protein with structural similarities with a DNA helicase (enzyme catalyzing DNA unwinding). Loss of WRN function results in a syndrome displaying the typical features of aging, but starting as early as the second decade of life: bilateral cataracts, graying of hair and alopecia, type 2 diabetes, atherosclerosis and hyperlipidemia, osteoporosis, etc. Another progeric manifestation is the Hutchinson-Gilford's syndrome, with a rather similar clinical manifestation but resulting from a point mutation in the gene encoding for a nuclear protein: lamin A/C (LMNA). Although the exact function of either protein is not fully established, recent experimental evidence point to the fact that they are involved in the process of DNA repair. The importance of maintaining a robust genomic stability led to the evolutionary development of powerful and flexible DNA repair systems that include mechanisms for dealing with both single-stand breaks (e.g., base excision repair and nucleotide excision repair) and double-strand breaks (e.g., homologous recombination or nonhomologous end joining). Although there are many reports of correlations between stability of DNA repair mechanisms and rate of aging in various animals (mammals) and, also, of an age-dependent functional decline in one or another DNA repair mechanism, other studies found no clear evidence for a drastic decline in DNA repair during aging, an observation taken simply to reflect the central role of genome stability for cell viability. In addition, accumulation of damage with age does not necessarily imply a decline in DNA repair – as any biological process,

genome maintenance systems are imperfect, and alterations can accumulate over time, particularly in animals with longer life spans.

A more recent line of investigation of the relationships between DNA damage and aging stems from the fact that genome maintenance involves not only the DNA repair systems but also the cellular responses triggered directly by the DNA damage. These responses include apoptosis, cellular senescence, and cell cycle arrest, known to cause age-related impairments in various tissues. Thus, one of the most ubiquitous response to unrepaired or improper repair double-strand breaks involves the ataxia-telangiectasia-mutated (ATM) kinase. Activated ATM, in addition to modulation of several cell cycle proteins DNA repair factors, targets p53, a central protein at the crossroad of several cell viability pathways. While p53 suppresses the onset of malignancy, having an indirect positive on lifespan, it also triggers cellular senescence and apoptosis. A strong theoretical argument for the involvement of such a universal and general cellular response in mediating the pro-aging effects of DNA damage is that the phenotype of aging is relatively constant from species to species and also, in general lines, from individual to individual whereas, with few exceptions, the exo- or endogenous induction of DNA damage is stochastic and should result in highly variable functional outcomes.

An important cellular theory of aging is the *cell senescence/telomere theory*. The idea of cell senescence was formulated in 1965, describing the fact that normal cells can undergo only a limited number of cell divisions (Hayflick's limit), after which the cells enter replicative senescence, remain quiescent, and then, after a period of time, die. Since the number of cell divisions varies from species to species (e.g., mouse cells divide roughly 15 times, while the cells for Galapagos tortoise divide 110 times), it has been proposed that this process of replicative senescence is an important regulator of life span and thus a contributor to aging (NB this senescence process, dependent on the cell replication, is different from the metabolic cellular senescence, that results from the accumulation with time of metabolic dysfunction, that result in functional impairment of various cellular activities, see below). It has been proposed that replicative senescence ultimately results from the loss of telomeres, which are specific chains of a repeating DNA sequences located at the ends of each linear chromosome. With each cell division, a small amount of DNA is necessarily lost on each chromosome end, resulting in ever-shorter telomeres, altered telomere structure, and, when the telomere is under a critical length, a stop of replication and eventual replicative senescence. Activation of the telomerase enzyme will regenerate telomeres, prevent replicative senescence, and immortalize human primary cell cultures. Importantly, in all cancer cells, there is an activation of telomerase or of an alternate pathway of telomere extension that avoids replicative senescence.

Although there is a wealth of correlative data (e.g., shorter telomeres in aged people or, more specifically, in individuals with neurodegenerative diseases, including Alzheimer's; induction of telomere shortening in condition of increased metabolic stress), a causal involvement of telomere reduction in aging is doubtful as telomerase-deficient mice do not age more rapidly. Instead, as with the other genetic theories of aging discussed above, it is more likely that replicative senescence influences aging through the various cellular responses it triggers. It has been described that senescent cells produce and secrete various degradative enzymes and inflammatory factors that alter the microenvironment and lead to disturbed tissue structure and function. Also, replicative senescence degrades and ultimately limits the regenerative potential of stem cell. The intracellular mechanism triggered by telomere shortening is the activation of the same tumor suppressor p53 protein. The type of p53-dependent cellular response (cell arrest, apoptosis, or senescence) is often cell type dependent and varies with the type of stimulus that triggers it and severity of stress that the cells are exposed to. Being a tumor suppressor protein, it is not surprising that mice mutated for p53 with loss of function have a dramatically increased incidence of cancer, while p53 signaling is altered in the majority of human cancers. However, if cellular

senescence, linked with p53 activation, acts to suppress tumor formation, how can it be explained that cancer is more prevalent with age when senescence is also increased? There is currently no generally accepted explanation, and it is likely that it results from subtle changes in the balance between several processes and factors, such that, due to its ample homeostatic and functional reserve, in the adult organisms, the functional and structural deleterious effects that senescent cells might cause to the tissues can be efficiently repaired by the normal tissue renewal processes. Thus, in the main, in the mature organisms, the main role of the p53-dependent senescence is to provide cancer protection. In contrast, in the aged organisms, the time-dependent accumulation of mutations (i.e., DNA damage), together with the unfavorable metabolic environment, and the decrease in the renewing capacity generate conditions suitable for cancer growth.

One of the most widely acknowledged theories of aging is the *Mitochondrial Free Radical Theory of Aging* (*MFRTA*), which has been presented in various guises, either as metabolic or as "wear and tear" theories, and linked to other hypotheses, such as the "rate of living" theory. The latter probably has the longest history, originating at the beginning of last century with the empirical observation of a relationship between metabolic rate, body size, and longevity, such that long-lived animals are, on average, larger. Further metabolic studies led to the proposal that the faster the metabolic rate of an animal, a standby for biochemical activity and for the effect of temperature, the faster the organism will age. In the mid-1950s, the mechanisms causing cell damage and death in response to ionizing radiation were becoming clearer: the production of free radicals, a highly reactive species of molecules characterized by the existence of a single unpaired electron in the outer layers of the atom. Due to their chemical properties, oxygen and nitrogen are the molecules most prone to become free radicals, and the instability of such a molecule renders them very reactive, generating chain redox reactions of sequential oxidation (loss of electrons) and reduction (gain of electrons) of a variety of cellular substrates. In many instances, such redox changes result in a modification of function of the target proteins, leading to loss of metabolic homeostasis and ensuing damage. If the free radicals attack is of limited intensity or duration, the cellular damage can be contained and either accumulate slowly over time or be repaired; more intense level of injury would result in cell death. The original form of the Free Radical Theory of Aging (FRTA) envisaged aging as resulting from the long-term accumulation of free radical–induced damage, affecting mainly nuclear DNA, which is very sensitive to the action of free radicals. An important development of this hypothesis came with the discovery that the free radicals can result not only from the effects of exogenous factors, such as irradiation, but are also a natural output of normal physiology. One of the reasons why this hypothesis of aging became so paradigmatic is that it linked with several previous views, such that a higher rate of metabolism would generate higher free radical loads and consequent damage, and lead to a higher rate of aging. In the mid-1980s, the FRTA was complemented with the mitochondrial perspective, with several observations contributing to this development. (1) The mitochondria are the major source of free radicals since two of the protein complexes that form the mitochondrial respiratory chain (aka, electron transport chain) generate stochastically, in an unregulated fashion, reactive oxygen species (i.e., oxygen free radicals). (2) Mitochondria possess specific mitochondrial DNA, that is, spatially located very near to the source of free radicals, in the mitochondrial matrix. (3) Mitochondrial DNA has limited repair capacity. (4) Mitochondrial DNA codes for some of the proteins in the respiratory complex, and DNA mutation could generate dysfunctional proteins, initiating a time (age)-dependent vicious circle of increased free radical producing. Thus, the strong formulation of the complete MFRTA flows along the following functional axis: (a) oxygen free radicals generated (mainly from mitochondria) as a function of metabolic rate cause cumulative oxidative damage, resulting in structural degeneration, functional decline, and age-related diseases, leading to (b) oxidative stress that is the

predominant cause of age-associated degenerative change, and thus (c) the mitochondrial free radicals are the cause of aging.

In the last few decades, a huge amount of experimental evidence accumulated to show that with age there is indeed an accumulation of mitochondrial oxidative damage and a progressive decline in mitochondrial function and performance. In many tissues, including the brain (which has a special position since the neurons are the only cell types in the body that are maintained in a postmitotic state, i.e., they do not divide), there is an age-dependent accumulation of global oxidative damage to proteins, DNA, and lipids. However, in the last few years, the availability of very powerful experimental models that allow genetic manipulations (full or conditional knock-in of proteins or knock-down of proteins, use of interference RNA as silencers of specific protein synthesis, etc.) led to the expression of serious reservations about the full validity of MFRTA. Thus, decreasing free radical levels with dietary antioxidants or by genetically induced overexpression of protein antioxidants, such as superoxide dismutase (SOD), that metabolizes the oxygen superoxide (a free radical) to hydrogen peroxide, or catalase, that metabolizes hydrogen peroxide to water and regenerates the gaseous oxygen, did not induce the expected significant increase in lifespan of the test animals. In contrast, inactivation of antioxidant activity while increasing the free radical levels did not determine a significant reduction of lifespan and even increased, in some instances, the lifespan.

It is worth assessing for a moment the reasons of the discrepancy between the two sets of data. The important point about most of earlier studies mentioned is that they were correlative, reporting that with age there is an increase in oxidative damage. However, correlation is not necessarily causation and implies the possibility that both aging and increased oxidation can be caused, at the same time, by another process(es), and, indeed, aging is viewed now as a multifactorial process. It also can be that oxidative stress might be the consequence of aging, with aging having some discrete cause, or causes, distinct from oxidative stress. Alternatively, oxidative stress might result from the failure of one particular maintenance system of the organism and thus participate in causing aging, but only as a factor amongst others. This perspective on the role of oxidative stress in actually causing aging has also practical implications, as it is still possible to advocate antioxidant therapies as being beneficial to health in counteracting the effects of free radicals, but not as a magic, blanket coverage anti-aging cure. In addition, each intervention should be critically evaluated, both because some antioxidant supplementation trials provided surprising results and because of an increasing number of studies showing the crucial roles of ROS in cellular signaling, and thus advocating against a too strong suppression of free radicals production.

Center for Epidemiologic Studies Depression Scale (CES-D)

Definition

The Center for Epidemiologic Studies Depression Scale (CES-D Scale) is a 20-item self-report measure designed to assess depressive symptoms over the previous week (Radloff, 1977). The CES-D assesses multiple symptom clusters, including depressed affect, lack of hope, feelings of guilt and shame, and somatic symptoms (e.g., disrupted sleep or appetite) with an emphasis on negative affect (Radloff, 1977). Sample items include "During the past week, . . .I felt that I could not shake off the blues even with help from my family or friends," and ". . .I felt that everything I did was an effort," (Radloff, 1977). Four items are worded positively and reverse coded to (a) ensure the respondent is attending to each question and not answering carelessly and (b) measure the respondent's positive affect (Radloff, 1977). Each item is rated on a frequency scale (0 = Rarely or None of the Time, 1 = Some or a Little of the Time, 2 = Occasionally or a Moderate Amount of Time, 3 = Most or All of the Time; Radloff, 1977). Total scores can range from 0 to 60; higher scores represent more depressive symptoms (Radloff, 1977).

The CES-D is one of the most commonly used measures for assessing the presence of depressive symptoms in adults, as it has good psychometric properties (Sharp & Lipsky, 2002; Vahle, Andresen, & Hagglund, 2000). The internal consistency of this measure is strong in both the general adult population ($\alpha = 0.85$) and among clinically depressed adults ($\alpha = 0.90$; Radloff, 1977). Further, reliability of the CES-D, as measured by test-retest correlations over periods ranging from 2 weeks to 12 months, has generally been in the moderate range (0.45–0.67), indicating adequate stability (Radloff, 1977). With regard to validity, the CES-D is capable of discriminating between the general adult population and psychiatric inpatients, as well as between severity levels of clinical populations (Radloff, 1977). Among clinical populations, it has also been shown to correlate positively with other measures of depression, including nurse-clinician ratings (0.56; Craig & Van Natta, 1976), and self-rating scales (0.44–0.75; Radloff, 1977). The CES-D primarily has been used to screen for high levels of depressive symptoms in community populations (Radloff, 1977). Scores above 16 denote a level of depressive symptoms which may require follow-up investigation (Zich, Attkisson, & Greenfield, 1990). Research regarding age, gender, and ethnic differences in the underlying factor structure and use of the CES-D is inconclusive to date, and as such, a definitive statement cannot be made (e.g., Callahan & Wolinsky, 1994; Hertzog, Van Alstine, Usala, Hultsch, & Dixon, 1990; Liang, Van Tran, Krause, & Markides, 1989; Roberts, 1980).

Recently, the CES-D has been used as a depression screening tool for adolescents as young as 14 years of age (e.g., Charbrol, Montovany, Chouicha, & Duconge, 2002; Cuijpers, Boluijt, & van Straten, 2008; Sharp & Lipsky, 2002). The CES-D appears to be reliable for use with adolescents of high school age (M age = 17, SD = 1.4; Chabrol et al., 2002). With a community sample of adolescents, the reliability of the CES-D has been satisfactory ($\alpha = 0.85$; Chabrol et al., 2002). Further, the factor structure of the CES-D appears to function similarly in adults and adolescents (four factors: depressed affect, positive affect, somatic and retarded activity, and interpersonal; Chabrol et al., 2002; Radloff, 1977). Using a clinical cutoff score of 22, the CES-D has been shown to have a specificity indicator of 74.31 and a sensitivity indicator of 90.48 in adolescent

community samples (Cuijpers et al., 2008), although there is debate regarding the most appropriate cutoff score for use with adolescents (e.g., Roberts, Andrews, Lewinsohn, & Hops, 1990).

Center for Scientific Review

Lee Ellington
Department of Nursing, College of Nursing, University of Utah, Salt Lake City, UT, USA

Basic Information

The Center for Scientific Review (CSR) resides within the National Institutes of Health (NIH) and is charged with the review of the scientific merit of NIH grant applications. The mission of CSR is to ensure that investigators' applications receive fair, constructive, and timely feedback, resulting in the goal of NIH to fund sound yet innovative research. A primary responsibility of CSR is to convene experts in the field to conduct peer review of grant applications. The CSR receives all grant applications for NIH and some applications from the U.S. Department of Health and Human Services, resulting in well over 110,000 applications per year. In 2009, CSR worked with 25,000 peer reviewers. The CSR consists of the director, referral officers, integrated review group chiefs, scientific review officers, and related administrative personnel.

When an application arrives at NIH, a CSR referral officer examines the application and routes it to the integrated review group that best fits the scope of the application. Within the integrated review group there are study sections, which are essentially peer review groups. Each study section is managed by a scientific review officer (SRO) and typically includes 20 or more scientists. The SRO assigns two to four peer reviewers for each application. Reviewers provide written critiques and provisional impact scores for each application and then attend an in-person review meeting. Approximately half of the applications are discussed by the reviewers and other members of the study section as a function of the provisional scoring process. The assigned reviewers present their critiques and then the discussion is open to the entire review group. After the general discussion, the assigned reviewers revisit initial overall impact scores and state their final score. The remainder of the study

section members record their scores privately. A few days after the review meeting, priority scores and percentile rankings are posted on NIH Commons and can be accessed by the principal investigator for each application. Whether the application was discussed by the full group or not, there will be written critiques and scores.

The CSR is independent from the NIH institutes or centers (IC) that make funding decisions. That is, CSR is concerned with scientific merit outside the context of funding priorities at the various institutes. After written critiques and scores are available, a second level of peer review is performed by the IC advisory councils. These councils consider the scientific merit of the application from CSR in conjunction with their institute's funding priorities to determine which grant applications will be funded. Applications that are not funded may be resubmitted a second time to CSR for peer review.

Major Impact on the Field

Behavioral medicine research is often funded by the NIH, and a number of study sections review behavioral science research applications. These study sections include scientists from the multiple disciplines represented within the Society of Behavioral Medicine and ensure that applications examining behavioral influences on health are fairly evaluated. The CSR website provides review group descriptions. Some examples of study sections which are well suited for reviewing specific behavioral science applications include behavioral and social consequences of HIV/AIDS, psychosocial risk and disease prevention, and social sciences and population studies. The SCR referral officer evaluates applications to find the most appropriate study section. The assignment is posted on ERA Commons for the principal investigator to assess prior to review.

Central Adiposity

Abdominal obesity; Apple shaped; Visceral adiposity

Definition

Central adiposity is the accumulation of fat in the lower torso around the abdominal area. Central adiposity is a function of both subcutaneous fat, which sits under the skin, and visceral fat, which surrounds the internal organs in the peritoneal cavity. Currently, it would seem that the toxic component of central adiposity is the visceral fat.

High levels of central adiposity have been associated with an increased risk of a number of diseases, including type 2 diabetes, hypertension, heart disease, and dementia. Of note, it would seem that central adiposity is independent of body mass index (a proxy of total adiposity) as a predictor of disease (even though the two are highly correlated). This increased risk is thought to be due to the hormonal action of visceral fat, which actively excretes adipokines, most of which impair glucose tolerance.

Central adiposity is most often measured as waist circumference (though the point of measurement varies across studies). However, there are other measures such as waist-to-hip ratio, waist-to-height ratio, and CT- and MRI-based visceral and subcutaneous fat.

While the causes of obesity and increased body weight are quite clear (an imbalance between energy intake and expenditure), the exact causes of individual increases in central adiposity are not known, i.e., why some people can have high total adiposity but not central adiposity and vice versa.

Brain and spinal cord

Definition

The vertebrate nervous system is divided into the central nervous system (CNS) and the peripheral nervous system (PNS). The CNS consists of two parts: the brain (located in the skull) and the spinal cord (located in the spine). The PNS is the division of the nervous system that is located outside the skull and spine consisting of two types of neurons: afferent (sensory) neurons which relay impulses toward the CNS and efferent (motor) neurons which relay nerve impulses away from the CNS (Breedlove, Watson, & Rosenzweig, 2010; Pinel, 2006).

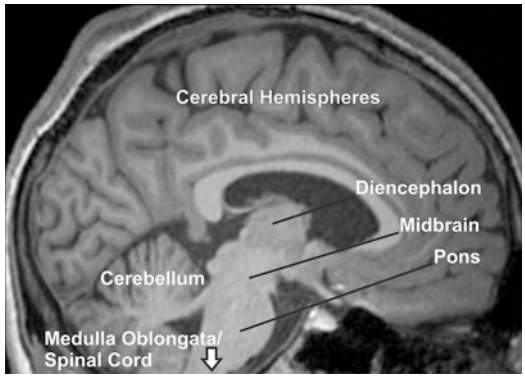
The CNS integrates the sensory information that it receives from the PNS (via the afferent nerves) and coordinates the behavior of the organism and the activity of all parts of the body (via the efferent nerves) (Pinel, 2006). Furthermore, the brain is processing not only simple motor behaviors or physical actions like walking or digestion but also all the complex cognitive, motivational, and emotional processes like affect, learning and memory, and especially those actions that are believed to be quintessential to humans like thinking, speaking, or creativity (Kandel, Schwartz, & Jessell, 2000).

Research on CNS functioning – neuroscience – is a multidisciplinary field that analyzes the biological basis of behavior and psychological processes. The term "neuroscience" was introduced in the mid-1960s, signaling the beginning of an era in which multiple disciplines – neuroanatomy, psychology, biology, medicine, pharmacology, and others – would work together cooperatively, sharing a common language, concepts, and goal, to understand the structure and function of the normal and abnormal brain. Currently, neuroscience is still one of the most rapidly growing areas of science (Squire et al., 2003).

Description

Anatomy

The CNS is the most protected organ of the body: It is encased by bone and covered by



Central Nervous System, Fig. 1 Sagittal MRI scan of a human brain with main structures: Cerebral hemispheres, diencephalon, midbrain, pons, and cerbellum. three protective membranes (1. dura mater, 2. arachnoid membrane/subarachnoid space, 3. pia mater). Also the cerebrospinal fluid has a protecting function: it supports and cushions the CNS. Additionally, the blood–brain barrier protects the brain from toxins that could enter the brain via the bloodstream. For instance, the degree to which psychoactive drugs influence psychological processes depends on their ease of penetrating the blood–brain barrier (Pinel, 2006).

The CNS is a bilateral and essentially symmetrical structure with seven main parts (see Fig. 1): (1) spinal cord, (2) medulla oblongata, (3) pons, (4) midbrain, (5) cerebellum, (6) diencephalon, and (7) cerebral hemispheres (consisting of cerebral cortex, basal ganglia, hippocampus, and amygdaloid nuclei) (Kandel et al., 2000). Other common nomenclatures for the parts of the CNS are as follows: spinal cord, myelencephalon (medulla), metencephalon (pons and cerebellum), mesencephalon (midbrain), and diencephalon and telencephalon (cerebral hemispheres) (Pinel, 2006, an integrated overview over both nomenclatures can be found in Breedlove et al. (2010)). An integration of both nomenclatures is summarized in Table 1.

The *spinal cord* is the most caudal part of the CNS. It receives and processes sensory information from the PNS: the skin, joints, and muscles of the limbs and trunk and controls movements of the limbs and the trunk. The spinal cord continues rostrally as the brain stem, which consists of the medulla oblongata, pons, and midbrain. The 12 cranial nerves are the only nerves of the PNS projecting directly into the brain rather than via the spinal cord.

The *medulla oblongata*, which lies directly above the spinal cord, includes several centers responsible for vital autonomic functions (digestion, breathing, control of heart rate).

The *pons*, which lies above the medulla oblongata, conveys information about movement from the cerebral hemispheres to the cerebellum.

The *midbrain*, which lies rostral to the pons, controls many sensory and motor functions like eye movement and coordination of visual and auditory reflexes.

Medulla oblongata, pons, and midbrain are often summarized as the *brain stem*. The brain stem receives sensory information from the skin and muscles of the head and provides motor control of the head via the cranial nerves. It also conveys information from the brain to the spinal cord and vice versa. Furthermore, the brain stem plays an important role in the regulation of arousal and awareness.

The *cerebellum* lies behind the pons and is crucially involved in the modulation of the force and range of movement, learning of motor skills and movement patterns, coordination, and tuning.

The *diencephalon* lies rostral to the midbrain and contains two structures: the thalamus, which processes most of the information reaching the cerebral cortex from the rest of the nervous system (and is thus often seen as the "gateway" to the cortex), and the hypothalamus, which is involved in the regulation of autonomic, endocrine, and visceral functions.

The *cerebral hemispheres* consist of a heavily wrinkled outer layer – the cerebral cortex (synonym in mammals: neocortex or isocortex) – and three deep-lying structures: the basal ganglia, the hippocampus, and the amygdaloid nuclei. The basal ganglia participate in regulating motor performance, the hippocampus plays a major role in the consolidation of the declarative memory, and

Central Nervous System, Table 1 A schematic view of the common nomenclatures of the brain, divided by main structures and substructures

Peripheral Nervous System (PNS)	Central Nervous System (CNS)											
	Spinal Cord	Brain										
		Myel-encephalon (medulla oblongata)	Met-encephalon		Mes-encephalon (midbrain)	Di-encephalon		Tel-encephalon (cerebral hemispheres)				
			Cerebellum	Pons		Thalamus	Hypothalamus	Cerebral cortex	Basal ganglia	Hippocampus	Amygdaloid nuclei	

the amygdaloid nuclei coordinate the autonomic and endocrine response of emotional states.

The *cerebral cortex* is divided into four anatomical distinct lobes: frontal, parietal, temporal, and occipital. The frontal lobe is involved in planning and executive functions, the parietal lobe in somatic sensation, the occipital lobe in vision, and the temporal lobe in hearing (and speech in humans).

Cell Types

There are two main classes of cells in the nervous system: nerve cells (neurons) and glial cells (from Greek *glia*, meaning glue). Glial cells far outnumber neurons – there are between 10 and 50 times more glia than neurons in the vertebrate CNS (Breedlove et al., 2010; Kandel et al., 2000).

Glial cells are support cells that provide the brain with structure and sometimes insulate neural groups and synaptic connections from each other. Also, they can communicate with each other and with neurons, and they directly affect neuronal functioning by providing neurons with raw materials and chemical signals that alter neuronal structure and excitability. Further important functions (like the myelination of neurons) are summarized in Kandel et al. (2000), Chap. 2 or Breedlove et al. (2010), Chap. 2.

Nerve cells are the main signaling units of the nervous system. A typical neuron has four morphologically defined regions: the cell body (soma), dendrites, the axon, and presynaptic terminals. The cell body is the metabolic center of the brain. Dendrites branch out in treelike fashion and are the main apparatus for receiving signals from other neurons. The axon extends away from the cell body and is the main conducting unit for carrying signals (action potentials: all or none impulses) to other neurons. Action potentials constitute the signals by which the brain receives, analyzes, and conveys information.

Near its end, the axon divides into fine branches that form communication sites with other neurons – the synapses. The nerve cell transmitting a signal is called the presynaptic cell, the signal receiving cell the postsynaptic cell. Between both cells lies the synaptic cleft. When an action potential reaches a synaptic terminal, neurotransmitters are released into the postsynaptic cleft as the neurons output signal. The number of released neurotransmitters is determined by the number and frequency of the action potentials in the presynaptic terminals. The released neurotransmitters act on the receptors of the postsynaptic neuron either in an excitatory (increasing the likelihood of an action potential of the postsynaptic neuron) or in an inhibitory (reducing the likelihood of an action potential of the postsynaptic cell) manner. Whether the effect is excitatory or inhibitory

does not depend on the type of released neurotransmitter but on the type of receptor in the postsynaptic neuron. One estimate puts the human brain at about 100 billion (10^{11}) neurons and 100 trillion (10^{14}) synapses. For details on nerve cell functioning see Kandel et al. (2000), Chap. 2; Squire et al. (2003), Chap. 3; Pinel (2006), Chap. 4; or Breedlove et al. (2010), Chap. 2.

Neurotransmitter Systems

This section will focus on the main neurotransmitter systems: ▶ dopamine (DA), norepinephrine (NE), ▶ serotonin (5-HT), glutamate, and gamma-aminobutyric acid (GABA), their organization, function, and dysfunction (Meyer & Quenzer, 2005).

Dopamine

DA is metabolized from the precursor DOPA. There are five main subtypes of DA receptors organized into D_1-like (D_1 and D_5) and D_2-like (D_2, D_3, and D_4) families. The dopaminergic system can be divided into three major pathways:

1. The nigrostriatal pathway, which originates in the substantia nigra (located in the midbrain) and innervates the striatum (part of the basal ganglia)
2. The mesolimbic pathway, which originates in the ventral tegmental area (located in the midbrain) and innervates various limbic structures, such as amygdala, nucleus accumbens, or hippocampus (all located in the deep lying structures of the cerebral hemispheres)
3. The mesocortical pathway, which also originates in the ventral tegmental area and innervates the cerebral cortex, particularly the prefrontal area

DA is also found in the hypothalamus, where it is involved in hormone secretion and in sensory structures.

Function and Dysfunction of the Dopaminergic System

The nigrostriatal pathway plays a crucial role in voluntary control of movement. ▶ Parkinson's disease, first described by the physician James Parkinson in 1817 as the "shaking palsy" causes a degeneration of dopaminergic neurons in the substantia nigra. The major symptoms of Parkinson's disease involve movement – tremor, rigidity, bradykinesia (poverty or slowing of movement) – and postural disturbances, but also cognitive dysfunctions.

The mesolimbic and mesocortical pathways are involved in motivated behavior, reinforcement of learning and emotional appetitive states (Alcaro, Huber, & Panksepp, 2007). That is why the dopaminergic system also plays a crucial role in drug abuse addiction. Most dopaminergic agonists, like amphetamine or cocaine, are addictive drugs because of their rewarding properties and the induced positive affective states. Furthermore these pathways are closely related to the GABA and opioid system, which is important for understanding the highly addictive potential of GABA agonists (like benzodiazepines and most probably alcohol) and opioid agonists (like morphine or heroin).

Also, a dysfunction of the dopaminergic system is observed in schizophrenia. The dopamine imbalance hypothesis suggests that schizophrenic symptoms are due to reduced dopaminergic function in the mesocortical neurons, along with excess dopaminergic function in mesolimbic dopaminergic neurons, resulting in impaired prefrontal cortex function. Also, the reduction of schizophrenic symptoms by DA antagonists (like Haloperidol, a typical antipsychotic, or Risperidone, an atypical antipsychotic, see below) supports the hypothesis that dopamine is crucially involved in schizophrenic symptoms. But is has to be pointed out that not all symptoms occurring in schizophrenia can be explained by dysfunctions of the DAergic system. For example, also dysfunctions and volume reductions of the hippocampus seem to play a crucial role. Also 5-HT seems to be involved in the development of schizophrenia (see below).

Norepinephrine

The central nervous noradrenergic system originates in the locus coeruleus, a small area of the pons, which projects to almost all areas of the cerebral hemispheres, thalamus, hypothalamus, cerebellum, and spinal cord. Noradrenergic

neurons play an important role in vigilance, arousal, and behavioral functions like hunger/eating, sexual behavior, fear and anxiety, and pain and sleep.

Serotonin

5-HT is synthesized from tryptophan, which comes from proteins in our diet. Pharmacologists have identified at least 14 5-HT receptor subtypes (Saulin, Savli, & Lanzenberger, 2011). The 5-HT system originates from a cell cluster called raphe nuclei (located in medulla, pons, and midbrain) which projects to virtually all structures of the cerebral hemispheres, thalamus, and hypothalamus.

Function and Dysfunction of the 5-HT System

The 5-HT system is involved in food intake, reproductive behavior, pain sensitivity, anxiety, learning and memory, and facilitation of motor output. In psychology, psychiatry, and pharmacology, serotonergic drugs are commonly used in treating depression. There are three major classes of antidepressants, which enhance the amount of 5-HT in the postsynaptic cleft in different ways: monoamine oxidase inhibitors, tricyclic antidepressants, and selective serotonin reuptake inhibitors (SSRIs). Although the pharmacological mechanisms of these drugs are well known, it is still not clear which of their neurochemical actions are responsible for their effectiveness in treating depression – especially regarding the fact that the pharmacological effects of the drugs occur within hours whereas antidepressant effects require weeks of chronic treatment.

Also, in pharmacological treatment of schizophrenia, blockade of 5-HT receptors has become a major topic of research in the past years, since the very effective atypical antipsychotics like Risperidone act not exclusively on DA but also on 5-HT receptors.

Another class of drugs that act on the 5-HT system are hallucinogens like LSD (the abbreviation LSD comes from the German chemical name for the substance: *l*ysergs*ä*ure*d*iethylamid; English: lysergic acid diethylamide) or psilocybin (found in "magic mushrooms"), which became temporarily popular in "psychological experiments" in Harvard in the working group of Timothy Leary in the 1960s and 1970s (Leary, Wilson, & Koopman, 1977).

Glutamate

Glutamate neurotransmitters have potent excitatory effects on neurons throughout the CNS. *N*-Methyl-D-aspartic acid or *N*-methyl-D-aspartate (NMDA) receptors are the main target site of glutamate.

Glutamate and, especially, NMDA receptors are thought to play a crucial role in learning and memory, particularly long-term potentiation. Especially the hippocampus has a very high density of NMDA receptors. NMDA receptor agonists impair the acquisition of various learning tasks.

Gamma-aminobutyric Acid

GABA is synthesized from glutamate. Many main areas of the brain are rich in GABA, including the cerebral cortex, hippocampus, basal ganglia, and cerebellum.

Function and Dysfunction of the GABAergic System

GABA is the main inhibitory neurotransmitter of the brain. Because of GABA's widespread inhibitory effect on neural excitability, treatment with GABA antagonists leads to seizures.

The effect of GABA on the GABA receptor is enhanced by CNS-depressant drugs such as benzodiazepines, barbiturates, and ethanol (alcohol). Due to their anxiolytic effects, benzodiazepines and barbiturates are often prescribed to treat anxiety disorders, although these substances have severe side effects. Among others, the sleep architecture is altered (reduced REM sleep), they are highly addictive, and can cause coma and death by respiratory depression (especially at high doses or with combined alcohol consumption). Another medicinal use of benzodiazepines is as anticonvulsants in the treatment of epilepsy.

Brain Circuits

Often, functionally related structures of the brain are integrated into one circuit such as the limbic system which is mainly associated with

emotional processes (Kandel et al., 2000, Chap. 50) or the basal ganglia. In the following, the basal ganglia will be described exemplarily

The *basal ganglia* comprise of striatum (putamen and caudate nucleus), pallidum, substantia nigra, and the subthalamic nucleus.

The basal ganglia are – beside the cerebellum – one of the largest subcortical motor systems. Cerebellum and basal ganglia appear to influence (via thalamus) the same cortical motor systems. While the basal ganglia output is inhibitory, the cerebellar output is excitatory. Discharge of many basal ganglia neurons correlates with movement and lesions or degenerations (like in Parkinson's disease, chorea Huntington, obsessive-compulsive disorder, or Tourette syndrome) cause severe movement abnormalities: slow voluntary movements or involuntary postures and movements. In order to distinguish the basal ganglia from the "pyramidal" corticospinal motor system, the basal ganglia are often termed "extrapyramidal" motor system.

However, beside motor control, the basal ganglia are also involved in nonmotor function and cognitive aspects of movement (Squire et al., 2003, Chap. 31).

Chances and Limitations of Neuroscience

The new research methods of neuroscience enhanced the knowledge of how mental phenomena are linked to processes in the brain, which allows, for instance, the mapping of mental processes to specific regions of the brain.

Nowadays it is possible to investigate by functional magnetic resonance imaging (fMRI) which brain regions are activated during the presentation of emotionally salient stimuli or cognitive tasks. However it has to be pointed out that research on the biological bases of mental phenomena does not per se enhance the understanding of psychological processes: it is a misunderstanding that biological processes can explain psychological phenomena.

On the contrary, mainly neuroreductionist conceptions of psychological processes (often favoring investigations of input–output relations) may abridge the development of complex theories on mental phenomena. No matter how precisely the brain is investigated – by microscope, imaging techniques, or in the future by even more exact methods – always the same physical objects will be found: neurons, synapses, neurotransmitters, ions, electrons, and protons, but not mental processes. "Granted that a definite thought, and a definite molecular action in the brain occur simultaneously, we do not possess the intellectual organ, nor apparently any rudiment of the organ, which would enable us to pass by a process of reasoning from the one phenomenon to the other. They appear together but we do not know why" (Mausfeld, 2010).

Central Tendency

J. Rick Turner
Cardiovascular Safety, Quintiles, Durham, NC, USA

Definition

Certain descriptive statistics provide concise yet meaningful summaries of large amounts of data. One category of such statistics is measures of central tendency. They provide a measure of a group's central value. Three measures of central tendency are the arithmetic mean, median, and mode, each of which has an entry in the encyclopedia.

Another way to conceptualize central tendency is to say that these measures provide an indication of the location of the data points. Imagine a set of data points ranging from 1 to 100. If the mean is 89, for example, this provides an indication that, overall, the data points are located toward the top of the range rather than toward the bottom. Conversely, if the mean is 27, this indicates that, overall, the data points are located toward the bottom of the range.

Measures of central tendency (consider here the arithmetic mean) are often presented along with measures of spread, or dispersion, of the individual values around the mean. It is possible to have a group of 100 numbers that range from 10 to 90, for example, and have a mean of 50. It is equally possible to have a group of 100 numbers that range from 45 to 55 and that also have a mean of 50. While the measure of central tendency, the mean, is the same in both cases, the dispersion is clearly greater in the former group of hypothetical numbers than in the latter group. Thus, the overall nature of the groups of numbers will differ despite their means being identical.

Cessation Intervention (Smoking or Tobacco)

Definition

Cessation interventions refer to treatments designed to assist individuals with stopping the

use of a particular substance, in this case tobacco. Cessation interventions may involve either behavioral or pharmacological treatment approaches or some combination of the two.

Description

Background

Tobacco use remains the single greatest preventable cause of morbidity and premature mortality in the United States (USA). Each year, cigarette smoking is responsible for more than 440,000 deaths, five million years of potential life lost, and $190 million in excess health-care expenditures and productivity losses in the USA alone. Worldwide, tobacco use accounts for more than five million deaths annually, with the total expected to increase to eight million by the year 2030 (World Health Organization, 2008).

In the USA, rates of cigarette smoking steadily declined in the years following the publication of the first Surgeon General's Report on Smoking and Health in 1964. In fact, since the mid-1960s, the prevalence of cigarette smoking has dropped by more than 50%. Rates of tobacco use have stabilized in recent years, however, with levels remaining essentially unchanged since 2005. Currently, 20.6% of the adult population smokes cigarettes (Centers for Disease Control and Prevention [CDC], 2010b). Among high school students, the prevalence of current (past 30-day) cigarette smoking is 17.2% (CDC, 2010a). As with adults, the rate of smoking has been relatively stable in recent years following a period of significant decline during the 1990s.

A variety of sociodemographic factors are associated with cigarette use (CDC, 2010b). Overall, men (23.5%) are more likely to smoke cigarettes than women (17.9%). Adults aged 25–44 years of age are most likely be cigarette smokers (24.0%), while those aged 65 and older are the least likely to smoke (9.5%). The prevalence of cigarette smoking is also inversely associated with both educational attainment and income. Smoking rates among those with less than a high school education are 28.5% compared with 11.1% for those with an undergraduate college degree and 5.6% for those with a graduate degree. The prevalence of smoking is also elevated among those who live below the poverty line (31.1%) relative to those at or above the poverty level (19.4%). With regard to geographic variations in cigarette use, rates are lowest for those living in the West (18.8%) and highest for those residing in the Midwest (23.1%). Rates of cigarette smoking are elevated among other subgroups as well. In particular, individuals with a history of psychiatric disorders and nonnicotine substance abuse tend to smoke at very high rates relative to the general population.

Although the onset of cigarette smoking continues through young adulthood, the vast majority of regular tobacco users initiate smoking prior to the age of 18. In the early stages of smoking, use tends to be episodic and is often isolated to specific social or environmental contexts (e.g., with friends, at a party). As tolerance to nicotine develops, however, the frequency and intensity of use increase. Following a period of regular use, many smokers become nicotine dependent, which is characterized by *tolerance* (the need for greater amounts of tobacco to achieve the same effect), *compulsive use* (difficulty controlling cigarette use), and nicotine *withdrawal* (a reversible and substance-specific syndrome of behavioral, cognitive, and physiological changes brought on by the cessation or reduction of tobacco use that causes distress or impairment in functioning) (American Psychiatric Association [APA], 2000). Signs of nicotine withdrawal include dysphoria or depressed mood, insomnia, irritability, frustration, or anger, anxiety, difficulty concentrating, restlessness, decreased heart rate, and increased appetite or weight gain (APA, 2000). Although it was once assumed that nearly all regular smokers were nicotine dependent, it is now recognized that a sizeable proportion of cigarette smokers do not meet formal criteria for nicotine dependence (Hughes, Helzer, & Lindberg, 2006). Unfortunately, for those who do become nicotine dependent, cigarette use tends to follow a chronic course lasting years or decades, often characterized by multiple relapse episodes.

