Quality-Adjusted Life Years (QALYs)

M. Bryant Howren
Department of Psychology, The University of Iowa & VA Iowa City Healthcare System, Iowa City, IA, USA

Definition

The *Quality-Adjusted Life Year* (QALY) is a standardized measure of disease burden which combines both survival and health-related quality of life into a single index. The QALY is primarily used in cost-effectiveness analyses to guide decisions regarding the distribution of limited health care resources among competing health programs or interventions for a population of interest, but has also been used to aid decisions regarding clinical management and individual patient care.

Conceptually based in expected utility theory, the QALY rests on the assumption that preference-weighted values may be attached to specific health states relative to the time spent in those states. Because the QALY incorporates both quantity and quality of life, it therefore provides a reasonable estimate of the amount of quality time (i.e., health benefit) an individual may experience as a result of a particular health program or intervention. Furthermore, comparisons between programs or interventions may be made both within a single disease and across different diseases. Consequently, the QALY has been widely used as an outcome measure in medicine, psychology, public health, and economics.

Calculation of the QALY requires various health states be assigned a value ranging from zero to one, with zero representing death and one representing ideal health. Health states considered worse than death (i.e., a health state valuation less than zero) can also exist and are assigned a negative value. In order to determine the values of each particular health state, respondents are asked to rate them relative to one another, or using an anchor point such as death. Several methods may be used to ascertain valuations, including preference measurement techniques such as the standard gamble or time trade-off, or through the use of rating scales, such as the EQ-5D, Health Utilities Index, Quality of Well-Being Scale, and SF-6D.

A number of limitations have been described with respect to the measurement and incorporation of QALYs. In particular, QALYs may be less useful in the context of preventive health programs (i.e., when health effects may not materialize for some time), or chronic diseases (i.e., where quality of life may be more important than survival). Other concerns include inconsistencies among valuations due to method variance, situations in which population-level preferences about a particular disease differ from preferences of the subgroup afflicted with the disease and, more generally, decisions regarding whose preferences should matter most when assigning values to specific health states. These limitations notwithstanding, the QALY serves as a straightforward, intuitive measure of disease burden and remains an important tool in health care decision-making.

Quantitative EEG Including the Five Common Bandwidths (Delta, Theta, Alpha, Sigma, and Beta)

Salvatore Insana
Western Psychiatric Institute and Clinic, Pittsburgh, PA, USA

Synonyms

Frequency analysis; Power spectral analysis; qEEG; Spectral analysis

Definition

Quantitative electroencephalography (qEEG) is an analytical technique that can be used to objectively describe the frequency and power of electroencephalography data.

Description

Quantitative electroencephalography (qEEG) can be used in any application where electroencephalography (EEG) is applied. In this entry, qEEG will be described in the context of its application

in the measurement of brain activity patterns that can be used to infer sleep. Sleep can be measured with polysomnography (PSG), which is currently considered the "gold standard" measure of sleep-wake states. EEG is an integral component to PSG, along with electrooculography (EOG), and electromyography (EMG). In order to assure standardized PSG measurement procedures, there are uniform practice parameters established by the American Academy of Sleep Medicine (AASM [Iber, Ancoli-Israel, Chesson, Quan, & AASM, 2007]). The AASM sleep-monitoring practice parameters include specified criteria for electrode placement, equipment calibration, and PSG acquisition. Once PSG sleep signals (i.e., EEG, EOG, and EMG) are appropriately recorded, the signals can be used together for visual analyses; additionally or alternatively, EEG can be independently used for quantitative analyses.

Visual PSG Analyses: When sleep is measured with PSG, the measured signals are typically sectioned into consecutive 30-s intervals throughout the entire PSG recording period. These 30-s intervals are termed "epochs." Within each epoch, the PSG measured signals (i.e., EEG, EOG, and EMG) are cumulatively used to differentiate sleep from wake, and to further classify sleep into different categories that are known as sleep stages. According to the AASM (Iber et al., 2007), sleep can be classified into four stages that include N1, N2, N3, and Rapid Eye Movement (REM) sleep. Sleep stage scoring is completed by a trained technician who visually interprets the PSG signals in accordance with the aforementioned standard practice parameters. Once visually scored, sleep can be described by variables that include, but not limited to, time spent in particular stages, latency to particular stages, arousals from sleep, and specific physiological events during sleep. Visually scored sleep can be displayed on a hypnogram plot.

Quantitative EEG analyses: When sleep is measured with EEG, the measured signals can be analyzed and described quantitatively by their frequency and power. There are mathematically detailed components to quantitative EEG analysis; these components will be broadly described (see reviews, Campbell, 2009; Thakor & Tong, 2004). Preliminary processing includes digitization and prefiltering. Typically, EEG signals are digitized at a rate of 256 Hz, are band-limited using a low-frequency and high-frequency filters (e.g., signals $\leq$0.5 and $\geq$64 Hz are removed) to remove irrelevant signals, and are decimated (e.g., halved to128 Hz) for the analyses. Low-frequency artifacts are removed; for example, epochs that were visually scored as wakefulness or movement artifact could be excluded. High-frequency EEG artifacts are removed; for example, an algorithm can be implemented that excludes a predetermined bin length (e.g., 4 s) if that bin exceeds a predetermined high-frequency threshold relative to the frequency in adjacent bins. Once artifacts are removed, a fast Fourier transformation (FFT) is implemented to analyze wave frequency (in Hertz) within the epochs; that is, epochs are analyzed according to moving windows that partially overlap with preceding and succeeding windows. For example, a 30-s epoch that is analyzed according to a 4-s window can have a 2-s overlap among windows, thus yielding 15 windows for the epoch. Common FFT window functions include Hanning, Hamming, Bartlett, and Welch; these functions differ in duration and window overlap lengths (Campbell, 2009; Thakor & Tong, 2004). Wave amplitude is sampled in microvolts and is squared to convert the wave amplitude to power; power is calculated within each frequency band, described below.

Power is grouped according to frequency within specific broad bands or frequency ranges. There are five commonly used frequency bands that are examined with spectral analysis. The frequency bands typically fall within the range of 0.5–32 Hz; however, these frequency bands can slightly vary by laboratory and can be further broken down into narrower components as guided by the research or clinical question. The behavioral functions that correspond to each frequency band during sleep have not been clearly elucidated; however, current theories are briefly mentioned. The delta band encompasses the frequency range of 0.5–4 Hz. Delta activity is positively associated with the homeostatic sleep

drive in such a manner that delta activity increases in correspondence to increased awake time (Dijk, Brunner, Beersma, & Borbély, 1990). The theta band encompasses the frequency range of 4–8 Hz. Similar to delta activity, theta activity is positively associated with the homeostatic sleep drive (Dijk et al., 1990). The alpha band encompasses the frequency range of 8–12 Hz. Alpha activity is positively associated with relaxed wakefulness and drowsiness associated with sleep onset (Cantero, Atienza, & Salas, 2002). Alpha activity is also present during REM sleep and is theorized as being a micro-arousal that can then lead to a full arousal during sleep; the purpose(s) of alpha associated arousals during REM sleep is unknown (Cantero & Atienza, 2000). The sigma band encompasses the frequency range of 12–16 Hz. Sigma activity is positively associated with sleep spindles and has been linked to learning, memory, and intelligence (Fogel & Smith, 2011; Geiger et al., 2011). The beta band encompasses the frequency range of 16–32 Hz. Beta activity is positively associated with physiological arousal and psychological stress (Hall et al., 2007).

Spectral EEG power within particular bandwidths changes throughout development (Gaudreau, Carrier, & Montplaisir, 2001). Spectral EEG power is highly variable across individuals, but demonstrates a trait-like "fingerprint" that is stable within individuals across nights (De Gennaro, Ferrara, Vecchio, Curcio, & Bertini, 2005), as well as across both sleep and wake states (Ehlers et al., 1998). Spectral EEG power has been implicated in a wide range of sleep research topics including stress (Hall et al., 2000), intelligence (Geiger et al., 2011), memory (Fogel & Smith, 2011), psychopathology (Tekell,et al., 2005), and sleep disorders (Buysse et al., 2001; Krystal & Edinger, 2010; Perlis, Smith, Andrews, Orff, & Giles, 2001).

Spectral power can be calculated for each EEG recording site (e.g., C3/M2, and C4/M1). Total, or absolute, power is the sum of all power frequencies, within each epoch, across all bandwidths analyzed. Relative power is the power per bandwidth divided by total power times 100. Relative power density can be used to describe individual differences in variability because it is standardized by an individual's total power. qEEG calculations are commonly paired with visually scored sleep stages; this pairing can yield power in particular bands during specific sleep stages (e.g., delta power during non-REM sleep [NREM]). Once analyzed, sleep power spectra can be visually displayed on modeled power frequency curves with frequency, in Hertz, on the X-axis and the logarithmic power transformation on the Y-axis. The modeled power frequency curve can represent the entire night, or a specified sleep state such as all NREM sleep, the first NREM sleep bout, all REM sleep, etc.

To date, neither qEEG standardized analyses nor practice parameters have been established; therefore, the qEEG techniques can vary by laboratory (e.g., Vasko et al., 1997). For instance, laboratories use different methods for identifying low- and high-frequency artifacts, choice of window for weighting epochs, definition of frequency broad band ranges, and the specific electrode placement used for analyses (e.g., C3/M2, C4/M1, or average of the two locations). Thus, when reporting qEEG values, a thorough description of the acquisition, processing, and interpretation techniques are of paramount importance.

Quantitative Trait Locus (QTL)

Matthew A. Simonson
Institute for Behavioural Genetics, Boulder, CO, USA

Synonyms

QTL

Definition

A quantitative trait locus (QTL) is a region of DNA that influences, or is otherwise associated with, a quantitative trait (Mackay, 2001). Unlike "Mendelian" traits, most traits that vary within a population are influenced by a large number of genes. The genetic effects of Mendelian traits are predominantly influenced by a single genetic locus that is inherited through simple and predictable patterns. Some examples of such traits in humans include blood type, albinism, and Huntington's disease (Dipple & McCabe, 2000). Alternatively, traits such as height, intelligence, risk for most forms of illness, as well as many others, are usually due to the combined effect of many genes and regulatory regions. Such traits vary over a continuous range and are quantifiable by the degree to which the trait is expressed (Weiss, Pan, Abney, & Ober, 2006).