Treatment

A variety of effective behavioral and psychopharmacological approaches are available for the treatment of tobacco use and dependence. The range of efficacious interventions for tobacco use includes public health-based approaches such as screening and brief advice and health policy initiatives. The present review, however, will emphasize clinical approaches involving behavioral and pharmacologic treatment strategies.

Behavioral treatments have long played an important role in the treatment of tobacco use and dependence. Behavioral approaches range from brief advice lasting just a few minutes to intensive group or behavioral counseling conducted over a period of weeks. A variety of different behavioral treatments have been applied to smoking cessation including aversive therapies such as rapid smoking and smoke holding, nicotine fading, problem solving and skills training, contingency management, relaxation training, and strategies emphasizing enhanced social support. Surprisingly, little is known, however, about the relative efficacy of the individual strategies or components. This is due, in part, to the fact that most treatment programs combine a variety of different behavioral strategies and tend to be evaluated as a whole rather than according to individual components. Nevertheless, sufficient evidence is available to support the efficacy of certain behavioral strategies. In the 2008 Update to the Clinical Practice Guideline for Treating Tobacco Use and Dependence, Fiore et al. identified two specific types of behavioral interventions and counseling that have proven effective for promoting smoking cessation. These included practical counseling and the provision of intratreatment social support. Practical counseling refers to general problem solving and behavioral skills training (e.g., setting a quit date, identifying high-risk situations, developing coping skills, and providing basic information about smoking and successful quitting). Intratreatment social support simply involves providing encouragement to smokers during their quit attempt, communicating caring and concern about the smoker, and encouraging them to talk about issues related to the quitting process, such as concerns they might have about quitting and experiences they encountered during prior quit attempts.

In addition to variability in content, behavioral interventions also differ with regard to ways of administering treatment. Evidence supports the use of several different formats for the delivery of behavioral treatment for tobacco use. Both individual and group counseling have been shown to be effective strategies for treating nicotine dependence. Proactive telephone counseling, in which an initial assessment is followed by a series of scheduled sessions initiated by the clinician, is another empirically supported mode of delivery. Self-help materials, while advantageous from cost and wide-scale dissemination perspectives, have demonstrated relatively modest success as a treatment strategy. Emerging data also suggest that of computer- and Internet-based cessation programs hold promise, although clear evidence regarding the characteristics and content of programs that are most effective is currently lacking.

Recent trends in the delivery of behavioral treatment for smoking cessation have emphasized the delivery of brief behavioral counseling for purposes of widespread dissemination. Such an approach is sound from a public health perspective in that it facilitates implementation and increases potential reach. Nevertheless, evidence strongly supports a dose–response association between treatment intensity and cessation outcomes. The number of treatment sessions and total amount of contact time are both positively associated with cessation outcomes such that more intensive interventions tend to be associated with a greater likelihood of cessation.

The most effective tobacco cessation interventions are those that combine behavioral and pharmacological treatment strategies. Indeed, treatments involving medication and behavioral counseling are significantly more effective than those using only one strategy or the other. There are currently seven medications considered to be first-line pharmacotherapies for smoking cessation based on their demonstrated safety and effectiveness in the general population. Five of these agents are forms of nicotine replacement therapy

(NRT): transdermal nicotine patch, nicotine gum, nicotine lozenge, nicotine nasal spray, and nicotine inhaler. The patch, gum, and lozenge are all available over the counter in the USA, while the spray and inhaler require a prescription. The two other first-line medications are bupropion hydrochloride (trade name Zyban®), an atypical antidepressant, and varenicline (trade name Chantix®), an $\alpha_4\beta_2$ nicotinic acetylcholine (ACh) receptor partial agonist. Each of these seven agents has strong empirical evidence to support their efficacy, with no single medication demonstrating clear superiority over the others. All are associated with an approximate doubling of the odds of successful quitting relative to placebo. Medication strategies combining bupropion with the nicotine patch as well as the nicotine patch with short-acting NRT (gum or nasal spray) have also been found to improve cessation rates relative to monotherapy comprised of either agent alone. Two other medications (the antihypertensive clonidine and the antidepressant nortriptyline) are considered to be second-line pharmacotherapies for smoking cessation. Although there is considerable evidence to support their efficacy for aiding smoking cessation, neither has yet been approved by the US Food and Drug Administration (FDA) for treating tobacco use and dependence. In addition, these agents tend to have a less favorable side effect profile than most of the first-line agents. For that reason, it is recommended that they be considered primarily among those for whom the first-line agents are contraindicated or who have not been successful at quitting using those medications. To date, there is insufficient evidence to support the efficacy of pharmacotherapy for use with pregnant women, light smokers, and adolescents. For that reason, guidelines recommend that treatment focus on behavioral strategies and counseling.

Despite the range of effective behavioral and pharmacological options for assisting with tobacco cessation, the vast majority of smokers do not use an empirically supported treatment during a given quit attempt. An estimated 65–80% of smokers who attempt to quit smoking do so without the aid of behavioral or pharmacological therapies (Shiffman, Brockwell, Pillitteri, & Gitchell, 2008; Zhu, Melcer, Sun, Rosbrook, & Pierce, 2000). Behavioral interventions are especially underutilized, with less than 10% of smokers using this form of treatment during any single quit attempt (Shiffman et al., 2008; Zhu et al., 2000). Furthermore, when smokers do make use of nonpharmacological treatment approaches, they tend to use self-help materials rather than strategies with greater empirical support such as individual, group, or telephone counseling (Shiffman et al., 2008). A variety of factors appear to contribute to the underutilization of effective smoking cessation treatments including a lack of awareness of available treatment options, a preference to quit smoking on one's own, perceived inconvenience, cost, and, in the case of pharmacotherapy, concerns about side effects.

Relapse Prevention

Nicotine dependence is becoming increasingly conceptualized as a chronic and refractory condition. Even among those who do receive evidence-based treatment for smoking cessation, most who attempt cessation eventually resume smoking following a given quit attempt. Although relapse can occur months or even years after an individual quits smoking, the vast majority occurs within the first 2 weeks. The long-term cessation rates for even the most successful interventions rarely exceed 30–35% (By comparison, for those who attempt to quit on their own without assistance, 1-year abstinence rates tend to be less than 5%). Perhaps surprisingly in light of the variety of new (primarily pharmacological) treatments that have become available over the past two decades, abstinence rates among participants in clinical trials have actually decreased over time (Inrvin & Brandon, 2000; Inrvin, Hendricks, & Brandon, 2003), leading to the speculation that those who continue to smoke, though fewer in number, are more likely to be nicotine dependent and to have comorbid psychiatric and substance use disorders that make it more difficult for them to successfully quit (Inrvin & Brandon, 2000).

Given the high rates of relapse among once abstinent smokers, much attention has been given

to trying to prevent tobacco users from resuming tobacco use following a successful quit attempt. Most of this work is based on the model originally developed by Marlatt for the treatment of alcohol use disorders (Marlatt & Donovan, 2005). The approach focuses on helping individuals to identify situations in which they may be especially tempted to smoke cigarettes (e.g., when consuming alcohol, during situations of elevated stress or dysphoria, when exposed to other smokers). Once these high-risk situations are identified, smokers can be taught to avoid them (at least in the short term) or to develop alternative coping strategies to help them manage the situation without smoking. Although conceptually appealing, relapse prevention interventions based on enhancing coping skills have generally not been shown to be effective for cigarette smoking. Other psychosocial and pharmacological approaches have similarly failed to reduce relapse rates in most cases. Methodological limitations associated with this literature, however, limit the conclusions that can be drawn regarding the relative effectiveness (or ineffectiveness) of different intervention strategies. Given the high rates of relapse, new strategies for helping to maintain abstinence over the long term are clearly needed.

Addressing Smokers Who Are Not Interested in Quitting

The treatment approaches described above apply primarily to those who express interest in quitting smoking. However, despite the fact that the vast majority of smokers indicate that they would like to quit, the proportion of tobacco users who express readiness to quit smoking at any given point in time is relatively small. Therefore, it is important to identify strategies for approaching the large number of smokers who indicate that they do not presently wish to make a quit attempt.

Historically, approaches to address tobacco use among cigarette smokers who express reluctance to quit focused on providing education about the harms of smoking and attempting to persuade them to quit. Such strategies tended to be paternalistic and proscriptive in style and based on the assumption that those who continued smoking did so primarily due to a lack of knowledge about the significant health risks. However, while health education does play an important role in smoking cessation and advice to quit from one's health or mental health-care provider is frequently cited as an important factor in motivating a quit attempt, treatment strategies that rely on confrontation and which solely emphasize the clinician's role as the health expert who knows what is best for the client typically meet with little success.

One approach that has been particularly influential in the field of health behavior change, and in the treatment of addictions in particular, is motivational interviewing (MI) (Miller & Rollnick, 2002). Motivational interviewing is a directive, client-centered approach to counseling that seeks to promote behavior change by helping people to explore and resolve ambivalence. The MI approach recognizes that the majority of smokers have mixed feelings about their tobacco use. While nearly all tobacco users acknowledge the health risks and can identify other negative consequences of smoking, most also perceive it as positively reinforcing and as playing an important functional role in their lives (e.g., negative affect reduction, stress management). Helping clients to recognize and resolve their ambivalence about quitting smoking is central to the MI approach. Rather than using direct persuasion in an attempt to enforce change externally, MI takes the perspective that the individual already possesses the motivation and skills necessary to make a change. Instead of viewing motivation as something an individual does or does not have, it is seen as fluid and susceptible to movement in either direction. The goal is to elicit and strengthen the motivation and commitment through the use of "change talk," in which the individual (rather than the clinician) makes his or her own argument for quitting smoking.

Four general principles help to guide the MI approach. The first involves *expressing empathy*, which entails making an attempt to view things from the perspective of the client. The second principle is to help the client to *develop discrepancy* between his or her values/goals and their current behavior. For example, individuals who

place being a good role model for their children and being available to support their family and friends in high regard can be helped to see how smoking is incongruent with these values. The third principle involves *rolling with resistance*. It is very common for individuals faced with decisions about modifying a health behavior such as tobacco use to demonstrate resistance to change, particularly if they feel their autonomy is being threatened. Rather than try to confront or fight the client's resistance, the MI approach contends that it can be much more productive to shift strategies and use this as an opportunity to further explore their views about the behavior. The final principle focuses on helping to *support self-efficacy*. An individual's belief that they are able to successfully make a change in their behavior is strongly associated with their likelihood of doing so. Therefore, fostering one's sense of their own self-efficacy by eliciting examples of past successes or providing illustrative cases of others who have made similar behavior changes can be very beneficial. In order to help facilitate these principles and resolve their ambivalence, MI utilizes interaction techniques such as open-ended questions, reflective listening, and providing positive affirmations.

Considerable evidence now supports the use of MI for helping individuals to change their smoking behavior. Although treatment effects tend to be modest, MI has been shown to successfully increase the likelihood of smoking cessation. The approach appears to be particularly effective for those expressing low motivation to quit. Due in large part to its collaborative and nonconfrontational style which respects an individual's ability to make their own decisions about when, how, and whether to change their behavior, MI also tends to be popular among both clinicians and clients.

Summary and Conclusions

Although public health policy initiatives and treatment advances have helped to reduce the proportion of the population that smokes cigarettes, tobacco use remains the leading cause of morbidity and premature mortality in our society. Several evidence-based behavioral and pharmacologic treatments have been found to significantly improve a smoker's chances of quitting successfully. However, most smokers fail to utilize effective interventions during any given quit attempt. Even among those who do receive empirically supported treatment, relapse rates remain very high. In order to continue progress in reducing rates of cigarette smoking, it is important to identify and implement strategies for increasing the use of evidence-based treatment for tobacco use and dependence, as well as for helping to reduce high rates of relapse among those who do attempt to quit.

Character Traits

Personality; Psychosocial traits

Definition

Character traits generally refer to the temporally stable and cross-situationally consistent individual patterns in how people think, act, and feel.

Description

Associations between character traits, health behaviors, and health outcomes have been well documented (Booth-Kewley & Vickers, 1994; Ozer & Benet-Martinez, 2006). Hostility and dominance, two components of the Type A behavior pattern, have been related to asymptomatic atherosclerosis, incident coronary heart disease, and cardiac-specific and all-cause mortality (Smith, 2006). Each of the five character traits that comprises the Five Factor Model, which has been recommended as a culturally robust framework by which to guide investigations of the association between personality and health outcomes (Taylor et al., 2009), has been linked to health behaviors, including wellness behaviors, accident control, traffic risk taking, and substance risk taking (Booth-Kewley & Vickers, 1994). These broad traits of the Five Factor Model include neuroticism (e.g., anxiety, hostility, and depression), extraversion (e.g., warmth, assertiveness, and positive emotions), conscientiousness (e.g., self-discipline, order, and achievement striving), agreeableness (e.g., altruism, trust, and compliance), and openness to experience (e.g., fantasy, esthetics, and feelings). Neuroticism has additionally been linked to both distress-relevant aspects of health (DeNeve & Cooper, 1998) and disease incidence (Friedman, Kern, & Reynolds, 2010). It has likewise been shown to predict, over more than four decades, subjective well-being, physical health, and longevity (Friedman et al., 2010). Other research has shown that extraversion and conscientiousness predict longevity, low agreeableness (trait hostility) and negative affectivity predict poorer physical health and earlier mortality, and creativity predicts health and is associated with resiliency (Ozer & Benet-Martinez, 2006). Moreover, a meta-analytic review has identified optimism as a significant predictor of positive physical health outcomes with regard to all-cause mortality, survival, cardiovascular outcomes, cancer outcomes, outcomes related to pregnancy, physical symptoms, immune functioning, and pain (Rasmussen, Scheier, & Greenhouse, 2009).

Although researchers initially considered whether single diseases (such as coronary heart disease) were associated with single character traits or personality types (such as hostility and Type A personality), Friedman and Booth-Kewley

(1987) offered evidence in contradiction to this paradigm. In their meta-analysis of five emotional facets of personality (including depression and anxiety) and five chronic diseases (including coronary heart disease) thought to be affected by psychosomatic factors, they identified a pattern of associations between multiple predictors and multiple disease outcomes. Friedman and Booth-Kewley's research pointed to a broader "disease-prone personality," and suggested the importance of assessing multiple character traits and multiple health outcomes in the same study (Friedman et al., 2010). Recent studies of the associations of the five traits of the Five Factor Model with health outcomes reflect this paradigm shift. For instance, Taylor and colleagues studied whether character traits from the Five Factor Model were associated with all-cause mortality in a general adult population in Scotland and found that high conscientiousness and openness were protective against all-cause mortality in men (Taylor et al., 2009).

Current research on character traits and physical health attempts to identify mechanisms by which personality gives rise to subsequent health outcomes, and a variety of mechanistic models have been proposed (Smith, 2006). Health behavior models suggest that character traits are associated with health behaviors, which in turn elicit health outcomes. An interactional stress moderation model posits that character traits contribute to appraisal and coping, which in turn lead to physiological responses and health outcomes. A transactional stress moderation model expands the interactional model by including the bidirectional effect of personality on exposure to stressful life circumstances and availability of stress-reducing resources. Finally, the constitutional predisposition model proposes that genetic or other psychobiologic factors underlie both character traits and the development of health outcomes.

Definition

Chemotherapy is a treatment of diseases using chemical agents or drugs, particularly the treatment of cancer by cytotoxic and other drugs. In a non-oncological setting, the term may also refer to the administration of antibiotics against microorganisms. Here, only cancer chemotherapy is discussed.

The main purpose of chemotherapy is to systemically kill cancer cells in the body. Most traditional drugs that are used in chemotherapy interfere with the ability of cells to grow and multiply. The variety of chemotherapy drugs are classified based on how they work. For example, alkylating agents, like cyclophosphamide, kill cells by directly attacking DNA. Antimetabolites, like methotrexate, interfere with the production of DNA and the growth and multiplication of cells. Topoisomerase-interacting agents, antimicrotubule agents, and miscellaneous chemotherapeutic agents are traditional chemotherapy drugs. These drugs target not only cancer cells but also normal cells in the body. In contrast, there has been a recent emergence of targeted therapy, which involves drugs that block the growth of only cancer cells by interfering with specific targeted molecules needed for carcinogenesis and tumor growth. Small-molecule tyrosine kinase inhibitors, like imatinib mesylate, and monoclonal antibodies, like trastuzumab, are used in targeted therapy.

Chemotherapy drugs can be administered orally, by injection, through a catheter or port, or topically. Chemotherapy drugs are most often administered in combination, based on the known biochemical actions of available anticancer drugs. To achieve superior outcome with combined cancer chemotherapy, drugs which function through separate cytotoxic mechanisms and have different dose-limiting adverse effects are administered together at full dosages. Patients may undergo chemotherapy at regular intervals, i.e., once a week and once a month, depending on the type of cancer and drug therapy.

As most chemotherapy drugs are toxic to cancer cells as well as normal healthy cells, they can cause a variety of side effects, including hair loss, anemia, loss of appetite, nausea, and vomiting.

Several behavioral medicine studies have also suggested impairment of cognitive functions, such as memory and attention, in some patients who receive chemotherapy, mostly as adjuvant treatment for breast cancer. This impairment is referred to as "chemo-brain" or "chemo-fog." Despite increasing research in this area, the mechanisms behind chemotherapy-induced cognitive impairment remain largely unknown. Future studies are expected to shed light on both the prevention and treatment of "chemo-brain."

Chesney, Margaret

Margaret A. Chesney
Department of Medicine & Center for Integrative Medicine, University of California,
San Francisco, CA, USA

Biographical Information

Margaret Chesney was born in Baltimore, Maryland. She graduated from Whitman College in 1971 and received her PhD in Clinical and Counseling Psychology from Colorado State University in 1975. She received postdoctoral training in psychiatry from the Western Pennsylvania Psychiatric Institute where she studied behavioral approaches to improving psychological and physical health. In 1976, she joined Stanford Research Institute (SRI) to carry out research on stress and health. In 1978, she became Director of the new Department of Behavioral Medicine at SRI. In 1987, she moved her research to the Department of Medicine, University of California San Francisco (UCSF), to contribute behavioral medicine perspectives to the prevention and treatment of HIV/AIDS.

From 2000 to 2003, while at UCSF, Chesney pursued policy studies as a Senior Fellow at the Center for the Advancement of Health in Washington, DC, and served as a Scientific Advisor to the Office for Research on Women's Health at the National Institutes of Health (NIH). In 2003, she became Deputy Director of the National Center for Complementary and Alternative Medicine (NCCAM) and a Senior Advisor to the Director of the Office of Behavioral and Social Sciences Research at NIH. In 2010, Margaret returned to UCSF as Professor in Residence in the Department of Medicine, the Osher Foundation Distinguished Professor in Integrative Medicine, and Director of the Osher Center for Integrative Medicine at UCSF.

Throughout her career, Chesney has chaired and served on numerous advisory groups for the NIH and the State of California, covering topics including health promotion and disease prevention, living with and beyond chronic illness, women's health, and health-care policy. She is currently the Associate Editor of *Psychology, Health and Medicine*. Chesney has been President of the Academy of Behavioral Medicine Research, as well as President of the American Psychosomatic Society and President of the Division of Health Psychology of the American Psychological Association. She received the Distinguished Scientist Award from the Society of Behavioral Medicine in 2011, the Director's Award for work in Mind-Body Medicine from the NIH in 2005, the Charles C. Shepard Science Award, from the Centers for Disease Control and Prevention in 1999, and the President's Award from the Academy of Behavioral Medicine Research in 1987. In 2001, she was elected to the Institute of Medicine. She received an honorary doctorate from her alma mater, Whitman College, in 2008.

Major Accomplishments

Chesney has been engaged in clinical practice and research in the areas of stress, mind-body

interactions, and health. Her earliest studies involved the use of relaxation-based exercises as an alternative to medication for managing pain. Extending this approach to coronary heart disease, Chesney carried out a number of studies to identify the coronary-prone features of the Type A behavior pattern. With colleagues at SRI, she reported that hostility, competitiveness, and depressed mood are characteristics associated with increased risk of coronary events. She followed this work with trials investigating lifestyle interventions designed to promote health, prevent disease, and enhance well-being in both women and men.

In the late 1980s, Chesney was invited to join the Center for AIDS Prevention Studies at UCSF to develop behavioral interventions for persons living with HIV/AIDS. With Susan Folkman, Chesney carried out research on stress and coping among caregivers of persons with HIV/AIDS and developed a cognitive behavioral intervention, Coping Effectiveness Training (CET), for persons with HIV/AIDS, based on stress and coping theory. Shown to be effective with HIV, CET has been successfully applied to enhance coping with other chronic conditions including spinal cord injury and cancer. In addition, Chesney developed measures of adherence and led randomized trials of behavioral strategies to increase adherence to the complex treatment regimens for HIV/AIDS. She was also one of two leaders of a San Francisco community-based study to encourage persons infected with HIV to seek immediate treatment within the first days of infection, a study that led NIH to create a network investigating treatment of "primary HIV infection."

Her interest in policy level interventions for health promotion brought Chesney to Washington, DC, and NIH where she became familiar with the emerging field of integrative medicine. Returning to UCSF, her current research is investigating breathing, a core feature of many behavioral or integrative medicine interventions. With David Anderson, she is investigating whether breathing patterns may be a mechanism by which mind-body interventions influence blood pressure, a major risk factor for cardiovascular disease.

Chest Pain

Definition

Acute chest pain is the common symptom of a multitude of medical conditions, ranging from the life threatening, such as myocardial infarction, pulmonary embolism, pneumothorax, and aortic dissection; to the less serious, such as esophageal reflux, peptic ulcer disease, and gallbladder disease; to benign entities, such as pericarditis, costochondritis, and panic attacks. As such, it is also one of the most frequent causes for ER presentation in the United States, accounting for as many as seven million visits annually. Rapid triage and accurate diagnostic workup are thus cornerstones of care for these patients (Cannon & Lee, 2008; Lee & Goldman, 2000).

The evaluation of acute chest pain begins with a thorough history and physical that helps to distinguish the underlying etiology and guide testing. For instance, clinical features that are suggestive of myocardial infarction include prior history of coronary artery disease, pain or pressure radiating to the arm or jaw, and association with nausea, vomiting, or diaphoresis (Panju, Hemmelgarn, Guyatt, & Simel, 1998). Pain that is pleuritic (i.e., worse with deep inspiration) can be caused by pulmonary embolism, while chest pain caused by aortic dissection is typically described as excruciating and tearing or ripping in quality, often radiating to the back. Pain that is worse with manual palpation, on the other hand, suggests a chest wall process such as costochondritis and is often reassuring. Rapid ECG at time of presentation is recommended to rule out ST-elevation myocardial infarction, and other testing such as serial biomarkers (e.g., cardiac troponins or creatine kinase MB isoenzyme), chest X-ray, and CT angiography of chest and thorax can be obtained based on the clinical suspicion (Cannon & Lee, 2008; Lee & Goldman, 2000). Despite the availability of these tests, however, the challenge remains to balance the need to correctly diagnose patients with life-threatening conditions with avoidance of the harm that can occur from unnecessary testing of those who are truly at low risk.

Acts of commission

Definition

Child abuse is defined as acts of commission that include the use of words or overt actions that cause harm, potential harm, or threat of harm to a child (Leeb, Paulozzi, Melanson, Simon, & Arias, 2008). These are deliberate and intentional acts of commission by a caregiver, whether or not harm to a child was the intended consequence.

A caregiver is defined as a person who at the time of the maltreatment is in a permanent (primary caregiver) or temporary (substitute caregiver) role. In a custodial role, the person is responsible for care and control of the child and for the child's overall health and welfare. A primary caregiver lives with the child at least part of the time and can include, but is not limited to, a relative or biological, adoptive, step-, or foster parent(s); a legal guardian(s); or their intimate partner. A substitute caregiver may or may not live with the child and can include coaches, clergy, teachers, relatives, babysitters, residential facility staff, or others who are not the child's primary caregiver(s).

Acts of omission, child neglect, are discussed in a separate entry.

Types

There are three different forms of child abuse that involve acts of commission: physical abuse, sexual abuse, and psychological/emotional abuse.

Physical abuse is defined as the intentional use of physical force against a child that results in, or has the potential to result in, physical injury (Leeb et al., 2008). Physical abuse includes physical acts that range from those which do not leave a physical mark on the child to those which cause permanent disability, disfigurement, or even death. Examples of physical abuse can include hitting, kicking, punching, beating, stabbing, biting, pushing, throwing, pulling, dragging, dropping, shaking, choking, smothering, burning, scalding, and poisoning.

Sexual abuse is defined as any completed or attempted sexual act, sexual contact with, or exploitation (i.e., noncontact sexual interaction) of a child by a caregiver (Leeb et al., 2008). Sexual acts include contact involving penetration, however slight, between the mouth, penis, vulva, or anus of the child and another individual. Sexual acts also include penetration, however slight, of the anal or genital opening by a hand, finger, or other object. Sexual acts can be performed by the caregiver on the child or by the child on the caregiver. A caregiver might also force or coerce a child to commit a sexual act on another individual (child or adult). Abusive sexual contact involves intentional touching, either directly or through the clothing, of the following: genitalia (penis or vulva), anus, groin, breast, inner thigh, and/or buttocks. Abusive sexual contact can be performed by the caregiver on the child or by the child on the caregiver. Abusive sexual contact can also occur between the child and another individual (adult or child) through force or coercion by a caregiver. Touching that is required for the normal care or attention to the child's daily needs does not constitute abusive sexual contact.

Noncontact sexual abuse can include any of the following: (a) exposing a child to sexual activity (e.g., pornography, voyeurism of the child by an adult, intentional exposure of a child to exhibitionism); (b) filming a child in a sexual manner (e.g., depiction, either photographic or cinematic, of a child in a sexual act); (c) sexually harassing a child (e.g., quid pro quo, creating a hostile environment because of comments or attention of a sexual nature by a caregiver to a child); and (d) prostituting a child (e.g., employing, using, persuading, inducing, enticing, encouraging, allowing, or permitting a child to engage in or assist any other person to engage in prostitution or sexual trafficking).

Psychological/emotional abuse includes intentional caregiver behavior that conveys to a child that he/she is worthless, flawed, unloved, unwanted, endangered, or valued only in meeting another's needs (Leeb et al., 2008). Psychological/emotional abuse can be continual or episodic (e.g., triggered by a specific context or situation). Psychologically/emotionally abusive behaviors often consist of blaming, belittling, degrading, intimidating, terrorizing, isolating, restraining, confining, corrupting, exploiting, or otherwise behaving in a manner that is harmful, potentially

harmful, or insensitive to the child's developmental needs or can potentially damage the child psychologically or emotionally.

Description

Prevalence

In 2008, US state and local child protective services (CPS) received 3.3 million reports of children being abused and/or neglected. CPS estimated that 772,000 (10.3 per 1,000) of these children had substantiated cases of child abuse and/or child neglect. Approximately three quarters of them had no history of prior victimization. Sixteen percent of the children were classified as victims of physical abuse, 9% as victims of sexual abuse, and 7% as victims of psychological/emotional abuse (USDHHS, 2010). The remaining children were classified as victims of child neglect. A recent national study estimated that 1 in 5 US children has experienced some form of child abuse or neglect in their lifetime, with a rate of 1 in 10 experiencing some form of child abuse or neglect in the past year (Finkelhor, Turner, Ormrod, & Hamby, 2009). In 2008, a CPS-based study found that African-American (16.6 per 1,000 children), American Indian or Alaska Native (13.9 per 1,000 children), and multiracial (13.8 per 1,000 children) children had higher rates of victimization than other racial groups, with slightly higher rates for girls (10.8 per 1,000 children) than boys (9.7 per 1,000 children) overall (USDHHS, 2010). Research has demonstrated similar negative sequelae for children who have substantiated CPS reports of abuse and for children who have alleged or suspected CPS reports of abuse (Hussey et al., 2005).

Etiology and Sequelae

A combination of individual, relational, community, and societal factors contributes to the risk of child abuse. Although children are not responsible for the harm inflicted upon them, certain characteristics have been found to increase their risk of being abused (Berliner, 2011; Centers for Disease Control and Prevention, 2009; Runyon & Urquiza, 2011). Individual child factors that increase a child's vulnerability include child age younger than 4 years and those children with special needs. Also, parents' lack of understanding of child development and parenting skills; parents' history of child abuse, substance abuse, and/or mental health issues; parental characteristics such as young age, low education, single parenthood, large number of dependent children, and low income; and nonbiological, transient caregivers in the home (e.g., mother's male partner) all seem to increase the risk of perpetration of child abuse in the home. Other risk factors for perpetration include poor social connections and support, family violence (e.g., intimate partner violence), poor parent-child relationships, parenting stress, community violence, and concentrated neighborhood disadvantage (e.g., high poverty and residential instability, high unemployment rates).

Extensive research demonstrates that child abuse can have devastating effects on physical and mental health. Abuse during infancy or early childhood can cause important regions of the brain to form and function improperly with long-term consequences on cognitive, language, and socioemotional development and mental health. Children may experience severe or fatal head trauma as a result of abuse. Nonfatal consequences of abusive head trauma include varying degrees of visual impairment (e.g., blindness), motor impairment (e.g., cerebral palsy), and cognitive impairments (Christian, Block, & The Committee on Child Abuse & Neglect, 2009). Also, the stress of chronic abuse may result in anxiety and may make children more vulnerable to problems such as posttraumatic stress disorder, conduct disorder, and learning, attention, and memory difficulties (Dallam, 2001; Perry, 2001). Studies have found abused children are more likely to be arrested or become involved in delinquent and violent behavior in adolescence and experience teen pregnancy, low academic achievement, and decreased high school graduation rates (Langsford et al., 2007). Abused children are also at increased risk for adverse health behaviors, such as smoking, alcoholism, drug abuse, and engaging in high-risk sexual behaviors, which often lead to certain chronic diseases as adults, including heart disease, cancer, chronic lung

disease, liver disease, obesity, high blood pressure, and high cholesterol (Runyan, Wattam, Ikeda, Hassan, & Ramiro, 2002). In one long-term study, as many as 80% of young adults who had been abused met the diagnostic criteria for at least one psychiatric disorder at age 21. These young adults exhibited many problems, including depression, anxiety, eating disorders, and suicide attempts (Silverman, Reinherz, & Giaconia, 1996). Abuse can also increase the likelihood of adult criminal behavior and violent crime (Widom & Maxfield, 2001). Finally, early child abuse can have a negative effect on the ability of both men and women to establish and maintain healthy intimate relationships in adulthood (Colman & Widom, 2004), which may also perpetuate the cycle of violence from one generation to the next.

Definition

The field of child development is concerned with the scientific study of human growth and functioning across the early stages of development (i.e., the prenatal period through adolescence) and within the multitude of contexts of daily life. Areas of interest include – though are not limited to – biological, cognitive, physical, social, and emotional change across the early portions of life. In all cases, an emphasis is placed on understanding how normative functioning changes or remains constant across time as a result of maturation and/or experience (Lerner, 2006). Child development is one aspect of the broader field of Developmental Psychology, which examines human growth and functioning across the entire lifespan.

Description

The field of child development is concerned with the scientific study of human growth and functioning throughout the early portions of life, including the prenatal period through adolescence. The entire human lifespan includes the prenatal period, infancy, childhood (early, middle, and late), adolescence (early, middle, and late), emerging adulthood, and adulthood (early, middle, and late) (Arnett, 2004; Santrock, 2012; Steinberg, 2011). One way the earliest periods of human life may be contemplated is in terms of chronological age. From this perspective, the prenatal period spans the time of conception through birth and lasts approximately 9 months for a typical pregnancy. Infancy encompasses from birth through 18 or 24 months of age. Early childhood includes from 18 or 24 months through 5 or 6 years of age. Middle and late childhood runs from 5 or 6 years through approximately 11 years of age. Adolescence is from around 11 years of age through approximately 18 years of age.

Child development considers the multitude of contexts of daily life that humans encounter. Areas of interest include – though are not limited to – biological, cognitive, social, and emotional developments, with an emphasis on how normative functioning and processes either change or remain constant across time as a result of maturation and/or experience (Lerner, 2006). *Biological processes* in infancy and childhood entail the growth and maturation of the internal organ systems and observable increases in both height and weight, and how these connect to the development and refinement of advancing motor skills. Subsequent biological growth in adolescence is demonstrated by secondary sexual maturation through the process of pubertal development and the attainment of more adult-like stature and weight. *Cognitive growth* in infancy and childhood includes rapid gains in language processing, production, and comprehension. Memory capacity expands and more sophisticated strategies for retention and recall are demonstrated. Also, individuals gain enhanced understanding of logic related to concrete concepts in childhood and to abstract concepts in adolescence. *Social growth* in infancy and childhood involves dependent interactions and attachments to caregivers and expands to include peer and friendship relationships. Later in adolescence, social networks expand to include cliques and significant others as increasingly intimate relationships develop. Early *emotional growth* in infancy and childhood entails the presence of primary feelings and the development of self-conscious emotions. Subsequent growth in adolescence involves enhanced understanding of societal rules for the display and regulation of emotions and coping with life's challenges.

These different domains of growth and development do not occur independently, but are interrelated. That is, an infant who smiles at the appearance of his or her father requires biological functioning (the sensation of seeing), cognitive and social functioning (recognition of and feeling attached to a familiar caregiver), and emotional functioning (smiling) (Santrock, 2012). Child development explores not only how these different domains develop but also how their interrelated processes are manifested in milestones associated with each of the early periods of human life. Prenatal development entails the development from a single fertilized egg to

a fetus that is able to function outside the mother's womb. The growth across the approximate 9-month period of time prepares the organism for the life ahead of it. In early childhood, individuals are making rapid strides in autonomy development and gaining self-control, which gets manifested in a variety of milestone achievements, such as potty training and turn-taking (Berk, 2003). Children are also being prepared to enter the formal education system at this time. In middle childhood, children typically enter the formal educational system and attend elementary school. Emphasis in milestone achievement is usually placed on academic ability, with fundamentals such as reading, writing, and basic mathematical skills attained and refined during this time. The social world of children also expands to include more peers and adults beyond family members. Extracurricular activities such as those involving sports and other cultural aspects of society (e.g., dance, music) are often initiated during this time (Santrock, 2012). During adolescence, an emphasis is often placed on the future, with preparation for later education, careers, and relationships being stressed. Increased time is spent with peers away from the family unit in less supervised settings. Increasingly, and across numerous contexts, responsibility is gained, along with enhanced expectations from others for self-reliant behavior and maturity. Rapid biological changes occur as result of pubertal development, which enables the adolescent to become capable of reproduction and leads to changes in social relationships. Self-images become more complex to incorporate sexual and identity development. More influence is sought within family functioning, which necessitates adjustments in how parents and siblings relate to the adolescent (Steinberg, 2011).

Theoretical approaches in child development can adhere to continuous or discontinuous conceptualizations. Continuous approaches cast development as gradually changing across time and experience, while discontinuous approaches cast development as being qualitatively distinct across each life stage. A scenario that illustrates the continuous approach is offered by Berk (2003), who suggested that babies and preschoolers may respond to the world in a manner very similar to how adults respond. That is, a child's thinking may be just as logical and well organized as that of an adult. He or she may demonstrate the ability to successfully sort objects in to different categories (e.g., clothes are separate from toys), show understanding when there are different quantities or amounts present (e.g., more cookies are in the jar than are on the plate), and retain information for long periods of time (e.g., go straight to where the DVDs are stored at grandma's house after not visiting for weeks). However, a child's thinking may be limited by how little experience he or she has had in interacting with the world. From this perspective, a child possesses the same skills as an adult, but has simply not acquired as much information or been able to refine these skills compared to adults. An example of a discontinuous approach to cognitive development includes the theoretical work of Jean Piaget, who emphasized the importance of adaptation to one's environment and increasing organization of knowledge across development (Piaget, 1954). He stated that cognition unfolded in an invariant manner, across four major stages: the sensorimotor period (experiencing the world through senses and actions), the preoperational period (representing things with words and images but lacking logical reasoning), the concrete operational period (thinking logically about concrete events, analogies), and the formal operational period (reasoning abstractly). According to Piaget, cognitive development could be described as occurring consistently across cultures and children were active agents and not merely passive recipients in their own development (Piaget, 1954).

Knowledge of child development is important to the field of behavioral medicine in numerous ways. Knowledge of normal child development can be extremely useful for parents, teachers, and health-care providers – as well as many others – who may encounter and interact with those who manifest diseases and/or deviations from normal development. Knowledge of typical development can aid in detecting and treating atypical development, and enables researchers and clinicians to develop the most appropriate care for children

with acute and chronic medical conditions, while also meeting children's developmental needs. Programs crafted for adult patients to educate or alter behaviors impacting health may not be appropriate for younger patients. Likewise, the effectiveness of health-care treatment of diseases and disorders in childhood can be directly impacted by biological or other developmental processes. For instance, changes in pubertal hormones among adolescents with type 1 diabetes can dysregulate glucose metabolism. By anticipating these biological changes, clinicians may be able to forewarn adolescent patients with type 1 diabetes and their parents and develop possible strategies to minimize deterioration in illness self-management during adolescence (Halvorson, Yasuda, Carpenter, & Kaiserman, 2005).

Child development research can also reveal periods of risk, when primary or secondary prevention efforts may be most effective. Health and health risk behaviors that affect morbidity and mortality in later life are established early in life. For instance, food selection choices (e.g., fast food versus more nutritionally balanced items) and decisions to be physically active may become consistent behaviors during childhood and adolescence. Similarly, high-risk behaviors (e.g., sexual experimentation, tobacco and alcohol use) often become relevant concerns during adolescence (Williams, Holmbeck, & Greenley, 2002). Thus, interventions to promote healthy behaviors and to prevent health risk behaviors may be most effective during childhood and adolescence. Other known periods of risk occur at important developmental transitions such as when rapid autonomy development among adolescents with pediatric conditions may conflict with the efforts of parental or family caregivers. Researchers in behavioral medicine/pediatric psychology have demonstrated the need to consider autonomy in the management of chronic conditions such as spina bifida and type 1 diabetes (Buchbinder, 2009; Friedman, Holmbeck, DeLucia, Jandasek, & Zebracki, 2009). Another period of risk that has gained recent attention for youth with chronic conditions is that of emerging adulthood, the time between late adolescence and the establishment of one's identity as an adult (ages 18–25 years). This transition is risky partially because it involves a transition from a pediatric to an adult health-care system (i.e., pediatrician may treat an individual until he or she is 18; age limits on parents' health insurance policy), which generally needs to be addressed during the earlier adolescent years. Unfortunately, the transition from adolescence to emerging adulthood or young adulthood remains a significant challenge for caregivers and their patients and the health-care system (Huang et al., 2011).

There are numerous professional organizations that support practice and research at the interface of child development and behavioral medicine. The Child and Family Health Special Interest Group of the Society of Behavioral Medicine is an interdisciplinary forum for researchers and clinicians to promote child health and development, prevent childhood illness and injury, and foster family adjustment to chronic illnesses. Other relevant organizations include the Society of Pediatric Psychology (Division 54 of the American Psychological Association), Society for Research on Child Development, Society for Research on Adolescence, and Eunice Kennedy Shriver National Institute of Child Health & Human Development.

Caregiver acts of omission

Definition

Child neglect is defined as acts of omission by a caregiver that include failure to provide for a child's basic physical, emotional, or educational needs and/or failure to protect a child from harm or potential harm (Leeb, Paulozzi, Melanson, Simon, & Arias, 2008). The resultant harm to a child may or may not be the intended consequence of the act of omission, but still represents neglect. Neglect typically consists of a chronic pattern of acts of omission by a caregiver that result in actual or potential harm to a child. However, there are specific singular instances where failure to supervise can result in significant harm to a child (e.g., injury, death).

A caregiver is defined as a person who at the time of the maltreatment is in a permanent (primary caregiver) or temporary (substitute caregiver) role. In a custodial role, the person is responsible for care and control of the child and for the child's overall health and welfare. A primary caregiver lives with the child at least part of the time and can include, but is not limited to, a relative or biological, adoptive, step-, or foster parent(s); a legal guardian(s); or their intimate partner. A substitute caregiver may or may not live with the child and can include coaches, clergy, teachers, relatives, babysitters, residential facility staff, or others who are not the child's primary caregiver(s).

Acts of commission, child abuse, are discussed in a separate entry.

Types

A caregiver's failure to provide a child's basic needs may result in specific types of neglect including: physical neglect, emotional neglect, medical neglect, and educational neglect (Barnett, Manly, & Cicchetti, 1993).

Physical neglect is defined as a caregiver's failure to provide a child adequate nutrition, hygiene, or shelter; or caregiver fails to provide clothing that is adequately clean, appropriate size, or adequate for the weather (Leeb et al., 2008).

Emotional neglect occurs when a caregiver ignores the child or denies emotional responsiveness or adequate access to mental health care

(e.g., pervasive failures by a caregiver to interact with a child that include consistently not responding to infant cries or to an older child's attempts to interact with the caregiver) (Barnett et al., 1993).

Medical neglect includes a failure by a caregiver to provide a child adequate access to medical, vision, and/or dental care, when access to care is available or when a caregiver fails to seek timely medical attention for a child when needed (Leeb et al., 2008). Medical neglect is also indicated when a caregiver fails to follow through with medical recommendations and/or treatment regimens (e.g., not consistently administering prescribed medications to a child), in which the caregiver's failure to follow through may result in harm to the child.

Educational neglect refers to a caregiver's failure to ensure that a child regularly attends school, which results in excessive absences (e.g., 25 or more days in 1 academic year) with no acceptable excuses (e.g., physician's note; Leeb et al., 2008). Educational neglect is also defined as the failure of a caregiver to enroll and maintain a child in school up until the age of 16.

With respect to a child's emotional and developmental level, failure to supervise a child's safety within and outside of the home is categorized as specific types of neglect including inadequate supervision and exposure to violent environments.

Inadequate supervision refers to the failure of a caregiver to ensure that the child engages in safe activities and uses appropriate safety devices so that the child is not exposed to unnecessary hazards and/or that the child is being supervised by an adequate substitute caregiver when the primary caregiver(s) is not available (Leeb et al., 2008). Inadequate supervision can also include circumstances where a caregiver knowingly fails to protect a child from maltreatment perpetrated by another caregiver. Under such conditions, the primary caregiver's behavior would be considered neglectful only if the maltreatment was recognized and allowed to occur. Regardless of the primary caregiver's knowledge of the maltreatment, the substitute caregiver's behaviors would be considered maltreatment.

Exposure to violent environments includes knowingly failing to take appropriate measures to protect a child from being exposed to pervasive violence (e.g., domestic violence) or dangerous conditions (e.g., selling drugs out of the home) within the home, neighborhood, or community (Leeb et al., 2008). Of course, such situations are an ethical challenge for the child protection field because in many circumstances, if one parent is being battered, he or she may be ill equipped and even unable to prevent his or her children from witnessing violence in the home.

Description

Prevalence

The most recent estimates of the prevalence of child abuse and/or neglect indicate that approximately 772,000 children (10.3 per 1,000 children in the population) are substantiated victims annually (USDHHS, 2010). Of the various forms of child abuse and neglect, approximately 552,000 children experience either neglect and/or medical neglect annually. Neglect is the most prevalent form of child maltreatment, with 71% of all substantiated cases of maltreatment being classified as neglect (USDHHS, 2010). However, neglect is often the most difficult form of maltreatment to recognize because physical evidence is rare unless a family's home environment is physically inspected or the neglect has resulted in an injury, specific medical problem (e.g., failure to thrive), or an exacerbated chronic medical condition (e.g., sickle cell disease).

Etiology and Sequelae

It is clear that no singular risk factor can adequately explain why children are neglected. Rather, a combination of individual, relational, community, and societal factors contributes to the risk of a child being neglected (Centers for Disease Control and Prevention, 2009; Cicchetti & Lynch, 1993; Erickson & Egeland, 2011). Although children are not responsible for caregivers' neglectful behaviors, certain characteristics have been found to increase their risk of being neglected (Centers for Disease Control

and Prevention, 2009). Child factors that increase vulnerability for neglect include being younger than 4 years old and having special needs (e.g., developmental disabilities, chronic medical conditions). A number of caregiver-specific risk factors contribute to an increased risk for the perpetration of neglect, including caregiver poor prenatal and postnatal medical care, a caregiver's lack of understanding of child development and parenting skills, lack of parental nurturance, substance abuse, caregiver mental health issues, poor parent-child relationships, and parenting stress (Stith et al., 2009). Other caregiver characteristics such as the caregiver's own history of maltreatment as a child, young age, low education, single caregiver household, and a large number of dependent children all have been linked to increased risk of child neglect. Other risk factors include low family income, poor social connections and support, family conflict and violence (e.g., intimate partner violence), community violence, and concentrated neighborhood disadvantage (e.g., high poverty and residential instability, high unemployment rates).

Child neglect has been found to have serious negative implications on children's cognitive, physical, and socioemotional development. However, the consequences of individual cases of child neglect vary and are impacted by a combination of factors, including the child's age and developmental status when neglected; the types of abuse and/or neglect experienced; the frequency, duration, and severity of the neglect; and the relationship of the perpetrator to the victim child (English et al., 2005; Chalk, Gibbons, & Scarupa, 2002). If children's needs for physical touch, emotional attachment to a caregiver, and caregiver-child interactions are neglected during infancy or early childhood, long-term consequences have been found in children's cognitive and socioemotional development. Research on neglected infants has demonstrated reduced brain wave activity and enlarged brain ventricles due to decreased brain growth (Perry, 1997, 2002). Neglected infants and young children are at increased risk for developmental delays, expressive and receptive language problems, decreased positive affect, emotion regulation difficulties, impulse control problems, physical aggression, noncompliance, anxious attachment to their caregivers, restricted positive views of the self, and social withdrawal (Dubowitz, Papas, Black, & Starr, 2002; Hildyard & Wolfe, 2002). Many of the problems observed in children who are neglected in early childhood remain in school-aged children including continued cognitive problems (e.g., poor performance on academic achievement tests and increased referrals for special education services), negative mental representations of the self and others, avoidance of peer interactions, limited social skills, and an increased prevalence of internalizing problems (e.g., depression, anxiety, peer rejection).

The effects of child neglect have also been implicated in adult functioning. Adults who have experienced neglect as a child are at increased risk for psychiatric disorders, substance abuse, violent behaviors, and intimate partner violence (Erickson & Egeland, 2011; Horwitz, Widom, McLaughlin, & White, 2001; Mersky & Reynolds, 2007; White & Widom, 2003; Widom, Marmorstein, & White, 2006).

Definition

Cholesterol is a steroid. It is essential to the proper functioning of cell membranes and the synthesis of many hormones critical to normal physiologic processes and health. When cholesterol is manufactured primarily by the liver, and to a lesser degree by the intestines and other cells in the body it is known as *endogenous*

cholesterol. On the other hand, cholesterol which one consumes and is absorbed into the blood stream via the gastrointestinal tract is known as *exogenous cholesterol*.

Description

Despite the essential role cholesterol plays in cell wall permeability and the synthesis of steroid hormones excessive amounts of circulating cholesterol and the low-density lipoprotein (LDL) subfraction of total cholesterol have been associated with an increase in cardiovascular morbidity and mortality. This increase in morbidity and mortality is likely related to the development of atherosclerosis, a disease of the large and intermediate arteries where plaques form on the lining of the artery. At some point the plaques may obstruct or at least impede the flow of blood through the vessel. High-density lipoprotein (HDL) subfraction of total cholesterol protects against the development of atherosclerosis by a less well-understood mechanism.

Clinical trials support the hypothesis that aggressive lowering of the LDL subfraction of cholesterol reduces CHD risk. Lifestyle modifications that include losing weight, reducing saturated fats and the intake of exogenous cholesterol, and increased physical activity can reduce the LDL subfraction in healthy as well as chronically ill populations; however, adherence to long-term dietary changes and increased physical activity can be difficult. If efforts to reduce LDL cholesterol using only lifestyle modification do not reduce LDL sufficiently, drug therapy should be considered. Efforts to reduce CHD risk by raising the HDL subfraction are not as promising.

The *Executive Summary of the Third Report of the National Cholesterol Education Program (NCEP) Expert Panel of Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults (Adult Treatment Panel III or ATP III)* provides an update of the panel's earlier clinical guidelines (ATP I and ATP II) for cholesterol testing and measurement. ATP I presented an approach to primary prevention of coronary heart disease (CHD) in persons with high LDL ($\geq$160 mg/dL) or borderline high LDL (130–159 mg/dL) and multiple risk factors. ATP II set a new optimal LDL level of $\leq$100 mg/dL for people with CHD. ATP III focuses on intensive LDL reduction in those with multiple risk factors.

Chromosomes

Definition

Chromosomes are self-replicating structures found within cells, containing and organizing cellular DNA. The DNA contains the nucleotide base sequence encoding the hereditary genetic information. In most *prokaryotes*, the entire genome is carried on a single circular strand of DNA comprising one chromosome. In e*ukaryotic* cells (cells with a nucleus), the genome is organized across multiple chromosomes.

Each eukaryotic organism has its own specific number of chromosomes. Humans are diploid and have 23 pairs of chromosomes: one set of two sex chromosomes and 22 pairs of autosomal chromosomes for a total of 46 chromosomes. Not surprisingly, given their name, sex chromosomes determine sex. Females have two X chromosomes, and males an X and a Y chromosome. Humans are diploid, which means that they have two copies of each chromosome. Other species have different numbers. In humans, autosomal chromosomes are identified by the numbers 1 through 22.

Chromosomes can be seen under a light microscope and individual chromosomes can be differentiated using special stains to band the chromosomes based on A/T vs. G/C content. The staining pattern results in a chromosome-specific karyotype, which was used in early genetic studies to identify major chromosomal abnormalities (loss/extra chromosomes, translocations, deletions, and breaks) associated with disease. For example, Down's syndrome, a genetic condition that causes physical and cognitive impairment, can be diagnosed via karyotyping to identify trisomy 21, the presence of three copies of chromosome 21 (Korenberg et al., 1994). However, most genetic variance occurs at a much smaller scale, at individual nucleotides such as in single nucleotide polymorphism (SNP) or groups of nucleotides, in microsatellites, and insertions-deletions.

Chronic Depression

Definition

Depression is a negative mood state that is generally characterized by feelings of sadness, discouragement, and hopelessness (American Psychiatric Association, 2000). Brief or transient feelings of depression (i.e., feelings lasting several minutes to several hours) are relatively common and are likely to be experienced by just about everyone at some point in their lives. However, more chronic forms of depression are less common and may be associated with significant interpersonal difficulties and functional impairments.

There now exist widely accepted, standardized diagnostic criteria that distinguish "normal" from "abnormal" forms of depression, the latter of which have been classified as "mood disorders" in the Diagnostic and Statistical Manual of Mental Disorders-4th Edition Revised

(DSM-IV-R) (American Psychiatric Association, 2000). Although chronic depression has been classified as a "mood disorder," it is important to recognize that mood disorders, which include such disorders as major and minor depressive disorder, dysthymia, cyclothymia, and bipolar disorders, actually represent syndromes, which are clusters of symptoms, only one of which is an abnormality of mood. However, chronic forms of depression also feature *vegetative* symptoms, including sleep, appetite, weight, and libido disturbances; *cognitive* symptoms, including decreased ability to concentrate, memory disturbances, decreased frustration tolerance, low self-esteem, and cognitive distortions; *impulse control* symptoms such as suicidal behavior; *behavioral* symptoms, including decreased motivation and interest in engaging in pleasurable activities, decreased ability to feel pleasure, and decreased energy; and *somatic* symptoms, including increased psychomotor agitation, nonspecific aches and pains, and headaches.

Chronic depression is a major cause of morbidity worldwide and represents the 4th most important contributor to the global burden of disease, accounting for 4.4% of all cases of premature mortality (Kastrup & Ramos, 2007). Lifetime prevalence rates of chronic depression vary greatly according to geographical location, with the lowest rates found in Japan (3%) and the highest rates found in the United States (17%) (Kessler, Chiu, Demler, & Walters, 2005; Kessler, Demler, Frank et al., 2005; WHO, 2001; Andrade & Caraveo, 2003; Kessler, Beglund & Demler, 2003; Kessler, Berglund, Demler, Jin, Merikangas, & Walters, 2005; Murphy, Laird, Monson, Sobol, & Leighton, 2000). On average, most countries report an average lifetime prevalence of about 10% (WHO, 2001; Andrade & Caraveo, 2003). Population studies have consistently shown major depressive disorder to be about twice as common among women relative to men, though the reasons for this remain unclear. The peak age of onset of major depressive disorder is between 20 and 40 years and is 1.5 to three times more prevalent among individuals with first degree relatives with a history of depression (American Psychiatric Association, 2000; Kessler et al., 2005).

The most common, widely accepted, and empirically validated treatments for chronic depression include pharmacotherapy (e.g., antidepressant medications including selective serotonin reuptake inhibitors [SSRIs] or selective serotonin and norepinephrine reuptake inhibitors [SSNRIs]), psychotherapy (e.g., cognitive-behavioral therapy [CBT] and interpersonal therapy [IPT]), or some combination of the two (American Psychiatric Association, 2000; Kessler, Demler et al., 2005). However, most major depressive episodes resolve spontaneously over time, irrespective of whether or not they are treated. The ▶ median duration of a major depressive episode has been estimated to be about 23 weeks, with the highest rates of recovery occurring within the first 3 months (Posternak, Solomon & Leo, 2006; Fava, Park, & Sonino, 2006). Research has shown that 80% of those suffering from their first major depressive episode will suffer from at least one more over the course of their life, averaging four episodes over their lifetime. However, the morbidity associated with *untreated* chronic depression has been compared to that of coronary artery disease, with mortality due to suicide affecting 30,000–35,000 individuals each year (Posternak et al., 2006). There are also enormous personal and societal costs associated with chronic depression, including higher rates of chronic illness (e.g., cardiovascular disease), decreased productivity, absenteeism and job loss, substance abuse, family dysfunction, and reduced overall quality of life (American Psychiatric Association, 2000; Posternak et al., 2006).

Definition

Chronic disease management refers to a variety of models to improve patient care for individuals affected by chronic disease.

Description

Chronic diseases typically require ongoing medical care and may limit activities of daily living. Examples include diabetes, hypertension, heart diseases, mood disorders, and asthma. Chronic diseases impact all countries, with increasing prevalence due to several factors (e.g., increased life expectancy, treatment advances, and changes in lifestyle behaviors; Singh, 2008). In the USA, over 40% of the population is living with at least one chronic disease (Centers for Disease Control and Prevention [CDCP], 2010). Historically, primary care practices were designed for the provision of acute care. In contrast, patients with chronic diseases typically require long-term treatment planning, symptom management, and regular follow-up with providers.

Chronic Disease Management Models

There is no single optimal approach to chronic disease management. Common components of chronic disease management models include care coordination across medical disciplines; regular monitoring and medication management; and tools to increase patients' self-efficacy for managing the daily challenges of their disease(s). Several strategies have been suggested to be both effective and applicable in patient care settings, including those with limited resources. Examples include tools for self-care (e.g., patient education), information collection (e.g., screening tools and disease registries), and service provision in community settings (Singh, 2008). A primary goal of most models is to help individuals become informed and active participants in their disease management, to reduce the duration and/or severity of disease-related disability. Mental health care is an important part of this process, as mental health problems such as depression can present significant barriers to patient self-care.

Current Approaches to Chronic Disease Management

Chronic disease management is an increasingly popular term used in health care policy and industry communications as a reference point for both cost containment and quality improvement. Current chronic disease management programs include both targeted models which focus on case management for patients who account for the most medical care utilization, and broader approaches which are based on assumptions that all chronically ill patients may benefit from regular assessment and tools for promoting self-care. Some programs are carved out to commercial vendors whereas others are integrated within managed care institutions. There are wide variations in program quality, content, type of communication with patients, and extent to which physician practices are involved.

Challenges of Patient Care

Meeting the needs of chronically ill patients is one of the greatest challenges facing current healthcare systems. The 2001 Institute of Medicine report, "Crossing the Quality Chasm: A New Health System for the 21st Century," emphasized that enduring improvements in disease management require multi-level changes to the environment in which healthcare organizations and providers function (Institute of Medicine [IOM], 2001). To date, healthcare delivery is complex and largely fragmented, with implications for care quality, efficiency, and safety. Several factors have been suggested to facilitate chronic disease management practices within existing primary care systems. These include practice reorganization to support regular follow-up appointments; incorporation of empirically supported strategies for enhancing patient self-care; and provider education, provider incentives, and information technology to support changes.

Chronic Disease or Illness

Tyler Clark
School of Psychology, The University of Sydney, Sydney, NSW, Australia

Definition

Chronic disease or illness is any disease or illness which is both long lasting and permanent. Chronic diseases normally cannot be prevented through vaccination nor are they curable through either medicine or time. For a disease to be classified as chronic, it must persist for a minimum of 6 weeks.

Description

Chronic diseases or illnesses are the leading cause of mortality in the world and are estimated by the WHO to represent 60% of all deaths (World Health Organization [WHO], 2010). Chronic diseases are mostly characterized by complex causality, multiple risk factors, long latency periods, a prolonged course of illness, and functional impairment or disability (Pencheon, Guest, Melzer & Gray, 2006). While the term chronic disease technically incorporates all long-lasting, permanent diseases, classification confusion may arise for diseases such as herpes zoster or seasonal asthma, which occur intermittently throughout the lifespan and fulfill

the technical requirements of the definition, but are typically categorized with those diseases which are not permanent, but fail to resolve and respond to treatment, such as chronic bronchitis (Last, 2007). Ten major chronic diseases include:

- Coronary heart disease
- Stroke
- Hypertension
- Hypothyroidism
- Diabetes
- Mental health problems
- Chronic obstructive pulmonary disease
- Asthma
- Epilepsy
- Cancer

The prevalence of chronic diseases increases across the lifespan and is often comorbid with other chronic diseases, with the average person aged >65 years having more than one chronic disease. Chronic disease is prevalent in both wealthy and poor countries, but is correlated with low socioeconomic status. The chronically ill constitutes an extremely large percent of home care visits, as much as 90% in the United States, as well as the majority of prescription drug use, days spent in hospital, doctor visits, and hospital emergency room admittance.

As chronic diseases persevere throughout the lifespan, they are accompanied by a high burden of disease: a measure of potential years lost, quality of life lost, and disability attributed to a disease (Broemeling, Watson, & Black, 2005). This burden of disease may include financial costs of chronic disease as well, such as the primary and tertiary health care costs of disease management and loss of workforce participation.

Risk Factors

Risk factors for chronic diseases such as coronary heart disease, stroke, and certain cancers include high cholesterol, high blood pressure, and low fruit and vegetable intake (MedicineNet.com, 2004). Chronic disease development is also associated with physical inactivity, obesity, alcohol, and tobacco use. Risk factors often co-occur and can operate synergistically, as well as with some psychosocial factors (e.g., hostility and family history; Gidron, Berger, Lugasi, & Ilia, 2002).

Chronic Disease Management

Chronic diseases exist across the lifespan and require long-term treatment and support. Treatment therefore focuses on disease management, which serves to decrease the duration or severity of impairment and disability associated with the disease. This management manifests in a variety of forms including but not limited to occupational or physical therapy and rehabilitation, psychological counseling and stress management, and self-management strategies, depending on the type and severity of the chronic disease. Many governments provide assistance or financial incentive programs to individuals with qualifying disabilities.

Chronic disease may have psychological and emotional ramifications such as denial, anxiety, and depression following diagnosis not only for the affected individual, but for family and friends as well, and these consequences may also affect prognosis. As a result, much effort in behavior medicine has focused on developing adaptive strategies for coping with chronic diseases.

Chronic Fatigue Syndrome

Urs M. Nater
Department of Psychology, University of Marburg, Marburg, Germany

Definition

Chronic fatigue syndrome (CFS) is defined by unexplained disabling fatigue of at least 6 months duration, accompanied by at least four out of eight of the following symptoms: impaired memory or concentration, sore throat, tender glands, aching or stiff muscles, multijoint pain, new headaches, unrefreshing sleep, and postexertional fatigue.

Description

Chronic fatigue syndrome (CFS) is a complex illness defined by unexplained disabling fatigue as its core feature and a combination of other accompanying symptoms, such as diffuse pain, subjective cognitive impairment, and sleep problems. The first formal case definition of the illness was published in the USA in 1988 (Holmes et al., 1988). In 1994, an international collaborative group published the current CFS research case definition (Fukuda et al., 1994). The 1994 case definition requires at least 6 months of persistent fatigue; this fatigue cannot be substantially alleviated by rest, is not the result of ongoing exertion, and is associated with substantial reductions in occupational, social, and personal activities. In addition, at least four out of eight of the following symptoms must occur with fatigue in a 6-month period: impaired memory or concentration, sore throat, tender glands, aching or stiff muscles, multijoint pain, new headaches, unrefreshing sleep, and postexertional fatigue. Medical conditions that may explain the prolonged fatigue as well as a number of psychiatric diagnoses exclude a patient from the diagnosis of chronic fatigue syndrome (Reeves et al., 2003). Consequently, a thorough medical history and physical assessment is required before the diagnosis can be formally established.

Comorbidity

There is a considerable overlap between CFS and psychiatric disorders. Recent data indicate that almost 60% of CFS cases in the population suffer from at least one comorbid psychiatric condition (Nater et al., 2009). Consistent with the fact that fatigue is a common symptom in depressive disorders, a substantial overlap in diagnoses of CFS and depression has been reported. However, there are also distinct symptoms, such as suicidal ideation, which are not more frequently present in CFS patients than in the general population. There are many patients with CFS who do not meet the current criteria for any other psychiatric disorder, indicating that CFS is not merely a psychiatric epiphenomenon.

Chronic fatigue syndrome often co-occurs with other medically unexplained syndromes such as fibromyalgia or irritable bowel syndrome. These disorders have in common with CFS the fact that they are defined as disorders that, after appropriate medical assessment, cannot be explained in terms of a conventionally defined medical disease (Barsky & Borus, 1999).

Taken together, CFS co-occurs and shares core symptoms with a variety of conditions, suggesting that similar pathways may be involved in the etiology and development of these pathological states.

Prevalence

Chronic fatigue syndrome is relatively common in the community, in primary care, and in hospital settings. The overall prevalence of CFS in the general population is reported to be between 0.1% and 2.5%. Prevalence rates vary significantly across studies, probably as a result of differences in diagnostic criteria and design. It is estimated that 2.2 million Americans suffer with CFS and that the disorder is more common in rural than urban populations (Bierl et al., 2004). Rates for CFS in primary care are higher than rates seen in the general population. Large community-based epidemiological studies in the USA indicate that CFS is equally or more common in African Americans, Hispanics and Native Americans, and in individuals who make less than $40,000 per year. However, in all these groups women are two to four times more likely than men to have CFS.

Pathophysiology

The pathophysiology of CFS is complex and far from being fully understood. Despite mixed findings in the vast literature of potential pathophysiological processes in CFS, tentative conclusions can be drawn concerning physiological systems that may be abnormal in at least some patients. It is important to remember, however, that it remains unknown whether any given abnormality represents a cause or a consequence of CFS.

Early etiological theories of the disorder focused on the immune system and infection with Epstein Barr and other latent viruses. Although cases of CFS may follow such infections, most studies have shown that infections are not a primary cause for the disorder.

A variety of immune system abnormalities have also been reported, including decreases in natural killer cell activity and increases in proinflammatory cytokines (Lorusso et al., 2009). Cytokines, such as IL-6 and TNF-alpha, have been implicated in the pathogenesis of fatigue and somnolence. Specifically, IL-6 participates in the pathogenesis of excessive daytime somnolence and post-exertional fatigue. In addition, alterations in the gene expression involved in immunity have been detected. Thus, immune factors seem to play an important role in CFS, although the exact mechanisms have not been fully established yet.

Patients with CFS also may have decreased functioning of the hypothalamic-pituitary-adrenal (HPA) axis, one of the body's primary stress response systems, which is also contributing to the peripheral and central causes of chronic pain and fatigue. Several studies report decreased levels of circulating cortisol and decreased adrenocortical reserve. This alteration may be associated with several symptoms typical for CFS, including fatigue, arthralgia, myalgia, exacerbation of allergic responses, feverishness, and changes in mood, cognition, and sleep. Cortisol exerts inhibitory effects on the secretion of cytokines, including IL-6, and helps return these cytokines to baseline levels after stress. Thus, alterations in the immune system have an impact on the endocrine system, and vice versa. In addition to decreased functioning, the HPA axis has also been reported to lose its normal diurnal rhythm in CFS patients (Nater et al., 2008). Clinical improvement has been associated with the normalization of this diurnal rhythm. The overall picture may be summarized as a relative hypoactivity of the HPA axis in CFS patients (Cleare, 2003).

It has been reported that abnormal autonomic nervous system (ANS) functioning may be common in patients with CFS, based on the fact that CFS includes typical autonomic symptoms, such as disabling fatigue, dizziness, diminished concentration, tremulousness, and nausea, and that at least some CFS patients demonstrate orthostatic intolerance when subjected to tilt table testing. Conversely, patients with postural orthostatic intolerance syndrome often manifest symptoms similar to those seen in CFS. Whereas there is some evidence for involvement of altered ANS functioning, it needs to be noted that some CFS symptoms, such as sore throat, myalgias, and

cognitive alterations, cannot be attributed to dysautonomia.

Also, studies of the central nervous system (CNS) in CFS have examined both structural and functional alterations. Various studies have pointed to subtle morphological changes in CFS, although these changes might not be specific for CFS. Functional studies have found potential explanations for some of the motor and cognitive dysfunctions typically described in CFS.

Finally, psychological and stress-related factors have been associated with CFS. Some authors consider CFS as the consequence of dysfunctional cognitive styles and maladaptive coping strategies. Many patients report an increase in life stress in the year prior to disease development. Recent findings from a prospective study indicated that stress levels prior to manifestation of CFS predicted the risk for developing CFS (Kato, Sullivan, Evengard, & Pedersen, 2006). In addition, adverse experiences early in life increased the risk of developing CFS in adulthood manifold and resulted in the above-mentioned hypoactivity of the endocrine stress system (Heim et al., 2009). Thus, stressful experiences seem to play an important role in triggering CFS symptoms. However, it is likely that stress interacts with other vulnerability factors. Ongoing or acute stressors might elicit physiological changes in the predisposed body, ultimately leading to pathophysiological changes associated with CFS.

Treatment

Numerous treatments have been applied to CFS patients with various results. Those with the best experimental data to support efficacy include graded exercise training and cognitive behavioral therapy (CBT) (White et al., 2011). CBT strategies for CFS typically involve organizing activity and rest cycles, initiating graded increases in activity, establishing a consistent sleep regimen, and attempting to restructure beliefs around self, as well as disease attributions (Malouff, Thorsteinsson, Rooke, Bhullar, & Schutte, 2008). Also, low dose corticosteroids have been reported to improve symptoms in two studies. However, these positive findings could not be replicated. Trials of antidepressants have yielded an equally confusing mix of positive and negative results, but in general these agents appear to be significantly less effective for CFS than for depression or anxiety disorders.

Definition

Chronic obstructive pulmonary disease (COPD), one of the leading causes of morbidity and mortality worldwide, is a chronic disease of the lung that is characterized by decreased air flow and associated abnormal inflammation of the lungs. The disease results from interaction between individual risk factors (like alpha1-antitrypsin deficiencies) and environmental exposures to toxic agents (like cigarette smoking). The main mechanisms that may contribute to airflow limitation in COPD are fixed narrowing of small airways, emphysema, and luminal obstruction with mucus secretions (American Thoracic Society, 1995; Global Initiative for Chronic Obstructive Lung Disease (GOLD), 2006; The COPD Guidelines Group of the Standards of Care Committee of the BTS Thorax 1997; Petty & Nett, 2001).

The definition does not use the terms chronic bronchitis and emphysema, although most patients with COPD have them. Chronic bronchitis is diagnosed based on the clinical presentation, such as a chronic cough and sputum production. The diagnosis of emphysema, which is the term used to describe damage to the air sacs in the lung, is made from a pathological and/or morphological standpoint.

The respiratory symptoms of COPD are dyspnea, chronic cough, and sputum production. The dyspnea may initially be noticed only during exertion. Patients with a COPD exacerbation complain of increased cough and sputum, wheezing, and dyspnea, with or without fever.

Most patients with COPD have a history of cigarette smoking or other inhalant exposure. Therefore, when a person with a history of exposure to risk factors, especially smoke, has dyspnea, chronic cough, and sputum production, a diagnosis of COPD should be considered. Measurements of lung function are essential for the diagnosis of COPD. It is also used to determine the severity of the airflow obstruction and follow disease progression. Spirometry measures forced vital capacity (FVC) and forced expiratory volume in 1 s (FEV1.0). An FEV1.0/FVC ratio less than 70% generally indicates airway obstruction.

The overall goals of treatment of COPD are to prevent further deterioration in respiratory function, relieve symptoms, improve quality of life, and reduce mortality (Global Initiative for Chronic Obstructive Lung Disease (GOLD), 2006).

First of all, reduction of risk factors is needed. All COPD patients with smoking habit should be encouraged to quit smoking. Even a few minutes counseling could be effective. Pharmacotherapy, such as nicotine replacement and varenicline, is also recommended. Preventive care is also very important, and all patients should be recommended to get an immunization, including influenza and pneumococcal vaccines.

The mainstay drugs of COPD are bronchodilators, and inhaled therapy is preferred. Beta agonists, anticholinergics, and methylxanthines are given alone or in combination depending upon the severity of disease and each patient's individual response to therapy. Inhaled glucocorticoids can reduce the frequency of the acute exacerbation, although it cannot improve lung function. Systemic glucocorticoids are not recommended for a long-time treatment. Mucolytic drugs might be beneficial for selected patients.

Non-pharmacological treatment is equally important for managing COPD. It includes pulmonary rehabilitation and oxygen administration. Pulmonary rehabilitation has been shown to improve exercise capacity, decrease dyspnea, and improve quality of life and should be considered as an addition to medication therapy for the patients at all stages of disease. Long-term oxygen therapy improves survival and quality of life in the patients with hypoxemia.

Definition

Chronic pain is typically defined as pain that continues in excess of 3–6 months regardless of the cause of the pain. Less commonly, chronic pain is defined as pain that persists beyond the point of any possible healing or any other useful function such as the enforcement of rest.

Description

Major advances in the understanding of pain began with the observations of the physician Henry Beecher during World War 2. Beecher noted that seriously wounded soldiers brought from the front line requested less-pain medicine

and reported less pain than he was used to seeing in his civilian patients. Beecher inferred that pain is not simply a response to physical injury or disease but also includes a cognitive and emotional component. Twenty years later, Canadian psychologist Ronald Melzack and British physiologist Patrick Wall published their gate control theory. Gate theory proposed that noxious and non-noxious sensory information interact in the spinal cord with descending influence from the brain. The theory explains pain experience as dependent upon that interaction rather than just the strength of a noxious stimulus. The precise details of the theory are less important than the dramatic impact gate control had on the understanding of pain. Gate control theory ended simplistic ideas of pain based on an isolated dedicated pathway from the periphery to the brain. It provided the first plausible physiological explanations for the influence of psychological states on pain experience through a brain-spinal cord loop. Most importantly, gate control theory shifted attention away from the stimulus and toward the spinal cord, brain, and the subjective experience of pain. After the gate it became increasingly apparent that pain cannot be reliably judged based upon an objective measure of injury or receptor activation and so assessment of pain requires subjective report – the "what it is like" to be in pain.

The shift in focus away from the noxious stimulus that triggers pain and toward the psychological experience of pain was particularly important for the understanding of chronic pain. Chronic pain conditions are often characterized by the lack of a stimulus that can explain the pain. Patients with phantom limb pain, for example, feel pain in a limb that has been amputated. Patients with causalgia suffer severe burning pain at a site of injury long after the injury has healed. Even in diseases where there is an ongoing trauma, such as patients with cancer or arthritis, the pain is typically difficult to predict based on objective measures of disease activity and continues beyond any period when cessation of activity and rest might facilitate healing. Thus, the understanding of chronic pain is not helped by a focus on injury or disease but by a focus on the experience of pain. Chronic, persistent pain is a distinct medical entity, syndrome, or disease in its own right, but it is not a disease that can be defined by objective markers such as provided by X-rays or histological tests; chronic pain is a disease defined by the subjective experience of pain. In short, chronic pain is a problem because it feels bad.

This understanding of chronic pain is further reflected in the international association for the study of pain (IASP) definition of pain, which states that pain is "an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage… pain is always subjective. Each individual learns the application of the word through experiences related to injury in early life." This definition recognizes a number of important facts about pain: (1) It is a multidimensional experience. (2) It is subjective. (3) It may or may not be associated with tissue damage.

The somewhat complex understanding of pain provided by the IASP is perhaps not especially important when considering acute pain. If someone hits their hand with a hammer, it is patently obvious that the pain was caused by the hammer and it is reasonable to assume that the pain will subside once the injury heals. Although it may be theoretically correct to point out that the pain is in the patient's mind, not their hand, and that the experience derives from psychology, and not the hammer, such points would be overly pedantic. When faced with an obvious injury it is reasonable to depersonalize the experience as a consequence of external forces, which rapidly lose their influence with healing. For patients with chronic pain, however, there is either no external force to blame or the external force never loses its influence. Either way, the experience is deeply personal and subjective.

The personal and subjective nature of chronic pain makes treatment difficult. Traditional treatment approaches involving periods of rest and analgesic medication use are typically unsuccessful in resolving chronic pain. Physicians and patients can easily become disillusioned when multiple treatments, used sequentially or in combination, fail to provide pain relief. In many

cases, physicians are left frustrated and patients dissatisfied with chronic, unremitting symptoms. Treatment approaches that focus on the patient's experience, what they feel and how they manage their feelings, are usually more successful. Cognitive behavioral therapy, for example, aims to modify the reciprocal relationships between sensation, cognition, emotion, and behavior so as to improve mood and decrease the disability associated with the pain. Cognitive behavioral therapy emphasizes the teaching of coping skills and the active role patients have in modifying how they think, feel, and believe. The aim is to reduce the negative impact of their pain even if the pain itself is not directly reduced.

Among adults, the prevalence of chronic pain where an identifying cause is difficult to find ranges between 2% and 40% depending on the study. Unsurprisingly, chronic pain substantially reduces quality of life and also generates considerable costs. In the Netherlands, for example, the cost of back pain alone equals 1.7% of the gross national product and in the UK, back pain results in the loss of over 150 million workdays annually. There is also evidence that the problem may be increasing. In the USA, the rate of disability claims associated with low back pain has increased over the rate of population growth by 1,400% since the early 1970s. Understanding chronic pain so as to address this increase and provide better treatments remains a considerable challenge.

Intervention approaches to improve function and promote successful adaptation to chronic pain.

Description

This entry briefly reviews non-pharmacological approaches to the management of pain-related health conditions and pain-related disability. The review is selective as opposed to exhaustive, with emphasis on interventions that have been systematically evaluated. Where possible, references to clinical manuals are provided for readers who are interested in learning more about the specific intervention techniques described.

Psychological Treatment of Pain

By the mid-1960s, mounting clinical and scientific evidence was calling for a model of pain that would consider both the physiological and psychological mechanisms involved in pain perception. The call was most compellingly answered by Melzack and Wall's gate control theory of pain. From an applied perspective, the work of Melzack and Wall evolved into behavioral conceptualizations of pain (Fordyce, Fowler, Lehmann, & De Lateur, 1968), contributing ultimately to the development of biopsychosocial models of pain (Gatchel, Peng, Peters, Fuchs, & Turk, 2007). Biopsychosocial models propose that a complete understanding of pain experience and pain-related outcomes requires consideration of physical, psychological, and social factors (Gatchel et al., 2007).

Behavioral/Operant Programs

The first programs that specifically targeted the psychological aspects of pain-related disability were based on the view that pain-related disability was a form of "behavior" that was maintained by reinforcement contingencies. In the 1960s and 1970s, Wilbert Fordyce and his colleagues applied the concepts of learning theory to the problem of chronic pain (Fordyce et al., 1968; Fordyce, 1976). The focus of Fordyce's approach to treatment was not on reducing the experience of pain but on reducing the overt display of pain. The targets selected for treatment were pain behaviors such as distress vocalizations, facial grimacing, limping, guarding, medication intake, activity withdrawal, and activity avoidance.

The first behavioral approaches to the management of pain and disability were conducted within inpatient settings that permitted systematic observation of pain behaviors, as well control over environmental contingencies influencing pain behavior (Fordyce, 1976). Staff were trained to monitor pain behavior and to selectively reinforce "well behaviors" and selectively ignore "pain behaviors." Results of several studies revealed that the manipulation of reinforcement contingencies could exert powerful influence on the frequency of display of pain behaviors (Fordyce, Roberts, & Sternbach, 1985). The manipulation of reinforcement contingencies was also applied to other domains of pain-related behavior and shown to be effective in reducing medication intake, reducing downtime and maximizing participation in goal-directed activity.

A number of clinical trials on the efficacy of behavioral treatments for the reduction of pain and disability yielded positive findings (Sanders, 1996). However, given the significant resources required to implement contingency management interventions, issues concerning the cost-efficacy of behavioral therapy for pain and disability were raised. Concern was also raised over the maintenance of treatment gains since reinforcement contingencies outside the clinic setting could not be readily controlled. In order to increase access and reduce costs, behavioral treatments were modified to permit their administration on an outpatient basis. This change in delivery format compromised to some degree the control over environmental contingencies and required greater reliance on self-monitoring and self-report measures (Sanders, 1996).

Back Schools

Although back schools were first developed in the late 1960s, the first published reports of the benefits of "back schools" only appeared in the literature in the early 1980s (Zachrisson-Forsell, 1981). The structure and content of back schools reflected the prevailing view of the time that "information" or "knowledge" could be powerful tools to effect change in behavior (e.g., pain-related disability) (Heymans, van Tulder, Esmail, Bombardier, & Koes, 2004).