To identify genetic regions that harbor QTLs, genetic markers are first identified across an organism's chromosomes. By examining whether a marker co-segregates with a trait through

a pedigree more often than expected by chance, the regions of the genome near those markers are thought to have some effect on the trait (Morgan, 1911). This method of mapping traits to regions of genomes has been applied to several model organisms, both plant and animal, for roughly 100 years. The mapping of QTL regions, called "linkage analysis," has enabled the identification of genes and causal polymorphisms for several human traits (Almasy & Blangero, 2009).

By locating which QTLs (and associated genes or regulatory regions) contribute to a trait, a better understanding of the genetic architecture of a phenotype is gained (Eaves 1994). Through an increased understanding of the genetic architecture of traits, more refined methods of analysis can be employed. By combining information from genome-wide linkage studies with genome-wide association studies (GWAS), susceptibility alleles that would have previously been overlooked can be identified (Howrigan, Laird, Smoller, Devlin, & McQueen, 2011). Also, if a region is identified as a QTL relevant to a phenotype, it can then be sequenced (Feltus et al., 2011). By analyzing the sequence in a region, a better understanding of the underlying biology of a trait can then be ascertained.

Racial Inequality in Economic and Social Well-Being

Kristine M. Molina
Department of Psychology, University of Miami, Miami, FL, USA

Synonyms

Racial/ethnic disparities; Social health

Definition

Racial inequalities in economic and social well-being refer to disparities or disproportionate differences between racial/ethnic groups in key areas (e.g., educational achievement, health status, housing quality) that shape a person's/groups' opportunities and chances for optimal functioning in society (Blank, 2001).

Description

Generally, indicators of economic and social well-being in the literature have included educational attainment, labor markets, economic status, health status, crime and criminal justice, and housing. As in many other aspects of our society, race/ethnicity remains a significant predictor of well-being. Economic and social well-being are socially patterned. In comparison with Whites, racial/ethnic minorities experience disproportionate lower (i.e., worse) rates on some of the aforementioned indicators. For example, racial/ethnic inequalities in educational attainment (e.g., high school completion, college graduation) are prevalent for African Americans/Blacks and Hispanics/Latinos compared with Whites, even though educational attainment for African Americans/Blacks has increased considerably in recent years. Of significance is that no improvements have been noted in racial inequalities for family income, the most widely used measure of overall economic well-being (Blank, 2001).

Although racial inequalities in economic and social well-being exist, with certain racial/ethnic groups (e.g., African Americans/Blacks; Latinos/Hispanics) being persistently disadvantaged in a number of areas, it has generally been assumed that all racial/ethnic groups experience these inequalities in a uniform manner. In fact, however, not only are there differences between racial/ethnic minority groups and majority racial/ethnic groups, there are also differences between and within racial/ethnic minority groups (Nazroo, 2003). For example, although also considered to be racial/ethnic minorities, Asian and Pacific Islanders, unlike African Americans/Blacks and Hispanics/Latinos, typically tend to do as well as

M.D. Gellman & J.R. Turner (eds.), *Encyclopedia of Behavioral Medicine*,
DOI 10.1007/978-1-4419-1005-9,

Whites on many measures of well-being (Blank, 2001). Likewise, although Hispanics/Latinos tend to experience inequalities in most measures of economic well-being, some subgroups of Hispanics/Latinos (e.g., Cubans) tend to fare better than others (e.g., Mexican Americans and Puerto Ricans) on these same measures.

Limited data exist to account for the heterogeneity that exists within racial/ethnic groups when conducting health research. Nonetheless, as a whole, racial/ethnic minorities (primarily African Americans/Blacks, Hispanics/Latinos, and American Indians/Alaskan Natives) tend to lag behind their White counterparts on most measures of economic well-being (e.g., educational achievement, personal and family income, employment) as well as being disproportionately represented in measures of social well-being (e.g., crime victims, being arrested and incarcerated) (Blank, 2001).

Racially structured inequalities threaten the well-being of racial/ethnic minority groups. Indeed, inequalities in any of the economic and social well-being measures may come to adversely affect health, either directly or indirectly (Nazroo, 2003). Racial inequalities in any one area of well-being tend to be closely linked to inequalities in other areas. For example, racial/ethnic groups that are less likely to complete high school are also less likely to have high earnings, and may therefore be less likely to have health insurance or access to quality health care. Thus, racial inequalities in economic and social well-being may come to create a cycle of accumulated disadvantages that can eventually take a toll on health (Blank, 2001; Braveman, Sadegh-Nobari, & Egerter, 2008).

At every stage of life, moreover, these social inequalities are linked to health. Indeed, from a life-course perspective, racial inequalities experienced in childhood, particularly those related to socioeconomic status (e.g., poverty, parental education, and income level), may also translate into accumulated disadvantage and can have significant effects on human development. Significantly, the health impacts of racial inequalities in economic and social well-being can be transmitted across generations (Braveman et al., 2008).

Without a doubt, racial inequalities in economic and social well-being have significant implications for population health. As noted by Williams and Jackson (2005, p. 331), persistent racial/ethnic disparities "violate widely shared U.S. norms of equality of opportunity and the dignity of each person" and as such, eliminating existing disparities is critical for the overall well-being of the entire society.

Racial/ethnic discrimination

Definition

Racism can manifest itself in multiple forms and at multiple levels. Jones (2000) noted there are three levels by which racism can occur: (1) institutional, (2) personally-mediated, and (3) internalized. Institutional-level ("structural") racism refers to discriminatory policies, practices, laws, and procedures embedded within an organizational infrastructure that disproportionately affect a particular racial/ethnic group. At the institutional level, racism can manifest itself in terms of material conditions (e.g., differential access to and quality of health care) or access to power (e.g., differential access to resources and information). Personally-mediated (individualized) racism refers to differential treatment based on race/ethnicity, resulting from negative attitudes, assumptions, and beliefs about a racial/ethnic group. Examples of personally-mediated racism include receiving poor or no service at restaurants, being devalued, and followed around in stores.

Internalized racism refers to a person's perception of themselves, including acceptance of negative societal belies and stereotypes about one's own racial/ethnic group. In contrast to institutional and personally-mediated racism, which generally do not have an identifiable source for its perpetrator, internalized racism does (Jones, 2000). Significantly, Jones (2000) added that by the time individuals experience personally-mediated or internalized racism, they will most likely have already encountered some level of institutional racism.

In general, ethnic minorities are more likely to experience and perceive racism (Shavers & Shavers, 2006). For example, racial/ethnic minority groups disproportionately experience structural racism, such as residing in segregated neighborhoods with concentrated levels of poverty, which is a result of discriminatory housing practices. These racialized contexts put racial/ethnic minority groups at risk for a number of deleterious health outcomes, since racial segregation and the adverse conditions experienced within this context generally include crowded housing and exposure to pollutants, which can affect both mental and physical health (Shavers & Shavers, 2006). Likewise, living in structurally and economically deprived communities also means that children have less access to high-quality public schools, which limits opportunities for social mobility and may indirectly have an effect on one's life chances and achieving optimal health (Shavers & Shavers, 2006). Considering the significant implications that institutional racism has on health (and a number of social outcomes), burgeoning research in public health is now focused on examining how structural factors influence health.

Interpersonal racial/ethnic discrimination, which is a direct outgrowth of racism (Williams, Lavizzo-Mourey, & Warren, 1994), has been one of the most widely studied in health research, although studies range in its measurement (Brondolo, Gallo, & Myers, 2010; Paradies, 2006). For example, many studies have measured the construct with single-item measures such as whether a person has been treated differently or unfairly due to their race or ethnicity, and many others have measured it with scales tapping into unfair treatment that could be attributed to race, ethnicity, gender, weight, among other factors. (Brondolo et al., 2010; Krieger, 1999; Paradies, 2006). Significantly, this form of racism has been found to strongly (inversely) relate to a number of mental and physical health outcomes and health-related behaviors, including higher risk for psychiatric disorders, chronic health conditions, smoking, illicit substance use, and alcohol use/abuse (Krieger, 1999; Paradies, 2006; Shavers & Shavers, 2006). It has been argued that these

outcomes result from the chronicity and perceived stressfulness associated with experiences of differential treatment based on race and ethnicity (Williams et al., 1994).

Although less studied in health research, internalized racism has significant implications for health, particularly because this form of racism is associated with the way people think and feel about themselves and members of their own group. Thus, changes in affect and cognition, for example, may in turn affect health through behavioral and psychophysiological mechanisms, which are likely to contribute to racial/ethnic disparities in health status (Brondolo et al., 2010).

Moreover, in contrast to socioeconomic status, which has been widely cited as an underlying factor of health disparities, racism has only recently (in the last two decades) gained considerable attention as a contributor to health disparities. In fact, racial/ethnic discrimination accounts for health disparities even after accounting for a number of other factors, including socioeconomic status (Shavers & Shavers, 2006). Indeed, the role of racism in public health is argued to be of substantial importance given the wide-ranging effects it may have on population health. That is, racism is a central social determinant of health status and an underlying mechanism of racial/ethnic health disparities (Williams et al., 1994). Further, although racism manifests itself in multiple ways, all forms of racism have been shown to independently relate to adverse health outcomes. Thus, racism at any level can result in not just individual-level effects but in population-level effects as well (Brondolo et al., 2010).

Prostatectomy

Definition

Radical Prostatectomy

Radical prostatectomy (RP) is a technique used to surgically remove the prostate gland and, commonly, the seminal vesicles, lymph nodes, and surrounding tissue. Surgeons have used RP to treat benign and malignant prostate disease for over 100 years. Advances in knowledge of pelvic anatomy, technology, and surgical techniques have positioned RP as a definitive treatment for localized prostate cancer. Currently, RP refers to several surgical approaches that vary, based on site of surgical entry and whether the surgery is "open" or uses minimally invasive "laparoscopic" techniques. These options include open retropubic (RRP), perineal (RPP), and laparoscopic and robotic-assisted laparoscopic (LRP) surgical approaches. Additionally, RP approaches may be used as first-line treatment for prostate cancer or second treatment after "biochemical recurrence" (i.e., rising prostate-specific antigen levels posttreatment). Other options for treatment include radiation, hormone therapy, or surveillance instead of active treatment.

Factors Influencing Receipt of Radical Prostatectomy

A number of factors influence patients' decisions to undergo active prostate cancer treatment. Factors specifically influencing receipt of RP treatment include patients' age, comorbid conditions, prostate cancer stage and grade, and the presence of metastases. Men who are older, or who have poor health status (e.g., obesity, comorbidities) and advanced stage or grade at the time of diagnosis are more likely to receive treatment modalities other than RP. Research is divided on the association between race/ethnicity and receipt of RP. Some authors have reported that African Americans are less likely to receive RP, possibly because of more advanced disease at diagnosis; while others report no ethnic variations in treatment patterns.