Back schools vary widely in terms of content, duration, and the intervention disciplines used to administer the program. The duration of back school interventions has ranged from a single information session to a 2-month inpatient program. Back school interventions have tended to use group formats with a didactic format where participants might be exposed to information about biomechanics, posture, ergonomics, exercises, nutrition, weight loss, attitudes, beliefs, and coping. As a function of the type of information being provided, the interventionist might be a physician, physiotherapist, occupational therapist, nurse, or psychologist (Linton & Kamwendo, 1987).

A recent review of randomized clinical trials of back school programs concluded that (a) back schools yielded benefit relative to treatment-as-usual interventions, (b) the treatment effect size was small, and (c) that back school programs implemented within occupational settings appeared to yield the most positive outcomes (Heymans, van Tulder, Esmail, Bombardier, & Koes, 2005).

Cognitive-Behavioral Programs

Cognitive-behavioral programs for the management of pain and pain-related disability began to appear in the 1980s (Turk, Meichenbaum, & Genest, 1983). CBT programs incorporated concepts drawn from earlier behavioral approaches as well as information-based approaches used in

back schools. The objective of many CBT programs is to equip individuals with the psychological "tools" necessary to adequately meet challenges of persistent pain (Turk et al., 1983).

Cognitive-behavioral interventions are currently considered the psychological treatment of choice for individuals coping with chronic pain and disability, (Gatchel et al., 2007). A number of clinical trials have demonstrated that these types of interventions can lead to clinically significant decreases in pain and emotional distress (Williams et al., 1996).

It is important to note that the term cognitive behavioral does not refer to a specific intervention but, rather, to a class of intervention strategies. The strategies included under the heading of cognitive-behavioral interventions vary widely and may include self-instruction (e.g., motivational self-talk), relaxation or biofeedback, developing coping strategies (e.g., distraction, imagery), increasing assertiveness, minimizing negative or self-defeating thoughts, changing maladaptive beliefs about pain, and goal setting (Turk et al., 1983). A client referred for cognitive-behavioral intervention may be exposed to varying selections of these strategies. The goals of CBT programs might also differ across settings and may include pain reduction, distress reduction, increased activity involvement, or return to work (Gatchel et al., 2007).

Stress Management Programs

Stress management programs represent a special case of cognitive-behavioral intervention. Stress management programs proceed from the view that, unless properly managed, chronic stresses can lead to a depletion of the individual's physical and psychological resources and, in turn, increase the individual's susceptibility to physical or psychological dysfunction (Lazarus & Folkman, 1984). Stress management approaches are considered separately from cognitive-behavioral pain management programs since the focus of stress management programs is not necessarily on managing pain symptoms or disability. Furthermore, while CBT programs are typically used for individuals who are work-disabled due to their pain condition, stress management programs have been used as preventive interventions for individuals who are experiencing symptoms of persistent pain but are still working. The primary focus of stress management interventions might be on stresses within the workplace or the individual's personal stresses (Feuerstein et al., 2004).

Problem-solving therapy is a variant of stress management programs that has recently been applied to individuals who are work-disabled due to musculoskeletal pain conditions (D'Zurilla, 1990; Smeets et al., 2008). Problem-solving therapy proceeds from the view that life stresses can be minimized if the individual is able to use appropriate problem-solving strategies to deal with difficult situations that might be encountered at the work place or in daily life. Problem-solving intervention programs will typically span several weeks (8–10 weeks) and might involve didactic lectures, group discussion, and homework assignments. The limited research that has addressed the efficacy of this form of intervention indicates that the addition of problem-solving therapy to usual treatment might improve return to work outcomes in individuals with disabling musculoskeletal pain (Smeets et al.).

Acceptance and Commitment Therapy

Acceptance and commitment therapy, also referred to as contextually based cognitive-behavior therapy, is a type of cognitive therapy that has evolved from Stephen Hayes' work on acceptance and adaptation (Hayes, Strosahl, & Wilson, 1999; McCracken, 2005). Proponents of ACT emphasize that they do use the term acceptance to refer to resignation but rather as a term to refer to the process of ceasing to struggle ineffectively against that which cannot be changed (Hayes et al., 1999). In the case of chronic pain, acceptance is viewed as a first step toward successful adaptation (McCracken, 2005). Acceptance is said to occur when the individual with chronic pain is willing to experience his or her pain without attempting to control it. Through treatment, individuals with chronic pain are taught to acknowledge their pain, observe it as a sensation, and then accept it as part of their

reality without judgment. Through treatment, individuals are also encouraged to focus on their values and to commit to activities consistent with their values, in spite of ongoing pain.

Several investigations have shown that ACT is effective in reducing pain intensity and self-reported disability (Vowles & McCracken, 2008). To date, ACT has only been used with individuals with long-standing chronic pain where the prospect of significant pain alleviation is realistic low. When symptom-focused treatment of the pain condition is unlikely to yield positive outcomes, acceptance-based interventions might represent a useful option for improving the quality of life of individuals with chronic pain. It is not clear whether ACT would be effective or even appropriate for individuals with recent onset pain where a substantive proportion of individuals would be expected to show significant recovery from their pain condition.

Risk-Factor-Targeted Interventions

Recent research on risk factors for prolonged pain and disability has prompted the development of risk-factor-targeted intervention programs (Sullivan, Feuerstein, Gatchel, Linton, & Pransky, 2005; Vlaeyen & Linton, 2000). The Progressive Goal Attainment Program (PGAP) was designed as a risk-factor-targeted intervention for individuals suffering from debilitating pain conditions (Sullivan, Adams, Rhodenizer, & Stanish, 2006). The primary goals of the PGAP are to reduce catastrophic thinking and fear of movement in order to promote reintegration into life-role activities, increase quality of life, and facilitate return to work. The intervention is typically delivered by occupational therapists, physiotherapists, or psychologists.

Since the PGAP is a risk-factor-targeted intervention, clients are only considered as potential candidates for the intervention if they obtain scores in the risk range on measures of catastrophic thinking, fear of movement, or disability beliefs. In the initial weeks of the program, the focus is on the establishment of a strong therapeutic relationship and the development of a structured activity schedule. The client is provided with a client workbook that serves as the platform for activity scheduling and contains the forms for various exercises that will be used through the treatment. Activity goals are established in order to promote resumption of family, social, and occupational roles. Intervention techniques are invoked to target specific obstacles to rehabilitation progress (e.g., catastrophic thinking, fear of movement, and disability beliefs). In the final stages of the program, the intervention focuses on activities that will facilitate reintegration into the workplace.

PGAP has been shown to be effective in reducing catastrophic thinking, fear of movement, and disability beliefs in individuals with whiplash injuries and work-related musculoskeletal injuries (Sullivan, Adams, Rhodenizer, & Stanish, et al., 2006). Research has supported the view that reductions in catastrophizing are significant determinants of treatment-related improvements in depressive symptoms, physical function, and return to work (Sullivan, Ward et al., 2005).

Graded Activity and Exposure

The premise underlying graded activity or exposure interventions is that disability can be construed as a type of phobic orientation toward activity (Vlaeyen & Linton, 2000). According to the fear-avoidance model, individuals will differ in the degree to which they interpret their pain symptoms in a "catastrophic" or "alarmist" manner. The model predicts that catastrophic thinking following the onset of pain will contribute to heightened fears of movement. In turn, fear is expected to lead to avoidance of activity that might be associated with pain (Vlaeyen & Linton, 2000). Prolonged inactivity is expected to contribute to depression and disability (Sullivan, Adams, Thibault et al., 2006). According to the fear-avoidance model, reducing fear of movement is a critical component of successful rehabilitation of individuals with debilitating pain conditions (Vlaeyen & Linton, 2000). Clients are typically only considered for exposure interventions if they obtain high scores on measures of fear of movement.

Graded activity or exposure to feared activities are treatment approaches that involve systematic exposure or engagement in activities that individuals avoid due to fears that they

might experience an exacerbation of their symptoms. Feared activities are initially identified and ranked hierarchically, from least to most feared activities. Beginning with the least feared activities, clients are systematically exposed to movements that comprise the activities that clients are currently avoiding. Clients are repeatedly exposed to specific movements until their fear of activity subsides. As clients overcome their fears associated with the least feared activities in their feared activities hierarchy, the exposure techniques are used on activities associated with higher levels of fear (Leeuw et al., 2007).

While graded exposure has been shown to be an effective intervention for reducing the fear of specific movements, its effects do not seem to generalize to un-targeted activities (Goubert, Francken, Crombez, Vansteenwegen, & Lysens, 2002). As such, the clinical significance of the intervention might depend on the degree to which important activities of daily living or occupational activities can be targeted. Graded activity and exposure interventions aimed at reducing fear of movement have been shown to be effective in reducing disability, reducing absenteeism, and facilitating return to work (Bailey, Carleton, Vlaeyen, & Asmundson, 2010).

Choosing Among Different Psychological Interventions

The intervention approaches described in this chapter differ in terms of their focus, structure, content, and objectives. With the range of potential intervention avenues currently available, the clinician might reflect on the question of which intervention approach might be most suitable for a particular client. Since little research has been conducting on matching client profiles to specific interventions, this question unfortunately cannot be addressed from an empirical standpoint. There are, however, various points of consideration that might assist the clinician in determining the most appropriate intervention for his or her client.

Few would question the importance of information provision in the management of chronic pain and disability. The more that clients understand about the nature of their pain condition, the more they will be able to play an active role in the management of their condition. As such, information-based approaches such as back schools might be an important element in the management of chronic pain. However, for most clients with chronic pain conditions, information alone is unlikely to yield clinically significant improvements in mood, suffering, or disability. Information-based techniques might best be viewed as important elements of a more comprehensive approach to treatment as opposed to stand-alone interventions.

For the greater part of the last two decades, psychosocial interventions were included primarily as part of tertiary care treatment for clients with long-standing chronic pain and disability. With little expectancy of clinical improvement of clients' pain conditions, the focus of many treatment programs was primarily on the alleviation of suffering. Cognitive-behavioral interventions that used distress reduction techniques such as relaxation, reappraisal, and cognitive restructuring were ideally suited to achieve reductions in suffering in clients with long-standing chronic pain (Morley, Eccleston, & Williams, 1999).

As research accumulated showing that psychological interventions yielded significant reductions in pain and emotional distress, there was greater interest in using psychological interventions for clients who were at earlier stages of chronicity (Sullivan, 2003). The term secondary prevention is used to describe interventions that are implemented for individuals considered "at risk" condition or chronic pain and disability but whose condition had not yet become chronic. With a less chronic population, treatment objectives of psychological interventions changed. Since many clients still had an employment-relevant skill set, and some might also have had a job to return to, there was an increased focus on return to function as a central objective of treatment, as opposed to a primary focus on reduction of suffering. Return to function is a central objective of interventions such as PGAP or graded exposure.

When treatment is initiated after a long period of chronicity, intervention strategies are more likely to address the consequences of pain and

disability (e.g., affective disorders, drug/alcohol overuse, family dysfunction) as opposed to risk factors for pain and disability. It is important for professionals working with clients with long-standing chronic pain and disability to have a background in mental health in order to be able to intervene on psychological conditions that might be compounding the client's pain condition. However, risk factors for chronicity are not necessarily psychological disorders nor would they necessarily be considered indices of dysfunction (in the absence of a pain condition). Nevertheless, their presence contributes to a higher probability that a pain condition will persist or worsen over time. The challenge to effective secondary prevention lies not only in the development of risk-factor targeted interventions but in developing mechanisms by which individuals at risk can be identified. Perhaps more so than is the case for psychological disorders, risk factors for chronicity may be particularly likely to go undetected during routine primary care. Treating physicians often become aware of psychological factors in pain and disability only once chronicity has developed and the client has become treatment resistant.

Since psychological risk factors for chronic pain and disability are not mental health conditions, the development of secondary prevention interventions opened the door for using professionals who were not mental health professionals to deliver psychological interventions for pain. Intervention programs like PGAP or graded exposure are more likely to use occupational therapists, physiotherapists, or kinesiologists as interventionists than psychologists. This should be viewed as a positive change since the shortage of psychologists involved in the treatment of pain severely limits access to psychological services for individuals with debilitating pain conditions.

Thus, chronicity and clinical complexity are two factors that will influence the type of psychological intervention that will be considered, the objectives of the intervention, and the training background of the professional that will be used to deliver the intervention. Undoubtedly, other psychological interventions will be added to the repertoire of psychological services offered to clients with debilitating pain conditions. It is paramount to consider the evidence base for psychological interventions for pain-related difficulties before offering them to clients with debilitating pain conditions. Offering interventions that are not evidence based increases the probability of treatment failure and is likely to contribute to further demoralization of a client already struggling with a heavy burden of distress and disability.

Chronobiology

Definition

Chronobiology is the science of periodic changes in physiology and behavior of living organisms (Halberg, 1969). It describes these *biological rhythms* with statistical methods (*chronobiometry*) and elucidates the underlying molecular/biochemical mechanisms at a cellular and systemic level, the entrainment of these internal timing systems by external time cues, the effects of timed light and drug therapy (*chronotherapy*, *chronopharmacology*, *chronotoxicology*), as well as disturbances of biological rhythms that may lead to pathology (Dunlap, Loros, & DeCoursey, 2004; Foster & Kreitzman, 2004; Koukkari & Sothern, 2006; Redfern & Lemmer, 2007). In behavioral medicine, the most relevant biological rhythms show a period of about 24 h (*circadian*), 7 days (*circaseptan*), 30 days (*circatrigintan*), or 1 year (*circannual*).

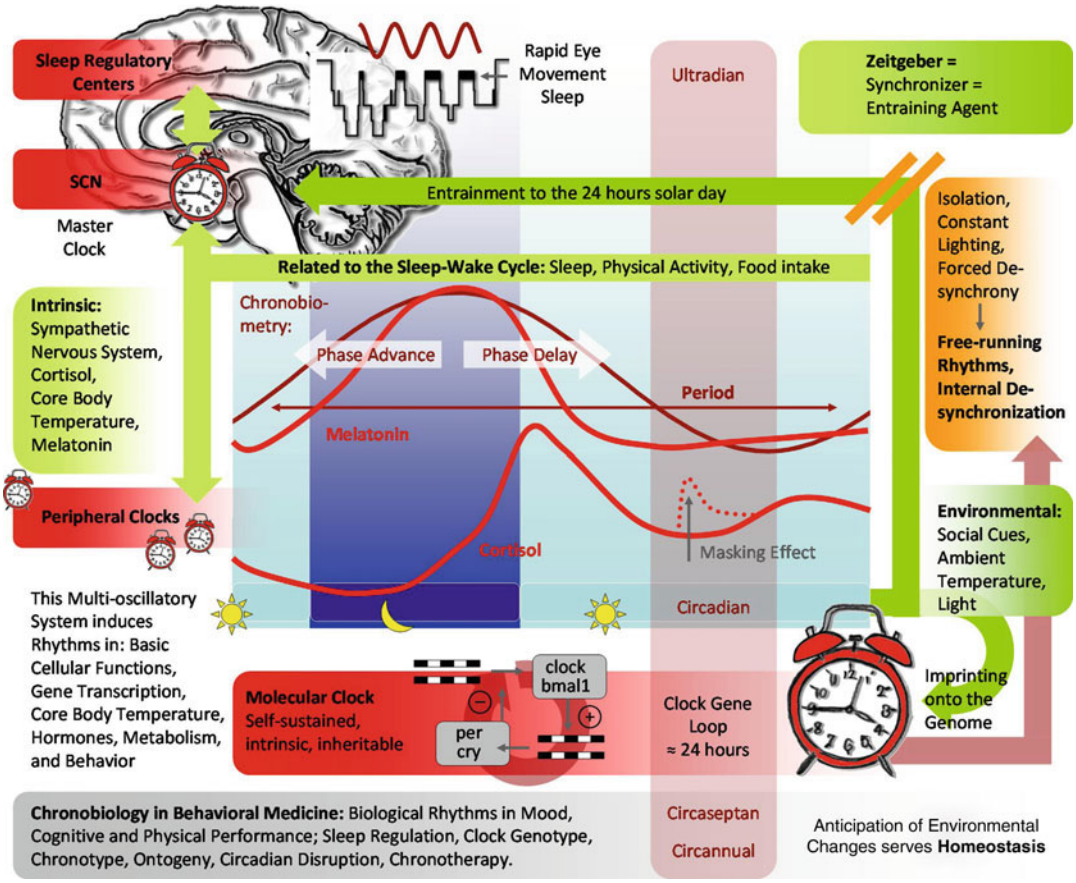
Description

Life is adapted to rhythms that are generated by movements of the Earth, the Moon, and the Sun

in relation to each other. Depending on the features of its habitat, every living organism on earth, including bacteria, plants, animals, and humans, shows rhythmic changes in physiology and behavior with different periods like that of tidal rhythms (~12 h, *circahemidian*), the daily light–dark cycle (~24 h, *circadian*), the weekly cycle (presumably stemming from alternations between spring- and neap-tides, ~7 days, *circaseptan*), the lunar cycle (~30 days, *circatrigintan*), and the seasons (~1 year, *circannual*). Periods that are longer than 1 day are called *infradian*, those that are shorter than 1 day are termed *ultradian*. Ultradian oscillations show very different periods and, like the 90 min of the non-REM-REM sleep cycle (REM: rapid eye movement), often lack an environmental counterpart.

Biological rhythms do not simply follow environmental changes but rather appear to anticipate them. They are still evident if an organism is deprived of any external time cue (*zeitgeber*) or in isolated cells in culture (e.g., white blood cells). Under such *free-running* conditions, a given rhythm period typically slightly deviates from the external cycle (e.g., 24.2 h instead of 24 h, hence the term "circa-dian") and this unmasked endogenous rhythm represents a trait with considerable interindividual differences (Aschoff, 1965). This indicates that environmental rhythms are adopted by inheritable internal time-keeping systems. It is assumed that endogenous timing mechanisms developed during evolution, with the goal of adapting the organism to relevant environmental changes (like the availability of food, exposure to predators, changes in ambient temperature, or periods of efficient reproduction) in an anticipatory manner. This anticipatory cycling is advantageous, e.g., with respect to energetic efficiency, and was therefore preserved by natural selection. The adaptation of living matter to environmental changes reflects a basic concept of physiology, i.e., *homeostasis* – the maintenance of the "internal milieu" of the organisms at a constant level (*setpoint*) despite external challenges. Core body temperature, e.g., is homeostatically regulated. In addition to the advantage of adaptation, more complex organisms might have benefited also from the separation of otherwise incompatible body and brain functions in time (e.g., encoding of new information during the active period and consolidation, i.e., the covert reactivation of "fresh" memory traces that is incompatible with active stimulus processing during the resting period).

To sum up, astronomically generated rhythms were evolutionary imprinted onto the genome of living organisms, creating anticipatory biological clocks and the organization of physiology and behavior in time (see Fig. 1). The underlying molecular machinery has been elucidated mainly for the circadian rhythm in the 1970s when the first *clock gene* was described in the fruit fly. By now many clock genes are discovered that are linked with their respective transcripts in an interlocked feedback loop that takes about 24 h for a full cycle. Activity in this feedback loop represents the molecular pendulum of the clock (Panda, Hogenesch, & Kay, 2002). In mammalian brain and peripheral organs, clock genes control basic cellular processes and up to 10% of the transcriptome in a tissue-specific manner. Though sophisticated, these self-sustained clocks are not precise – as it becomes evident under free-running conditions – and therefore have to be reset and synchronized (*entrainment*) by an external zeitgeber (*synchronizer, entraining agent*). The most important zeitgeber is light. Photic entrainment is provided by nonvisual retinal cells that convey the information about light and darkness to the hypothalamic *suprachiasmatic nuclei* (SCN), called the "master clock." In a hierarchic structure, the SCN signals to other brain centers (like sleep regulatory centers) and synchronizes clocks in peripheral tissues via the sympathetic nervous system and the hypothalamic-pituitary-adrenal axis. Apart from light, further external and internal synchronizers are ambient and core body temperature, sleep, physical activity, melatonin, food intake, and social cues. So, workdays and weekends are likely synchronizers for circaseptan rhythms, whereas circannual rhythms are assumed to be entrained by the length of the daily light span and changes in environmental temperature.



Chronobiology, Fig. 1 Environmental rhythms like the 24 h light–dark cycle were evolutionary imprinted onto the genome of living matter. Clock genes and their transcripts built up the molecular clock that ticks in the hypothalamic suprachiasmatic nuclei (SCN), but also in many if not all cells of the human body. As these molecular clocks are not precise they are synchronized (entrained) by zeitgeber. Environmental zeitgebers reset the phase of the SCN that itself signals to sleep regulatory centers and synchronizes peripheral clocks by intrinsic and activity-related factors. This multi-oscillatory system induces rhythms in physiology and behavior that are synchronized to environmental rhythms and therefore serve to anticipate external challenges (homeostasis). Two hormonal rhythms are depicted that can be statistically described (chronobiometry). Experimental procedures in chronobiology aim to dissect the effects of endogenous clocks from entraining and masking influences. Apart from circadian rhythms, chronobiology also describes oscillations with periods that are shorter than 1 day (like the ultradian rhythm of rapid eye movement sleep) and with periods of about 7 days (circaseptan) and about 1 year (circannual). Important aspects of chronobiology in behavioral medicine are summarized in the *grey box*

In animals and humans, this complex time-keeping system of clock genes and SCN regulates the sleep-wake cycle and induces rhythmic changes in cognitive and physical performance, core body temperature, hormone levels, and metabolism. Chronobiologists assess such rhythms with inferential statistical tools (*chronobiometry*) either under "natural," i.e., entrained, conditions or in experimental settings that allow to dissect the endogenous component of these rhythms from *masking* environmental factors or behaviors. Experimental designs use isolation procedures (cave or bunker experiments) or constant lighting conditions in humans and animals, respectively, to eliminate external time cues. Emerging free-running rhythms may then differ among parameters in terms of their period such that, e.g., the sleep-wake-cycle may

desynchronize from the rhythm of core body temperature (*internal desynchronization*) (Aschoff, 1965). The *forced desynchrony protocol* intentionally induces such an effect. It exploits the fact that an endogenous rhythm can only be entrained to periods that differ not too much from its own period (*range of entrainment*). If, therefore, the sleep-wake cycle is experimentally scheduled to 28 h, the rhythm of core body temperature runs out of phase with its own free-running period. Another elaborate approach used to dissociate the circadian rhythm from masking influences in humans is the *constant routine protocol*. In this protocol, the participants stay awake for more than 24 h under constant ambient light and temperature, in a supine position in bed with hourly isocaloric snacks and beverages. All these methods aim to scrutinize the contribution of multiple endogenous oscillators as well as entraining environmental, intrinsic, and activity-related factors to biological rhythms. In addition, they address the bidirectional interactions between the circadian system and sleep.

To unravel molecular mechanisms of biological rhythms chronobiologists study genetically manipulated animals (*knockouts* or *mutants* of certain clock genes in the whole genome or in individual organs), silence clock gene activity with *RNA interference* (RNA: ribonucleic acid) or couple clock genes with *luciferase* to allow continuous long-term monitoring of gene activity in cell cultures as well as in vivo (Panda et al., 2002). Human research focuses on twin studies and clock gene *polymorphisms*. *Clock genotypes* can then be set into relation to the circadian preference of individuals (*chronotype*, i.e., whether one is a "lark" or an "owl") that is assessed by investigating the phase of rhythms under "natural" entrained conditions by means of questionnaires, diaries, actigraphy, or *dim light melatonin onset* (DLMO). In this context, ontogenetic research elucidates the phase shifts that occur during lifetime, i.e., the phase delay in adolescence and the phase advance in the elderly (Phillips, 2009).

Chronobiology is an interdisciplinary science covering all fields of medical practice and research. Circadian, circaseptan, circatrigintan, and circannual rhythms are described in all disciplines of clinical medicine with respect to physiological functions, laboratory findings and the incidence of disease symptoms. In addition, efficacy and potential side effects of medical interventions show time dependency (*chronopharmacology, chronotoxicology*). Disruption of biological rhythms, as evident in shift workers, travels across time zones (*jet lag*), but also due to modern lifestyle, compromises mood, sleep, cognitive and physical performance, activates the stress axes, and may eventually lead to pathology and disorders like major depression, metabolic syndrome, obesity, immunosuppression, low grade systemic inflammation, and cardiovascular diseases. Conversely, sleep curtailment, chronic stress, high fat diet, many infections, and autoimmune diseases are associated with *circadian disruption* thus feeding into a vicious circle (Phillips, 2009). These relationships, however, also offer therapeutic options of re-entraining biological rhythms by means of zeitgebers (*chronotherapy, chronobiotics*), as it is done with bright light therapy in mood disorders and the administration of melatonin to prevent jet lag. The optimal timing of such interventions can be assessed by *phase-response curves* representing an important research tool of chronobiology. In addition, cognitive behavioral therapy can alleviate circadian and sleep disruption in psychiatric and neurologic diseases. As epidemiological data indicate that circadian disruption and associated sleep curtailments increase the incidence of metabolic and cardiovascular diseases and the risk of cancer, it is the goal of future research to elucidate if re-entrainment of biological rhythms can likewise be beneficial to prevent these diseases in shift workers and the elderly.

Church-Based Interventions

Definition

Refers to any research, clinical, public health, or data collection initiative targeted to a faith-based organization or community.

Description

Academicians, clinicians, and researchers have partnered with church-based or faith-based organizations for the purposes of descriptive and interventional research, launching pilot programs and studying public health problems for years. There are multiple advantages to partnering with such populations for these purposes. These groups tend to be established communities, with an organized, recognized authority structure that provides a support network for all those within the group. This infrastructure is well suited to allow investigation of social and public health issues. Secondly, the groups share a common belief and value system, allowing for an assessment of how those beliefs affect behaviors. To the extent that health-related lifestyle behaviors are dictated by religious beliefs, studies of these populations can address health outcomes, such as

those explored in the Nun's study (University of Minnesota), or the influence of genetics on health, as in studies of the Old Order Amish (Hsueh et al., 2000). Finally, depending on the size of the faith community, it is possible to capture a large number of potential study subjects within one faith community or a network of faith communities.

Recognizing that church- and faith-based organizations could be significant partners in addressing social and health-related issues, President George W. Bush established the White House Office of Faith-Based and Community Initiatives in 2001 as a means to allow faith-based organizations to apply for federal funding to implement social service programs. Under criticism from the Americans United for the Separation of Church and State and the American Civil Liberties Union, safeguards were put into place that prevent these groups from advancing their religious agendas while administering programs using federal funds. In 2009, President Barack Obama changed the name of the organization to the White House Office of Faith-based and Neighborhood Partnerships. The Department of Health and Human Services now houses the Center for Faith-based and Neighborhood Partnerships. This center does not administer grants but provides information on building and sustaining partnerships for community-based programs. Several other US government departments currently host initiatives for faith-based and community partnerships, including the Substance Abuse and Mental Health Services Administration and the US Department of Agriculture.

Research interventions conducted within the context of church- or faith-based organizations can be effectively conducted only with careful consideration in advance of the church and community challenges, selection of the right faith community to meet the needs of the project, understanding of how to best implement the project without offense and skillful marketing strategies. Rev. Melvin Tuggle (2000) offers specific guidance on related principles and how to approach and interact with faith communities in inner-cities in "It is Well with My Soul: Churches and Institutions Collaborating for Public Health." In this book, Rev. Tuggle suggests the importance of approaching these collaborations as a true partnership and makes specific recommendations for ensuring a successful collaboration.

Churches and faith communities can also be starting points for interventions designed to be expanded to the community at large. By introducing a program, initiative, or intervention at a church, potential participants may observe the enthusiasm of those already engaged and create support for expansion of the project beyond the church group. With careful planning in advance and a thoughtful, respectful approach, it is possible to create a true partnership for research or clinical care projects to improve public health.

Definition

A circadian rhythm is an approximately 24-h cycle of a biochemical, physiological, or behavioral process that is generated by internal biological clocks. In most animals, the intrinsic rhythm of the clock (cycle length) is slightly longer than 24 h, but normally the clock is synchronized to the 24-h day (entrainment) by environmental time signals (zeitgebers), the primary one of which is solar light. In the absence of timing signals (temporal isolation), circadian rhythms free-run on a non-24-h cycle, expressing the intrinsic rhythm of the clock. The process of synchronization involves daily, stimulus-induced adjustment (phase shifts) that compensate for the difference between the intrinsic period of the internal clock and the period of the environmental cycle. Light can induce phase shift that varies in magnitude and direction depending on the circadian phase of exposure. Light exposure in the subjective morning resets the internal clock to an earlier time, while light exposure in the early subjective night resets the clock to a later time. Intensity of the light, duration of the light pulse, and the spectral characteristics of the light determine the magnitude of a phase shift at any specific circadian phase. Blue light is an efficient wavelength to shift the circadian rhythms.

The suprachiasmatic nucleus (SCN), which is situated bilaterally in the hypothalamus, just above the optic chiasm, is of central importance in the generation and entrainment of mammalian circadian rhythms. Destruction of SCN disrupts a wide variety of circadian rhythms. Photic entrainment is thought to be largely mediated by retinal photoreceptors. Approximately one third of SCN cells are photically responsive which is believed to result from glutamatergic stimulation of N-methyl-D-aspartate receptors through the retinohypothalamic tract. Photic and glutamatergic stimulation of SCN cells in the early subjective night causes phase delay, whereas such stimulation late in the subjective night causes phase advance.

Circadian rhythms in some species can also be shifted and entrained by stimuli other than

light, such as exercise, social stimuli, or feeding. These so-called nonphotic zeitgebers may in some cases engage a circadian pacemaker system separate from that affected by light. Nonphotic influences on the clock phase appear to be mediated by the geniculohypothalamic tract, neuropeptide Y, and serotonergic pathways. Although the mechanism that constitutes exercise to promote phase shift in the human circadian clock is unclear, exercise during the late subjective day has been shown to produce a phase advance of the rhythm, whereas exercise during most of the subjective night produces phase delays.

Definition

Classical conditioning is learning by association and focuses on what happens before an individual responds. It is often used in behavioral training. Perhaps, the most well-known example of classical conditioning is that of Pavlov's dogs. Pavlov measured salivation responses in dogs. Before conditioning, he rang a bell and noted that there was no increase in saliva from the dogs. Then, during conditioning, he rang a bell (unconditioned stimulus) and immediately put meat powder (conditioned stimulus) on the dogs' tongues which caused them to salivate (unconditioned response); he continued this several times. Finally, after conditioning, he rang the bell again but without food and the dogs salivated (conditioned response). Pavlov used classical conditioning so the dogs associated an unrelated stimulus (the bell) with food. Thus, they eventually produced the same saliva response they would for food with the bell. For further details, see Coon and Mitterer (2010) (Fig. 1).

Clinical Agreement

Medical agreement

Definition

It is important in both clinical medicine and research to assess the extent to which different individuals (e.g., clinicians, observers) observe and report the same phenomenon (Jekel, Katz, Elmore, & Wild, 2007). Ideally, there would be perfect intraobserver agreement (the same person would always observe and report the same phenomenon in an identical manner), and perfect interobserver agreement (different people would observe and report the same phenomenon identically). However, these ideals are precisely that: they describe an ideal scenario, and real-life scenarios are often quite different. Elmore, Wells, Lee, Howard, and Feinstein (1994) studied both intraobserver and interobserver agreement among radiologists' interpretations of a specific mammogram, demonstrating that radiologists can differ, sometimes substantially, in their interpretations of mammograms and in their recommendations for management.

Quantifying the extent to which clinical agreement exists in a given situation is therefore important. Consider the following hypothetical data presented by Jekel et al. (2007) concerning clinical agreement between two clinicians regarding their diagnosis of the presence or absence of a cardiac murmur upon physical examination of 100 patients:

	Clinician number 1		
Clinician no. 2	Murmur present	Murmur absent	Total
Murmur present	30	7	37
Murmur absent	3	60	63
Total	33	67	100

These data show the following:

1. For 30 patients, the clinicians both determined the presence of a murmur.
2. For 60 patients, the clinicians both determined the absence of a murmur.
3. For 7 patients, Clinician number 2 determined the presence of a murmur while Clinician number 1 determined the absence of a murmur.
4. For 3 patients, Clinician number 1 determined the presence of a murmur while Clinician number 2 determined the absence of a murmur.

The maximum possible degree of clinical agreement is equal to the total number of patients, i.e., 100. This would occur when the two clinicians made the same determination for every patient. As already noted, this is an ideal but unlikely scenario. (Actually, the operationalization of the term "ideal" in this context has another aspect when making clinical judgments: Ideally, both clinicians make the same and CORRECT determination; it is a theoretical possibility that they could agree 100% of the time and also be wrong 100% of the time.) Various calculations can be conducted to quantify the degree of agreement.

The actual degree of agreement is 90 out of 100 cases. This value is typically presented as a percentage, which is 90% (the numbers here are deliberately chosen to facilitate straightforward calculations). However, purely by random chance, it is possible that the clinicians would agree sometimes. Imagine a scenario in which

the two clinicians were asked simply to write a list of 100 terms, each time choosing between "murmur present" and "murmur absent." Probabilistically, there would likely be some agreement. A key question therefore becomes: To what extent does the degree of clinical agreement between the two clinicians improve upon chance agreement alone?

The kappa test ratio provides an answer to this question. In this case, the mathematics (not presented here) lead to a kappa test ratio of 0.78, which is typically expressed in percentage terms, i.e., 78%. To put this in perspective, consider the arbitrary but useful divisions for the interpretation of kappa scores as presented by Sacket, Haynes, Guyatt, and Tugwell (1991):

1. Less than 20% represents negligible improvement in the degree of clinical agreement over chance alone.
2. 20–39% represents minimal improvement.
3. 40–59% represents fair improvement.
4. 60–79% represents good improvement.
5. 80% and above represents excellent improvement.

These hypothetical data yielded a kappa score of 78%, as noted already, meaning that this degree of improvement would fall in the "good improvement" category. With regard to real data, Jekel et al. (2007) stated that "the reliability of most tests in clinical medicine that require human judgment seems to fall in the fair or good range."

Clinical Decision-Making

J. Rick Turner
Cardiovascular Safety, Quintiles, Durham, NC, USA

Decision analysis; Medical decision-making

Definition

Clinicians must make treatment decisions on a daily basis, and these decisions, or recommendations (final decisions are best made by the "health team" of a physician and his or her patient) should be based on the best available evidence. The terms "evidence-based medicine" and "evidence-based practice" have become part of the health lexicon, and "evidence-based behavioral medicine" is also an established term (see the ▶ Evidence-Based Behavioral Medicine (EBBM) entry in this encyclopedia for a detailed discussion).

While clinical decision-making relies on evidence, the evidence in the medical literature (with the exception of case reports) typically describes the experience of a population of patients rather than an individual patient. Evidence-based clinical decision-making, therefore, requires "the application of population-based data to the care of an individual patient whose experiences will be different, in ways both discernible and not, from the collective experience reported in the literature" (Katz, 2001). He also observed that "All of the art and all of the science of medicine depend on how artfully and scientifically we as practitioners reach our decisions. The art of clinical decision-making is judgment, an even more difficult concept to grapple with than evidence."

Decision analysis is a formalized approach to making complex clinical decisions that relies on plotting a "decision tree" containing the various options and then rating each in terms of

probability and utility. In this way, the clinician attempts to make explicit the quantitative principles upon which a given clinical decision will be based. Once these principles have been identified from the literature, both the clinician and the patient can consider them, challenge them as appropriate, and systematically eliminate treatment (or nontreatment) options until a clear preference emerges (Katz, 2001).

Definition

Clinical practice guidelines "are systematically developed statements to assist practitioner and patient decisions about appropriate health care for specific clinical circumstances" (Field & Lohr, 1990). Good practice guidelines should be specific, comprehensive, and yet flexible enough to be useful (Field & Lohr, 1992).

Description

Clinical practice guidelines are needed because early reports suggested that less than 5% of medical treatment decisions were based on strong research evidence; about half were based on shared clinician beliefs that had minimal scientific support and half were based on personal opinion (Field & Lohr, 1990). Well-constructed clinical practice guidelines hold the promise of providing information to enable clinicians to choose the best treatments, diagnoses, or screening practices available, and regulators to set policy based on the current state of scientific knowledge. Practice guidelines can assist policymakers and public health advocates to be able to better determine which behavioral medicine practices should be reimbursed (Davidson, Trudeau, Ockene, Orleans, & Kaplan, 2004). Risk management – that is, the effort to lower or curb the number of poor outcomes and potential for malpractice litigation – is another possible

reason for developing clinical practice guidelines. They can also be used when considering accreditation and certification for education programs and individual clinicians. However, the primary reason for developing and then implementing clinical practice guidelines is the expectation that they will improve the patient, the public, and the community's health.

Each clinical practice guideline differs with respect to the practice it covers, the way in which the evidence is collected, the rules used to judge a practice as useful, and the way in which these guidelines are communicated to influence patient care. Essentially, some organization, whether a governmental body, a professional society, or an empanelled group of experts, reviews the evidence to support a specific screening, diagnostic, or treatment practice and then provides a guideline advising on the usefulness of that practice. *Evidence-based* practice guidelines are often distinguished from *consensus* practice guidelines that are informed by relevant research but not necessarily guided by systematic evidence reviews (Davidson et al., 2004).

American Heart Association (AHA), for example, has set out an explicit and formal review system for creating a guideline. The need for the guideline, the composition of the members of the writing group, and the approval process are all prespecified. Second, the criteria for searching for the evidence, the grade that will be given the evidence, and the summary statement similarly must also follow the prespecified system. For example, evidence for benefit of a drug or a preventive action is considered "A" if there are multiple randomized controlled trials or meta-analyses from multiple populations that all show benefit to the patient or the community. The AHA methodology handbook for creating systematic practice guidelines can be found as a pdf at: http://www.americanheart.org/presenter.jhtml?identifier=3039683.

Similarly, the United States Preventative Services Task Force has set up a system for objectively obtaining and reviewing all evidence for preventative services and releases guidelines advising practitioners and patients about the level of evidence to support or refute the use of certain interventions http://www.uspreventiveservicestaskforce.org/methods.htm. There are many other bodies who create clinical practice guidelines, such as the American Psychiatric Association http://www.psych.org/mainmenu/psychiatricpractice/practiceguidelines_1.aspx and the CDC-sponsored Community Guide (Briss et al., 2000) http://www.thecommunityguide.org/about/index.html.

A examination of where to find clinical practice guidelines revealed that most first look online and prefer governmental agency guidelines over others (Burgers, Cluzeau, Hanna, Hunt, & Grol, 2003). There is an excellent resource to look for any relevant clinical practice guidelines that is run by AHRQ – The National Guideline Clearing house – http://www.guideline.gov/.

There are some excellent educational references that explain how to locate, evaluate, and then, if relevant, use the information in practice guidelines (Hayward, Wilson, Tunis, Bass, & Guyatt, 1995; Wilson, Hayward, Tunis, Bass, & Guyatt, 1995). For a systematic approach to assessing guidelines, the AGREE instrument is available. http://www.agreecollaboration.org/

There is no formal accrediting body or a professional society in behavioral medicine that regularly produces practice guidelines; locations of guidelines that may be useful for behavioral medicine can be found in this citation (Davidson et al., 2004).