Complications of Radical Prostatectomy

RP approaches produce similar cancer-control outcomes but vary in terms of peri- and postoperative complications. Perioperative complications include neurological, bowel, rectal, and bladder injuries; deep venous thrombosis; and pulmonary embolism. While there are less data for LRP, it appears that rates for many perioperative complications are low for LRP but somewhat higher than rates for RRP and RPP. More common perioperative complications include urine leakage into the abdominal cavity, restrictive narrowing of the bladder neck, and excessive blood loss requiring transfusion. Higher rates of complications occur during RRP and RPP than during LRP. Many perioperative complications can be corrected surgically after discovery. Patients opting for surgical intervention tend to experience postoperative complications at significantly higher rates than those opting for other prostate cancer treatment modalities (e.g., electron beam radiation).

Urinary and bowel incontinence and sexual dysfunction are well-documented postoperative complications of RP. For example, RP causes changes in urinary function (i.e., urgency, frequency, control, incomplete emptying), irrespective of surgical approach. Urinary effects are usually immediate, and recovery times may vary substantially for men who develop stress urinary incontinence. Men may take as long as 2–3 years before regaining some measure of continence after RP, though patients rarely experience continuous or complete incontinence. Post-RP continence rates at 12 months are between 40% and 95%, with patients at high-volume facilities achieving better continence rates. Hence, it is recommended that patients be monitored for 1 year post-RP before introducing medical or surgical interventions for urinary incontinence, as this issue may resolve with time. Findings from previous trials suggest that Kegel exercises and biofeedback prior to surgery may improve post-RP continence rates. In addition to provider- and facility-level factors, factors such as older age at the time of surgery, higher body mass index, higher prostate volume, perioperative RP bladder injury, and previous history of lower urinary tract symptoms or radiation therapy also contribute to post-RP urinary continence outcomes.

Post-RP sexual dysfunction is a complex phenomenon, with erectile dysfunction occurring in 25–85% of patients. This postoperative complication is more likely the result of a combination of the aging process, the disease itself, and RP treatment; but preoperative sexual function, comorbid health conditions, and lifestyle or behavioral factors (e.g., tobacco and alcohol use) are also contributing factors. Patients experiencing erectile difficulties immediately after surgery may gradually regain sexual function, particularly those with higher sexual functioning pre-RP; men have reported partial recovery of sexual function upwards of 2–4 years after surgery. Additional post-RP sexual effects include sterility, changes in penile length, and changes in orgasms resulting from concurrent removal of the prostate and seminal vesicles during RP.

Postoperative changes in bowel functioning are another potential complication of the RP surgical approach. Symptoms include increased frequency or urgency, diarrhea, and rectal bleeding. Men with post-RP bowel incontinence may report decline in bowel function at 4 months after surgery. As with urinary continence, many patients experiencing bowel dysfunction may recover function within the first year post-RP, while others may struggle with symptoms for years after treatment.

The Psychological Impact of Radical Prostatectomy

Advances in prostate cancer screening and detection are contributing to increasingly early prostate cancer diagnoses. A related trend concerns the often direct linkage between diagnosis and active treatment. Combined, these trends virtually ensure that younger men and those with low-risk prostate cancer will be offered treatment that they may or may not take and experience related side effects potentially for decades. In addition to medical complications, there are mental health and psychological complications.

A number of studies have examined psychosocial outcomes after prostate cancer treatment, including general, cancer-specific, and disease-specific health-related quality of life (HRQOL). General HRQOL encompasses a number of health domains related to mental/emotional, social, and physical/functional well-being. Cancer-specific instruments broadly assess the impact of having cancer across various health domains, while disease-specific instruments evaluate aspects of specific cancers. Commonly used general and cancer-specific HRQOL measures include the Medical Outcomes Survey Short Form-36 (or shorter versions) and the European Organization for Research and Treatment of Cancer Quality of Life Questionnaire (EORTC-QLQ-30), respectively. The Prostate Cancer Index (PCI) and Expanded Prostate Cancer Index: Composite (EPIC) are widely used disease-specific instruments.

Peer-reviewed literature provides strong evidence concerning the relationship between receiving RP and reduced HRQOL from chronic urinary, sexual, and bowel complications. Based on longitudinal studies, men receiving RP initially experience problems across general HRQOL domains, such as vitality/energy and role-physical well-being that substantially resolve over the course of the first year; most will return to preoperative general HRQOL levels across many domains during that time period. In terms of cancer-specific or disease-specific HRQOL, receiving RP is linked to immediate decrements in urinary and sexual function. Urinary function reaches its nadir around 3 months post-RP and gradually improves until years 2–3. At year 2, a substantial number of men's urinary function scores have not returned to preoperative levels, and they continue to report some degree of daily urine leakage. RP patients also experience decreased sexual functioning, reaching its nadir at 6 months post-RP and gradually improving through years 2–4. Yet return to presurgery levels of sexual function may not be possible for substantial numbers of patients; only about 34% of men undergoing RP return to preoperative levels by year 5. Men experiencing persistent erectile dysfunction may experience radical shifts in body image and confidence in initiating sexual intimacy, causing them to question their masculine and sexual identities.

Thus, post-RP complications cause a number of psychological, emotional, and social concerns that have lasting impact on men's HRQOL, including changes in masculine self-image and confidence and anxiety about cancer recurrence. The RP-HRQOL relationship is influenced by a number of demographic and psychosocial factors. Younger men undergoing RP experience greater recovery in terms of urinary and sexual function than their older male counterparts at 1-year post-prostatectomy. They also report lower urinary and sexual bother scores on average than older men. Men who are married or white are significantly more likely to return to pre-RP general HRQOL levels than their unmarried or racial/ethnic minority counterparts. Married men experience greater recovery in general health and social well-being domains; while those who are white experience gains in the physical, social well-being, and role-physical domains. Moderating or mediating psychosocial factors include health literacy, perceived stress, treatment satisfaction, and fear of recurrence.

Interventions exist that ameliorate many of the post-prostatectomy physical complications. For example, nonpharmacological interventions such as Kegel exercises or erectile aides (e.g., penile pumps) are available. Some RP patients may also experience enhanced sexual functioning with PDE-5 inhibitor usage; over one half of patients who initiate pharmacological penile rehabilitation recover natural erectile function by 18 months post-RP. Interestingly, a number of men with erectile difficulties will discontinue treatment after the first failed intervention, despite evidence suggesting that men attempting two or more options are more likely to find effective treatment.

A growing number of randomized controlled trial-tested interventions are targeting prostate cancer patients and caregivers in clinically modifiable areas, such as physical and psychological symptom management, literacy and culturally appropriate educational materials, decisional aids, marital communication and adjustment, and other areas. Integrative psychological and behavioral approaches to prostate cancer treatment-related complications are warranted for improving HRQOL after RP. Behavioral medicine researchers and clinicians will increasingly be called upon to lend their expertise as part of multidisciplinary teams or in disseminating study results within clinical settings.

Randomization

J. Rick Turner
Cardiovascular Safety, Quintiles, Durham, NC, USA

Definition

Randomization is a process of randomly assigning experimental subjects to one of the treatment groups so that many potential influences that cannot be controlled for (e.g., height, weight) or cannot be determined by observation (e.g., specific metabolic pathway influences in pharmaceutical clinical trials) are likely to be as frequent in one treatment group as they are in the other. The goal of randomization is to eliminate bias.

Randomization occurs after a subject's eligibility for a clinical trial has been determined and before any experimental data are collected. The process facilitates the random assignment of subjects to different treatment groups with the intent of avoiding any selection bias in subject assignment.

As discussed in the entry titled "▶ Hypothesis Testing," inferential statistics requires the random assignment of subjects to different treatment groups to allow differences in responses between treatment groups to be connected to the treatments received. Randomization means that other potential sources of influence on the data have been randomly allocated to each treatment group. That is, subjects have an independent (and usually, but not necessarily, equal) chance of being in the different groups. While subjects are typically randomized to two treatment groups in a 1:1 ratio, generating the same number of subjects in each group, other randomization ratios can be used. For example, a ratio of 2:1 for an active treatment versus a placebo treatment would mean that two thirds of the subjects would be randomized to the treatment group and one third to the placebo group. Such an unequal randomization ratio has various implications, including the consequence that the statistical power to detect a difference between the groups is not as high as it would be if the same number of subjects had been used and the number of subjects in each group had been equal.

As noted, the goal of randomization is to eliminate bias. This includes subject bias, based on their knowledge of which treatment group they have been assigned to (this is not possible on all occasions, and can be particularly difficult in studies of behavioral medicine interventions), and investigator bias. Investigator bias is eliminated by preventing researchers from deliberately assigning subjects to one treatment group or the other. Two possible unconscious or conscious biases on the part of the researcher that are thus removed are an inclination to place less healthy subjects in the treatment group receiving the intervention they believe to be most beneficial, and an inclination

to place the more healthy subjects in the group receiving a "favored" intervention to demonstrate its superiority.

Randomized Clinical Trial

J. Rick Turner
Cardiovascular Safety, Quintiles, Durham, NC, USA

Synonyms

Randomized concurrently controlled clinical trial; Randomized controlled clinical trial

Definition

A randomized clinical trial is one in which the subjects in each treatment group have been placed in that group by a randomization procedure. Randomization involves randomly assigning experimental subjects to one of the treatment groups so that many potential influences that cannot be controlled for (e.g., height, weight) or cannot be determined by observation (e.g., specific metabolic pathway influences that may be relevant to the efficacy or safety of interventions in the trial) are likely to be as frequent in one treatment group as they are in the other (Turner, 2010).

Description

The fundamental goal of randomization is to eliminate bias (or, pragmatically, to reduce it as much as possible). This includes subject bias, based on their knowledge of which treatment/intervention group they have been assigned to, and investigator bias. Investigator bias is eliminated by preventing investigators from deliberately assigning patients to one treatment group or the other. Two possible unconscious or conscious biases on the part of the investigators that are thus removed are an inclination to place less healthy subjects in the treatment group receiving the intervention they believe to be most beneficial, and an inclination to place the more healthy subjects in the investigational intervention group to demonstrate its superiority.