There is an optimistic assumption that the application of clinical practice guidelines results in better patient outcomes (Spring et al., 2005). However, rigorous program evaluation to support this assertion is only in its beginning stages. Grimshaw and others (Grimshaw & Russell, 1993) conducted a systematic review to address this question by examining evaluations of clinical guideline implementation for specific clinical conditions and preventative services. Of 59 papers, all but 4 detected significant improvements in the process of care following the introduction of guidelines. They concluded that explicit guidelines do improve clinical practice, but careful evaluation is always required. As few explicit behavioral medicine clinical practice

guidelines exist, little is known about the adoption of evidence-based guidelines and their use in other fields, and certainly, this is uncharted within behavioral medicine (Spring et al.).

It is also by no means certain that using practices recommended by practice guidelines will decrease health care costs; in medicine, it has sometimes increased them (Sackett, Rosenberg, Gray, Haynes, & Richardson, 1996). However, in the absence of evidence-based practice guidelines, managed care organizations and other policymakers may reimburse the most economical treatment (Pincus, 1994), a measure that would certainly restrict practice (Spring et al., 2005). The value of clinical practice guidelines for behavioral medicine is that, by making it possible to distinguish between effective and ineffective treatments, it encourages all of us to make informed decisions about training, about practice, and about reimbursement.

Clinical Predictors

Yori Gidron
Faculty of Medicine and Pharmacy, Free University of Brussels (VUB), Jette, Belgium

Definition

This term often refers to biomedical factors known to influence or predict health outcomes. These are taken into account in clinical practice, when estimating a patient's prognosis. Additionally, clinical predictors are considered in clinical research, when trying to test new etiological or prognostic factors, and there is a need to statistically control for known or previously established clinical predictors, which could possibly explain the role of the new tested factors. In behavior medicine, this is often the common approach, when testing the effects of a psychosocial factor on health outcomes. Often, it is crucial

to control for the effects of clinical predictors in behavior medicine, as clinical risk factors are either important in predicting prognosis, and since they may be associated with and partly explain the prognostic effects of psychosocial factors. In coronary heart disease, clinical risk factors can include left ventricular ejection fraction, number of occluded vessels, troponin levels, and comorbidities. In cancer, clinical risk factors can include performance level, tumor stage, and treatments. In surgery, clinical risk factors can include age, severity of surgery, and comorbidities.

Chida, Hamer, Wardle and Steptoe (2008), in their meta-analysis of over 160 studies, tested and found that psychosocial factors significantly predicted incidence and prognosis in cancer, and this was maintained also when statistically controlling for confounders, which included clinical predictors. One example in heart disease is the study by Denollet et al. (1996) showing that type D personality (high distress and social inhibition) predicted mortality from coronary heart disease, independent of clinical risk factors. Testing for such factors provides important strength to the claim that psychosocial factors affect health outcomes, independent of biomedical factors. This then justifies the need to consider and intervene in modifying psychosocial factors beyond targeting biomedical clinical predictors alone.

Definition

Clinical settings include primary, secondary, tertiary, and quaternary care settings. Primary care clinical settings are typically the first point of contact individuals have with the medical system. The majority of health care, including mental health care, is provided in the primary care setting. Family medicine (family practice), internal medicine, pediatric, and sometimes obstetrics and gynecological clinics are classified as primary care clinical settings. Primary care clinical settings are distinguished from other speciality care settings because no referral is needed for care and it is the source of care continuity and advocacy for the patient. The full spectrum of health care from health promotion, disease prevention, and assessment and treatment of acute and chronic medical conditions occurs in primary care (American Academy of Family Physicians, 2011; Shi & Singh, 2010).

The remaining clinical care settings are distinguished by the complexity of speciality care that can be provided (Shi & Singh, 2010). Secondary clinical settings include referral treatment facilities and specialists who do not typically have first contact with patients, but are not as specialized as those in tertiary care. Cardiology, dermatology, oncology, pulmonology, and urology clinics are examples of secondary clinical settings. Acute care provided in an emergency room and mental health care provided by

specialists (e.g., psychologists, psychiatrists), although they do not require referrals, are commonly classified as secondary care. Tertiary clinical settings use highly specialized facilities and providers to assess and treat referred patients. In tertiary clinical settings patients may receive complex surgeries (e.g., coronary artery bypass grafts) or intensive care when they are critically ill (e.g., intensive care units). Quaternary clinical settings offer unique, very highly specialized care, typically associated with regional, national, and/or academic health centers. Organ transplantation is one example of the care typically provided in a quaternary clinical setting.

Description

In the United States, the fastest growing segment of the population is older adults (i.e., 65 years and older) and the majority of their medical care will be provided in family and internal medicine primary care clinics. Concurrently, the Patient Centered Medical Home (PCMH) (American Academy of Family Physicians (AAFP), American Academy of Pediatrics (AAP), American College of Physicians (ACP), & American Osteopathic Association (AOA), 2007) concept and the National Center for Quality Assurance's accreditation process of the PCMH are reshaping the primary care clinical setting. The purpose of these efforts has been to facilitate the relationship between patients and their personal physicians. A key principle of the PCMH is the focus on the "whole person" and the biopsychosocial preventive care, acute care, chronic care, and end of life care needs of individuals at all stages of their lives.

Behavioral medicine is practiced across all clinical settings. Specialists in behavioral medicine commonly work in secondary (e.g., cardiology, chronic pain, oncology, and sleep) and tertiary clinical settings. In these clinics the behavioral medicine specialist works as part of a multidisciplinary, interdisciplinary, or transdisciplinary team to research, assess, and/or treat the biopsychosocial needs of patients. For example, behavioral medicine specialists may work with patients recovering from coronary artery bypass surgeries, patients diagnosed with cancer, or diabetes. Behavioral medicine specialists may conduct research, teach classes, or provide individual treatment related to managing the biopsychosocial factors (e.g., improving medication adherence, increasing social support, smoking cessation, stress management, weight management) associated with effective disease management. Sometimes specialized clinics are formed, such as a chronic pain or sleep clinic, where behavioral medicine specialists work with other secondary and tertiary providers to assess and treat the specific physiological, cognitive, and behavioral factors contributing to chronic pain and sleep disruption.

To meet the complex, chronic healthcare needs of the aging population, researchers and providers are continuing to focus on behavioral medicine in secondary and tertiary care settings. Increasingly behavioral medicine specialists are also collaborating with and integrating into the primary care clinical setting to assist the primary care team in meeting the complex health care needs of the elderly in a manner that brings evidence-based behavioral medicine assessment intervention to where the bulk of the elderly receive care. There are a variety of ways to describe how behavioral medicine services are integrated into primary care including co-location and embedding (American Academy of Family Physicians (AAFP), American Academy of Pediatrics (AAP), American College of Physicians (ACP), & American Osteopathic Association (AOA), 2007). Co-location may simply mean that the behavioral medicine services are offered in the same physical structure as the primary care clinic, but assessments and care are consistent with the standard of care typically followed by the behavioral medicine specialist (e.g., a psychologist seeing patients for 50-min hours) and maintaining separate records. An embedded behavioral medicine specialist is a primary care team member who follows the standard of care within primary

care (e.g., 15–30 min appointments) and documents all care within the primary care medical record. The Primary Care Behavioral Health model (Hunter & Goodie, 2010; Robinson & Reiter, 2007) is one of the most widely used examples of an embedded service. In contrast to the Primary Care Behavioral Health model is the Care Management model, which uses a specialist, often a nurse, to assist with the education and coordination of care of patients. The care manager helps to ensure that patients are getting the services they need from the medical system. Some clinics are blending Primary Care Behavioral Health and Care Management models to optimize the benefits of both care models.

Definition

A clinical trial is a procedure in behavioral and biomedical research that is conducted to investigate potential treatments and effects of medical interventions. The public and US National Institutes of Health (NIH) service site, www.ClinicalTrials.gov, provides updated information on clinical trials regarding background and history, availability, results and outcomes, and links to other useful resources. Clinical trials may be designed to examine the effects of certain medications (e.g., different types of drugs or doses of drugs; Kahn et al., 2008, The Lancet) or behavioral interventions (e.g., a smoking cessation program; Moller, Villebro, Pedersen, & Tønnesen, 2002, The Lancet). There are many protocols and regulatory measures in place that must be adhered to for a clinical trial to be established. Once the clinical trial has been approved, researchers recruit healthy volunteers and/or patients to participate in the study. Patients may receive some benefit from the trial, such as access to a new medication; however, there are clinical trials where the patient/volunteer does not gain direct benefit from participating, such as serving in the control group (i.e., the placebo) or participating in a trial that includes a long-term design in which the treatments will not be available in the near/foreseeable future. These aspects will be different across clinical trials as the type, size, purpose, length, and location of trials will vary.

Clusters

J. Rick Turner
Cardiovascular Safety, Quintiles, Durham, NC, USA

Definition

A cluster is a term used in environmental epidemiology. A disease cluster can be defined as "an unusual aggregation, in time or space or both, of occurrences of a disease" (Hertz-Picciotto, 2008). This means that an assessment of "usual" must occur. Usual rates of the disease can be determined from the distribution of occurrences in the same location in other time periods, in one or more similar locations at the same time period, or in larger areas than the specific locale of interest.

The theory of random sampling means that, at times, "chance clusters" will occur. Therefore, this possibility must be borne in mind when starting to investigate a particular cluster phenomenon. Consider the example of clusters of cancer in neighborhoods or small areas. It is of considerable importance to assess whether there is likely to be a specific environmental influence that is causing the cluster. If it is indeed likely, concerted efforts to identify the influence can be planned. However, if it appears particularly unlikely, such investigation (and the necessary resources to complete it) may not be advisable immediately.

Jekel, Katz, Elmore, and Wild (2007) discussed an instructive example concerning cancer. If the types of cancer in an identified cluster vary considerably, and are of the more common types (e.g., lung, breast, colon, prostate), it is probably the case that there is not a specific environmental hazard in the immediate locale. In contrast, if most of the cases in the cluster are of only one or a small number of cancers (especially leukemia, or brain or thyroid cancer), a more intensive investigation may be appropriate.

Reports to local, state, and federal agencies of perceived clusters are made frequently by concerned individuals or groups, physicians, and other health-care professionals. A balanced approach must be taken that balances public well-being with the acknowledgment that the majority of these reports do not lead to the identification of a common causal exposure. It is typically difficult to draw a conclusion from a single cluster, even one in which the aggregation of a disease seems particularly unusual.

Definition

Normal Hemostasis

Hemostasis is a complex and highly regulated physiological process that maintains a balance between the liquid state of blood within the vasculature and the induction of blood clot formation following injury.

As such, it involves multisystem interactions between components of the vessel wall, blood cells (mainly platelets), and plasma proteins (Colman et al., 2005; Kaushansky et al., 2010).

The following events are involved in the hemostatic process:

1. Vasoconstriction: When the blood vessel ruptures, the wall of the vessel immediately contracts to reduce blood flow and thereby prevent blood loss.
2. Platelet activation: Platelets adhere to the vessel injuries via von Willebrand factor and aggregate with fibrinogen to form platelet plugs (primary hemostasis).
3. Blood coagulation: Clot formation occurs as a result of coagulation that is mediated by blood-clotting factors. Blood-clotting factors are inactive forms of proteolytic enzymes. When converted to active forms, they trigger a cascade of reactions that comprise the clotting process. At the initiation of coagulation, small amounts of thrombin are generated via FXa formation by the TF:FVIIa complex ("extrinsic pathway"). Large amounts of thrombin generation ("burst") follow; this process is dependent on FXa formation via FIXa- and FVIIIa-mediated complexes on an activated platelet surface. Generated thrombin converts fibrinogen to insoluble fibrin, which forms a meshwork cross-linked by factor XIIIa. The fibrin fibers subsequently enclose platelets, erythrocytes, leukocytes, and other plasma proteins to form blood clots (secondary hemostasis).
4. Fibrinolysis: The blood clot is dissolved when healing is complete, thereby assuring long-term vascular patency.

Disturbances of Blood Coagulation

The human hemostatic system is dependent on a delicate equilibrium between procoagulant and anticoagulant factors that interact with each other to ensure effective hemostasis at the sites of vascular injury. The procoagulant forces include platelet adhesion, aggregation, and fibrin clot formation, while the anticoagulant forces include the natural inhibitors of coagulation and fibrinolysis.

Any disruption in the balance between clot formation and clot dissolution can result in either thrombosis (due to hypercoagulation) or hemorrhage (due to hypocoagulation) (Colman et al. 2005).

Congenital disorders of coagulation include those conditions in which there are deficiencies or excessive amounts of either procoagulant or anticoagulant factors, manifesting as excessive clotting or bleeding. These disorders can have a profound effect on the overall health, well-being, and quality of life of affected children. Further, thrombotic tendencies can be related to acquired risk factors, including obesity, immobilization, diabetes, and hypertension.

Coffee is the drink most consumed by adults after water. Caffeine is the psychoactive substance contained in coffee, tea, soda, cocoa, and chocolate.

Description

In this entry, we will summarize the main effects known about coffee and caffeine consumption on health based on the numerous studies published over the last 10 years. The recent studies have reported the beneficial effects of moderate doses of coffee (3–4 cups per day) on alertness, vigilance, and cognitive abilities. However, coffee/caffeine can disturb sleep and generate anxiety. Its lifelong consumption slows down age-related cognitive decline and decreases the risk for developing Parkinson or Alzheimer's disease, as well as type 2 diabetes and numerous cancers (cancers of the digestive tract, breast, endometrial, and skin in particular). Coffee has no negative influence on cardiovascular health. However, coffee/caffeine should be consumed in moderation during pregnancy. The data summarized here come from both animal preclinical and human studies and in numerous cases originate in reviews and meta-analyses of the studies published in a given area. This large wealth of data allowed the evolution of the negative vision present in most minds that coffee was not good for health.

Coffee is the drink most consumed by adults. Caffeine is the psychoactive substance contained in coffee, tea, soda, cocoa, and chocolate (Table 1). It is also found in analgesic medications, energetic drinks, and over-the-counter slimming creams. The mean world consumption of caffeine, the major constituent of coffee (Table 2), is 1 mg/kg/day in adults from which about 80% come from coffee. It reaches 2.4–4.0 mg/kg/day in the USA and Canada, up to 7.0 mg/kg/day in Scandinavia. In 7–10-year-old children, caffeine consumption ranges from 0.5 to 1.8 mg/kg/day in developed countries, mainly from sodas and chocolate.

Low to moderate consumption of caffeine (50–250 mg, equivalent to a small to 2 large cups of coffee in one sitting) generates positive effects: feelings of well-being, relaxation, good mood, energy, increased alertness, and better concentration. The consumption of high to very high doses (400–800 mg, or 5–10 large cups of coffee in one sitting) leads to negative

effects: nervousness, anxiety, aggressiveness, insomnia, tachycardia, and trembling. The moderate consumption of coffee and caffeine (3–4 cups/day) has no harmful effects on health (Table 3).

Caffeine absorption by the gastrointestinal tract reaches 99% in 45 min. Caffeine crosses all biological membranes, including the blood–brain barrier and brain concentration is close to plasma concentration. The half-life of caffeine ranges from 0.7 to 1.2 h in the rat and 2.5–4.5 h in humans. It is reduced by 30–50% in smokers, increased twofold by oral contraception, and considerably prolonged during the third trimester of pregnancy, as well as in the newborn and infant less than 6 months old.

Caffeine acts as an antagonist at adenosine receptors. Adenosine is a neuromodulator that regulates the release of neurotransmitters, mainly excitatory. Among the four types of adenosine receptors, A1, A2A, A2B, and A3, caffeine displays most of its biological effects by binding to A1 and A2A receptors. The antagonism at these receptors explains the stimulatory effects on caffeine on brain activity (Fredholm, Bättig, Holmén, Nehlig, & Zvartau, 1999).

Coffee/Caffeine and the Central Nervous System

Alertness and Sleep

The consumption of 1–4 cups of coffee (100–400 mg caffeine) daily increases alertness, proportionally to the quantity absorbed. This effect is particularly marked after sleep deprivation and when alertness is decreased as during the post-lunch dip, night and shift work, and regular cold.

A moderate consumption – 1–2 cups of coffee before bedtime – leads to difficulties and delays in going to sleep up to 3 h post intake. It also decreases the temporal organization of slow and REM sleep and the quality of deep sleep. The consequences are night awakenings, nightmares, difficulties to stand up, and sleepiness during the day. The effects vary and are more marked in elderly and occasional consumers. Moreover, the polymorphism of the gene coding for

the A2A adenosine receptor determines the interindividual sensitivity to the effects of caffeine on sleep (Rogers et al., 2010).

Sensory and Intellectual Abilities

A moderate consumption of coffee (1–4 cups per day) facilitates cognitive functions, while higher intake has rather negative effects on intellectual function. These effects depend on sex, age, time of the day, and whether consumption is chronic or not. Low caffeine consumption increases sensory and perceptive discrimination abilities. Attention is increased even at low levels of intake, 100 mg caffeine (1 cup of coffee), markedly in sleep-deprived subjects.

Up to 4 cups/day, coffee decreases reaction time. The effects are more prominent in suboptimal conditions, as at awakening, at night, in fatigued subjects, during long-lasting tasks, and in occasional consumers. The effects depend on dose and consumption habits. Caffeine does not directly improve learning and memory abilities. These effects seem rather indirect and linked to better concentration and capacity to focus attention (Nehlig, 2010).

Anxiety and Pain

Beyond 600 mg in one sitting, caffeine increases anxiety. The response largely differs between individuals and there is a link between the state of anxiety and two polymorphisms of the gene coding for A2A adenosine receptors (Rogers et al., 2010).

Moderate caffeine consumption reduces tension headache, migraine, dental and abdominal pain through its analgesic effects, directly via adenosine receptors and indirectly by the potentiation of the analgesic action of aspirin and ibuprofen (Nehlig, 2004).

Caffeine and Dependence

The abrupt cessation of caffeine intake may lead to moderate withdrawal symptoms but only in

about 10–20% of the population. These are mainly headaches, fatigue, lack of concentration, anxiety, irritability, and occasionally, nauseas. They start usually 12–24 h after abrupt caffeine cessation and last 2–3 days. They do not occur if caffeine consumption is reduced progressively. There is no tolerance to the central effects of caffeine.

Furthermore, caffeine does not activate the cerebral circuits of dependence, neither in humans after the consumption of 200 mg caffeine (2 cups of coffee) nor in rats at doses mimicking human levels of intake, i.e., 0.5–5.0 mg/kg (½ to 5 cups of coffee). Caffeine has rather reinforcing properties on its consumption. Doses of caffeine from tea or coffee (40–100 mg) appear sufficient to act as reinforcers (Nehlig, 2004).

Coffee/Caffeine and Cognition: Normal and Pathological Aging

Cognitive functions (reaction time, rate of perception, and treatment of information) remain stable until 60 and slow down between 60 and 80. Cognitive decline is accelerated by poor lifestyle, vascular diseases, genetic factors, oxidative stress, and inflammation.

Normal Age-Related Cognitive Decline

Lifelong caffeine consumption allows improving cognitive functions (reaction time, verbal and visuospatial memory) in elderly subjects. Some studies reported positive effects in both sexes while others only observed an effect in women. The positive effect of coffee/caffeine is most prominent in the oldest subjects, over 80. This association is not found with decaffeinated coffee, indicating the role of caffeine and is significant for consumptions as low as 2–3 cups of coffee/day. Thus, the usual consumption of coffee/caffeine over lifetime could increase the cognitive reserve of elderly subjects (Ritchie et al., 2007; Santos, Costa, Santos, Vaz-Carneiro, & Lunet, 2010).

Coffee and Alzheimer's Disease

Alzheimer's disease (AD) is the most frequent cause of dementia, leading to progressive cognitive decline. AD is characterized by elevated brain levels of b-amyloid peptide (Ab). The mean estimated risk between coffee/caffeine consumption and the development of AD is reduced by 23% for consumers compared to nonconsumers. The lowest risk to develop AD is found in consumers of 3–5 cups of coffee daily. The confirmation of the reduction of the risk of AD by coffee/caffeine consumption still needs prospective studies including more cases (Santos et al., 2010).

In transgenic mice developing AD, the chronic addition of caffeine to drinking water at a dose equivalent to 5 cups of coffee daily improves learning and memory, and reduces the concentrations of Ab peptide in hippocampus, the cerebral region that controls memory. Moreover, caffeine drinking in aged mice with AD allows reversing the working memory deficit and reducing cerebral Ab peptide concentration (Arendash & Cao, 2010).

Caffeine and Parkinson's Disease

The consumption of coffee and caffeine reduces the relative risk (RR) to develop Parkinson's disease (PD). There is a global 25% decreased risk of developing PD in coffee/caffeine consumers versus nonconsumers with risk reductions up to 80% for the intake of 4 cups of coffee daily. The preventive effect is linked to caffeine since regular coffee, tea, and caffeine decrease the risk while decaffeinated coffee does not (Costa, Lunet, Santos, Santos, & Vaz-Carneiro, 2010).

In women, data are less clear. In those not taking hormonal therapy, coffee is as preventive as in men. In women taking hormones, caffeine is preventive in low consumers while the risk is increased fourfold in those drinking 6 cups of coffee or more daily compared to nonconsumers (Ascherio et al., 2003). These differences could be linked to the polymorphism of the gene coding for one enzyme of caffeine metabolism (CYP1A2 rs762551) and to an interaction between caffeine and some forms of estrogen receptors (Palacios et al., 2010).

The mechanism involved in the preventive effect of caffeine in PD is its antagonism at A2A adenosine receptors. Caffeine improves parkinsonian symptoms and potentiates the effects of L-dopa, the classical treatment of PD.

Coffee and the Cardiovascular System

Coffee has negative effects on some biological markers of risk of coronary heart disease (CHD). Paradoxically, a high coffee consumption does not increase the risk of CHD. A recent meta-analysis of 21 prospective cohort studies showed that compared to low consumption (<1 cup/day in the USA and <2 cups/day in Europe), the combined relative risk (RR) of CHD for moderate coffee consumption (3–5 cups daily) is significantly reduced by 18% in women and 13% in men (Wu et al., 2009).

Likewise, in large populations with a long follow-up there is no influence of coffee (less than 5 cups/day) on the risk of heart failure (RR 0.87 for 2 cups/day) and RR 0.89–0.94 for all other levels (at least 3 cups/day) compared to men consuming less than 1 cup/day, confirming the lack of effect of moderate coffee consumption on heart failure (Ahmed, Levitan, Wolk, & Mittleman, 2009).

Furthermore, the consumption of coffee does not increase the risk of atrial fibrillation or flutter whatever be the dose. Even consumers of 1–3 cups or more than 4 cups of coffee daily reduce their risk of arrhythmias by 7 or 18%, respectively, compared to nonconsumers (Klatsky et al., 2010).

Coffee intake increases systolic and diastolic blood pressure by 1.2 and 0.5 mmHg, respectively. At an equivalent dosage, caffeine intake has a more marked hypertensive effect (4.2 and 2.4 mmHg, respectively). However, coffee is not considered a risk factor for arterial hypertension. Boiled coffee has the strongest effect, followed by filtered and instant coffee; decaffeinated coffee increases systolic blood pressure by 0.9 mmHg and decreases diastolic pressure by 0.15 mmHg (Noordzij et al., 2005).

Filtered, instant coffee, and espresso do not significantly modify lipid metabolism while unfiltered boiled coffee increases total cholesterol, mainly the low-density lipoproteins and triglycerides, and should be avoided (Thelle, 2005).

In conclusion, there is no apparent cardiovascular risk linked to coffee consumption, except possibly in some patients at risk that should also stop smoking, increase physical exercise, and improve their diet.

Coffee and Cancer

Cancers of the Digestive Tract

Lifelong consumption of coffee reduces the risk of developing liver cancer by 38 à 59% compared to nonconsumers. The underlying mechanisms remain to be clarified (Arab, 2010; Cadden, Partovi, & Yoshida, 2007; Nkondjock, 2009).

The risk of colorectal cancer is reduced by 17% in coffee consumers and up to 30% in highest consumers. This protection linked to coffee seems to involve the anticarcinogenic properties of the diterpenes and antioxidants of coffee, the stimulation of the secretion of biliary acids and neutral sterols in the colon, and the stimulation of colon motility (Galeone et al., 2010).

There is no association between coffee consumption and the risk of developing stomach or pancreas cancer. There is no evidence to support a harmful effect of coffee consumption on prostate cancer risk. Caffeine intake does not change the risk of esophagus or larynx cancer and reduces the risk of oral cavity or pharynx cancer by 39% for the consumption of 4 cups of coffee/day (Turati et al., 2011).

Breast, Ovary, and Endometrial Cancer

In postmenopausal women, there is usually no relation between caffeine/coffee intake and breast cancer. During premenopause, the risk reduction reaches 50% in women consuming at least 4 cups coffee daily compared to low consumers (1–2 cups/day). Also, in premenopausal women that carry the *BRCA1* or *BRCA2* mutation, which increases the risk of breast cancer, the risk is reduced by 25–70% by a consumption of 4–6 cups of coffee daily. This beneficial effect is limited to caffeinated coffee (Arab, 2010).

While there is no relation between coffee/caffeine intake and ovary cancer, coffee consumption of at least 3 cups daily reduces the risk of developing endometrial cancer by 60% (Arab, 2010).

Prostate, Kidney, Bladder, and Skin Cancer

Prostate cancer and kidney cancer are not influenced by the duration or quantity of coffee consumed (Arab, 2010; Park et al., 2010).

The most recent data on bladder cancer report a lack of association in women and 26% increased risk in men consuming coffee. However, a critical risk factor is linked to the type of water used to prepare coffee. Chlorinated tap water increases bladder cancer while mineral water does not. The results of most epidemiological studies allow now excluding a strong relation between coffee and bladder cancer. The major risk factors are smoking and other dietary factors (Arab, 2010; Pelluci et al., 2010).

In mice, caffeine added to drinking water or topically destroys skin cells damaged by UVB irradiation. Caffeine also doubles the mortality of human skin cells damaged by UVB, and hence could decrease the risk of skin cancer. The underlying molecular mechanism is similar in both species and leads to the hypothesis that caffeine applied topically could potentially protect human skin against the harmful effect of UVB (Heffernan et al., 2009; Lu et al., 2008).

Coffee and Type 2 diabetes

Since 2002, over 20 studies devoted to the relation between coffee consumption and the risk of developing type 2 diabetes reported a largely reduced risk linked to frequent coffee intake across diverse populations. It is similar in men and women, obese and nonobese subjects. Most studies suggest a dose–response curve with larger risk reductions for high coffee intake. In general, the consumption of at least 4 cups daily is associated to a 30–40% decreased risk of type 2 diabetes compared to nonconsumers. For lower intakes, the risk decreases by 7% for each additional coffee cup. This inverse association is observed with caffeinated and decaffeinated coffee, with or without sugar but not with caffeine alone.

Antioxidants from coffee, such as chlorogenic and quinic acids, are potential candidates for this preventive effect since they can act as regulators of carbohydrate metabolism (Huxley et al., 2009; Pimentel, Zemdegs, Theodoro, & Mota, 2009; van Dam et al., 2008).

Caffeine, Fertility, Pregnancy, Fetal and Neonatal Growth

The effects of coffee ingestion on various parameters of reproduction, pregnancy, and fetal development were reviewed recently (Peck, Leviton, & Cowan, 2010).

Effects on Fertility

In natural pregnancies, there is no link between caffeine consumption and reduction of fertility. Likewise, caffeine does not influence the number of ovocytes collected and fertilized, the number of embryos transferred and successfully reaching term in in vitro fecundations. For male fertility, there is no association between caffeine intake and the number, mobility, morphology, DNA status of spermatozoids, and the onset of pregnancy (Peck et al., 2010).

Effects on the Course of Pregnancy

Caffeine ingested by the mother is very rapidly absorbed, crosses the placental barrier, and distributes in all fetal tissues, including the central nervous system. The half-life of caffeine is dramatically increased in the fetus (over 100 h) deprived of the enzymatic equipment necessary for caffeine catabolism.

Most studies did not find any association between a daily caffeine intake lower than 300 mg (3 cups of coffee) and the risk of miscarriage. Moreover, when accounting for the severity of nauseas that often lead to a reduction in coffee/caffeine consumption, the RR for miscarriages drops from 1.5 to 1.7 for a daily caffeine consumption of 300–500 mg to 1.0–1.1. Recently, a RR of 2.2 for miscarriages was found at a caffeine intake higher than 200 mg/day. However, this study did not carefully control for confounding factors such as degree of smoking and duration of the nausea period. By caution, several associations advised women who wish to start a pregnancy to limit their caffeine intake to quantities lower than 200 mg/day, while others maintained the earlier limit of 300 mg/day.

The vast majority of studies did not find any association between caffeine and fetal growth whatever the dose. After adjustment for smoking

and alcohol, a few studies observed fetal growth retardation for caffeine intake ranging from 300 to 800 mg/day. Fetal growth is more sensitive to caffeine during the first than during the third trimester of pregnancy and intrauterine growth retardation is only significant over 600 mg/day caffeine. There is no consistent report of an association between total exposure to caffeine and the risk of early (≤34 gestational weeks) or late premature delivery (35–37 weeks) (Peck et al., 2010).

Animal data showed dose-dependent teratogenic effect of caffeine, only at very high doses, over 80 mg/kg (60–80 cups of coffee in one sitting). In humans, no study reported any increase in the incidence of congenital malformations in babies born from women consuming large quantities of caffeine (300–1,000 mg/day) during their whole pregnancy.

Effects on Postnatal Development

Caffeine enters maternal milk but has no consequence on its composition and stimulates its production. Hence, women are advised to consume their coffee after instead of before lactating.

Studies on psychomotor development are reassuring. The prenatal consumption of caffeine does not influence the Apgar score, suction reflex, weight, height, or psychomotor behavior assessed during the first year. No effect could be shown on the intellectual quotient, motor skills, or vigilance at 4 and 7 years (Nehlig & Debry, 1994).

In conclusion, a moderate caffeine consumption (lower than 200/300 mg/day), in all forms, does not seem to notably influence fertility and fetal growth. There is still some doubt for higher dosages and it is wise to recommend women that wish to start a pregnancy, or are pregnant, not to go over the reasonable limit of 200/300 mg/day caffeine.

Caffeine and Sports Activity

Most studies reported positive effects of caffeine on performance in endurance tests; the distance covered over a given time or speed in running and cycling are increased, the efficacy in final sprinting is improved and the delay before sensing pain or exertion is increased. Likewise, in team sports like rugby, soccer, and field hockey that alternate prolonged activity with bouts of intense activity, caffeine supplementation provides beneficial effects. Caffeine is also beneficial in long-distance swimming, rowing, and middle and distance running races. In brief, physical exercise involving strength and power such as lifts, throws, and sprints the effects of caffeine are less clear and variable. Women also benefit from caffeine in sports activities ranging from recreational activities to rowing competitions, mainly when trained and moderately active (Burke, 2008).

The effective dose of caffeine depends on the level of training, habituation to caffeine, and type of exercise. Usually, the efficacy of caffeine is optimal at doses of 1.5–4.5 mg/kg in nonconsumers, 3–6 mg/kg in moderate consumers, and 6.5–9.5 mg/kg in high consumers. The ergogenic effects of caffeine are more variable when caffeine is absorbed in a drink like coffee compared to the anhydrous form (capsules or tablets) (Burke, 2008; Astorino & Robertson, 2010).

The effects of caffeine on muscle metabolism are still unclear. Caffeine was suggested to mobilize fatty acids from adipose tissue to spare muscle glycogen. In reality, it seems that caffeine has rather a central effect central on fatigue or facilitates muscle function. Caffeine co-ingested with carbohydrates can enhance their absorption and oxidation during exercise. In endurance cycling, golf, and team sports, performance is more largely improved by caffeine + carbohydrates than by either constituent given alone. Caffeine reduces also pain in caffeine consumers as found in cycling, leg and arm muscle training, and other endurance activities (Goldstein et al., 2010).

Conclusion

The data presented here reflect a large number of studies performed over the last decade on coffee and health. This wealth of data allowed the evolution from the negative idea that coffee/caffeine could not be good for health because the consumer was enjoying these drinks too much. It is now widely accepted that

the moderate consumption of caffeine (3–4 cups coffee daily) in the context of a balanced diet has no negative impact on human health. In fact, on the basis of the data on normal cognitive decline, Parkinson's and Alzheimer's disease, type 2 diabetes, and cancer, the consumption of coffee appears even beneficial for human health.

Definition

Cognitions are internal mental representations best characterized as thoughts and ideas. Cognitions result from, and are involved in, multiple mental processes and operations including perception, reasoning, memory, intuition, judgment, and decision making.

As internal mental states, cognitions are not directly observable but are still amenable to study using the scientific method. Cognitions can be subjectively elicited on questioning or experimentally measured using reaction times, psychophysical responses, or real-time neuroimaging techniques to infer internal processing.

As cognitions play a fundamental role in determining behavior, the study of cognitive factors facilitates a better understanding of processes and outcomes in health, health behavior, illness, and disability. Examples of cognitions with particular relevance for behavioral medicine include illness perceptions (Leventhal, Diefenbach, & Leventhal, 1992); biases and distortions in decision making (Kahneman & Tversky, 1979); attitudes, beliefs, and perceptions of control (Ajzen, 1991); and the executive functions (Williams & Thayer, 2009).

Definition

The concept of cognitive appraisal was advanced in 1966 by psychologist Richard Lazarus in the book *Psychological Stress and Coping Process*. According to this theory, ▶ stress is perceived as the imbalance between the demands placed on the individual and the individual's resources to cope (Lazarus & Folkman, 1984). Lazarus argued that the experience of stress differs significantly between individuals depending on how they interpret an event and the outcome of a specific sequence of thinking patterns, called appraisals (Lazarus, 1991).

Cognitive appraisal refers to the personal interpretation of a situation that ultimately influences the extent to which the situation is perceived as stressful. It is the process of assessing (a) whether a situation or event threatens our well-being, (b) whether there are sufficient personal resources available for coping with the demand of the situation, and (c) whether our strategy for dealing with the situation is effective (Lazarus, 1991). This process can then be further subdivided into three categories: primary appraisal, secondary appraisal, and reappraisal:

- *Primary appraisal* refers to the initial evaluation of the situation, deemed as benign positive (positive), threatening (negative), or irrelevant (neutral). If the situation is appraised as being irrelevant or benign positive, no heightened physiological arousal occurs and the situation will not be perceived as stressful. If the situation is appraised as negative, the individual will make a secondary appraisal in regard to harm (harm-loss), threat, or challenge.
- *Secondary appraisal* refers to the evaluation of an individual's ability or resources to cope with a specific situation. Secondary appraisal interacts with primary appraisal to determine emotional reaction to a situation. A harm (harm-loss) appraisal is the assessment that damage has occurred as a result of the situation and the necessary resources to effectively cope with the situation may not be available. Threat appraisals occur when it is anticipated that the situation may result in loss or harm in the future and the resources to effectively cope with the situation may not be available. A challenge is perceived when a situation is demanding but ultimately can be overcome, resulting in the individual benefiting from the situation. Both harm and threat appraisals result in the situation being deemed as stressful, whereas a challenge appraisal does not.
- Reappraisal is the continuous reevaluation of a situation based on the availability of new information. This step of reappraisal takes place throughout the entire process and can change the way an individual perceives a situation.

Definition

Cognitive behavioral therapy is a classification of psychotherapies which integrate cognitive and behavioral theories and methods. CBT approaches share fundamental assumptions that cognitions mediate situational responses and that changes in cognitive activity can affect therapeutic changes in emotions and behaviors.

Description

Brief History of CBT

CBT interventions represent an integration of behavioral and cognitive theories and methods. Behavior therapy emerged in the 1950s and 1960s through research on clinical applications of classical and operant conditioning theories (e.g., systematic desensitization; Eysenck, 1966; Wolpe, 1958). Behavior therapy emphasizes the primacy of behaviors, and radical behaviorists view thoughts as a type of internal behavior. The primacy of thoughts in shaping situational responses appears in early philosophical traditions ranging from Stoicism to Buddhism (Wright et al., 2006). Formally, the cognitive underpinnings of CBT emerged in the 1960s and 1970s, largely through developments by Albert Ellis (rational emotive therapy; 1957) and Aaron T. Beck (cognitive therapy; 1963, 1964) and contributions from Alfred Adler, George Kelly, and behaviorists described above. Rational emotive therapy has been considered the first of the cognitive interventions to appear; it introduced a novel, directive approach to challenging patients' irrational beliefs. Beck's cognitive therapy also emphasized a primary role of cognitions in psychiatric problems, and he formally described the maladaptive cognitive biases associated with depression as targets for therapeutic change.

The coalescence of cognitive and behavioral therapies over the past few decades has been due to several factors, including the challenges of applying behavior theory to the complex range of human behaviors (for example, obsessional thinking), the introduction of a formalized cognitive therapy for depression, and the growing support for CBT interventions in both research and practice. Behaviorists view behavior change as the primary goal of therapy, whereas cognitive theorists view behavior strategies as means for affecting change. Yet both schools share a commitment to applying the scientific method to clinical problems and their treatments. Since the early works which focused primarily on depression and anxiety, CBT models have since been expanded to explain and treat a wide range of psychiatric disorders.

A number of membership organizations support CBT research and practice, and their histories reflect the history of CBT itself. For instance, in 1966, the Association for Advancement of Behavioral Therapies (AABT) was founded by behaviorists due to their dissatisfaction with the psychoanalytic model. The name was formally changed to the Association for Behavioral and Cognitive Therapies (ABCT) in 2005, to reflect the increasing influence of cognitive theory and methods. Similarly, the British Association for Behavioural Psychotherapy (BABP) was founded by behaviorists in 1972; its scope was broadened in 1992 when it became The British Association for Behavioural and Cognitive Psychotherapies (BABCP).

CBT Model of Clinical Symptoms

CBT emphasizes the role of individuals as active information processors. The meaning we apply to a situation shapes our emotional reactions to the situation and what we may do to cope with our emotions. Our behaviors, in turn, affect our

thought patterns and emotional responses. In other words, cognitions, emotions, and behaviors are intimately linked. These relationships are illustrated in the following scenario:

A supervisor had begun to criticize two employees, J.F. and A.B., for minor errors at work. J.F. interpreted the situation to mean that he was a poor performer and a liability to his department. This caused J.F. to feel dejected, which led him to increase his efforts to please the supervisor. J.F. began to work late at night; drink more coffee to stay awake; and consequently experience fatigue and anxiety the next day. This led him to make more errors at work, creating a self-fulfilling prophecy which strengthened his anxiety and negative beliefs about himself. Meanwhile, A.B. presumed that the supervisor was simply singling her out for criticism. This caused A.B. to feel irritated, which led her to act indifferently toward the supervisor while maintaining her current level of work performance. Her relationship with the supervisor deteriorated, reinforcing A.B.'s belief that people are generally disrespectful.

This scenario highlights that two different interpretations without clear evidence led to quite different emotional and behavioral consequences. These interpretations also could reinforce longstanding negative beliefs about the self (in the case of J.F.) or the world (in the case of A.B.). This is a key learning point for individuals during therapy. In the long term, entrenched patterns or styles of thinking and behaving can become associated with clinically significant distress. Indeed, psychiatric disorders are distinguished by distinct profiles of cognitive and behavioral bias. In his original work, Aaron T. Beck described depression as the result of negative thinking about the self, world, and future (1963, 1964). Other examples include phobias as the inaccurate perceptions of danger, and suicidality as the perception of hopelessness and deficits in problem-solving skills.