Randomized concurrently controlled clinical trials are generally regarded as the "gold standard" for providing compelling evidence that an intervention is effective. The treatment can be of various kinds, including pharmacological and behavioral. In the realm of behavioral medicine, two examples of interventional treatments are physical exercise and cognitive behavioral therapy. These interventions would be tested against one or more control interventions. These can be "active controls," i.e., an intervention that is established to be efficacious in this context. They can also be "placebo controls," i.e., interventions that are not able to be efficacious in this context, but whose implementation involves as many as possible of the same demands and benefits that the interventional treatment makes on, and provides to, subjects in the interventional group. Matthews (2006) commented as follows:

"Over the last two to three decades randomized concurrently controlled clinical trials have become established as the method which investigators must use to assess new treatments if their claims are to find widespread acceptance. The methodology underpinning these trials is firmly based in statistical theory, and the success of randomized clinical trials perhaps constitutes the greatest achievement of statistics in the second half of the twentieth century."

Compelling evidence is sought that the investigational intervention is statistically significantly (and then clinically significantly) more effective than the comparator intervention. Such evidence is generated via the use of inferential hypothesis testing and a resultant p-value of less than 0.05.

(Despite its attained prominence, the value of 0.05 was not ordained, but conceived by the renowned statistician Sir Ronald Fisher. Had he decided, for example, that odds of 1 in 25, with an analogous p-value of 0.04, were more suitable for this purpose than odds of 1 in 20, modern science might be held to a different standard.)

Randomization occurs after a subject's eligibility for a clinical trial has been determined and before any experimental data are collected. The process of randomization is facilitated by the generation of a randomization list. This list is generated (often by a random-number generator) in advance of recruiting the first subject. The list is generated under the direction of the trial statistician, but, to maintain confidentiality, is not released to the statistician until the completion of the study.

Inferential statistics requires the random assignment of subjects to different treatment groups to allow differences in responses between treatment groups to be connected to the treatments administered. Randomization means that other potential sources of influence on the data have been randomly allocated to each treatment group. That is, subjects have an independent (and usually, but not necessarily, equal) chance of receiving either the investigational intervention or a control intervention.

Kay (2007) highlighted several methods of randomization, including simple randomization, block randomization, and stratified randomization. Simple randomization involves assigning treatments to subjects in a completely random way. While this strategy is attractively simple, it is not advisable in the case of small trials. In the example of a trial involving 30 subjects randomized to two treatment groups, the probability of a 15–15 split, the most powerful from a statistical analysis point of view, is only 0.144, while the probability of a split of 11–19 or even more unbalanced is 0.20. While 30 subjects is a small number that is used for illustrative purposes here, some researchers advocate not using simple randomization schedules in trials with less than 200 participants. In such trials the stratified randomization approach is recommended. Many clinical trials in behavioral medicine are likely to involve such numbers of subjects, in contrast to therapeutic confirmatory trials in the pharmaceutical industry, where several thousands of subjects are typically employed.

Concurrent control is a critical feature of these trials. The term "control" has already been discussed here. The term "concurrent" simply means that the control treatment should be given at the same point in time (and also under the same conditions) as the intervention of interest.

[2]Institute of Metabolic Science, Addenbrookes Hospital, Metabolic Research Laboratories, University of Cambridge, Cambridge, UK

Synonyms

Idiopathic Raynaud's Phenomenon; Primary Raynaud's Phenomenon

Definition

Raynaud's disease is a reversible vasospastic phenomenon triggered in susceptible patients by exposure to cold and/or emotional stress. The condition is characterized by arterial and arteriolar vasoconstriction, most commonly affecting the distal extremities such as the hands or, less commonly, the feet. The vasoconstriction produces a characteristic pallor and cyanosis of the involved digits (ischemic phase) followed by subsequent reperfusion and digit erythema, or redness.

Description

General Information

Raynaud's disease, or primary Raynaud's phenomenon, was first described in 1862 by Maurice Raynaud, who observed the characteristic color changes of the hands of affected patients during episodes of vasospasm. Modern medicine differentiates Raynaud's disease, or primary Raynaud's phenomenon, which is an idiopathic disorder, from secondary Raynaud's phenomenon, which is commonly associated with rheumatologic or autoimmune causes and which often has a more severe clinical course.

Raynaud's disease predominantly affects females, with an estimated prevalence of 6–20% of women and 3–12.5% of men, and is more common in colder climates. The symptoms in Raynaud's disease typically begin prior to the age of 30, may involve associated pain or numbness during episodes of vasoconstriction, and tend to affect the extremities symmetrically. They can vary considerably in severity, with most individuals experiencing mild to moderate symptoms and others experiencing symptoms that are intermittently debilitating. Rarely, episodes of vasospasm in Raynaud's disease can progress to ulceration or necrosis of the involved digits.

Role of Stress

The exact relationship between emotional stress and Raynaud's disease is not clear. While most episodes of vasospasm in Raynaud's disease are caused by exposure to cold temperatures, emotional stress has long been thought to play a role in precipitating symptoms as well. In fact, management of Raynaud's disease during the mid-1900s fell under the purview and management of psychiatry and psychoanalysis, treated with questionable success with psychotherapeutic techniques. In more recent studies, patients have reported a role for stress in triggering Raynaud's attacks in up to 33% of episodes, experienced by a self-reported 21% of Raynaud's disease sufferers. Initially, it was hypothesized that Raynaud's patients who were susceptible to stress-triggered attacks may be more likely to manifest higher levels of anxiety in general, termed "trait anxiety," although the accuracy of this characterization is unclear. Studies in the 1980s failed to show any significant differences in measures of anxiety or "neuroticism" based on psychologic questionnaires. A study of the quality-of-life impact of primary Raynaud's phenomenon suggested that patients suffering from the disease reported worse quality of life than control subjects and were more likely to report the subjective experience of moderate to severe anxiety symptoms. It remains uncertain, however, whether these findings inform an underlying psychiatric predisposition among Raynaud's sufferers to stress-triggered episodes or if the results are simply commonly seen complications of long-standing chronic disease.

Suspected Pathogenesis

The proposed pathogenesis of Raynaud's disease is not fully elucidated but seems to be closely related to the sympathetic nervous system, a physiologic mechanism triggered frequently by physiologic or emotional stress. Scientists have found that Raynaud's disease sufferers show an increased peripheral responsiveness to circulating catecholamines, or stress hormones, which are increased in all individuals in response to cold temperatures or emotional stress. People diagnosed with Raynaud's disease have been shown to have an increased sensitivity of the alpha-2 adrenergic receptors in peripheral blood vessels that detect these hormones, perhaps either through altered characteristics of the receptors themselves or through an increased density of receptors. By this model, levels of circulating catecholamines caused by emotional stress that would not typically trigger vasoconstriction in normal individuals could understandably trigger vasospasm in patients who are more sensitive to their effects, either with or without a predisposition to higher anxiety states.

Researching Stress and Raynaud's Disease

Efforts to study the effects of stress in Raynaud's disease have frequently produced equivocal and at times conflicting results. Early research in the 1940s and 1950s focused on measuring finger temperature in relation to emotional states to determine if emotional distress could cause vasospasm. While some initial studies documented correlative evidence of markedly decreased finger temperatures in Raynaud's patients exposed to emotional stressors, this correlation was not consistently replicated over the next decades. Some studies even documented an increased finger temperature among Raynaud's sufferers in response to a provoked stress responses.

More recently, efforts to delineate the effect of stress in triggering Raynaud's attacks have revealed the possibility of a patient cohort that shows an increased susceptibility to emotional stress-triggered Raynaud's attacks, characterized by a higher trait anxiety scores than other Raynaud's sufferers. The Raynaud's Treatment Study in 2001 suggested that, while perceived stress alone did not seem to predict an increase in Raynaud's disease, increased anxiety scores were associated with more frequent attacks, particularly at warmer temperatures, as well as a higher reported severity of attacks at all temperatures and increased pain at temperatures greater than 40°. The observed effects were small but significant. It has been proposed that the effects of stress carry greater impact at higher temperatures than lower temperatures because of the absolute increase in cold-induced vasospasm below 40°. The effects of stress may only be observable at higher temperatures, where vasospasm is less universally triggering for Raynaud's sufferers.

Treatment

Understandably, the possible role of stress in triggering Raynaud's symptoms has led to the development and study of stress reduction-based interventions. Early recommendations of relaxation techniques have not shown any statistical benefit in studies. Cognitive-behavior treatments have been tested in small populations, again without any demonstrated benefit. Among nonpharmacologic treatments for Raynaud's disease, behavioral treatments seem to be the most effective in diminishing symptoms. For an in-depth discussion of behavioral treatments in Raynaud's disease, refer to "Raynaud's Disease and Behavioral Treatments."

Idiopathic Raynaud's Phenomenon; Primary Raynaud's Phenomenon

Definition

Raynaud's disease is a reversible vasospastic phenomenon triggered in susceptible patients by exposure to cold or emotional stress. The condition is characterized by arterial and arteriolar vasoconstriction, most commonly affecting the distal extremities, that produces a characteristic pallor and cyanosis of the involved digits (ischemic phase) followed by subsequent reperfusion and digit erythema, or redness.

Description

Symptoms of Raynaud's disease, including vasospasm and associated pain or numbness, are frequently amenable at least in part to conservative approaches to treatment. These initial approaches focus on avoidance of potential environmental triggers which can vary according to individual patients but most often relates to exposure to cold temperatures. To minimize the risk of cold exposure, patients are advised to practice full body insulation since other areas of exposed skin besides the hands can precipitate attacks. Patients are advised to avoid sudden changes in temperature as well. Discontinuation of known vasoconstrictive medications, smoking cessation, avoidance of vibration, and discontinuation of caffeine consumption have also been counseled. Some individuals also benefit from a swing-arm maneuver that causes pooling of blood in the distal extremities to counteract the effects of vasoconstriction, shown in some people to abort the onset of a Raynaud's attack. While a majority of Raynaud's disease sufferers respond well to these recommendations with at least some reduction in the severity and frequency of symptoms, others require more aggressive pharmacologic or even behavioral interventions, described below.

For patients who do not respond to conservative interventions, the next step in treatment is frequently the initiation of a medication to inhibit vasospasm, such as calcium channel blockers. This class of medication has been shown in multiple studies to help decrease the rate of Raynaud's attacks and to mitigate the severity of attacks in a significant number of patients. Reports of side effects from these medications are common, including orthostatic hypotension, edema, headache, tachycardia, and constipation. Given poor tolerance of pharmacotherapy in some patients, behavioral treatments have been concurrently developed and researched to provide an alternative to medications. These interventions, most notably thermal biofeedback, autogenic training, and classical conditioning, have been tested head to head with medical treatments in some studies and have been shown to have potential benefit.