Applications of the CBT Model in Behavioral Medicine

The CBT model can be particularly useful in behavioral medicine, to capture biopsychosocial aspects of health promotion and disease management. Research evidence strongly supports links between cognitions, feelings, and health behaviors. For instance, many chronic medical conditions are associated with elevated risk for depression. Depressed individuals, in turn, have difficulties with motivation, interest, and problem solving, and are therefore less likely to practice self-care behaviors such as physical activity, healthy eating, and adherence to medical regimens. The following scenario illustrates these relationships:

S.P. had been prescribed a daily HIV medication for the past year. She did not believe that the medication did much to manage her condition. Every morning, she would dread looking at the medication bottle. It was a reminder that she was ill, and this reminder provoked other familiar thoughts that her life was over and that she would never find a romantic partner due to her HIV status. These thoughts, in turn, reminded her that she was profoundly alone. For S.P., it was easier to ignore the sight of the bottle and skip her medication dose, which she frequently did. However, the thoughts remained and often provoked painful depressed moods which decreased her motivation and energy to answer phone calls from her friends. S.P. spent most of her time at home alone, which reinforced her beliefs about being undesirable to others. Most recently, she missed her regular HIV primary care visit. It seemed too difficult to secure a ride to the clinic, and she thought, "What's the point anyway, this disease is not going away."

This scenario shows bidirectional relationships between depression and poor HIV self-care. In practice, the CBT case formulation would address how inaccurate cognitions, emotional distress, and coping behaviors are influencing each other in a perpetuating loop, which serves to maintain both depression and poor self-care. The case formulation would also help to highlight key areas for CBT intervention to break this loop. In developing the CBT treatment plan, a therapist may draw systematically from CBT strategies, including: (1) providing psychoeducation about depression, HIV, and HIV medications; (2) increasing engagement in activities

which promote enjoyment and sense of mastery; (3) challenging severe negative beliefs; and (4) problem-solving medical adherence. This approach highlights that all three domains (cognitions, emotions, and behaviors) are being addressed. Common CBT intervention elements are described further in the next section.

Common Elements of CBT Interventions

In CBT interventions, the therapist actively collaborates with the patient (i.e., "co-therapist"). They work together to identify and alter problematic patterns of thinking and behaving, and thereby help the patient manage negative emotions and improve quality of life. The therapist first collects information about the patient's presenting problems, and then shares and revises the CBT case formulation with the patient. This formulation directly informs the therapy. The therapist and patient work together to set a treatment plan and articulate goals at the outset of therapy, and to set agendas at each therapy session. During the course of CBT, the therapist may use Socratic questioning to guide patients in their own discovery of problematic patterns in their thinking and behaving. Sessions are problem oriented and typically focus on building skills which address these patterns. "Homework" assignments encourage the patient to rehearse and problem-solve the skills in real-life situations. Throughout treatment, progress is monitored using symptom inventories (for example, the Beck Depression Inventory [BDI] or the Hospital Anxiety and Depression Scale [HADS]) as well as informal feedback. Most CBT interventions are intended to be time limited; the ultimate goal is for patients to become increasingly independent in their use of the skills until the therapist is no longer needed.

The following is a sample of common CBT intervention strategies:

Psycho-education is used throughout CBT interventions. A critical component of CBT is to engage patients in understanding the CBT model, the rationale for treatment, and the therapeutic methods as applied to their clinical problems. In other examples, CBT for panic disorder includes information on physiologic activation, whereas a patient on long-acting pain medications may benefit from understanding the impact of missed or delayed medication doses.

Behavioral strategies are used to help patients break unhelpful behavior patterns such as fear avoidance or depressive inactivity. For example, exposure methods involve generating a hierarchy of situations that induce fear and avoidance, and conducting structured "experiments" which increase real-life or imaginal exposure to these situations. In behavioral activation, the patient is guided to increase activity level by generating a list of activities that promote enjoyment and sense of mastery, and then setting and monitoring daily or weekly activity goals.

Cognitive strategies are used to promote optimal thinking about difficult situations. As a primary example, cognitive restructuring is a framework for recognizing negative, inaccurate thoughts and replacing them with alternative ones that are more realistic and helpful. This may involve several steps: write down the situation; list negative thoughts that occurred during the situation; list emotions that arise when having these thoughts; identify cognitive distortions or errors that may underlie each thought; challenge each thought; and generate rational responses. The rational responses are self-statements that are used to reduce distress and view situations in a more helpful light.

Considerations for CBT in Behavioral Medicine Populations

CBT interventions have been incorporated into the American Psychiatric Association clinical practice guidelines for a wide range of psychiatric disorders. However, chronic medical conditions introduce some unique aspects to consider during CBT evaluation and delivery. Psychiatric symptoms can overlap with or mask disease symptoms and treatment side effects (for example, cancer-related fatigue, dyspnea, or uncontrolled pain), underscoring the importance of assessment and differential diagnosis for behavioral medicine patients. Also, health cognitions and emotional distress levels can be dynamic, changing over time in response to disease-related events (for example, receiving

medical test results), uncertain disease courses, or certain disease progression. For many medical conditions, disease symptoms fluctuate, influencing mobility, fatigue, and cognitive functioning. Adaptations to CBT protocols have been recommended to incorporate these factors. For instance, behavioral activation and homework assignments can be adapted so that patients modulate daily activities according to current level of energy (activity pacing). Cognitive restructuring can be supplemented with acceptance-based or problem-solving strategies when negative health cognitions reflect both realistic and unrealistic elements, and both controllable and uncontrollable stressors.

For the sample scenario of S.P., described above, a CBT intervention might proceed as follows:

The therapist worked with S.P. to generate a CBT model of her depression and problems with HIV self-care. Socratic questioning was used to help S.P. discover links between her thoughts (perceived impact of HIV on her value as a person); feelings (sadness and loneliness); and behaviors (medical non-adherence and self-isolation). The therapist and S.P. used this model to develop a treatment plan and set goals. S.P.'s main goal was to repair some of the meaningful relationships in her life. The therapist provided psycho-education about depression and HIV. S.P. began to internalize that self-care was a step toward improving relationships with others. Behavioral activation was introduced to help S.P. increase engagement in activities that she used to enjoy and that could give her opportunities to challenge her belief that others would reject her. Activities were modified on days when S.P. experienced fatigue or medication side effects. Cognitive restructuring helped S.P. develop healthier cognitions such as more neutral perceptions of HIV medications. Finally, problem solving was introduced to help S.P. organize her efforts toward increasing her adherence and enhancing her social support. While S.P. experienced setbacks, she increasingly began to recognize her tendency to make devaluing statements about herself during stressful situations, and she continued to work toward changing this pattern.

CBT Applications in Behavioral Medicine

There is growing evidence to support CBT interventions to improve health behaviors, enhance quality of life, and reduce psychological symptoms among individuals with medical comorbidities. For instance, Safren, Gonzalez and Soroudi (2008) developed a CBT intervention for depression and medical adherence (CBT-AD) in patients with chronic illness such as diabetes or HIV. Cognitive behavioral stress management (CBSM) is a group intervention developed by Antoni, Schneiderman and Ironson (2007) to improve quality of life in HIV-infected adults, which has since been adapted for cancer survivors (Penedo, Antoni, & Schneiderman, 2008). CBT strategies have also been adapted to treat or reduce disability associated with a range of specific medical concerns. Examples include nicotine dependence, obesity, chronic illness rehabilitation, hypertension, and various functional pain and fatigue conditions. For instance, CBT protocols for either nicotine dependence or obesity may include goal setting; psychoeducation; self-monitoring (recording number cigarettes or food intake per day); stimulus control (reducing contact with environmental cues that trigger smoking or overeating); and coping skills for relapse prevention.

Definition

Cognitive factors refer to characteristics of the person that affect performance and learning. These factors serve to modulate performance such that it may improve or decline. These factors involve cognitive functions like attention, memory, and reasoning (Danili & Reid, 2006).

Cognitive factors are internal to each person and serve to modulate behavior and behavioral responses to external stimuli like stress. Performance on various activities of daily living has been found to be affected by these factors. Executive functions, for example, have been shown to predict ability to live independently in older adults such that those with poorer executive functioning are less able to live independently (Vaughn & Giovanello, 2010). Turning to behavioral responses to stress cognitive factors is known to play a role in posttraumatic stress disorder. The nature of the memory of the trauma may play a role in PTSD, that is, persistent PTSD is often associated with memories of the trauma that are poorly elaborated and not well integrated into the person's autobiographical memory (Dumore, Clark & Ehlers, 2001). More generally cognitive style may serve as an important cognitive factor. Messick (1994) refers to cognitive style as

characteristic modes of thinking, perceiving, problem solving, and remembering that may influence how a person approaches a problem or task.

Cognitive Function

Definition

Cognitive function derives from the term cognition which refers to the internal mental processes studied in a subdiscipline of psychology termed cognitive psychology. These internal mental processes underlie how people perceive, remember, speak, think, make decisions, and solve problems. Cognitive function is a general term used to describe many different functions such as memory and attention thought to be components of the mind (Benjafield, Smilek, & Kingstone, 2010).

Description

Cognitive functions are internal and are inferred from behavior using measures such as accuracy in performing a task like recalling a list of words or the time taken to find some word on a page of text. The study of cognitive functions derives from the information processing approach which argues that these functions involve operations occurring at various processing stages. The identification of these processing stages is typically based on a model of the cognitive function of interest. Using this model, a task thought to reflect the cognitive function of interest is manipulated in such a way as to place demands on the processing stages identified. If we use memory as an example, the task of recalling a list of words can be manipulated to place demands on two processing stages: encoding or putting words into memory or retrieval involving retrieving words from memory. The encoding stage is emphasized when demands are placed on just recognizing whether words presented were in the list, while the retrieval stage is emphasized when demands are placed on recalling the words from the list. The study of cognitive functions then involves the use of experimentation through manipulation of task demands. This use of the scientific method spawned the development of another subdiscipline of psychology termed cognitive science.

The study of cognitive functions involves not only identifying the processing stages but also the strategies used and the errors made. Turning again to memory function and word list recall as an example, one strategy used involves semantic clustering where the person creates groupings of words from the list based on the meaning category such as clothes or fruit. This clustering serves to improve recall of the words. With regard to errors, intrusions and false positive

errors in recalling words from the list provide insight into the integrity of memory. Intrusions are errors where the person recalls a word not on the list, while false positive errors occur when the person is read a list of words some of which were not on the recall list. A false positive error is one where the person endorses a word that was not on the list. Both of these errors indicate that the ability to discriminate in memory between words on the recall list from those not on the list is impaired.

This information on cognitive functions has been used in the development of psychological tests designed to examine cognitive functions (Hodges, 2007). These tests are administered to groups of people categorized based on factors such as age, sex, and years of education. Performance of these people is then used as normative data against which to compare performance of people who take the tests in the future. These comparisons involve determining the average and the standard deviation for each group in the normative sample. The mean and standard deviation are reference points to determine where relative to the mean a person taking the test falls. The distance the person's score falls relative to the mean is measured in standard deviation units. The number of units above or below the mean reflects the percentage of people in the normative sample who are above or below the mean. Thus, if we use the memory test as an example, a person with a score at one standard deviation unit above the mean would be at a point where 84% of people fall at or below this score. This approach to measurement termed psychometrics reveals the relative strengths of a person on various cognitive functions. This pattern of strengths is used in the subdisciplines of psychology called clinical psychology and educational psychology to direct people into education programs and work placements. The alternative to patterns of strengths is patterns of weakness in cognitive functions. Such patterns are used in a subdiscipline of psychology called clinical neuropsychology to identify cognitive impairments.

Another focus of study with regard to cognitive functions is the brain correlates of these functions. One approach called cognitive neuroscience uses functional neuroimaging and correlates patterns of brain activity to the processing stages in various cognitive functions. The other approach called clinical neuropsychology uses psychometrics alluded to above to identify patterns of impairment in cognitive functions arising from some type of brain damage and correlates these impairments with measures of brain damage using structural (e.g., MRI) and functional (e.g., fMRI) brain imaging.

Cognitive Impairment

Definition

Cognitive impairment refers to problems people have with cognitive functions such as thinking, reasoning, memory, or attention.

Description

Cognitive impairment can be present at any point in a person's lifespan (Kolb, & Whishaw, 2009).

Early in life, cognitive impairment may arise from, for example, genetic syndromes, prenatal drug and alcohol exposure, trauma, or oxygen deprivation during or after birth.

Cognitive impairment in childhood and adolescence may result from a number of conditions. Examples include malnutrition, heavy metal exposure, metabolic disorders, trauma to the brain, and side effects of drug treatments for cancer or Parkinson's disease (Ogden, 2005).

With age conditions such as traumatic brain injury, neurodegenerative disorders such as Alzheimer disease, stroke, brain tumors, and brain infections can cause cognitive impairment.

In some cases, cognitive impairment is reversible if the cause is identified and treated. For example, cognitive impairment arising from stroke due to a blockage of a blood vessel can be prevented if drugs designed to break up the blood clots are administered within hours of the formation of the clot. Similarly, cognitive impairments associated with metabolic disorders can be reversed with treatment of the disorder.

Cognitive impairment is defined as a disruption to some cognitive function such as memory (Lezak, Howieson, & Loring, 2004). Identifying a cognitive impairment requires a comparison of performance to some expected level of performance. In some cases, this expected performance is defined informally, for example, a person who is unable to remember the name of a life-long friend is thought to exhibit a cognitive impairment. In most cases, it is these cognitive impairments defined on the basis of informal expected level of performance which results in the person visiting a health-care practitioner for a more thorough investigation.

Such more thorough investigations identify cognitive impairments using more formal standards called norms which reflect expected performance on standardized tests of cognitive functions such as memory (Hebben, & Milberg, 2009). These tests are administered to groups of people categorized on factors such as gender, age, and years of education. Performance of these people forms normative data against which is compared performance of people who take the tests in the future (Strauss, 2006). These comparisons require determining the average and the standard deviation for each group in the normative sample. The mean and standard deviation are points of reference to determine where relative to the mean a person taking the test falls. The distance the person's score falls relative to the mean is measured in standard deviation units. The number of units above or below the mean reflects the percentage of people in the normative sample who are above or below the mean. Thus, if we use the memory test as an example, a person with a score at one standard deviation unit above the mean would be at a point where 84% of people in the normative sample fall at or below this score. This point is termed the 84th percentile. This approach to measurement reveals the relative strengths or weaknesses of a person on a cognitive function. A weakness is termed an impairment or deficit and reflects performance at one standard deviation unit below the mean at the 16th percentile. At this point, 84% of the people in the normative sample lie above this score.

This psychometric approach to identifying a cognitive impairment is often accompanied by a more qualitative approach where particular errors or strategies in test performance are of interest. For example, in the context of a memory impairment involving learning a list of words, the person may recall or recognize a word that was not on the list. This error reflects an impairment in discrimination in memory which provides some insight into the nature of the memory impairment.

Mediating cognitions

Definition

Cognitive mediators are mental processes or activities that take place between the occurrence of a stimulus and initiation of an associated response. Such processes can occur immediately following the stimulus (i.e., within microseconds), or they may be a more delayed response, taking days or weeks. These processes are delineated by mediation models of health experiences and behaviors which, in contrast to direct stimulus-response models, propose that events produce an effect on individual responses indirectly via cognitive mediators. Cognitive mediators include interpretation of information, information retrieval, judgments and evaluations, reasoning, and other mental processes. These processes may be conscious or nonconscious (i.e., automatically elicited outside of one's awareness), and they can be distinguished from affective mediators involving emotional processes.

Mediational models have been used to better understand the cognitive processes involved with a variety of health experiences, behaviors, and outcomes. Early behavioral medicine research on cognitive mediators examined their influence on pain perception and health status of individuals with medical conditions. More recently, research on cognitive mediators includes evaluations of their roles in the use of health-promoting behaviors such as smoking cessation, physical activity, dietary behavior, and behaviors for reducing skin cancer risk.

Definition

Cognitive restructuring is a strategy to recognize negative, inaccurate thoughts and replace them with alternative ones that are more realistic and helpful. This cognitive strategy, a key part of cognitive behavioral therapy, promotes optimal thinking about a stressful or overwhelming situation to reduce emotional distress. Cognitive restructuring may involve several steps: write down the situation; list negative thoughts that occurred during the situation; list emotions that arise when having these thoughts; identify cognitive distortions or errors that may underlie each thought; challenge each thought; and generate rational responses. The rational responses are self-statements that are used to feel better about the situation.

Cognitive restructuring may help individuals with a chronic illness to manage how the illness affects their perceptions of themselves, their relationships, and their future. For example, an individual may be experiencing persistent anxiety since his return to work following a myocardial infarction. The individual may be encouraged to identify a specific situation that is making him anxious ("My supervisor pointed out some errors in my work"); his negative thoughts ("I can't do anything right since I had my heart attack," and "I'll probably get fired"); and his resulting emotions (fear, despair). Through cognitive restructuring, the individual may work on challenging his thoughts and generating alternative responses: "I don't have any evidence that my supervisor is dissatisfied with my work in general. I have been taking care of myself since my heart attack. No one is perfect, and in the future, I can leave more time to check my work." The individual may then assess whether the rational responses help him to reduce his distress and view his situation in a more helpful light.

Definition

Cognitive strategies are sets of mental processes that are consciously implemented to regulate thought processes and content in order to achieve goals or solve problems. Self-regulation theories of behavior focus on cognitive strategies as playing a critical role in guiding goal-directed behavior. Cognitive strategies are primary targets for numerous intervention approaches, including cognitive behavior therapy (CBT), mindfulness-based interventions, and acceptance and commitment therapy (ACT). Cognitive strategies include those directing attentional focus (e.g., attentional engagement or distraction), cognitive reframing or reinterpretation of distressing experiences, imagery techniques, and mental rehearsal of positive statements.

Within the health setting, pain management is one area in which cognitive strategies may be useful. Examples include distraction, where one diverts attention away from the painful stimulus and towards a non-painful alternative; imagery, such as imagining a favorite scene or other non-painful image; and redefinition, where pain cognitions related to threat or fear are replaced with constructive or nonthreatening thoughts. Cognitive strategies can also be of benefit to individuals with chronic illnesses who are experiencing psychological distress or difficulty managing their conditions. Within the context of health promotion, mental imagery techniques have been demonstrated to increase physical activity among sedentary adults.

Cohort Study

Jane Monaco
Department of Biostatistics, The University of North Carolina at Chapel Hill, Chapel Hill, NC, USA

Synonyms

Follow-up study; Observational designs; Observational studies; Observational study

Definition

A cohort study is an observational study design in which subjects are usually selected based on their risk factor exposure and followed over time to evaluate whether they develop the outcome of interest (usually disease).

Description

Cohort studies are commonly used in behavioral medicine research to investigate associations in which experimental designs are unethical or too costly. In a cohort design, participants who have not experienced the outcome of interest are selected, usually based on whether or not they have been exposed to the risk factor of interest. Therefore, a cohort study design is efficient when the exposure is relatively rare but the outcome of interest is common. For example, a cohort design was used in a study of the association of prenatal polychlorinated biphenyl (PCB) exposure with behavior issues and cognitive disability (Lai et al. 2002). A cohort design is also appropriate when the exposure is common.

The most common type of cohort study, a prospective cohort study, identifies subjects without the outcome of interest (such as disease-free participants) at the outset of the study and then follows them forward through time to assess their outcome (or disease) status. Because the subjects have not experienced the outcome at the outset of the study, this prospective design is less susceptible to many types of bias compared to other observational study designs, such as case-control studies. Included in the prospective cohort study design are large studies such as the Framingham Study in which participants were selected for logistical reasons. By recruiting a large number of residents from the single community of Framingham, Massachusetts, follow-up was simplified, and investigators were able to study prospectively the associations between multiple risk factors and outcomes among the participants (Dawber, Kannel, & Lyell, 1963).

Not all cohort studies are conducted prospectively. In a retrospective cohort study, both the exposure and outcome may have occurred at the time of the initiation of the study. These retrospective, sometimes called historical, cohort studies are often conducted using data previously collected for other purposes. For example, pregnant women drivers involved in motor vehicle crashes were identified by linking Washington State Patrol records to birth and death certificates (Wolf et al., 1993). The exposure of interest, seatbelt use at the time of the crash, was determined using the police reports. Investigators determined pregnancy outcomes (including low birth weight and fetal death) based on the birth and fetal death certificate data. This retrospective cohort study found the risk of a low-birth-weight infant was higher among unrestrained female drivers compared to those wearing a seat belt at the time of the crash.

In a cohort study, investigators must follow both the exposed and unexposed subjects equally carefully to avoid detection bias. If the exposed subjects are followed more closely, then an excess number of outcomes may be detected within the exposed group resulting in an overestimate of the exposure effect. Also, loss to follow-up may result in biased results when that loss is associated with the exposure and outcome.

Some characteristics of cohort studies:

- Usually more expensive and time consuming than case-control designs; less expensive than an experimental design
- Often used when the exposure is rare

- Not practical when outcome of interest (disease) is rare or has a long-latency period
- Appropriate when studying multiple outcomes
- Usually can only address a single risk factor
- When information collected prospectively, reduces potential for bias
- Can be impacted by loss to follow-up
- Can compute incidence and relative risk of outcome directly
- Often considered stronger study design compared with case-control studies, but weaker study design compared to randomized trials that investigate analogous associations

Cold pressor task

Definition

The cold pressor test is a widely used experimental technique for human pain or stress induction, involving immersion of the hand or forearm in cold water. First documented as a test of cardiovascular stress reactivity (Hines & Brown, 1936), its application in investigation of pain perception, mechanisms, and treatment is due to a gradually mounting painful sensation of mild to moderate intensity. As water temperatures used are within the range considered noxious (below 15°C), nociceptors (pain receptors) are activated and transmit an aversive signal to the CNS. While nociception-transduction ion channels involved have been identified, the exact mechanisms of cold pain are not fully elucidated (Basbaum, Bautista, Scherrer, & Julius, 2009).

Like other pain inductions, the cold pressor allows fast and precisely controlled evaluations not possible in a clinical context. Apparatus for the task is a tank of circulating water of temperature most often between 0°C and 5°C, with instruction to immerse the hand until too uncomfortable to continue. A maximum time limit per immersion of 3–5 min is normally applied. Quantitative measurement can then be made of pain threshold (point first perceived as painful), tolerance time, and perceived intensity and unpleasantness. The technique is regarded as safe for pain evaluations in children, usually at a slightly higher water temperature (von Baeyer, Piira, Chambers, Trapanotto, & Zeltzer, 2005).

Upper respiratory infection (mild)

Definition

The common cold is the familiar name for a mild upper respiratory infection (URI). Symptoms of the common cold include nasal congestion, mucus production, sneezing, cough, and sore throat (Eccles, 2005). The common cold is caused by any of a number of viruses, most often one of the rhinoviruses (see ► Common Cold: Cause).

URIs are responsible for 50% of all acute illnesses, with common colds accounting for most of that proportion. While symptoms are often mild, the common cold often confers a heavy burden on patients, healthcare providers, schools, and workplaces. Approximately 62 million cases of the common cold occur each year in the United States. In addition, 20 million school days are lost annually as well as 22 million work days due to the common cold (Adams, Hendershot, & Marano, 1999).

The incubation period for the common cold largely depends on the virus that causes it. On average, symptoms begin 2–3 days after virus exposure and infection. From the onset of the first symptoms, severity usually peaks within 2 days. Overall, the duration of the common cold is usually 7–10 days (Eccles, 2005).

Because only a proportion of people who are exposed to cold viruses actually develop symptoms, the common cold has become a fertile ground for studying psychosocial and behavioral

factors that influence vulnerability to infection. Viral challenge studies expose healthy individuals to common cold viruses and then keep them in quarantine over several days to assess who develops infection and symptoms and who does not. Prior to virus exposure, a plethora of behavioral and psychological measures are performed in order to assess the roles these factors may play in illness susceptibility.

Within these experimental studies, individuals are determined to have a cold if they (1) are infected with the challenge virus and (2) meet a set of predetermined criteria based on subjective symptom reports and objective physiological measurements. Infection is determined by the presence of viral shedding (i.e., replication of the virus in the host environment). Viral shedding is assessed by administering a nasal wash, which flushes the nasal cavity and sinuses, and then culturing a sample of the exposed wash solution for the presence of replicating virus. Presence and severity of cold symptoms, i.e., runny nose, sore throat, nasal congestion, etc., are assessed via observation and participant report. Objective measures of cold severity include mucus production and mucociliary clearance function. Mucus production is assessed by collecting used tissues from participants and measuring their weight; nasal mucociliary clearance, or how effective the body is in clearing mucus from the nasal passage, is assessed as the time it takes for a dye administered in the nostrils to reach the nasopharyx (Doyle, McBride, Swarts, Hayden, & Gwaltney, 1988). Additional measures, such as lung function, may also be taken.

Through these common cold studies, several behavioral and psychosocial factors have been found to greatly increase susceptibility to infection, including sleep patterns, social integration and stress. These topics are discussed further in ▶ Common Cold: Cause and ▶ Common Cold: The Stress Factor.

Definition

The common cold is a mild upper respiratory illness that results from infection with any of more than 200 viruses, most notably the rhinoviruses. The rhinovirus family is comprised of over 100 different viruses, with the relative prevalence of each being dependent on a number of factors, from geographical area to time of year. Overall, rhinoviruses make up approximately 30–50% of all acute respiratory illnesses, but in the fall season this proportion jumps to about 80%. Coronaviruses comprise another family of viruses that cause the common cold. Infections with coronaviruses are estimated to account for 7–18% of adult colds, and in contrast to rhinovirus infections, tend to be most prevalent during the winter and spring months. Additional cold viruses include parainfluenza, respiratory syncytial virus (RSV), the adenoviruses, and the enteroviruses which collectively account for

a comparatively small percentage of infections. In addition, 20–30% of common cold cases are of unknown origin (Heikkinen & Jarvinen, 2003).

Cold viruses are highly contagious, and interpersonal transmission of colds typically occurs in one of two ways: (1) inhaling viral particles that are released into the air in tiny droplets when infected persons cough, sneeze, or blow their nose; or (2) coming into contact with surfaces that have been contaminated by infected secretions (e.g., a doorknob that was touched by an infected person immediately after coughing into his or her hand) and then touching one's own eyes, nose, or mouth.

Several factors have been found to influence whether individuals become infected following exposure to a cold virus and/or the severity of their symptoms once infected. Most of these findings have derived from viral challenge studies wherein healthy individuals are exposed to cold viruses (most often rhinoviruses), placed under quarantine, and monitored by trained medical staff for objective signs and subjective symptoms of a cold (see ▶ Common Cold). Of all potential susceptibility factors, stress has been the most explored. Accordingly, the role of stress in cold susceptibility is discussed in a separate entry (see ▶ Common Cold: The Stress Factor). Stress, however, is far from being the only factor that has been found to influence who develops colds. For example, smokers are more likely than nonsmokers to become infected with the cold virus and, consequently, to develop illness symptoms (Cohen, Tyrrell, Russell, Jarvis, & Smith, 1993). Social relationship factors have been found to influence cold susceptibility as well. People who are high in trait sociability (which is thought to be an important determinant of quantity and quality of social interaction) and those with more diverse social networks are less susceptible to colds than their less sociable and less socially integrated counterparts (Cohen et al., 1997; Cohen, Doyle, Turner, Alper, & Skoner, 2003a). A third identified susceptibility factor is affect. Specifically, greater positive affect is associated in a dose-response manner with reduced likelihood of developing a cold (Cohen, Doyle, Turner, Alper, & Skoner, 2003b). Importantly, all of these factors remained associated with cold susceptibility even when controlling for age, sex, body weight, and season of exposure.

Definition

One of the most consistent findings from viral challenge studies (see ▶ Common Cold) is that

the experience of stress is positively associated with susceptibility to the common cold. Here stress is defined as a psychological state resulting from outside factors or events placing demands on an individual that exceed his or her resources or ability to cope (Cohen, Kessler, & Gordon, 1995). Although stressful experiences such as bereavement and care giving have long been believed to suppress host resistance, the common cold studies were the first to demonstrate the role of the stress factor under prospective, controlled conditions.

Cohen, Tyrrell, and Smith (1991) conducted one of the first studies to explore the role of stress in susceptibility to the common cold. The authors assessed several stress factors, including life events and perceived stress in a sample of healthy adults, and then experimentally exposed these individuals to a cold virus or to a saline control. Despite controlling for several person and environmental factors, the researchers observed a dose-response association between stress and clinical colds: more stress was associated with an increased likelihood both of becoming infected and displaying clinical symptoms. Furthermore, they also found that long-lasting social stressors accounted for the greatest infection risk. These stress factor effects were all independent of potential mediators such as smoking, diet, alcohol use, and sleep quality. Cohen et al. (1998) further explored several types of stressors linked to the common cold and found that severe, chronic stressors – especially work and interpersonal stressors, lasting 1 month or longer – conferred a substantial risk of developing a clinical cold after virus exposure. Moreover, the longer the stress duration, the greater the relative risk of a cold. Again, these differences could not be completely explained by environmental, person-related, or behavioral factors.

An important feature of the common cold is that associated symptoms (sneezing, congestion, etc.) are caused by the body's immune response to the virus, not the virus per se. Most symptoms result from the production of pro-inflammatory cytokines that recruit other immune cells to fight the infection. Several "host" factors influence the immune system's response to infection and how severe resulting symptoms will be. These include age, general health, and past infection experience. However, the repeated finding of greater stress being associated with increased risk for colds independent of behavioral factors or health practices suggests that stress may be influencing the immune system, as well, by suppressing some resistance processes. For example, in influenza challenge studies, increased psychological stress was associated with higher pro-inflammatory cytokine concentrations, particularly interleukin (IL)-6 (Cohen, Doyle, & Skoner, 1999). In an experimental study in which stress was induced in a laboratory setting, Marsland, Bachen, Cohen, Rabin, and Manuck (2002) found that being exposed to a stressor was associated with increases in immune markers, such as circulating natural killer cells and cytotoxic T cells. These studies suggest that stress may be acting through major immunological pathways to increase symptoms of infectious illnesses.

Common Disease-Common Variant

Definition

The common disease-common variant (CDCV) hypothesis predicts that for any given common disease, the genetic risk will be due to common variants with high frequency in the population (Pritchard & Cox, 2002; Reich & Lander, 2001).

The allelic spectrum, i.e., the frequency of the allele in the population and the number of disease-predisposing alleles, of common diseases is still not well understood. The number of common variants contributing to any given common disease will most likely vary from less than 100 to several thousands, with many of these variants having a low effect on the disease (Padhukasahasram et al. 2010).

Genome-wide association studies (GWAS) have succeeded at identifying common variations, many with low effect sizes (odds ratio ~1.2–1.5). However, there are many more left to be identified. A number of reasons have been suggested as to why GWAS have not identified more variations. These include rare variations contributing to common diseases, phenotypic heterogeneity, sample size, or regions missed by single nucleotide polymorphism (SNP) microarrays.

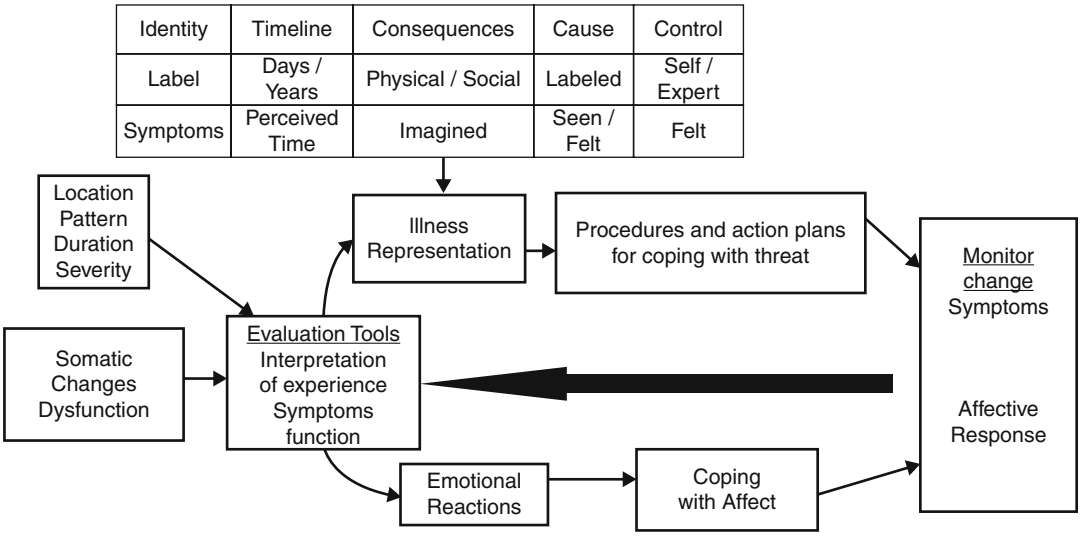
Definition

The common-sense model of self-regulation explains how individuals respond to and manage health threats. It proposes that people actively engage in problem-solving by developing mental models of health threats, subjective and objective treatment goals, and practices and procedures most likely to achieve those goals.

Description

Background

The origins of the common-sense model of self-regulation (CSM) can be traced to the parallel model proposed by Leventhal in the early 1970s to understand how individuals



Common-Sense Model of Self-regulation, Fig. 1 Individuals assess somatic changes based on the features of the changes by using evaluation tools (e.g., location, pattern, duration, or function) and comparing these features against illness prototypes. If deemed to be a health threat, the individuals develops cognitive and emotional representations of the threat. The cognitive representation consists of five bi-level domains. Cognitive and emotional representations guide the selection of coping procedures and the criteria for assessing effectiveness of these procedures (e.g., changes in symptom and/or affectivity). Evidence of success or failure to achieve desired changes will be used by the individual to re-assess the illness representation

respond to fear-arousing communications (Leventhal, 1970). Similar to the parallel model, the CSM posits that when a threat is perceived (e.g., physical symptoms or changes in function), individuals develop two parallel, yet interrelated, representations of the stimulus: cognitive and emotional (Leventhal et al., 1997). These representations and their content specify the actions (i.e., behaviors) in which individuals engage to remove the health threat. The CSM proposes that the processes involved in the self-regulation of health threats are regulated by a TOTE (Test-Operate-Test-Exit) system with both feedback and feed-forward loops (Miller, Galanter, & Pribram, 1960).

Common sense self-regulation is divided into three phases (Leventhal & Cameron, 1987). In the first stage, the perceptual stage, a discrepancy between a perceived input and a reference value is detected (i.e., health threat). At this stage, the individual develops a common sense illness representation of the potential health threat. In the second stage (i.e., the response stage), the individual selects and performs actions (i.e., coping procedures) to reduce the discrepancy. The illness representation developed during the perceptual stage will help select the types of coping procedures used by the individual during the response stage. In the last stage, the appraisal stage, the results of the action(s) aimed at reducing or eliminating the discrepancy are evaluated. If the actions are successful in dealing with the threat, the loop stops. If unsuccessful, the individual may reassess the representation and form a new illness representation, and/or select and perform new corrective actions. This loop will continue until the threat has been successfully removed or controlled.

Illness Representations

The CSM assumes that people are active problem-solvers who continuously assess the meaning of somatic sensations and/or changes in function by forming cognitive and emotional illness representations (see Fig. 1). Illness representations have a bi-level structure that includes an abstract level (i.e., disease labels and chronological time) and a concrete level

(i.e., symptoms and experienced time). Initially, the CSM identified five defining aspects of illness representation: identity, timeline, causes, consequences, and controllability. Abstract features of *identity* include the label applied to the health threat (e.g., diagnosis or name of the condition). Concrete features of *identity* refer to how the threat is experienced (e.g., symptoms and/or changes in function). *Timeline* refers to the objective (i.e., abstract: duration in minutes or hours) and perceived (i.e., concrete: perceived duration) temporal features of the health threat. *Causes* refer to the diagnosed (i.e., information conveyed by the doctor) and perceived (i.e., leaving home with wet hair) factors that caused the health threat. The causes of a threat can be grouped into external agents (e.g., virus, bacteria, or stress), internal susceptibilities (e.g., age, genetics), and behaviors (e.g., smoking). *Consequences* include both anticipated (i.e., abstract) and perceived and experienced (i.e., concrete) physical, psychological, social, and economic effects that the health threat will produce. Controllability refers to whether the person expects and perceives the health threat to be susceptible to control by experts (e.g., physician) and/or the self.

The existence of a sixth domain, "illness coherence," has been proposed by Weinman and collaborators (Moss-Morris et al., 2002). Illness coherence is a metacognition that refers to the extent to which an individual believes that the various features of an illness hang together. For example, someone who suffers from a cold would expect that symptoms such as a runny nose and a sore throat would last for a couple of weeks. However, if unusual symptoms are experienced or if the timeline of the symptoms is longer than expected, the individual will have trouble making sense of the health threat. Low coherence has been shown to have an impact on other dimensions of illness representations and on the appraisal and enactment of coping procedures.

Illness representations and their content serve as guides for the selection, performance, and evaluation of actions used to manage illness episodes. Feedback from these actions can reshape the representations and alter subsequent coping actions. For instance, actions taken to ameliorate a stomachache could involve drinking herbal tea or having a bland diet, whereas a headache might lead the person to take an over-the-counter pain reliever. The appraisal of the effectiveness of these actions will also vary depending on the specific content of the representations. For example, the expected timeline for ridding oneself of a stomachache is likely several hours to a day, while the expected timeline for determining that a pain reliever is effective in dealing with a headache could be to 1–2 h at most.

Appraisal of Health Threats. When a deviation from "normal function" is detected (e.g., a health threat such as somatic symptoms or declines in physical function), the individual will promptly engage in an automatic scanning process in which the properties of the health threat are assessed (Leventhal, Breland, Mora & Leventhal, 2010). These properties are compared against illness prototypes developed through prior personal experience, observation of others, and media exposure (cf. Fig. 1). Prototype checks are used evaluate somatic and/or functional changes with respect to features such as their location (e.g., head, stomach, chest), duration (e.g., perceived and clock time), rates of change (e.g., sudden onset or insidious), consequences (e.g., disrupts breathing or impairs walking), causes (e.g., exposure to sick people or perceived stress), and sensory properties (e.g., sharp or dull). If the features of the somatic or functional changes match an illness prototype, then a preliminary illness representation will be formed and lead the individual to engage in actions to remove or control the threat (i.e., coping procedures). A further appraisal of the threat will be conducted based on the perceived effects of these coping procedures. Feedback from coping procedures will provide critical information to either confirm or disconfirm the preliminary illness representation. For instance, a headache and a runny nose may be the result of a cold or of seasonal allergies. If the symptoms occur around spring, then the person may decide to take an antihistamine pill to help clear the symptoms. If after a few hours the symptoms

are not relieved, then the tentative "allergies" representation may be discarded, and a new health threat appraisal process will begin.