Behavioral treatments have been developed alongside medical therapies in treating Raynaud's disease, in part due to the known side effects of many medications but also due to early evidence that principles of biofeedback may be very effective in controlling patient's symptoms.

Biofeedback is a behavioral technique developed in the last 40 years that links involuntary physiologic processes, such as heart rate, which often occur below the level of conscious awareness, to sensory stimuli that are easily perceptible and able to be tracked to note variations in these unconscious processes. Patients then use this information to manipulate the target physiologic response (e.g., slowing heart rate through conscious focus).

This technique has been applied to Raynaud's disease in several forms, the best-researched of which is thermal biofeedback. Thermal biofeedback (also called finger temperature biofeedback) is a behavioral treatment first studied in Raynaud's patients in the 1970s. The technique instructs individuals in the use of sensory feedback to convey an increase in finger temperature by facilitating peripheral vasodilation. This technique has been shown in several small studies to have strong efficacy in reducing Raynaud's attacks by up to 92.5%, particularly when the initial training was conducted during exposure to cold temperatures. Improvements in symptoms have been observed as long as 3 years from the time of initial training. Further studies, including those comparing the effectiveness of thermal biofeedback to standard medical therapies, have been inconclusive. The wide variability in study results is thought to be attributable to the underlying difficulty in teaching the technique, which often requires intensive instruction to achieve mastery. Patients who do achieve mastery are frequently able to facilitate hand rewarming through practiced conscious intervention in high-risk environments that would previously have trigged episodes of vasospasm. Despite these results, a recent head-to-head comparison of nifedipine, a standard medical treatment for Raynaud's, and thermal biofeedback was unimpressive, although authors highlighted the limitations in assessing the behavioral technique due to strong evidence that participants had not achieved mastery of the technique during the study, which likely significantly reduced its apparent effectiveness.

Another technique that may be in some part considered a relative of biofeedback is autogenic training. This technique was first introduced in the early 1930s within the mental health community to promote stress management and relief from somatic symptoms often related to anxiety. AT is a relaxation method consisting of passive self-monitoring of physiologic sensations such as heart rate to then inform self-initiated verbal cues intended to cause a desired change in physiologic effect or modification of the initial sensation. This technique has been applied to treatment models in Raynaud's disease through cultivation of an awareness of finger temperature and the application of cuing to trigger peripheral vasodilatation. The effectiveness of this technique is unclear. Some studies have shown an increase in finger temperature (often a measured outcome in Raynaud's research) that equals the observed efficacy of thermal biofeedback interventions, with reports of similar clinical efficacy. Combining the two techniques does not appear to convey any additional benefit, however.

Classical conditioning is a principle that pairs a behavior with a predictable outcome, such as salivation in response to the presentation of food, to an alternate stimulus to link the alternate stimulus with the outcome through repetitive training. In application to Raynaud's disease, Raynaud's disease sufferers have been conditioned to respond to exposure to cold temperatures with peripheral vasodilatation after serial exposures to cold ambient temperatures with concurrent immersion of the person's hands in warm water. Over time, patients were observed to have increased blood flow simply with exposure to cold temperatures even without the added exposure of warm water immersion. This technique, while not as well studied as thermal biofeedback, also has been shown to have a possible effect in decreasing the frequency and severity of Raynaud's attacks.

Less well-studied interventions have included progressive relaxation and guided imagery. These techniques focus on relieving emotional stress and providing improved relaxation. Progressive relaxation is a tool that involves the progressive contraction of muscle groups followed by sequential release of muscle tone to achieve a global state of relaxation. Guided imagery is a technique that teaches patients to directed imagining of calming or peaceful imagery to facilitate relief from anxiety and stress. Both techniques been studied in conjunction with

other behavioral interventions such as thermal biofeedback, but not as a stand-alone treatment.

Behavioral treatments such as thermal biofeedback, autogenic training, and classical conditioning have been shown to have variable effects on the symptom frequency and severity of Raynaud's disease sufferers, although evidence overall is supportive for a role of these treatments among this patient population. Certainly, further research will help to clarify the role of these interventions and to elucidate the mechanism by which their effect is mediated.

Readiness for Return-to-Work (RRTW)

Timothy Wolf
Department of Occupational Therapy and Neurology, Program in Occupational Therapy, St. Louis, MO, USA

Synonyms

Vocational assessment

Definition

Readiness for return to work is the complex decision-making behavior related to returning to work after an injury or illness. In this process, individuals must consider their self-efficacy surrounding their ability to return to work; the interaction of the many third parties involved in returning to work including the employer and the healthcare and insurance providers; as well as the state of their disability as it interacts with the demands of the job. This term was originally conceived by Franche and Krause (2002) in their conceptual model for readiness for return to work.

Description

Work disability is often determined by an evaluation of impairments following injury or illness. This most often focuses on physical impairments which is apparent in most work evaluation methodologies, i.e., functional capacity evaluation. The limitation in this approach is that the

healthcare community has long known that work disability involves a lot of factors beyond what impairment can explain. Workers who are seemingly more impaired may return to work very quickly and without difficulty while workers who are seemingly less impaired may struggle with returning to work or never attempt to return to work at all. The notion of readiness for return to work is used to help address this limitation in current work assessment methodologies. The concept for readiness for return to work was developed by Franche and Krause (2002) to provide a framework for work disability research and practice that would account for the multiple factors that influence work disability. These factors include physical (i.e., impairments), psychological (i.e., self-efficacy related to completing the demands of the job), and social (i.e., the employee's interactions in the work environment, with healthcare providers/health insurance companies). They developed the Readiness for Return to Work model in order to combine these factors to explain return to work behaviors. The Readiness for Return to Work model incorporates two well-known theoretical models to explain a work-disabled person's behavior regarding return to work. First, the Phase Model of Occupational Disability provides a framework for understanding the developmental component of disability (Krause & Ragland, 1994). Second, the Readiness for Change Model provides a framework for understanding the motivation to change behavior relative to returning to work (Prochaska & Diclemente, 1983).

Further work with the Readiness for Return to Work model has focused on the application of the Readiness for Change Model to work behavior to help understand work-disabled individuals' motivation to return to work following injury or illness. There are five stages within the Readiness for Change Model that an individual will progress through (Prochaska & Diclemente, 1983):

- *Precontemplation*: Workers are not thinking about returning to work and are not making plans to do so either.
- *Contemplation*: Workers are considering return to work but are still not engaging in the planning process to do so.
- *Preparation for action*: Workers are seeking information about returning to work and are also looking for feedback on their ability to meet the demands of the workplace. In addition, workers are making plans to return to work.
- *Action*: Workers return to work in some capacity.
- *Maintenance*: Workers use their skills and social support to help cope with adversity they encounter in returning to work in order to maintain their ability to work.

Within this model, it is important to note that workers can relapse anytime and start regressing through these stages. The Readiness for Return-to-Work Scale (RRTW) (Franche, Corbiere, Lee, Breslin, & Hepburn, 2007) is used to determine the worker's present stage. The results might be helpful for healthcare providers to determine support and resources needed for the worker to be able to return to work. This information can also be use to tailor interventions for the worker in order to improve the effectiveness of rehabilitation efforts.

Evaluation of potential public health impact; Internal and external validity issues

Definition

RE-AIM is an acronym for an assessment and planning framework that addresses individual and setting-level factors that are related to the overall public health impact of health behavior interventions (Glasgow, Vogt, & Boles, 1999). Interventions are defined in a broad sense to include community programs, clinical practices, environmental changes, and policy approaches intended to promote healthy lifestyle behaviors. The acronym represents the following dimensions: reach, effectiveness/efficacy, adoption, implementation, and maintenance. Reach is an individual-level measure and is defined as the number of participants, participation rate among of the target population, and representativeness of the participants. Efficacy or effectiveness is also an individual-level measure and is defined as change in the primary outcome, impact on quality of life, and assessment of potential negative outcomes. Efficacy is assessed under optimal circumstances, while effectiveness is assessed under more context relevant circumstances (Flay, 1986). Adoption is a setting-level indicator and is defined as the number, percent and representativeness of settings and educators who agree to deliver an intervention. Another setting-level dimension is implementation which determines the cost of and extent to which the intervention is delivered as intended and, in some cases, is defined as the degree of participant adherence to intervention protocol (Estabrooks & Gyurcsik, 2003). Finally, maintenance is conceptualized at both the individual and setting level. At the setting level, maintenance is defined as the extent to which an intervention is sustained over time (Glasgow et al., 1999). At the individual level, maintenance is defined as the degree to which behavior changes are sustained 6 months or longer after the intervention is complete (Glasgow et al.).

Description

The RE-AIM framework was developed in response to the need to expand the evaluation of health behavior interventions beyond simply assessing efficacy or effectiveness to include criteria related to external validity. The underlying proposition of the RE-AIM framework is that evidence which is contextual, practical, and robust is more likely to facilitate the translation of health behavior interventions into typical clinical or community practice. Further, considering each of the RE-AIM dimensions during the planning phase is hypothesized to result in interventions that can be widely adopted by different sites and personnel, having the ability for sustained and consistent implementation at a reasonable cost, reaching large numbers of people (especially those who can most benefit), and producing replicable and long-lasting effects with minimal negative impacts (Glasgow & Emmons, 2007; Klesges, Estabrooks, Dzewaltowski, Bull, & Glasgow, 2005). Unfortunately, a number of reviews of literature investigating the degree to which RE-AIM information is reported across behavioral interventions suggest that data across the dimensions related to external validity are rarely reported and that inconsistent techniques have been used to operationalize RE-AIM assessments (Glasgow, Klesges, Dzewaltowski, Bull, & Estabrooks 2004). The remainder of this chapter will be dedicated to outlining guidelines for assessing each RE-AIM dimension.

Three general data elements are necessary to assess reach: the number of participants, the number of potential participants, and comparative information on the target population. Determining the number of individuals who participate in or are exposed to a given intervention is relatively straightforward. However, determining an appropriate denominator to calculate participation rate can be more difficult. For example, in one research project, the goal was to promote physical activity following a health maintenance visit at a local health care clinic using a 24-week program (Almeida et al., 2005). There were a number of possible denominators to choose from: the total number of adult patients, the total number of adult patients who were not meeting recommended physical activity guidelines, and the total number of patients who were not meeting recommended guidelines and came in for a visit. The key determining factor for selecting the appropriate denominator was fairly simple: the denominator that reflected insufficiently active patients who were exposed to recruitment activities. The total number of patients that attended a health maintenance visit over the course of the study recruitment was 1,518. Of those 1,518 individuals, 607 were eligible, 218 were referred, and 115 participated. Thus, the participation rate was calculated as 19% based on the sample size ($n = 115$) and the number of eligible individuals exposed to recruitment activities ($n = 607$). To determine the representativeness of the sample, the study sample was compared to the demographic profile of the catchment area of the clinic. Nonparticipants were more likely to be older females. However, the participants were representative of the racial and ethnic composition of the community (Almeida et al.).

Methods to determine the efficacy or effectiveness of a behavioral intervention have been exhaustively covered by other authors (e.g., Flay, 1986). Briefly, a comparison of the ability of an intervention(s) to change a primary study outcome either under optimal or more real-world conditions provides estimates of efficacy or effectiveness, respectively. The comparison of changes in quality of life adds a dimension to effectiveness that allows a more patient-centered perspective and standardization for comparison across interventions targeting different primary outcomes. The focus on unintended negative consequences can range from issues related to safety or changes the reduction of one health behavior in favor of increasing another (e.g., participants who quit smoking and replace that behavior with eating unhealthy snack foods). Other issues related to improving the external validity of documenting effectiveness include assessment of differential attrition across participants with different demographic profiles and the use intention-to-treat analyses.

Adoption is conceptualized similarly to reach, but addresses participating settings or delivery personnel rather than intervention participants. As with reach, three data elements are necessary: the number of participating settings, the number of potential settings where the intervention could be delivered, and comparative information on the population of potential settings. Adoption can also be assessed within a given setting and based on the staff who would ultimately deliver an intervention. A simple example of adoption at the setting level is provided in a paper on Walk Kansas, a statewide nutrition and physical activity intervention intended for delivery by a county Cooperative Extension agent in each of the 105 (i.e., denominator) counties in Kansas (Estabrooks, Bradshaw, Dzewaltowski, & Smith-Ray, 2008). Forty-eight county agents agreed to participate, reflecting an adoption rate of 46%. To determine representativeness, a survey that was administered to all Cooperative Extension agents prior to Walk Kansas was used. The results indicated that less physically active county agents were less likely to deliver the program and smaller population counties were less likely to deliver the program.

Implementation can be assessed in a number of ways: observation of the delivery of intervention components, checklists for those delivering the intervention, or the degree to which participants engage in intervention components. Further, cost of implementation can be collected using self-reported or direct observation of the resources and time needed for delivery. Schillinger,

Handley, Wang, and Hammer (2009) provide an example of reporting on the dimension of implementation of an automated telephone intervention to support diabetes self-management. They assessed the degree to which automated telephone support calls were completed across the 9-month intervention and found that 94% of the participants completed at least one automated call. Of those participants, the range of calls completed was from 22 to 39 (out of 39 possible calls). Costs of implementation were assessed at for the automated telephone intervention at $782 per participant (Schillinger et al., 2009).

Assessment of effectiveness or efficacy indicators 6 months after an intervention is completed and the degree to which an intervention is sustained in a delivery setting post research funding are the key components to evaluating the maintenance. Thus the data necessary to determine efficacy or effectiveness of an intervention (i.e., primary outcome, quality of life, and potential negative outcomes) are identical to the data necessary to determine maintenance with the only caveat being the time of assessment. As continued concerns with recidivism and poor adherence to newly acquired health behaviors, the prevalence of research on individual-level maintenance has increased. Less available in the literature is information on the degree to which programs are sustained once research is completed. This is not surprising as most research studies are not designed to lead to a sustained program over time. However, researchers embedded within delivery systems like the Veterans Administration are beginning to examine the degree to which new behavioral interventions can be sustained once the formal testing of effectiveness is completed (Stetler, Mittman, & Francis, 2008).

A common question related to the RE-AIM framework is: Which dimension is most important? Some argue that the answer is obvious – effectiveness. However, one could also argue that reach is equally important. For example, an intervention with no potential for broad reach is just as irrelevant as one with no potential for effectiveness. From a setting level, if an intervention cannot be adopted in typical delivery settings, or implemented as intended, or sustained, it will not achieve a strong public health impact even if research studies indicate it is highly effective. Still, there is some interest in understanding how the dimensions of RE-AIM may interact to generate a significant public health impact (Glasgow, Klesges, Dzewaltowski, Estabrooks, & Vogt, 2006). Future research into the interplay between reach, effectiveness, cost or adoption, implementation, and sustainability will help to inform public health practice related to health behavior interventions. Other areas of promise include examining cost across RE-AIM dimensions, rather than just as it is associated with implementation, and cost-effectiveness and the role of adaptation and local innovation in real-world implementation studies.

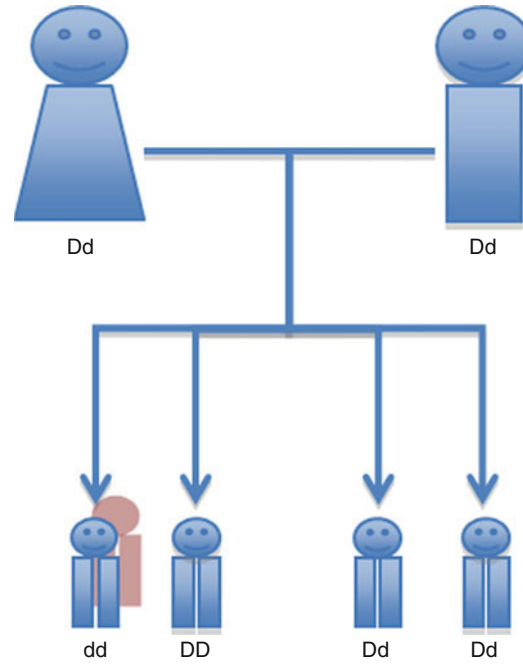
Recessive Inheritance

Laura Rodriguez-Murillo[1] and Rany M. Salem[2]
[1]Department of Psychiatry, Columbia University Medical Center, New York, NY, USA
[2]Broad Institute, Cambridge, MA, USA

Definition

A trait that is inherited in a recessive fashion only manifests phenotypically in homozygous individuals, i.e., when the individual has two copies of the same recessive allele. Humans have two versions of all autosomal genes, called alleles, one from each parent. The recessive trait is hidden in the heterozygous individual (Dd) if the other allele is inherited in a dominant fashion, and so this person is a called a "carrier" of the recessive allele, but does not manifest the disease or trait. A recessive trait can only be passed to the offspring if both parents carry (Dd or dd) and transmit the recessive allele to their offspring. In the scenario where both parents are heterozygous carriers of the recessive trait, the children have 25% chance of inheriting two copies (dd) of the recessive allele and exhibiting the recessive trait (see pedigree figure, Fig. 1). An example of a disease with a recessive inheritance is Tay-Sachs disease that occurs when a child has two defective copies of the HEXA gene, neither of which can be successfully transcribed and form a functional enzyme product (Myerowitz & Costigan, 1988).



Recessive Inheritance, Fig. 1 Recessive inheritance diagram. Highlighted individuals are affected by the disease after inheriting one recessive allele from each carrier parent (dd)

Recruitment of research participants

Definition

Recruitment of research subjects is the process by which individuals are recruited as potential subjects in a research study. Upon learning full details of the study by reading the Informed Consent Form, eligible individuals may or may not decide to participate: Nonetheless, they have participated in the process of recruitment.

Description

While individual investigators can play an important role in subject recruitment – their access to potential subjects likely having been a reason for their being selected to participate in the trial – the primary responsibility for subject recruitment can fall on the principal investigator/holder of the grant that is funding the behavioral medicine research study. For all but the smallest studies, creation and implementation of a recruitment strategy and plan is an important and potentially critical operational step. This plan should be a formal written document that carefully considers best-case and worst-case scenarios, takes into account various timing influences (e.g., national holidays and typical vacation periods, seasons of the year, likely onset of flu season), and has contingencies built in to address all anticipated potential recruitment barriers.

Spilker (2009) provided the following operational definition of recruitment:

- Identifying potential pools of subjects and specific individual subjects who may be eligible to enroll in the trial.
- Attracting those individuals to consider participation.
- Discussing the trial with them.
- Prescreening subjects.
- Having subjects read an informed consent form, answering any questions they may have, and then having the subjects sign the consent form.
- Conducting a more complete and formal screening procedure.
- Being able to state that subjects are now enrolled in the trial.

Recruitment is of ongoing interest to a principal investigator throughout a trial, and there are several common metrics addressing

this. One is "first subject first visit," the date on which the first subject completes his or her first visit to the investigational site. In cases where there are multiple investigational sites another metric of interest is the date when 50% of the sites have each enrolled at least one subject.

Traditional subject recruitment strategies include the following:

- Advertisements on radio and television, and in print media.
- Mailing flyers to individuals and patient advocacy groups.
- Data mining from insurance company databases.
- Using web sites to publicize the trial.
- Posting information on a hospital's bulletin board.
- Hospital staff wearing lapel pins that bring attention to the trial.

Cabell (2009) recently discussed another approach that focuses on understanding and utilizing the "patient pathway," the route by which patients receive treatment. By understanding and documenting the pathway via which patients with the disease or condition of clinical concern receive their current medical care, it becomes possible for recruitment specialists to reach out to clinicians and other behavioral medicine specialists who provide the care. This allows the specialists to access the appropriate patients and, should they be willing, recruit them as subjects for the trial.

While this entry focuses primarily on subject recruitment, it has become widely accepted that principal investigators need to devote considerable resources to subject retention as well as recruitment: The ultimate goal is for an enrolled subject to complete participation in the trial. Many characteristics of a subject's participation in the trial can influence the likelihood that he or she will complete the trial, including:

- The length of the treatment period. All subjects have personal and professional lives, and events that preclude trial completion – personal or family illness, relocating, financial difficulties – do and will happen. Some trials have relatively long treatment periods, and the researcher cannot alter this, but the length should alert the researcher to the need for appropriate contingency plans.
- How onerous participation is. If the trial's protocol requires subjects to undergo many procedures at many visits, withdrawal rate may increase. The burden of the trial should be considered at the protocol development phase, with an eye to decreasing noncritical subject tasks, such as filling out a large number of questionnaires that do not address the primary objective.
- Ease of traveling to the investigational site(s). If many subjects participating at a given site have to travel a considerable distance, and/or at considerable expense, each time they visit the site, the PI is well advised to address this proactively.