Lack of experience with a specific condition or unusual presentation of symptoms can create confusion during the matching and appraisal process and result in negative consequences such as delayed care seeking or poor illness management. For example, gastric pain caused by gallstones could be attributed to indigestion or stomach flu if a person has never been exposed to gallstones and the symptomatology associated with gallstones previously because the location is similar (i.e., abdominal area). This could lead individuals to engage in watchful waiting which, in turn, could increase the risk of serious consequences such as emergency hospitalization due to blockage of the pancreatic duct. Conditions that do not manifest according to the prototypes people have can result in inadequate management or control of the threat. For instance, the symptoms that people with congestive heart failure usually experience (e.g., swollen legs, breathing and sleeping problems) are not the symptoms that a person with a "heart" condition is supposed to experience (e.g., palpitations). This mismatch can result in poor adherence to medical treatment because the heart condition does not represent an immediate threat. Similarly, depressive symptomatology may not be properly identified and treated among older adults, because they are less likely to experience symptoms of dysphoria (i.e., depression without sadness, Gallo, Rabins, Gallo, & Rabins, 1999). Low negative affect will make the matching processes difficult for both the individuals who experience depressive symptoms and mental health professionals because the symptoms do not fit with a "depression prototype."

Treatment Representations

From the CSM perspective, treatment representations are conceptualized using the same framework as illness representations (Leventhal et al., 2010). That is, treatment beliefs are assumed to have an identity (e.g., "diuretic"), timeline (e.g., for how long one should take the medications or time for treatment to effect changes), causal factors (e.g., works by killing bacteria), control (e.g., cure and control of disease symptoms), and consequences (e.g., addiction or improved quality of life). Research directly examining these dimensions of treatment representations is limited. Several studies conducted by Leventhal and collaborators, however, have assessed some of these facets (e.g., Halm, Mora, & Leventhal, 2006). These assessments have focused on aspects such as triggers that initiate the use of medication (e.g., "I use medications when I have symptoms"), control (e.g., "My medicines protect me from becoming worse"), consequences ("My health in the future depends on my medications"), and emotional reactions ("How worried are you about the side effects of your medication?"). Evidence from these studies have shown that these aspects of treatment representations are strong predictors of illness self-management.

A different view of treatment representations has been put forth by Horne, Weinman, and Hankins (1999). Based on common sense regulation principles, Horne and collaborators identified commonly held beliefs about medications and medical treatments and grouped them into "general" and "specific" concerns about medications. "General concerns" encompass beliefs that medications, in general, are overprescribed by practitioners (i.e., overuse) and beliefs that medicines can be harmful and addictive (i.e., harm). "Specific concerns" address the beliefs that a prescribed medication is necessary for and efficacious in controlling a particular condition and concerns about the harmful effects of a medication prescribed for a specific illness.

Despite the apparent differences, both views are conceptually consistent. Further, the CSM could be used as a more general framework within which the two major domains (i.e., general and specific concerns) can be organized. For instance, specific beliefs include both cognitive and emotional aspects of treatment representations. Similarly, some specific beliefs about the necessity of medications can be categorized as beliefs about the consequences of treatment (e.g., my health in the future depends on medicines).

Measurement

Because of their central role in the CSM, most measurement efforts have focused on developing instruments to assess the content of illness and treatment representations. These efforts have been guided by two different approaches. In the first approach (i.e., domain-based approach), investigators develop measurement to assess content relevant to the specific illness condition under investigation. Researchers who use the second approach (i.e., instrument-based approach) prefer the use of basically the same instrument and items across domains.

The domain-based approach requires close familiarity with the health threat (i.e., illness condition) to be studied. Although illness representations of various conditions may share some features, they can be highly divergent in terms of how they are experienced by individuals, their consequences, and their management. Thus, to develop valid and relevant items, one needs to rely on the use of theory, pilot interviews with patients who suffer a given condition, and input from practitioners (Leventhal & Nerenz, 1985). Items developed by using this approach usually focus on very specific aspects of illness and treatment representations in order to gain a more detailed understanding of underlying psychological processes and mechanisms. The resulting instrument may consist of single-item subscales that may be unique for the illness condition being studied (e.g., Halm et al., 2006). The development of items to assess treatment representations is conducted in a similar fashion. When developing items to assess treatment representations, one must pay special attention to issues such as the cues used by individuals for initiating and evaluating action (e.g., Do symptoms or objective information such as blood glucose monitoring initiate self-management?), the expected time for observing effects, and the specific behaviors used to control or eliminate the health threat (e.g., complementary medicine, rest, and distraction).

The instrument-based approach is best represented by multi-item questionnaires developed to assess both illness and treatment representations. The Illness Perception Questionnaire (IPQ) assesses the five original domains of illness representations (i.e., identity, timeline, consequences, causes, and controllability), emotional representations, and illness coherence (Moss-Morris et al., 2002). The items do a good job of providing a snapshot of people's illness representations. Two versions of the IPQ are available: the IPQ-R which is the long version and consists of over 50 items and the brief IPQ which includes eleven questions (Broadbent, Petrie, Main, & Weinman, 2006). The IPQ questions are standard, though it is possible to make modifications to the items' wording and/or include a condition-specific symptom list, to reflect the illness condition being investigated. The IPQ has been successfully used in a wide range of studies examining various chronic conditions such as asthma, diabetes, cardiovascular disease, and rheumatic conditions.

To date, the only instrument that assesses treatment representations is the Beliefs about Medications Questionnaire (BMQ) developed by Horne et al. (1999). The BMQ is a multi-item instrument that comprises two scales that assess general and specific concerns about medicines. Similar to the IPQ, the wording of the items is standard but can be modified to reflect the different types of treatments. For example, pill can be substituted for inhaler. Research has shown that the aspects of treatment representations assessed by the BMQ predict self-management and medication adherence across various chronic conditions (e.g., Horne & Weinman, 1999).

Both approaches present different limitations and offer unique advantages. The domain-based approach has most often been criticized for relying on single-item measures to assess the various aspects of illness representations. The assumption underlying this criticism is that single items have low reliability. However, there is no evidence to suggest that single items do not make reliable assessments (Wanous, Reichers, & Hudy, 1997). The main advantage of this approach is that the development of domain-specific items can facilitate the theoretical understanding about the precise pathways linking illness and treatment representations, behaviors, and health outcomes within each

illness conditions. The downside of domain-based measures is that the uniqueness of items makes it difficult to compare findings across illness conditions.

Because the IPQ-R and the BMQ include multiple items to assess each construct, the estimation of reliability is not an issue. However, because there are several instances in each subscale where items are similarly worded, the multi-item nature of the scales does not result necessarily in a more precise instrument. In addition, as indicated by Broadbent, Petrie, Main, and Weinman (2006), the large number of items makes it difficult to use when resources are limited. Length of the instrument has been addressed by the development and validation of the brief IPQ. The main advantage of these instruments is that the wording of items is consistent across studies and illness conditions, which facilitates comparisons. It is important to note, however, that psychometric research is needed to determine whether these instruments are invariant across people with different illness conditions and across countries.

Combining both approaches will most likely have the greatest impact from both a research and an applied perspective. A set of items such as those from the brief IPQ would provide investigators with a core set of items that could be employed in all studies, thus enabling future comparisons. The addition of domain-specific items to the brief IPQ would allow investigators to delve into specific issues unique to the health threat under investigation.

Interventions and the CSM

A basic corollary of the emphasis the CSM puts on the content of illness and treatment representations and the actions specified by these representations is that successful interventions require an adequate model of the problem. This implies that interventions will vary depending on the health status of the target population (e.g., well vs. not well) and on the type of illness conditions individuals have if the target population for the intervention consists of people with chronic conditions. For instance, primary prevention interventions (e.g., screening or lifestyle changes) that target individuals who feel healthy require that investigators understand the factors that make them feel vulnerable to health threats (e.g., perceived risk based on age or family history). Interventions with persons suffering from chronic conditions require investigators to have a detailed understanding of the disease and its context. If the interventions are aimed at improving self-management, for instance, investigators need to know the cues that impede or facilitate behaviors (e.g., symptoms), beliefs about treatments (e.g., risk of addition), and the complexity of the treatment.

The context in which the intervention is delivered will also affect the foci and the delivery of interventions. For example, interventions to improve adherence to medical treatment may have different targets for change depending on whether they are delivered in the office of a primary care physician or in the community. Primary care physicians can focus on eliciting illness and treatment representations and negotiate with patients a representation that encourages adherence to medical treatment. For a condition such as asthma, if patients hold an acute view of the condition and, therefore, use inhaled corticosteroids only when having symptoms, then the primary care physician may provide them with appraisal tools to disconfirm this inaccurate belief. Such patients may be instructed to climb up one flight of stairs for a few days and take notice of their breathing, before beginning their daily regime of medications. This simple instruction should help patients realize that without their medication, their breathing becomes more difficult with minimal exercise, despite the absence of noticeable symptoms prior to the exercise. This could provide experiential evidence for the patient that asthma is present even when asymptomatic. To solidify this more accurate illness representation, these patients may then be instructed to repeat this exercise after following the inhaled corticosteroid regime as prescribed and notice improvements in their breathing after climbing up stairs. This second part of the intervention can allow patients to link improvements in breathing with the regular use of medications. Thereby, the reformulation of

their illness representation can be a life-saving tool. A community-based, population level intervention, unlike the physician-patient dyad interaction described above, is likely to deal with patients whose beliefs may differ widely. In this case, attempting to change each individual's representations may not be feasible. A more effective and efficient approach would focus on modifying management behaviors, such as how to incorporate the use of inhaled corticosteroids into one's daily routine, by, for example, leaving the inhaler on the kitchen or dining room table, the proper technique to use the inhaler, and incorporating abstract information (e.g., peak flow meter readings) into the monitoring of asthma. An intervention focusing on patient-doctor interaction has provided important evidence that physicians can successfully elicit patients' illness representations during medical visits (de Ridder, Theunissen, & van Dulmen, 2007). Unfortunately, this intervention did not test whether discussion of illness representations results in improved health outcomes.

Despite the consistent and robust findings that illness and treatment representations are powerful determinants of behaviors (Hagger & Orbell, 2003), interventions using principles from the CSM are sparse. The results of these interventions, nonetheless, are quite promising. Interventions with patients suffering from chronic conditions have demonstrated that changing illness representations has an important effect on health outcomes (e.g., Petrie, Cameron, Ellis, Buick, & Weinman, 2002). However, specific pathways through which changes in illness representations affect health are not yet clearly understood.

Concluding Remarks

Although the CSM is a sound and powerful theoretical framework, there is still much to do to improve the understanding of the cognitive and emotional determinants of health-related behaviors. Two key issues that need more research attention can be highlighted. First, enormous progress has been made in the study of illness and treatment representations, but less is known about how other aspects of the CSM such as appraisal tools, coping procedures, and criteria to appraise coping procedures interact to influence self-regulation. Not only is such knowledge necessary for better understanding of psychological phenomena but also for the design of more effective and potentially life-saving interventions. Emotional aspects of illness and treatment representations constitute another area that requires more research. Emotional representations have been shown to play an important role in care seeking and self-management (e.g., Mora, Robitaille, Leventhal, Swigar, & Leventhal, 2002); however, their interaction with illness representations in determining behaviors is not yet fully understood. Progress in these areas will greatly benefit from basic behavioral medicine research conducted in conjunction with intervention research. If properly designed and theoretically sound, intervention studies can provide strong evidence of causal relations. A comprehensive mapping of mechanisms, however, may require the use of nontraditional designs that focus on changing well-delimited processes in a sequential manner (i.e., tailored, stepwise interventions).

Theoretical progress should occur simultaneously with advances in measurement (Petersen, van den Berg, Janssens, & Van den Bergh, 2011). Testing the full CSM will require that researchers develop adequate measurement. Initiatives such as the NIH PROMIS provide a good model to follow (Cella, Gershon, Lai, & Choi, 2007). The creation of item banks based on theoretical and practical considerations would afford investigators both a common set of tools to allow comparisons and flexibility to address issues unique to the research problem. This will also require that researchers adopt current measurement strategies such as item response theory to examine the psychometric properties of their instruments.

Communication Skills

Yori Gidron
Faculty of Medicine and Pharmacy, Free University of Brussels (VUB), Jette, Belgium

Definition

Communication skills are an essential medium through which physicians interact with patients, in order to diagnose and treat patients. According

to Ong, de Haes, Hoos, and Lammes (1995), doctor-patient communication has three main roles: (1) to create a positive interpersonal relationship, (2) exchange information, and (3) make treatment-related decisions. A positive interpersonal relationship includes facilitation of trust between the patient and a health professional that enables honest bidirectional expression of concerns and report of behaviors (e.g., risky behaviors, nonadherence). Exchange of information is the basis of the doctor-patient interaction, where information from patient to doctor enables the latter to arrive at more accurate diagnoses and more suitable and effective treatments. Similarly, exchange of information from physician to patient enables the doctor to inform the patient about risks of unhealthy behaviors (e.g., smoking) and benefit of others (e.g., self-monitoring of glucose levels or of physical activity). Finally, adequate communication helps physicians decide about patient-tailored treatments, suitable to their age, culture, levels of information-seeking, family history of an illness, comorbidities, etc.

According to research (e.g., Di Blasi, Harkness, Ernst, Georgiou, & Kleijnen, 2001; Ong et al., 1995), doctor-patient communication skills (e.g., information giving, listening, reassuring) affect patients' satisfaction from treatment, understanding and recall of the interaction with doctors, adherence to medical regimes, and actual health outcomes. The influence of communication skills on patient recall is important given that patients can at times recall very little of the information provided to them during consultations. A review on this topic found 14 studies on verbal variables and patient outcomes and showed that factors such as empathy, reassurance, "psychosocial talk," humor, and patient-centered talk correlated with positive health outcomes. The same review identified eight studies on nonverbal communication and patient outcomes and showed that factors such as head nodding, forward leaning, and less mutual gaze correlated with positive health outcomes (Beck, Daughtridge, & Sloane, 2002). Communications skills can be, and are taught, as part of medical education in many medical schools worldwide. Studies show that such training positively influences patients' health outcomes including blood pressure and glucose stability (Inui, Yourtee, & Williamson, 1976). Interestingly, doctors' communication skills also influence patients' decision making (van den Brink-Muinen et al., 2006), an important finding in an era where patients take a more active role in their health care.

Communication involves three elements: sender, receiver, and message. In nonverbal communication, the message does not involve words, but rather employs *body language*. There are three major sorts of nonverbal communication. S*ymbolic nonverbal communication* is the intentional encoding of a message that is decoded by the receiver, the grammar and vocabulary of which must be learned by both sender and receiver. It is propositional in that it is capable of logical analysis (e.g., it can be false). Symbolic nonverbal communication includes sign language, finger spelling, and pantomime, as well as facial expressions and gestures associated with language. In Ekman and Friesen's (1969) analysis, the latter include *emblems* with specific "dictionary" definitions, *illustrators* of what is said, and *regulators* of interaction flow. Left hemisphere damage produces deficits in both linguistic and symbolic-nonverbal communication.

Spontaneous communication involves the display of a motivational-emotional state by the sender and a pickup of that display by the receiver. It is non-intentional, based upon innate displays and preattunements that coevolved, that is, that evolved simultaneously with the function of communication. Preattunements may be associated with mirror neuron systems that respond immediately and automatically to displays. The elements of spontaneous communication are *signs*, being inherent aspects of the referent (as smoke is a sign of fire). If the sign is present, the referent must be present by definition so that spontaneous communication is nonpropositional. Spontaneous displays include facial expressions, affective vocal prosody or paralanguage, postures and gestures, eye behaviors, touch (haptics), spatial behaviors (proxemics), and olfactory cues (e.g., pheromones). Right hemisphere damage produces deficits in communication via facial expression and affective prosody.

The third sort of nonverbal communication involves the intentional management of the display by the sender to manipulate the receiver (*deception*) or to follow *display rules*: learned rules about what displays are appropriate under what circumstances. Buck and van Lear (2002) termed this *pseudospontaneous communication*: it is symbolic on the part of the sender but spontaneous on the part of the receiver. The ability to influence others' emotions successfully is an important aspect of *charisma*. Ekman and Friesen (1975) identified expression management techniques: a person might *modulate* the intensity of the display, *qualify* a felt display by adding an additional display, and *falsify* the display in several ways: *neutralizing* and showing no display, *simulating* an unfelt display, or *masking* what one actually feels by showing a different, unfelt display.

Community Coalitions

Definition

The definition of community coalition can vary depending on the discipline of origin and different variables of interest (Gentry, 1987). However, a common definition used in community health is "a group of individuals representing diverse organizations, factions, or constituencies within the community who agree to work together to achieve a common goal" (Feighery & Rogers, 1990).

Description

Types of Coalitions

Historically, a diverse number of models have been conceptualized through which to understand the ways in which coalitions function in their communities. These include collaboration approaches, empowerment, asset-based approaches, constructions of risk and protective factors for intervention development, citizenship models promoting citizen participation, and promotion of community development (Francisco, Fawcett, Wolff, & Foster, 1996). Other approaches to understanding coalitions focus, more specifically, on optimal internal functioning of these organizations (e.g., Allen, 2005 and Foster-Fishman, Berkowitz, Lounsbury, Jacobson, & Allen, 2001).

Community Coalition Action Theory

While each of these emphasis and proposed mechanisms of action includes their own framework for understanding the successful development of a coalition, the single most comprehensive framework is the Community Coalition Action Theory as proposed by Frances Butterfoss and Michelle Kegler (2009). This examination of the structure and development of coalitions specifically in community change contexts was formulated through extensive research, practice, and review of the field. It is comprised of 14 major constructs each with its own set of theory propositions.

Construct 1: Stages of Development

In this construct, it is proposed that coalition building is cyclical. Coalitions develop in three general stages (formation, maintenance, and institutionalization), but these stages recycle as new members are recruited, plans change, or new issues are added. At each stage, specific factors unique to that stage and to that coalition enhance coalition function and progression to the next stage.

Construct 2: Community Context

Here it is proposed that contextual factors have a significant impact on the function and effectiveness of the coalition. These factors include but are not limited to geography, sociopolitical environment, social norms surrounding collaborative efforts, and timing.

Construct 3: Lead Agency/Convener Group

Coalitions form when a lead agency or convening organization responds to an opportunity, threat, or mandate. Through their review of the state of the field, the authors propose here that the formation of the coalition is more likely when the convener group provides support and resources during the formation stage (e.g., technical assistance, financial and material support, credibility, and networks and contacts). They also argue that enlisting community gatekeepers to develop credibility and trust with others in the community is a way to increase the success of coalition formation.

Construct 4: Coalition Membership

The authors propose, around membership, that coalitions begin by recruiting an initial core group of highly committed members. They also propose that effective coalitions eventually expand this established core group to include a broader constituency of partners that represent the more diverse needs, interests, and groups in the community.

Construct 5: Operations and Process

In order to ensure an effective internal process, five necessary components are proposed: open and frequent communication among staff members, shared and formalized decision making, effective conflict management, positive relationships among members, and the perception by members

that the benefits of participation outweigh the costs of participation.

Construct 6: Leadership and Staffing
Here it is proposed that effective coalition functioning, collaboration, and planning are improved by strong leadership and skilled, paid, staff.

Construct 7: Structure
The proposition in this construct is that having formalized rules, roles, structures, and procedures leads to routinized operations being better sustained and to overall coalition effectiveness.

Construct 8: Pooled Member and External Resources
Here it is proposed that that synergistic pooling of resources from members and from the community leads to effective assessment, planning, and implementation strategies.

Construct 9: Member Engagement
The authors propose that satisfied and committed members will participate more fully in the work of the organization.

Construct 10: Assessment and Planning
The proposition here points to evidence that shows that successful implementation of coalition efforts is more likely when comprehensive assessment and planning occur.

Construct 11: Implementation of Strategies
The proposition here is that community change is more likely to occur of coalitions direct their efforts at multiple levels.

Construct 12: Community Change Outcomes
This proposition highlights the fact that coalitions that can change community policies, practices, and environments are more likely to achieve long-term success and increases in community capacity to address future issues.

Construct 13: Health and Social Outcomes
Here the authors propose that the ultimate indicator of coalition effectiveness is improvement in health and social outcomes.

Construct 14: Community Capacity
The final construct in this model proposes that, as a result participating in a successful coalition, organizations, and community members, achieve increases in capacity and social capital that allow them to address health and social issues in the future.

Coalition Evaluation

Historically, there have been a wide variety of approaches to evaluating the effectiveness of coalitions. These evaluations have employed qualitative, quantitative, and mixed methodologies and typically have examined coalitions at one or more of the following levels: process and infrastructure, specific programs and interventions, health status or community change outcome, and extent of community capacity building (Butterfoss, 2007; Granner & Sharpe, 2004). Given the wide variety of coalitions, their reasons for existing, and the mechanism by which they propose to act on their communities, Berkowitz (2001) argues that this diverse set of evaluation strategies is necessary if evaluators are to effectively understand the degree to which coalitions are successful.

While acknowledging the necessary diversity of coalition evaluation strategies, Butterfoss (2007) proposes ten overall principles to guide coalition evaluation:

1. The evaluation should involve a process of partnership between coalition and evaluator.
2. The evaluation design should be informed by research, previous evaluations, and community wisdom.
3. The evaluation should actively include the participation of all stakeholders.
4. The evaluation process should be used to assess, reflect, improve, and inform.
5. Expectations for the evaluation should be made clear for all stakeholders.
6. Issues of power and privilege should be explicitly identified and addressed at the start.
7. The evaluation should constantly seek to foster positive relationships and trust among evaluators, community participants, practitioners, and funders.

8. The process of evaluation should be closely integrated into ongoing functions and activities.
9. The evaluation process, itself, should be periodically reevaluated to ensure that it continues to meet the coalition's needs and in order to apply findings to ongoing decision making and learning.
10. Findings should be shared frequently with all stakeholders in a format that is accessible to them.

Evaluations the follow these principles can help coalitions in a number of ways (Butterfoss, 2007; Butterfoss & Francisco, 2004): providing accountability to the community and funders for the actions of the coalition, determining whether coalition objectives are met, improving program implementation, increasing awareness and support of the coalition in the community, informing policy decisions, and contributing the empirical literature on best practices.

Community Sample

J. Rick Turner
Cardiovascular Safety, Quintiles, Durham, NC, USA

Definition

Community samples are used in community trials, or community intervention trials, i.e., trials in which the intervention is implemented at the community level. This contrasts with clinical trials, where intervention is implemented at the level of the individual subject.

Consider the example of testing the dental health advantages of adding fluoride (fluoridation) to drinking water. Realistically, a study investigating the influence of fluoridation would need large community samples. A classic study was reported by Ast and Schlesinger (1956) in which the drinking water for one town in New York State was fluorinated and the water for a second town in the state was not. The towns were chosen to be as similar as possible so that any difference in dental health could reasonably be attributed to the influence of interest, i.e., presence or absence of fluoride in the water. The study provided compelling evidence that fluoridation is both effective in reducing dental caries and a safe public health practice.

Exposure status in community trials, therefore, is assigned to an entire community rather than to individuals. Typical outcomes of interest include the risk of disease or the frequency of a health behavior (Hartge & Cahill, 2008). Since the unit of observation is the community, the assessment of potential confounders can also occur at the community level, and thus appropriate care in that regard is needed.

Definition

Community-based participatory research (CBPR) is a set of principles and techniques designed to involve community members as collaborators in every aspect of the research process, including design, funding, implementation, and dissemination (Higgins, Maciak, & Metzler, 2001; Israel et al., 1998). Fully realized, CBPR includes shared expertise between researcher and community, shared decision making, and mutual ownership of the research enterprise and its results. Effective CBPR normally results from a long-standing, trusting relationship between an academic research team and a community-based organization (CBO) (Israel et al., 1998; Viswanathan et al., 2004). CBPR is of particular value to health researchers, public health professionals, and community leaders attempting to address health disparities influenced by social determinants (e.g., socioeconomic status, race, ethnicity, literacy, nutrition, environmental health). CBPR also holds relevance for policymakers attempting to turn community-needs assessments into evidence-based action or to translate basic and clinical research findings into population-wide practice.

Research Process

CBPR adheres to the same high-quality research standards that apply to health and behavioral research designs, including observational studies, cohort studies, and randomized controlled trials. CBPR distinguishes itself, however, by involving community members (through needs assessments, iterative community-based meetings, and other opportunities for comment) in every stage of the research process. Beginning with the research question, community members help define the health outcomes, behaviors, and environmental factors to be addressed by the research proposal. A community advisory committee, normally chaired by a community-based stakeholder, is often an integral part of the research process. In the spirit of mutual expertise and collaboration, CBPR research protocols often employ community residents as members of the research team, and they may include support for research facilities and research materials housed inside a community-based facility (Stratford et al., 2003; Vander Stoep, Williams, Jones, Green, & Trupin, 1999). All study interventions, research trainings, survey materials, informed-consent documents, and other materials include input and guidance from community members. Measures employed in CBPR usually include social determinants of health and cost-effectiveness variables from the community perspective. Study results are normally shared with the community advisory committee or other community members for feedback and interpretation before they are shared with outside audiences. With attention to community standards and research ethics, results are also disseminated across the community. In the case of interventions determined to be effective, sustainability planning that includes community leaders is a critical element of the CBPR process.

Health Behavior Change

CBPR enables researchers to be sensitive and responsive to the cultural, political, and social context of health behaviors. This includes challenges and opportunities for influencing sensitive health behaviors (e.g., smoking, drug use, sexual practices, domestic violence, obtaining screening tests that involve pelvic or rectal exams) and other health behaviors that can only effectively

be addressed at the community level (e.g., nutrition, physical activity).

Ethical Considerations

CBPR may also present constraints for the conduct of ethical research. In choosing the primary research topic or question, a community-driven process may not yield a result that meets the academic considerations of relevance, novelty, and generalizability. Similarly, community members may object to the publication of study findings or interpretations, even if "objective" research methods were applied. Funding and other rewards for CBPR also may introduce ethical dilemmas. In optimal circumstances, community representatives and organizations should be reimbursed fairly for their participation. If addressed early and forthrightly, many of these ethical concerns may be mitigated. Effective should include gaining insight and assent from all available community leaders, providing appropriate training if appropriate to participants, ensuring financial and nonfinancial recognition for participants, and clarifying rules for ownership and use of study data, analyses, and publications.

Definition

Comorbidity occurs when an individual experiences two or more disorders at the same time (Eaton, 2006). Comorbidities can occur sequentially, or they can become symptomatic simultaneously. Disorders that are considered comorbidities can be either physical or psychological in nature. It is a common occurrence

that a disorder in one domain (e.g., a physical disorder of spinal cord injury) will trigger or exacerbate a disorder in another domain (e.g., a psychological disorder of depression). Two disorders within the same domain are also considered comorbidities (e.g., depression and anxiety, or chronic obstructive pulmonary disorder and ischemic heart disease). There are some disorders that are such frequent comorbidities that they may eventually be combined under a single label and treated as a single syndrome (e.g., metabolic syndrome which often includes high blood pressure, Type 2 diabetes, obesity, hypercholesterolemia, and dyslipidemia).

Treatment providers will often assess for comorbidities in order to tailor the best treatment approach to that individual. Being aware of a patient's comorbidities allows a treatment provider to educate the patient, consider additional treatment options, and potentially begin treatment for the comorbidity.

Definition

The definition of Comparative Effectiveness Research (CER) for the Federal Coordinating Council reads as follows (HHS.gov):

Comparative effectiveness research is the conduct and synthesis of systematic research comparing different interventions and strategies to prevent, diagnose, treat, and monitor health conditions. The purpose of this research is to inform patients, providers, and decision-makers, responding to their expressed needs, about which interventions are most effective for which patients under specific circumstances. To provide this information, comparative effectiveness research must assess a comprehensive array of health-related outcomes for diverse patient populations. Defined interventions compared may include medications, procedures, medical and assistive devices and technologies, behavioral change strategies, and delivery system interventions. This research necessitates the development, expansion, and use of a variety of data sources and methods to assess comparative effectiveness.

The inclusion of "behavioral change strategies" makes CER of immediate interest in the field of behavioral medicine.

Description

Sox and Greenfield (2009) discussed various important steps in the development and formalization of CER. A seminal article was published

by Wilensky (2006), and an Institute of Medicine (IOM) report called for a national initiative of research that would support better decision making about interventions in health care (IOM, 2008). A major step occurred when President Obama signed into law the American Recovery and Reinvestment Act of 2009 (ARRA), which allotted US$1.1 billion to CER. The legislation created a Federal Council on CER, and asked the IOM to elicit input from a broad array of stakeholders on which research topics should have the highest priority for funding through the ARRA and to then develop a list of the highest-priority topics for the Secretary of Health and Human Services to consider. The IOM committee formulated a more succinct definition of CER: "CER is the generation and synthesis of evidence that compares the benefits and harms of alternative methods to prevent, diagnose, treat and monitor a clinical condition, or to improve the delivery of care. The purpose of CER is to assist consumers, clinicians, purchasers, and policy makers to make informed decisions that will improve health care at both the individual and population levels."

As Kupersmith and Ommaya (2010) noted, The US Department of Veterans Affairs (VA) has a long history of conducting CER. Along with pharmaceutical interventions, they have had a large focus on behavioral interventions. The success of their CER program has been facilitated by several important aspects of scientific infrastructure related to (1) research question refinement, (2) study design, planning, and coordination, (3) evidence synthesis, and (4) implementation research. In publications that had VA coauthors in two major medical journals, 25% of the published studies were classified as CER. In the future, the CER enterprise will move toward increased input from clinicians in the choice of research topics and enhanced consideration of other methodologies besides the randomized controlled trial. Concato et al. (2010) reviewed and discussed the use of observational studies in CER, focusing on the following: (1) understanding how observational studies can provide accurate results, comparable to those from randomized clinical trials; (2) recognizing strategies used in selected newer methods for conducting observational studies; (3) reviewing selected observational studies from the Veterans Health Administration; and (4) appreciating the importance of fundamental methodological principles when conducting or evaluating individual studies.

Bonham and Solomon (2010) observed that the success of the federal investment in CER will hinge on using the power of science to guide reforms in health-care delivery and improve patient-centered outcomes (as will be true for other sources of investment in this area). They noted that "Translating the results of comparative effectiveness research into practice calls for the rigors of implementation science to ensure the efficient and systematic uptake, dissemination, and endurance of these innovations." Academic medicine is in a strong position to help in various ways: thoroughly integrating its research and training missions with clinical care that is focused on patient-centered outcomes; building multidisciplinary teams that include a wide range of experts such as clinicians, clinical and implementation scientists, systems engineers, behavioral economists, and social scientists; and training future care providers, scientists, and educators to carry innovations forward (Bonham and Solomon, 2010).

An informative discussion was recently provided by Blumenthal (2011) in a paper entitled "New frontiers in cardiovascular behavioral medicine: Comparative effectiveness of exercise and medication in treating depression." As noted, Blumenthal and his colleagues began investigations into cardiac rehabilitation, which they considered to be a "new frontier for behavioral medicine." That field of investigation laid groundwork that has now provided the opportunity to compare exercise therapy, an established component of cardiac rehabilitation, with antidepressant pharmacotherapy as a treatment for depression in cardiac disease patients. Two randomized clinical trials have now been conducted, and, following a detailed discussion of their findings, the author commented as follows: "While these results are preliminary and should be interpreted with caution, it appears that exercise may be comparable with conventional

antidepressant medication in reducing depressive symptoms, at least for patients who are willing to try it, and maintenance of exercise reduces the risk of relapse" (Blumenthal, 2011).

Complex Traits

Abanish Singh
Duke University Medical Center, Durham, NC, USA

Definition

Mendelian genetics put forward the concept of dominant and recessive traits, where the phenotypes are controlled by single genes. These traits are known as monogenic or Mendelian traits. Though there are many genes that control Mendelian traits, in contrast, there are features or traits in human genetics which are controlled by multiple genes and whose inheritance does not follow the rules of Mendelian genetics. Such traits are known as complex traits.

Examples of complex traits include disorders such as autism, cardiac disease, cancer,

diabetes, Alzheimer's disease, and asthma. Complex traits are believed to result from gene-gene and gene-environment interactions, genetic heterogeneity, and potentially other yet unknown reasons.

Definition

Computed axial tomography, or CAT scan, utilizes computer algorithms to combine series of two-dimensional X-ray images (tomographs) to produce three-dimensional representations of the insides of objects. It is used in clinical medicine to noninvasively visualize potential pathologies inside the human body. By eliminating the superimposition of adjacent structures and distinguishing different tissue types based on their densities, CAT scans are able to generate high-resolution images of particular anatomic regions. Intravenous and oral contrast agents can also be used to further enhance image quality, helping to distinguish vasculature and bowel lumen from the surrounding tissue, respectively. Common uses of CAT scan include scanning of the head/brain, to assess strokes, intracranial bleeding, or tumors; of the chest, to assess lung parenchyma, pulmonary embolism, or diseases of the great vessels such as thoracic aortic aneurysm or dissection; of the abdomen and pelvis, to assess pathologies such as kidney stones, appendicitis, pancreatitis, diverticulitis, intra-abdominal abscesses, and various visceral malignancies; and of the bones, to identify osteoporosis and delineate complex fractures (Buzug, 2008). In recent years, there has also been ongoing development of multidetector computed tomography (MDCT) scanners, allowing for further enhanced spatial and temporal resolution. These technological advances have made possible new modalities of CT imaging, such as virtual colonoscopy for colon cancer screening or cardiac CT to visualize coronary arteries as well as other structures of the beating heart (Achenbach & Daniel, 2008).

The popularity of CAT scans has also led to concerns with regard to their potential adverse effects. In addition to the risk of renal injury associated with the use of iodinated intravenous contrast, there has been recognition that the widespread use of CAT scans has led to increased radiation exposure for the general population, with recent estimates showing they may contribute to 1.5–2.0% of all cancers in the United States (Brenner & Hall, 2007). Due to these considerations, it has been recommended that in addition to developing better protocols with lower radiation doses, the decision to obtain a CAT scan for an individual patient should be made judiciously, taking into careful consideration the trade-off between clinical benefit and potential harm, so as to avoid excess testing and radiation exposure.

Concordance

Jennifer Wessel
Public Health, School of Medicine, Indiana University, Indianapolis, IN, USA

Definition

Among a pair of twins, the twin pair exhibits an identical phenotype. Within the twin pair, both

individuals share or lack the trait or disease under investigation. Measuring concordance can also be done among siblings or other family members. Greater concordance in MZs versus DZs is suggestive evidence for a genetic contribution to a disease. Concordance is measured as the number of pairs that both exhibit (or not) the trait divided by the total and presented as a percentage.

Condom Use

Definition

Condom use implies that an FDA-approved latex condom covered the entire head and shaft of the penis from the start of sex (initial penetration) until sex ended (no more penetration). The term also implies that the condom was used properly, thereby avoiding breakage, spillage, leaking, and slipping off the penis. The term applies to penile-vaginal penetration, penile-oral penetration, and penile-anal penetration. In research studies, when a person uses condoms consistently and correctly, he is classified as "having no risk exposure," meaning that he has not engaged in unprotected vaginal sex (UVS), unprotected oral sex (UOS), or unprotected anal sex (UAS). The same classification applies to females who are the recipients of penetrative sex that is 100% condom protected. In addition, condom use can also imply the consistent and correct use of a polyurethane sheath that is closed at one end (intended to cover the cervix) and open at the other end (for penile penetration). Known as the "female condom," this device is also worn by males who will be receptive partners in the act of penile-anal sex.

Description

Condom use is currently the single best method of reducing the global AIDS pandemic and the ever-expanding pandemic of sexually transmitted infections such as Chlamydia, gonorrhea, syphilis, trichomoniasis, genital herpes, and chancroid. The degree of protection conferred by condom use varies as a function of the infection. Evidence is strongest relative to protection against the transmission and the acquisition of the human immunodeficiency virus (HIV). Emerging evidence suggests that condoms can be highly protective against the male insertive partner's acquisition of gonorrhea, Chlamydia, and syphilis. Evidence also supports the protective value of condoms against these same infections for the receptive partner. However, for infections such as human papillomavirus (HPV) and genital herpes (HSV), the protective value of condoms is not

nearly as good simply because these infections spread by skin-to-skin contact of genital areas that condoms do not cover. Nonetheless, it is indeed correct to say that condom use does offer partial protection against HPV and HSV.

Despite the tremendous public health value of condom use, prevailing sociopolitical climates have frequently precluded efforts to educate men and women about condoms and their correct use. This lack of education has proven to be problematic in that a large number of studies show that men and women experience multiple errors and problems when using condoms. The most common error, reported by both men and women, is known as incomplete use. This means that the condom was put on after penetrative sex had begun and/or it was taken off before penetrative sex had ended. Both behaviors have been linked to arousal and erection issues as well as ill-fitting condoms. In addition, condoms that lose their lubrication during sex may be removed prematurely (rather than simply adding lubricant). Breakage is the next most common problem with condom use. Rather than being a problem inherent in the production of condoms, breakage occurs as a consequence of user errors such as applying oil-based lubrication, not leaving an air space in the reservoir tip upon application, using condoms that are too small for the penis, letting condoms contact sharp objects (including teeth and jewelry) and failure to add adequate amounts of water-based lubricants during prolonged sex. The next most common problem is having condoms slip off the penis, either during penetrative sex or during the act of withdrawing the condomized penis after male ejaculation occurs. Loose-fitting condoms, not unrolling condoms all the way to the base of the penis, erection issues, use of erection enhancing drugs, and poorly lubricated condoms have all been associated with slippage during sex. Mistakes that people make when using condoms include putting the unrolled condom on the penis upside down and then "flipping" it over so it will unroll (thereby introducing per-cum [semen] into the outside tip of the condom thus compromising protection). Studies have shown that people will "switch" from one sexual act to another without changing condoms in between acts, thereby creating issues with disease transfer. The sheer volume of condom use errors and problems reported by men and women strongly suggests that all too often condoms fail because the users lacked proper education. These forms of condom failure are also an unfortunate omission in studies of condom effectiveness, thereby creating a bias toward the null hypothesis (i.e., that condoms do not work).

A broad range of behavioral and social issues inextricably surround condom use. For example, a robust finding has been that people are more likely to use condoms with new or "casual" sex partners and far less likely to do so with established partners. Thus, a challenge in behavioral medicine is promoting condom use among at-risk, established, couples. Also, condom use and the use of hormonal contraceptives tend to be inversely correlated, meaning that condom use is reduced or abandoned when a couple begins using highly reliable contraception methods. Here, the challenge in behavioral medicine is to promote the dual use of condoms and contraception. A similar dynamic may exist in relation to vaccines for HPV and microbicidal agents designed to prevent HIV infection – as people perceive less risk as a consequence of the vaccine or microbicide they may reduce or abandon condom use. Condom use will also be problematic in cultures (or among couples) that value reproduction – an inherent downside of condom use for disease prevention is that the behavior precludes desired conception. Low arousability and erection loss are also issues that greatly affect condom use, with several studies indicating incomplete use or lack of use to increase arousability and help maintain erection. The challenge here to behavioral medicine is integrating sex therapy with STI prevention.

Definition

Ethical principle that dictates communications are "privileged" and may not be discussed or divulged to third parties.