Specific retention strategies include:

- Providing reimbursement for expenses such as parking, meals, and babysitting.
- Calling subjects shortly before each visit to remind and assure them that provisions for their attendance are in place.
- Paying for, or actually providing transportation to and from the site.
- Providing escorts from and back to a parking lot, particularly if it is not well lighted, and/or in bad weather.
- Optimizing the environment in the subject waiting area. This can include having sufficient and appropriate magazines that are not 5 years out of date, providing toys for children who accompany subjects out of necessity, and ensuring that all trial staff treat the subjects courteously at all times.
- Reminding the subjects throughout the trial that their participation is extremely valuable in evaluating a new behavioral medicine intervention that, if successful, may provide considerable benefit to many patients. This can be done verbally and also by sending out regular newsletters.

Recurrence Risk Ratio

Jennifer Wessel
Public Health, School of Medicine, Indiana University, Indianapolis, IN, USA

Definition

Recurrence risk ratio is a measure of familial aggregation of disease. When a genetic factor(s) cannot be measured directly, information on disease status among family members of an affected individual can be used to derive a genetic risk ratio. It can provide a rationale for performing genetic studies to identify the susceptibility alleles and has been used extensively in the mapping of complex diseases. The recurrence risk ratio, λ_R, is the ratio of disease manifestation in other family members to the affected individual compared with the disease prevalence in the general population.

The sibling recurrence risk ratio is commonly used, where the numerator would represent the risk of manifesting the disease given that one's sibling is affected:

$$\lambda S = \frac{\Pr(\text{D in a sibling}/\text{affected case})}{K}$$

where K is the prevalence of the disease in the general population.

Regression Analysis

J. Rick Turner
Cardiovascular Safety, Quintiles, Durham, NC, USA

Synonyms

Linear regression; Multiple regression; Regression modeling

Definition

In regression analysis it is assumed that a change in variable x will lead to a change in variable y. It is often the case that the researcher wishes to predict the value of y for a given value of x (Campbell, Machin, & Walters, 2007).

Consider the case of linear regression and the plotting of a fitted regression line. In cases where linear regression is appropriate there is only one independent variable. Conventionally, the dependent variable is plotted on the vertical axis (y-axis) and the independent variable is plotted on the horizontal axis (x-axis). The equation

$y = \alpha + \beta x$ is defined as the linear regression equation. Alpha (α) is the intercept, and Beta (β) is the regression coefficient (Greek letters are used to clarify that these are population parameters). The regression equation is a model that is used to describe or model the relationship between y and x. When the graph is plotted, alpha is the value of the equation when $x = 0$, and beta is the slope of the line drawn (plotted). An increase of x of one unit will be associated with a change in y of beta units.

A set of data is used to create the plot, and then to draw the regression line. Imagine a set of data describing hemoglobin levels and age in a set of 20 women. The individual subjects' data can be represented as a set of 20 paired observations, and these points can be plotted on the graph. The best fitting linear regression line is then drawn. This line enables the determination of alpha and beta. Then, for any value of x, the appropriate value of y as given by this model can be calculated.

Since outcomes in behavioral medicine research are often influenced by more than one independent variable, the linear regression model can easily be extended to the technique of multiple regression. Multiple regression can address various questions of interest, including examination of the relationship between continuous variables while allowing for a third variable, and adjusting for differences in confounding factors between experimental groups (Machin et al., 2007). Examples are provided in the "References and Readings" section of this entry.

Definition

According to the World Report on Disability, rehabilitation is "a set of measures that assist individuals who experience, or are likely to experience, disability to achieve and maintain optimal functioning in interaction with their environments" (World Health Organization [WHO], 2011).

Description

Rehabilitation literally means "redressing" (*Latin habitat – dress*). While there are many definitions of this concept, the world health organization (WHO) has defined rehabilitation as "a process aimed at enabling disabled persons to reach and maintain their optimal physical, sensory, intellectual, psychological and social functional levels. Rehabilitation provides disabled people with the tools they need to attain independence and self-determination." Thus, the aim of rehabilitation has traditionally been seen as facilitating the normalization of human functioning after injury, disease, or due to congenital defects. It is usually said to comprise a number of coordinated measures of medical, psychological, social, educational and vocational nature. The Convention of the Rights of Persons with Disabilities, in its article 26 calls for " appropriate measures . . . to enable persons with disabilities to attain and maintain their maximum independence, full physical, mental, social and vocational ability, and full inclusion and participation in all aspects of life" (United Nations, 2006).

Background. Modern rehabilitation originated in British experiences of people with spinal cord injuries during the Second World War, where the neurosurgeon Dr. Ludwig Guttman at Stoke-Mandeville pioneered the development of reliable rehabilitation programs for those with paraplegia and tetraplegia. Apart from crisis intervention, these programs placed strong emphasis on conservative treatment of the spinal fractures and on preventive measures, such as prophylactic bed positioning to avoid pressure sores, to empty the urinary bladder at regular intervals, and to train adequate techniques for breathing and coughing in high injuries. Effective techniques for independently taking care of personal hygiene as well as transferring were also developed, e.g., between a bed, a chair, and a wheelchair, including the effective handling of transport vehicles. After post-acute rehabilitation, a lifelong follow-up ensued. The result was that the remaining number of life years increased from 1 to 2 years after the injury (even in young people), to today's normal life span for a paraplegic person, usually at an independent level, and a moderately reduced life span for the tetraplegic person, as a rule partly dependent.

In the mid-twentieth century, Physical and Rehabilitation Medicine (PRM) was established as an independent specialty in Western health care. It currently defines itself as "concerned with the promotion of physical and cognitive functioning, behavior, quality of life (activities and participation) and with the prevention, diagnosis, treatment and rehabilitation management of people with disabling medical conditions and co-morbidity across all ages" (Gutenbrunner, Ward, & Chamberlain, 2007).

Rehabilitation services have gradually been expanded to include people disabled by stroke, neurological disease, traumatic brain injury, chronic pain, cardiac and pulmonary insufficiency, cancer, mental disorders, and other disabling conditions. Generally speaking, rehabilitation can be considered a re-adaptive process, where the disabled person adapts his/her set of values to a different, more restricted life situation. Originally, rehabilitation was based on a biomedical model, where problems in functioning of an individual were seen as due to a deviation from "normal" organ function. In the 1970s, the social model of disability was launched by disabled people's organizations, where problems in functioning were instead viewed as society's exclusion (by its design and organization) of such persons. These models have more recently been replaced by the biopsychosocial model of disability, recognizing biological as well as social factors (ICF, WHO, 2001). This model is now acknowledged among both organizations of people with disabilities and among professional organizations.

The Interdisciplinary Team

It was recognized that many different health professions apart from physicians and nurses were necessary in the daily work to fulfill the multiple needs of people receiving rehabilitation services. This led to the development of *rehabilitation teams*, supervised by the rehabilitation physician. Today, these teams ideally contain psychologists (with cognitive-behavioral or

neuropsychological background), physiotherapists, occupational therapists, social workers, nurses and sometimes vocational specialists, speech therapists, and recreational therapists. The expected norm in such *interdisciplinary* teams is group decision making, both in assessment, rehabilitation planning, and treatment. In the team, the disabled person is considered the most important member, both in planning and in decision making.

Rehabilitation Strategies

Common rehabilitation strategies are used, where the various team professionals contribute important components. The team members share responsibility for the rehabilitation given. The team conference, led by anyone of the team members, is the important forum for lateral communication and for decision making. A comprehensive rehabilitation plan is formulated, where time frames, types of intervention, and responsible therapists are given, all communicated to and agreed with the disabled person. This concept allows a free exchange of ideas, may benefit from group synergies in problem solving, and facilitates the use of common strategies and coordination. However, it can be time consuming and the team members need training in the team process.

Disability Assessment, Rehabilitation and the ICF

An important part of the work is disability assessment, usually with a team approach, and greatly helped by the development of the International Classification of Functioning, Disability and Health (ICF) (WHO, 2001). Special rating instruments provide supplementary information in this task. The ICF is based on the biopsychosocial model and is a *components of health* classification. It has advanced the understanding and assessment of disability in that it classifies both problems in human functioning (health conditions) and the context in which people with different levels of functioning live and act. The problems are characterized in three interconnected areas:

Impairments are problems in body function or structure such as a significant deviation or loss.

Activity limitations are difficulties an individual may have in executing activities.

Participation restrictions are problems an individual may experience in involvement in life situations.

It is the *interaction* between a health condition and contextual factors, both environmental and personal that may be experienced as a *disability*. *Environmental factors* make up the physical, social, and attitudinal environment in which people live and conduct their lives, whereas p*ersonal factors* are the particular background of an individual's life and living, and may include gender, race, age, other health conditions, fitness, lifestyle, habits, upbringing, coping styles, social background, education, profession, past and current experience, overall behavior pattern and character style, individual psychological assets, and other characteristics.

Disability and Rehabilitation. Defining disability as an interaction means that disability is no longer the attribute of the person (World Report on Disability; WHO & World Bank, 2011).The prevalence of disability in different countries varies greatly, not only due to differences in definitions but also in context, including cultural values. The current definition of rehabilitation (supra), "a set of measures that assist individuals who experience, or are likely to experience, disability to achieve and maintain optimal functioning in interaction with their environments," emphasizes firstly that disability is something experienced, i.e., subjective, and secondly that changing an individual's environment, e.g., by housing adaptation or by educating the family to change attitudes, is also part of rehabilitation. Consequently, rehabilitation is cross-sectional and often carried out by health professionals in cooperation with specialists on education, social welfare and employment. The fact that disability is seen as a subjective experience may also explain the core role of cognitive therapy as an important component in many rehabilitation programs, where modifications of thought patterns along with influencing the links between the individual's thoughts, emotions, and behaviors is vital.

ICF and Rehabilitation. It is obvious with the evolvement of the ICF as a conceptual model and

Rehabilitation, Table 1 ICF-based conceptual description of rehabilitation strategy, modified version (ICF terms are marked in bold; from Meyer et al., 2011 with permission)

Rehabilitation is the health strategy which, based on WHO's **integrative model** of **functioning, disability and health** applies and integrates
Approaches to assess **functioning** in light of **health conditions**
Approaches to optimize a **person's capacity**
Approaches that build on and strengthen the resources of the **person**
Approaches that provide a **facilitating environment**
Approaches that develop a **person's performance**
Approaches that enhance a person's health-related quality of life in partnership between person and provider and in appreciation of the person's perception of his or her position in life over the course of a **health condition** and in all age groups; along and across the continuum of care, including hospitals, rehabilitation facilities and the community, and across sectors, including health, education, labor and social affairs; with the goal to enable persons with **health conditions** experiencing or likely to experience **disability** to achieve and maintain optimal **functioning**

the disability concept that rehabilitation should be defined in relation to these notions. An attempt to do so was elaborated in cooperation with several professional rehabilitation organizations by Stucki, Cieza, and Melvin (2007) and importantly, further developed by integrating the perspective of the disabled person to describe rehabilitation as a health strategy (Meyer et al., 2011) (Table 1).