Description

Confidentiality is a term that commonly applies to conversations between health care providers and patients. Legal protections are available to prevent physicians from revealing certain discussions with patients, even under oath in court. However, the rule only applies to information shared between physician and patient during the course of providing medical care. Traditionally, medical ethics has viewed the duty of confidentiality as a relatively nonnegotiable tenet of medical practice. Issues regarding the confidentiality of health information passed between patients, providers, and insurers led to the evolution of regulatory language to protect patient privacy.

The Health Insurance Portability and Accountability Act of 1996 (HIPAA) includes in its language specific direction for the management of protected health information (PHI) in both clinical and research arenas. The Privacy Rule protects all "individually identifiable health information" held or transmitted by a covered entity or its business associate, in any form or media, whether electronic, paper, or oral. The Privacy Rule calls this information "protected health information (PHI)."

"Individually identifiable health information" is information, including demographic data, that relates to the individual's past, present, or future physical or mental health or condition; the provision of health care to the individual; or the past, present, or future payment for the provision of health care to the individual, and that identifies the individual or for which there is a reasonable basis to believe it can be used to identify the individual. Individually identifiable health information includes many common identifiers (e.g., name, address, birth date, social security number). There are no restrictions on the use or disclosure of de-identified health information. De-identified health information neither identifies nor provides a reasonable basis to identify an individual.

Privacy rules apply only to covered entities. Covered entities are defined as a healthcare provider (physicians, nurse practitioners, psychologists, dentists, clinics, nursing homes, pharmacies, etc.), health plans (insurance companies, Health Maintenance Organization (HMOs), etc.), or a healthcare clearinghouse (entities that process nonstandard health information they receive from another entity into a standard format). Individuals, organizations, and agencies that meet the definition of a covered entity under HIPAA must comply with the rules' requirements to protect the privacy

and security of health information and must provide individuals with information regarding their rights with respect to their health information. If an entity is not a covered entity, it does not have to comply with the Privacy Rule.

Researchers are also bound by the rules regarding confidentiality of protected health information. Generally speaking, researchers are required to safeguard the privacy of all health information obtained in the course of screening or enrollment in a study to the extent permitted by law. In certain types of research, there may be a high risk of identifying information that if disclosed, could have adverse consequences for subjects or damage their financial standing, employability, insurability, or reputation. Certificates of confidentiality are issued by the National Institutes of Health (NIH) to protect identifiable research information from forced disclosure. They allow the investigator and others who have access to research records to refuse to disclose identifying information on research participants in any civil, criminal, administrative, legislative, or other proceeding, whether at the federal, state, or local level. By protecting researchers and institutions from being compelled to disclose information that would identify research subjects, certificates of confidentiality help achieve the research objectives and promote participation in studies by assuring confidentiality and privacy to participants.

Confounding Influence

J. Rick Turner
Cardiovascular Safety, Quintiles, Durham, NC, USA

Definition

When investigating the influence of a factor of interest, it is critically important to keep all other potentially relevant influences as constant as possible. That is, the only reasons for differences in how subjects respond to the treatments in a research study should be the nature of the treatments (interventions) themselves. Extraneous influences are called confounding influences: They make it harder to isolate and hence evaluate the degree of influence of the factor of interest.

The list of potential confounding influences for a given study can be extensive and vary from study to study. It is therefore the responsibility of the researcher to design the study and structure the study's research methodology such that confounding influences are controlled to the greatest degree possible.

One example from other entries can be found in the entry titled "► Crossover Design." In these study designs, each subject receives all of the interventions in the study. Because of the potential confounding influence of the order in which the interventions are completed (e.g., subjects may tend to respond better to the first intervention rather than the last, regardless of the nature of the intervention), this factor needs to be controlled for. This potential issue is elegantly solved by counterbalancing the order in which the subjects receive the treatments. In a two-treatment study, for example, half of the subjects would receive Treatment A first and Treatment B second, and the other half would receive the treatments in the reverse order.

Using different but comparable nomenclature, the goal of a research study is to identify one source of systematic influence, the influence that is systematically provided by the factor of interest in the study. It is essential to remove all other

identifiable sources of systematic influence, such as the order in which treatments are administered. Other simple examples include not administering Treatment A only to males and Treatment B only to females, and not administering Treatment A only to relatively young subjects and Treatment B to relatively old subjects.

The process of randomization is a powerful tool used to disperse influences that cannot readily be controlled equally (randomly) across the subjects in a study, thereby removing unwanted systematic influences.

Congestive Heart Failure

Division of Cardiology, Columbia University Medical Center, New York, NY, USA

Heart failure

Description

Congestive heart failure is a condition in which the heart cannot provide enough cardiac output for the metabolic demands of the body. The prevalence of heart failure has been estimated at 2% and is expected to grow due to improved survival of people with cardiac conditions (Mann, 2008). The lifetime risk of developing heart failure has been estimated at 20%. Coronary artery disease is the most frequent cause of heart failure (60–75%) (Lloyd-Jones et al., 2002). Etiologies for heart failure aside from coronary artery disease include viral inflammation of the heart, also known as myocarditis; alcohol toxicity; or genetic mutations.

One way to classify heart failure is according to left ventricular ejection fraction, a measure of contractile function. "Systolic heart failure" is defined by the presence of reduced left ventricular ejection fraction, usually <40%. About half of patients with heart failure may still have preserved left ventricular ejection fraction, so-called heart failure with normal ejection fraction (HFNEF) (Maeder & Kaye, 2009). This is often thought to be due to impaired left ventricular relaxation, or "diastolic dysfunction," but can also occur in the setting of other conditions such as anemia or renal dysfunction.

Symptoms of this condition can include shortness of breath, peripheral edema, and fatigue. Worse symptomatology has been associated with greater mortality risk. New York Heart Association class is one way to indicate the symptom severity of someone with heart failure (Mann, 2008):

Class I – no symptoms and no limitation in ordinary physical activity

Class II – slight limitation during ordinary activity

Class III – marked limitation in activity due to symptoms, even during less-than-ordinary activity

Class IV – symptoms even while at rest, mostly bedbound patients

The prevailing view of pathogenesis of systolic heart failure involves a neurohormonal hypothesis. After an initial insult that results in damage to heart muscle, a number of compensatory systems are activated, mainly involving overactivity of the sympathetic nervous system. Activation of the renin-angiotensin-aldosterone system results in salt and water retention, as well as constriction of peripheral blood vessels. This short-term adaptation leads to detrimental increases in left ventricular size and wall thinning, also referred to as remodeling.

The overall prognosis in patients with heart failure is poor, with 1-year mortality as high as 30–40% without treatment (Mann, 2008). Depression has been estimated by a meta-analysis to occur in about 21% of heart failure patients, and its

presence is associated with worse cardiovascular outcomes and higher overall mortality (Rutledge, Reis, Linke, Greenberg, & Mills, 2006).

The hallmark of pharmacologic therapy for heart failure involves treatment with angiotensin converting-enzyme (ACE) inhibitors and beta blockers, which are known to improve long-term mortality. Of note, there is a relative lack of evidence for therapies for treatment of heart failure with normal ejection fraction, although blood pressure control is thought to play an important role in treatment.

Behavioral interventions for heart failure may include cessation of tobacco/alcohol use, reduction in salt intake, and exercise in selected patients. The *H*eart *F*ailure: *A C*ontrolled *T*rial *I*nvestigating *O*utcomes of Exercise Trai*N*ing (HF-ACTION) trial was performed in 2,331 ambulatory patients with heart failure and reduced left ventricular ejection fraction (average 0.25) (O'Connor et al., 2009). The intervention consisted of a group-based, supervised exercise program for 3 months with transition to home exercise. During a median follow-up duration of 30 months, a nonsignificant reduction in the primary endpoint of all-cause mortality or hospitalization was achieved (HR 0.93, 95% CI 0.84–1.02. $p = 0.13$). Exercise training was also found to be relatively safe in the intervention group.

Definition

Many studies employ a randomized controlled trial (RCT) design to test the efficacy of products or services. However, inconsistencies in reporting trial information and outcomes of RCTs have stymied the usefulness of these trials in regards to providing readily available data from trial findings. These shortcomings led to the development of Consolidated Standards of Reporting Trials (CONSORT). CONSORT dictates that trial authors answer a series of checklist questions and provide a flowchart representing the trial when reporting outcomes.

The CONSORT Statement seeks to improve reporting information from RCTs, including increasing transparency of trial procedures and outcomes. As of 2010, there are 25 checklist items that cover what information should be included in the title/abstract, introduction, methods, results, discussion, and other (registration, protocol, and funding). In addition, authors adhering to CONSORT Statement guidelines should include a flow chart that depicts, in part, number of participants screened, excluded and why, randomized, received product or service, lost to follow-up and why, assessed, and included in data analysis.

CONSORT was originally developed in the 1990s and has since been amended multiple times. Individuals from varied backgrounds have taken part in forming the specifics of the guidelines. A committee representing the purpose of the CONSORT Statement meets regularly to review, assess, and change as needed statement guidelines. Thus, making this document one that is continually evolving to best represent the reporting of the scientific methods of an RCT. Multiple peer-reviewed, scholarly journals follow the reporting guidelines set forth by the CONSORT Statement which has led to consistency across journals in terms of reporting style. Evaluations have been completed to assess the impact of implementing the CONSORT Statement. Analyses of trial reporting before and after the time period of guideline availability have demonstrated a substantial improvement in transparency of procedures and outcomes as a result of the CONSORT Statement.

Construct Validity

Annie T. Ginty

Definition

Construct validity is the extent to which the measurements used, often questionnaires, actually test the hypothesis or theory they are measuring. Construct validity should demonstrate that scores on a particular test do predict the theoretical trait it says it does.

There are two subsets of construct validity: convergent construct validity and discriminant construct validity. Convergent construct validity tests the relationship between the construct and a similar measure; this shows that constructs which are meant to be related are related. Discriminant construct validity tests the relationships between the construct and an unrelated measure; this shows that the constructs are not related to something unexpected. In order to have good construct validity one must have a strong relationship with convergent construct validity and no relationship for discriminant construct validity.

Continuity of Care

Marie Boltz
College of Nursing, New York University, New York, NY, USA

Definition

Continuity of care refers to the seamless provision of health care between settings and over time (Gulliford, Naithani, & Morgan, 2006).

Traditionally, patients have viewed care continuity as a permanent relationship with a dependable, caring health care professional. This view, defined as interpersonal continuity of care, implies that the identified professional is the sole source of care and information for the patient. To health care providers, care continuity has historically implied the exchange of information, e.g., between shifts of nurses, between units of a healthcare facility, and between providers such as acute care and a nursing home. Coleman and colleagues (2006) define the flow of information between different locations or different levels of care within the same location as "transitional care" necessary to ensure the coordination and continuity of health care as patients move through different settings. Organizational approaches that facilitate transitions between settings are the use of transitions coach to educate the patient and family, and coordinate among the health professionals involved in the transition (Coleman, Parry, Chalmers, & Min, 2006) and the transitional care nurse (Naylor et al., 2004) who coordinates the discharge plan and coordinates the plan in the home.

Chronological or longitudinal continuity of care describes health care interactions that occur in the same place, with the same medical record, and with the same professionals, so that there is consistent knowledge of the patient by those providing the care (Saultz, 2003). Interdisciplinary or team-based continuity implies allows previous knowledge of the patient to be present even when the patient requires a wide range of services.

Given that healthcare needs can rarely be met by a single professional or a single provider setting, a multidimensional model of continuity of care is a logical choice, (Gulliford, Naithani, & Morgan, 2006) one that provides a longitudinal and interdisciplinary approach, while providing the dependability and relational aspects of interpersonal continuity. This model relies on integration, coordination, and the sharing of information between different, but stable providers. Evaluation of continuity of care can be conducted from the patient perspective, i.e., the experience of care, or satisfaction with the coordination of care and its interpersonal aspects. It also includes the provider's evaluation of outcomes and care processes (team functioning and case management effectiveness).

Definition

Contraception, or birth control, is any method, action, device, or medication used to prevent pregnancy. Various methods of contraception include blockage of the sperm from reaching the egg, killing or damaging sperm, preventing the release of an egg from the ovaries, or changing the uterine lining so a fertilized egg will not attach. Many factors can help couples choose the most appropriate contraception based on frequency of sex, plans for pregnancy, age and overall health, side effects, number of sexual partners, protection against sexually transmitted infections (STIs), and contraceptive failure rates. Contraceptive failure rates are most often reported as two numbers, the theoretical failure rate or the rate of contraceptive failure when the method is used correctly during every act of intercourse. The actual failure rate takes into account the actual variation in consistency of contraceptive usage (see Table 1).

Description

The various methods of contraception include barrier methods, natural methods, hormonal methods, intrauterine devices (IUDs), emergency contraception, and surgical sterilization.

The barrier method provides a mechanical or chemical barrier to the sperm from reaching the egg. The most common form of the barrier method is the male condom, which is usually made of thin latex. New materials have been developed and include polyurethane and styrene and styrene ethylene butylenes styrene. These materials have a longer shelf life and can be used with oil-based lubricants without increasing the risk of condom breakage. Male condoms are relatively inexpensive, easily accessible, and carry few health risks. Health risks include hypersensitivity to the latex or lubricant inside the condom. If used correctly every time, male condoms are very effective and carry only a 2% theoretical failure rate; actual failure rates are around 15%.

Female condoms are soft plastic film linings with flexible rings at both ends (see Fig. 1). When used correctly and consistently, this type of contraception carries a slightly higher theoretical and actual failure rate than male condoms at 5% and 21%, respectively. Female condoms are more expensive than male condoms due to the polyurethane material they are made from. Both male and female condoms are a beneficial form of contraception because they not only protect against pregnancy, but also provide protection against sexually transmitted infections (STI).

Spermicides are another barrier method and come in the form of foams, jells, suppositories, creams, films, and tablets. The most widely used types contain nonoxynol-9 and octoxynol-9.

Contraception, Table 1 Overview of contraceptive methods

Method	Failure rate (%) Theoretical/actual		Benefits	Health risks/side effects and disadvantages
Barrier Condom Male condom Female condom	2.0 5.0	15.0 21.0	Provides STI protection Male condoms are relatively cheap and widely available May provide protection against conditions caused by STIs	Occasional hypersensitivity to latex or lubricant inside condom May lead to decreased sensitivity Female condoms are costly and bulky
Spermicide	18.0	29.0	Widely available in many forms and relatively inexpensive	Can cause vaginal or penile irritation Risk of urinary tract infection Frequent use of nonoxynol-9 may increase risk of HIV One of the least effective methods when used alone
Diaphragm Cervical cap Parous women Nuliparous women	6.0 20.0 9.0	16.0 32.0 16.0	May help protect against certain STIs May help protect against cervical cancer	Can cause vaginal or penile irritation May lead to the development of Toxic Shock Syndrome if left in place for too long Risk of bladder irritations that can lead to urinary tract infections
Natural Fertility awareness Coitus interruptus Lactational amenorrhea (LAM)	– 4.0 1.0	25.0 27.0 2.0	Completely natural LAM helps encourage healthy breast-feeding patterns, which benefits both mother and child	Requires motivation and a commitment to learning High failure rates LAM can only be used a maximum of 6 months after delivery
Hormonal methods Combination estrogen and progesterone Pill Injection Patch Vaginal ring	0.3 0.5 0.3 0.3	8.0 3.0 0.8 0.8	Available in many forms Provides many non-contraceptive health benefits including reduced risk of: Ovarian and endometrial cancer, PID, ovarian cysts, osteoporosis, iron-deficiency anemia and dysmenorrhea	Can cause dizziness, headache, nausea, weight changes, mood changes, and breast pain Cary risk of cardiovascular complications such as deep vein thrombosis and pulmonary embolism Risk of heart attack and stroke is present but rare

Progesterone only Pill Injections	0.5 0.3	8.0 3.0	Can be used by women who are nursing and for whom estrogen is contraindicated	May cause irregular bleeding, mood changes, weight gain, dizziness, headaches, and nausea
Intrauterine devices Copper T IUD Levonorgestrel IUD	0.6 0.2	0.8 0.2	May help protect against endometrial cancer After initial insertion requires little maintenance Copper IUDs can remain in uterine and work effectively for up to 10 years Levonorgestrel can be effective for up to 5 years Levonorgestrel IUD has been used to help treat menorrhagia and dysmenorrhea Copper IUD can be used as emergency contraception if placed within 5–8 days of unprotected sex and is the most effective form of emergency contraception	Side effects such as bleeding, pain, perforation, and infection are rare but can be serious May increase the risk of pelvic inflammatory disease if gonorrhea or Chlamydia is present before the insertion If pregnancy does occur, the risk of spontaneous abortion is increased by up to 50% May change bleeding patterns causing increased bleeding and menstrual pain in first few months Levonorgestrel IUD can cause headaches, nausea, dizziness, and weight gain
Surgical sterilization Female sterilization Male sterilization	0.5 0.2	0.5 0.2	Very few side effects Permanent form of contraception and therefore requires no other contraceptive efforts 3 months post operation Helps protect against pelvic inflammatory disease	Complications of surgery and anesthesia are possible Requires a back-up method of contraception for first 3 months post operation

Contraception, Fig. 1 Female condom

Spermicides are inserted deep in the vagina at least 30 min prior to sexual intercourse and create a chemical barrier by killing or inactivating sperm by causing the membrane of the sperm cell to break. Research has shown that frequent use of nonoxynol-9 can damage lower genital tract epithelial surfaces and may increase the risk of HIV infection. New spermicides are being developed to replace nonoxynol-9. When used alone, spermicides are one of the least effective forms of contraception and it is recommended that they be used in conjunction with other forms of contraception. Spermicides do not protect against STIs and carry risks of local tissue irritation.

A diaphragm is a latex rubber cup with a flexible rim that covers the cervix. It is placed in the vagina before intercourse and remains there for 6–8 h after intercourse. It is most often used in conjunction with a spermicide. Diaphragms are relatively effective with a 6% theoretical failure rate and actual failure rate of 16%. However, diaphragms must be prescribed and fitted by a healthcare provider and carry risk of vaginal or penile irritation, urinary tract infection, and in rare cases toxic shock syndrome.

A cervical cap is a small, soft cup that fits snugly over the cervix and is used in conjunction with a spermicide. It is a more effective form of contraception in nulliparous women. Like diaphragms, cervical caps must be fitted by a healthcare provider and carry many of the same health risks.

Natural methods of contraception used to control pregnancy include fertility awareness, coitus interruptus, and lactational amenorrhea. Women using fertility awareness identify ovulation based on body symptoms or the calendar. Symptom-based methods include monitoring cervical mucus changes around the time of ovulation. These changes include the mucus becoming thin and watery. The symptothermal method includes taking regular basal body temperatures to recognize a decrease, which occurs prior to ovulation, and monitoring other cues such as abdominal cramps, breast tenderness, and changes in cervical position to predict ovulation. Calendar methods of fertility awareness include the standard day method and the calendar rhythm method. The standard day method tracks the menstrual cycle counting from the first day of bleeding as day 1; days 9 through 18 are considered fertile days. The calendar rhythm method requires a record of the number of days in a menstrual cycle for 6 months, with estimates of the fertile period calculated by subtracting 18 from the length of the shortest cycle – this day is the estimated first day of the fertile period. To estimate the end of the fertile period, subtract 11 from the length of the longest cycle – this is the estimated last day of the fertile period. These calculations should be updated monthly using the most recent cycles. Fertility awareness is considered one of the least effective forms of contraception, especially in women with irregular menstrual cycles. The theoretical failure rate for fertility awareness is 10%, while the actual failure rate is about 25%.

A second natural method of contraception is coitus interruptus, or withdrawal of the penis from the vagina before ejaculation. The theoretical failure rate is quite low at about 4%, but the actual failure rate is around 27%, which makes this form one of the least effective methods. Pre-ejaculate can be deposited into the vaginal canal prior to ejaculation and contributes to the high failure rate. A male who has recently ejaculated prior to sex should first urinate and clean the tip of the penis to remove any sperm from the previous ejaculation.

The last natural method of contraception is lactational amenorrhea. This method can be used by nursing mothers after delivery because frequent breast-feeding suppresses hormones that cause ovulation. Because the suppression of ovulation is variable, this type of contraception

should not be used longer than 6 months after delivery.

Hormonal methods of birth control suppress ovulation to prevent pregnancy and are the most widely used form of reversible contraception in the United States. Combined estrogen and progesterone and progesterone-only methods are the two available forms of hormonal birth control. Combined birth control methods come in many forms including oral pills, transdermal patches, monthly injections, and vaginal rings. Depending on the form being used, failure rates for combined hormonal contraception vary. Theoretical failure rates for all forms are below 1%; however, some actual rates can be as high as 8%.

The second form of hormonal contraception is progesterone-only contraception. Because this contraception does not contain estrogen, it is advantageous for women who are breastfeeding and for women in whom estrogen is contraindicated. Progesterone-only contraception comes in the form of oral pills and injections that work by thickening the cervical mucus, inhibiting sperm movement, and disrupting the menstrual cycle to prevent ovulation. Generally progesterone-only contraception is not as effective as combination contraception and carries actual failure rates of 8–10%.

Intrauterine devices (IUDs) are the most widely used form of reversible contraception globally. An IUD is a small plastic or metal device that is inserted by a healthcare provider into the uterus. The two most common forms are the copper-bearing IUD and the levonorgestrel IUD. The copper IUD is a plastic frame (or "7") with copper sleeves around it. The levonorgestrel IUD is a plastic T-shaped device that releases small amounts of levonorgestrel, a form of progesterone. The IUD causes a sterile inflammatory response in which sperms are destroyed or immobilized by inflammatory cells. In addition to this inflammatory response, the levonorgestrel further provides contraceptive effect by thickening cervical mucus and causing atrophy of the endometrium. The copper in copper IUDs adds to the contraceptive effect by hampering sperm motility, making it difficult to reach the fallopian tubes. Most IUDs can be left in place for 5–10 years and are therefore a long-term contraceptive plan with little maintenance required after the initial insertion. They are highly effective with theoretical and actual failure rates below 1%.

Emergency contraception is a form of contraception that can be utilized after unprotected sex or after a contraceptive failure. Emergency contraception comes in two forms, pills and an emergency copper IUD insertion, and prevents pregnancy by inhibiting ovulation, fertilization or implantation based on the form used. Emergency contraceptive pills are high doses of either a combined estrogen and progesterone pill or a progesterone-only pill. To be most effective, emergency contraception should be taken as soon as possible after unprotected sex, but can also be effective if taken within 5 days of unprotected intercourse. Emergency insertion of a copper IUD within 5–8 days of unprotected sex is a very effective form of emergency contraception.

Sterilization is a form of permanent contraception and can be done in both men and women. In females, tubal ligation involves a surgical occlusion of both fallopian tubes preventing an egg from entering the uterus. Vasectomy is a male sterilization procedure that involves ligation of the vas deferens. Because these procedures are meant to be permanent, reversal surgery is rare, and when done, rarely successful. Unlike tubal ligation, a vasectomy is not immediately effective and another contraceptive method should be used for the first 3 months post operation. In the past 30 years, the rate of sterilization as a form of contraception has increased dramatically and is currently one of the most widely used forms of contraception. Failure rates are extremely low with both the theoretical and actual rates below 1%.

Globally, many social determinants influence the choice of contraceptive and include gender and the role of women in a culture, age, socioeconomic status, marital status, education level, and religion. For example, in the United States, women aged 22–44 who are less educated are more likely to use sterilization as a contraceptive method while college-educated women of the same age range more often use pills as the preferred method of contraception. Some

religious beliefs sanction natural methods of contraception to space pregnancies as opposed to using hormonal or barrier methods that prevent pregnancy from occurring. Surgical sterilization is most often used by an older population while the pill is the preferred form in the population below the age of 30. The percentages of contraceptive users and the most widely used forms vary by country.

Comparator group; Concurrent control (which applies only in some settings)

Definition

A control group is a group of subjects against whose information the information gathered from an investigational group is compared.

To judge the effectiveness of a therapeutic behavioral intervention, or the harm done by engaging in behavioral activities such as smoking, it is necessary to have a reference point. This is provided by data collected from individuals who are deliberately similar to those in the investigational group in as many ways as possible with the single exception of receiving the therapeutic intervention or having engaged in the behavior of concern.

Control groups can be used in experimental studies and nonexperimental (often called observational) studies. Testing the effectiveness of a therapeutic behavioral intervention in a group of individuals who have not previously received it would fall into the category of an experimental study: The researchers administer an experimental treatment. To control for the fact that simply participating in the study may have a sizeable therapeutic benefit (caused by a variety of potential factors, including the extra medical attention given to these subjects), it is necessary to have a control group that experiences all of the circumstances experienced by those in the investigational group with the exception of the intervention of interest. This can be a difficult challenge for those developing the experimental methodology to be used in the study.

Cook-Medley Hostility Scale

Matthew Calamia
Department of Psychology, University of Iowa, Iowa City, IA, USA

Definition

The Cook-Medley Hostility Scale (Ho Scale) (Cook & Medley, 1954) is a 50-item scale derived from the Minnesota Multiphasic Personality Inventory. The creators viewed it as a measure of "chronic hate and anger." Scores on the Ho Scale are related to a variety of health-relevant variables, including alcohol consumption, insulin resistance, and waist-to-hip ratio (Bunde & Suls, 2006). Scores on the Ho are predictive of coronary artery disease and all-cause mortality even after controlling for other health risk factors (Miller, Smith, Turner, Guijarro, & Hallet, 1996). In contrast to the extensive evidence for its predictive validity, the exact construct(s) measured by the scale have been the subject of some debate. A variety of competing measurement models have been proposed, with no clear favorite based on psychometric criteria (Contrada & Jussim, 1992). Although groups of items relating to constructs ranging from hypersensitivity to aggressive responding have been identified, the core factor of the Ho Scale may be best described as reflecting cynicism. A unidimensional index of that primary factor can be derived from the overall scale and was found in at least one study to maintain the predictive ability of the entire scale (Strong, Kahler, Greene, & Schinka, 2005).

Coping

Charles Carver
Department of Psychology, University of Miami, Coral Gables, FL, USA

Definition

Coping is efforts to prevent or diminish threat, harm, and loss, or to reduce the distress that is often associated with those experiences.

Description

The concept of coping presumes the existence of a condition of adversity or stress. A person who must deal with adversity is engaged in coping. Thus, coping is inextricably linked to stress. It is often said that stress exists whenever people confront situations that tax or exceed their ability to manage them (Lazarus, 1966; Lazarus & Folkman, 1984). Whenever a person is hard-pressed to deal with an obstacle or impediment or looming threat, the experience is stressful. Adversity takes several forms. *Threat* refers to the impending occurrence of an event that is feared will have bad consequences. *Harm* refers to the perception that bad consequences have already come to pass. *Loss* refers to the perception that something of value has been taken away.

People respond to perceptions of threat, harm, and loss in a wide variety of ways, many of which are labeled coping. Coping is generally defined as efforts to prevent or diminish threat, harm, and loss, or to reduce the distress that is often associated with those experiences. Some theorists prefer to limit the concept of coping to voluntary responses (Compas, Connor-Smith, Saltzman, Thomsen, & Wadsworth, 2001). Others include automatic and involuntary responses as well (Eisenberg, Fabes, & Guthrie, 1997; Skinner & Zimmer-Gembeck, 2007). It should be noted that it is not easy to distinguish between voluntary and involuntary responses to stress. Furthermore, responses that are intentional and effortful when first used may become automatic with repetition. Some discussions of coping also include unconscious defensive reactions as aspects of coping. This entry is limited, however, to responses that are recognized by the person who is engaging in them.

Distinctions and Groupings Among Coping Responses

Coping is a very broad concept with a long and complex history (Compas et al., 2001; Folkman & Moskowitz, 2004). A great many distinctions have been made within the broad domain (Skinner, Edge, Altman, & Sherwood, 2003). Some of the more important distinctions are described in the sections that follow.

Problem-Focused Versus Emotion-Focused Coping

The first distinction made in modern examination of coping was that made between problem-focused and emotion-focused coping (Lazarus & Folkman, 1984). Problem-focused coping is directed at the stressor itself: taking steps to remove or to evade it, or to somehow diminish its impact if it cannot be evaded. For example, if the arrival of a hurricane is forecast, a homeowner's problem-focused coping might include bringing all potted plants indoors, putting up storm shutters, and buying batteries for use in flashlights. As another example, if layoffs are expected at one's place of employment, problem-focused coping might include saving money, applying for other jobs, obtaining training to enhance hiring prospects, or working harder at the current job to reduce the likelihood of being let go.

Emotion-focused coping, in contrast, is aimed at minimizing the emotional distress that is triggered by stressful events. Because there are many ways to reduce distress, emotion-focused coping includes a very wide range of responses, ranging from self-soothing (e.g., relaxation, seeking emotional support), to expression of negative emotion (e.g., yelling, crying), to a focus on negative

thoughts (e.g., rumination), to attempts to escape cognitively from the stressful situation (e.g., avoidance, denial, wishful thinking).

Problem-focused and emotion-focused coping have different initial or focal goals. The focal goal determines which category a particular response is assigned to. Some behaviors can serve either a problem-focused or an emotion-focused function, depending on the goal behind their use. For example, seeking support is emotion focused if the goal is to obtain emotional support and reassurance; on the other hand, seeking support is problem focused if the goal is to obtain advice or instrumental help.

Although it is easy to distinguish between them in principle, problem-focused coping and emotion-focused coping also tend to facilitate one another. Effective problem-focused coping diminishes the threat or harm, but by doing so, it also diminishes the distress generated by that threat. Effective emotion-focused coping diminishes negative emotions, making it possible to consider the problem more calmly. This often leads to better problem-focused coping. This interwoven relationship between problem- and emotion-focused coping makes it more useful to think of the two as complementary coping functions, rather than as two fully distinct and independent coping categories.

Engagement Versus Disengagement

What turns out to be a particularly important distinction is the distinction between engagement or approach coping and disengagement or avoidance coping (e.g., Skinner et al., 2003). Engagement coping is aimed at actively dealing with the stressor or stress-related emotions. Disengagement coping is aimed at avoiding confrontation with the threat or avoiding the stress-related emotions. Engagement coping includes problem-focused coping and forms of emotion-focused coping such as support seeking, emotion regulation, acceptance, and cognitive restructuring. Disengagement coping includes responses such as avoidance, denial, and wishful thinking. Disengagement coping is often emotion focused, because it typically involves an attempt to escape feelings of distress. Some disengagement coping is almost literally an effort to act as though the threat does not exist, so that no reaction is needed, behaviorally or emotionally. Wishful thinking and fantasy can distance the person from the stressor, at least temporarily, and denial creates a boundary between reality and the person's experience.

Although disengagement coping has the aim of escaping distress, it is generally ineffective in reducing distress over the long term, because it does nothing about the threat's existence and its eventual impact. If you are experiencing a real threat in your life and you respond to it by going to the movies, the threat will generally remain when the movie is over. Eventually, it must be dealt with. Indeed, for many types of stress, the longer a person avoids dealing with the problem, the more difficult or complex it becomes, and the less time is available to deal with it when one does finally turn to it. Finally, some kinds of disengagement coping can create problems of their own. Excessive use of alcohol or drugs can create social and health problems, and shopping or gambling as an escape can create financial problems.

Some have extended the concept of disengagement coping to include giving up on goals that are threatened by the stressor (Carver & Connor-Smith, 2010). This differs from other disengagement responses, in that it addresses both the stressor's existence and its emotional impact by abandoning an investment in something else. Disengaging from the threatened goal may allow the person to avoid negative feelings associated with the threat. Depending on the nature of the goal being abandoned, however, this sort of disengagement can also have adverse secondary consequences.

Accommodative Coping and Meaning-Focused Coping

Most adaptive coping is one or another form of engagement coping. Within engagement coping, distinctions also have been made between attempts to control the stressor itself, called primary control coping, and attempts to adapt or adjust to the stressor, termed accommodative or sometimes secondary control coping (Morling & Evered, 2006; Skinner et al., 2003). The term accommodative is perhaps to be preferred

because it does not carry connotations of exerting control, or of being secondary to other coping efforts.

The concept of accommodative coping is rooted in analyses of the process of successful aging (Brandtstädter & Renner, 1990). It refers to adjustments within the self, which are made in response to constraints inherent in one's life situation. In the realm of coping, accommodation applies to responses such as acceptance, cognitive restructuring, and scaling back of one's goals in the face of insurmountable interference. Another kind of accommodation is self-distraction. Self-distraction is somewhat controversial. Self-distraction is often thought of as disengagement coping. However, there is also evidence suggesting that intentionally engaging in positive activities is a useful means of adapting to uncontrollable events (Skinner et al., 2003).

A concept that is related to accommodation is what has been called meaning-focused coping. In meaning-focused coping, people draw on their beliefs and values to find benefits in stressful experiences or remind themselves of positive aspects of their lives (Tennen & Affleck, 2002). Meaning-focused coping may include reordering one's life priorities and focusing on the positive meaning of ordinary events. The concept of meaning-focused coping has roots in evidence that positive as well as negative emotions are common during stressful experiences, that those positive feelings influence people's outcomes, and particularly the fact that people try to find benefit and meaning in adversity (Helgeson, Reynolds, & Tomich, 2006; Park, Lechner, Antoni, & Stanton, 2009). Although this concept emphasizes the positive changes a stressor brings to a person's life, it is worth pointing out that meaning-focused coping also represents an accommodation to the constraints of one's life situation. Meaning-focused coping involves reappraisal of the situation. It appears to be most likely when stressful experiences are uncontrollable or are going badly.

Stepping Back

This brief review is far from exhaustive. Nonetheless, it should make clear that there are many ways to group and organize coping responses. Further, it should be clear that these distinctions do not form a neat matrix into which all coping reactions can be sorted. A given response typically fits several places. For example, seeking emotional support is engagement, emotion-focused, and accommodative coping. Each distinction that has been introduced can be useful for answering certain questions about responses to stress. No one distinction fully conveys the structure of coping. The distinction that appears to be the most important is that made between engagement and disengagement. Interestingly enough, this is a distinction which also maps well onto goal-based models of personality functioning and social behavior (e.g., Carver & Scheier, 1998).

Relations Between Coping and Well-being

In some respects, the question that everyone wants answered is not "what are the ways in which people cope?" but "how do coping responses affect well-being?" Behind this question lie a number of thorny methodological issues (Carver, 2007). Among them are issues of how often coping should be measured, what time lag should be assumed and thus investigated between coping efforts and eventual outcomes, and whether coping should be viewed as a cluster of responses or a sequence of responses.

In meta-analyses of relations between coping and well-being, effect sizes are typically small to moderate. Coping generally has been linked more strongly to psychological outcomes than to physical health (Clarke, 2006; Penley, Tomaka, & Wiebe, 2002). Nonetheless, most kinds of engagement coping relate to better physical and mental health in samples coping with stressors as diverse as traumatic events, social stress, HIV, and prostate cancer (Clarke, 2006; Littleton, Horsley, John, & Nelson, 2007; Moskowitz, Hult, Bussolari, & Acree, 2009; Penley et al., 2002; Roesch et al., 2005). However, some other less volitional responses that might be seen as reflecting engagement, including rumination, self-blame, and venting, predict poorer

emotional and physical outcomes (Austenfeld & Stanton, 2004; Moskowitz et al., 2009). Higher levels of disengagement coping typically predict poorer outcomes, such as more anxiety, depression, and disruptive behavior, less positive affect, and poorer physical health, across an array of stressors (Littleton et al., 2007; Moskowitz et al., 2009; Roesch et al., 2005). Acceptance coping seems to be a double-edged sword. Acceptance that occurs in the context of other accommodative strategies is helpful, but acceptance that reflects resignation and abandonment predicts distress (Morling & Evered, 2006).

Relations between coping and adjustment also vary with the nature, duration, context, and controllability of the stressor. In meta-analyses of both children and adults, it appears to be important to match one's coping to the stressor's controllability and to the resources that are available. Active attempts to solve problems help when dealing with controllable stressors, but the same responses are potentially harmful when dealing with uncontrollable stressors (Aldridge & Roesch, 2007; Clarke, 2006). Similarly, taking responsibility for uncontrollable stressors predicts distress, but taking responsibility is unrelated to adjustment in the context of controllable stressors (Penley et al., 2002). In contrast, emotional approach coping (e.g., self-regulation and controlled expression of emotion) appears to be most useful in the context of uncontrollable stressors (Austenfeld & Stanton, 2004).

One caveat must be applied to all of these conclusions about the effects of coping. Although coping is almost universally viewed as an ever-changing response to evolving situational demands, most coping research fails to reflect this view. Many studies assess only dispositional coping (overall coping styles), or one-time retrospective reports of overall coping with some stressor. Those studies tell virtually nothing about how timing, order, combination, or duration of coping affects outcomes. In contrast, Tennen, Affleck, Armeli, and Carney (2000) proposed that people typically use emotion-focused coping largely after they have tried problem-focused coping and found it ineffective. This suggests an approach to studying coping in which the question is whether the person changes from one sort of coping to another across successive assessments as a function of lack of effectiveness of the first response used.

The impact of a given coping strategy may be quite brief. For this reason, laboratory and daily report studies are essential to understanding the effects of situational coping strategies (Bolger, Davis, & Rafaeli, 2003). The small number of daily report studies of coping make it clear that the impact of coping changes over time, with responses that are useful one day sometimes having a negative impact on next-day mood or long-term adjustment (DeLongis & Holtzman, 2005). Laboratory research also is useful in disentangling stressor severity from individual differences in stress appraisals by using standardized stressors. Lab studies also make it easier to supplement self-reports with observations of coping and assessment of physiological responses.

Definition

A copy number variant (CNV) is a type of genetic variation in which a sequence of nucleotides is repeated in tandem multiple times in an individual's genome. The variability arises from the gain and/or loss of genetic material, causing the number of repeat copies to vary in a population. In contrast to single nucleotide polymorphisms (SNPs), which affect only one nucleotide, CNVs are much larger, ranging from one kilobase to several megabases in size (Conrad et al., 2010). Large CNVs may contain genes, resulting in gene duplication or deletion.

CNVs are inherited, but can also arise de novo (although a rare event) via genomic rearrangements such as deletions, duplications, inversions, translocations, and transposons activity. It is estimated that the human genome contains ~20,000 CNVs (Mills et al., 2011) and covers up 12% of the human genome (Redon et al., 2006). CNVs have been associated with several diseases, including schizophrenia (Xu et al., 2008), autism (Sebat et al., 2007), and others (The Wellcome Trust Case Control Consortium, 2010). The full extent to which they contribute to human disease is not known (Conrad et al., 2010).

Coronary Artery Bypass Graft (CABG)

Definition

Coronary artery bypass graft, or CABG, is a surgical procedure performed to treat advanced coronary atherosclerotic disease.

Description

By using segments of other arteries and veins as conduits to bypass diseased portions of the coronary arteries, CABG can improve cardiac function by restoring blood flow to areas of the heart that were inadequately perfused. The most commonly used grafts include saphenous vein grafts, harvested either openly or endoscopically from the lower extremities; free radial grafts, which are segments of the radial arteries from either wrists; and left or right internal mammary arteries (LIMA or RIMA), which arise from the

subclavian arteries and are anastomosed distally to the target coronary vessels. Currently, the LIMA is most frequently used to bypass the left anterior descending artery (LAD) due its excellent long-term results, while vein grafts, which have much higher rates of graft failure, are used to bypass the other coronary vessels (Morrow & Gersh, 2008).