Community-Based Rehabilitation

If there are few health professional resources such as in developing countries, *community-based rehabilitation* (CBR) performed locally by community groups, health assistants, families, and friends may be an alternative (Chatterjee, Patel, Chatterjee, & Weiss, 2003; Gona, Xiong, Muhit, Newton, & Hartley, 2010; Dalal, Zawada, Jolly, Moxham, & Taylor, 2010). CBR started in Europe as rehabilitation in the home or in the work place in the 1970s as a cheaper alternative to institution-based rehabilitation and has spread rapidly in low-income countries, often advocated and performed by human rights activists and non-health professionals working with development with the additional goal to transform and strengthen local communities in third world countries.

The Effectiveness of Rehabilitation

The evidence base for the effectiveness of modern rehabilitation is now considerable, e.g., for traumatic brain injury and stroke (Cicerone, et al., 2011), spinal cord injury (Martin Ginis, Jetha, Mack, & Hetz, 2010), chronic musculoskeletal pain (Norlund, Ropponen, & Alexanderson, 2009; Schonstein, Kenny, Keating, & Koes, 2003), cardiac insufficiency (Dalal et al., 2010), breast cancer (Duijts, Faber, Oldenburg, van Beurden, & Aaronson, 2011), and some mental diseases (Twamley, Jeste, & Lehman, 2003).

In summary, rehabilitation as the health strategy of functioning represents a unique health service delivery system that contributes markedly to restoring and maintaining health for people with disabilities in most developed countries, but has insufficient resources in others. It is often substituted by voluntary community-based services in developing countries. Since many of the functional disturbances treated emanates from the nervous system, the rapidly expanding new neurobiology, having demonstrated plasticity, regeneration, and adult-born neural stem cells in adult man, will provide fascinating new therapeutical possibilities for the rehabilitation of persons with disabilities in the years to come.

Relapse, Relapse Prevention

M. Kathleen B. Lustyk
School of Psychology, Family, and Community, Seattle Pacific University, University of Washington, Seattle, WA, USA

Synonyms

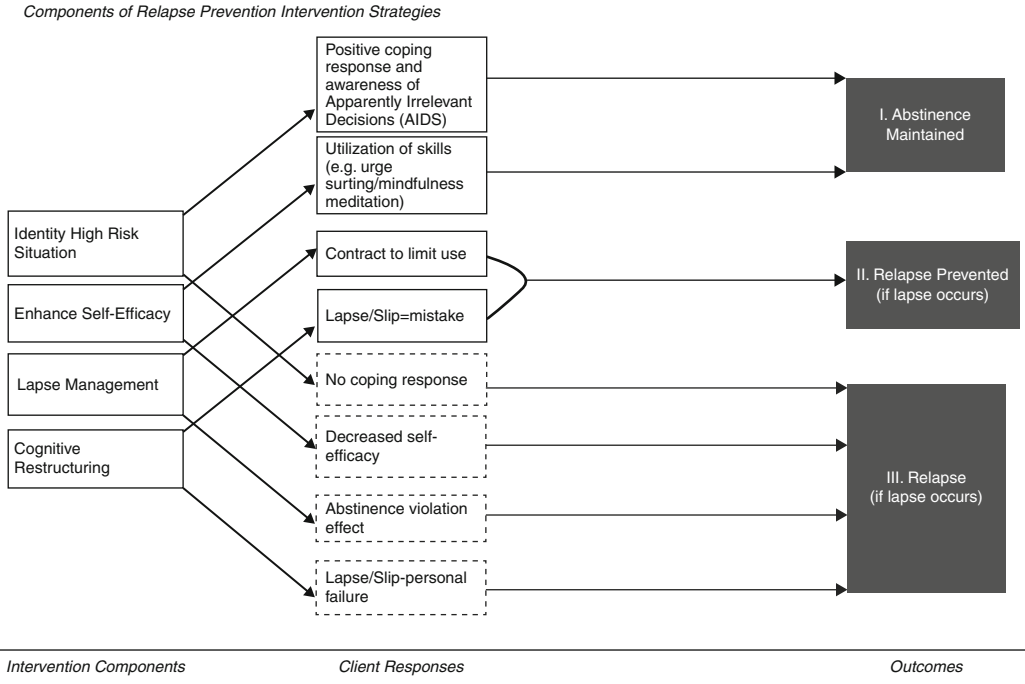
Remission and remission prevention

Definition

Relapse, as a clinical term, is the loss of ground gained toward health or the return of a bad habit following a period of cessation. Not unlike a lapse, which is a single occurrence of the habitual behavior, relapse is often associated with feelings of guilt and shame, and accompanied by self-degrading thoughts. Relapse prevention is an approach to therapy or education that teaches ways to indentify and anticipate triggers or precipitators of relapse. Relapse prevention also teaches behavioral coping strategies for managing high-risk situations in which triggers are present as well as coping strategies for urges, cravings, and negative emotional states that often precipitate relapse.

Description

In the model of addiction, relapse is the return to problematic substance use following a period of abstinence. Relapse is a major roadblock to treatment efficacy, as the majority of addicts who attempt abstinence will relapse. Given what we know about the neurobiology of addiction, the



Relapse, Relapse Prevention, Fig. 1 During the early stages of relapse prevention treatment, the client and clinician collaborate to (a) identify high-risk situations, (b) enhance client self-efficacy, (c) prepare for possible lapses or slips (d), and undergo cognitive restructuring (see *Intervention Components boxes* on *left*). Implementation of these four primary intervention components results in a reduced probability of relapse by increasing positive responses from the client. For example, abstinence is maintained through positively responding to high-risk situations and utilizing skills such as urge surfing to cope with cravings (see first two *Client Responses boxes*). In the case that a lapse or slip occurs, clients are encouraged to adhere to a contract to limit use and avoid full-scale relapse (see third and fourth *Client Responses boxes*). In addition to skills that promote increased self-efficacy, cognitive aspects of relapse are also addressed with the client. Lapses are reframed to equate with mistakes rather than personal failures. Subsequently, the guilt and shame of a "personal failure" are supplanted by a learning experience. Through lapse management and cognitive restructuring, the abstinence violation effect is avoided, and relapse is prevented. Poor client responses and potential outcomes are illustrated via the *dashed Client Responses boxes* and pathways from *Intervention Components* to *Outcomes* (Adapted from Marlatt & Donovan, 2005)

high occurrence of relapse is not surprising. With addiction, the brain's pleasure circuit is usurped such that what was once perceived as a pleasurable experience (e.g., drug use) becomes necessary to prevent a painful experience (i.e., withdrawal). With addiction, habit circuits involved in behavior, become entrained. For example, with habitual drug use, a trigger can produce a small amount of activity in the pleasure circuit and this pleasure "appetizer" can increase the desire or craving for the abused substance as well as the motivation to seek out and use the abused substance. Thus triggers can tap the habit circuitry, which may ultimately result in relapse.

Triggers or precipitators of relapse often arise in interpersonal situations where people or the environment can serve as powerful reminders of the pleasure and behaviors that once sustained the addiction. For example, an abstinent alcoholic may find the pub they used to frequent a powerful cue for drinking. Stress and other negative emotional states may also serve as triggers, especially if the habitual behavior served to reduce stress or improve negative affect.

An abstinence violation effect (AVE) may compound the impact of negative affect on relapse. In the presence of a trigger, relapse is not inevitable. The way in which a person approaches the trigger can have profound effects on the outcome. If, for example, people find themselves in high-risk situations whereby triggers result in a lapse, they may respond by removing themselves from that situation and chalk it up to a learning experience such that they will need to face similar situations differently in the future. Another response would be to suffer an AVE whereby the person berates himself or herself for failing to remain abstinent. They may convince themselves that they will never be successful in managing their addiction and give in to full relapse.

Relapse prevention therapy targets these high-risk situations by helping people recognize them while offering helpful coping skills and management strategies to avoid relapse. In terms of changing habits, willpower as the motivation to change needs to be linked with "skillpower" – as the saying goes, "where there's a will, there's a way." Coping skills provide the "way" to change addictive behavior in relapse prevention. The components of relapse prevention therapy along with client responses and potential outcomes are shown in Fig. 1. By identifying high-risk situations and engaging in behaviors aimed at enhancing self-efficacy, managing lapses, and restructuring thought processes, the substance abuser may prevent relapse. As shown in Fig. 1, client responses that are associated with relapse prevention and maintained abstinence include positive coping responses and skill utilization which may involve overt behaviors such as removing oneself from a high-risk situation to engaging in mental training aimed at reducing the negative consequences of craving. An innovative therapy known as mindfulness-based relapse prevention builds upon the basic tenets of relapse prevention therapy while incorporating mindfulness training as a way of tapping one's metacognitive abilities to further cope with urges and cravings. Specifically, mindfulness teaches one how to cultivate nonjudgmental, nonreactive present moment awareness. This type of awareness can allow for a kind of "space" between a person's sensations or feelings and their ultimate reaction to them. This space may ultimately break the habit cycle. Readers interested in learning more about mindfulness-based relapse prevention therapy are referred to the Bowen, Chawla, and Marlatt (2011) reference listed below.

Relative Risk

J. Rick Turner
Cardiovascular Safety, Quintiles, Durham, NC, USA

Definition

Relative risk is best defined in conjunction with absolute risk. For this example, we can define risk as the likelihood of an adverse consequence in two behavioral medicine interventions, Treatment A and Treatment B. Imagine that the risk is 1 in 10 for Treatment A and 2 in 10 for Treatment B. In this case, a relative risk statement can be made, saying that the probability of the event occurring following Treatment B is twice the probability of the event occurring following Treatment A. However, the same relative risk statement can be made for probabilities of 1 in 1,000,000 and 2 in 1,000,000. However, the absolute risks are vastly different: 1 and 2 in 10; and 1 and 2 in a million.

Description

Relative risk is often captured by a relative risk ratio. Consider a hypothetical trial in which the interventional treatment group receives a stress-reduction program intended to become an add-on treatment for patients with a serious disease that leads to heart attacks. This group of subjects is already receiving certain medication that is the "standard of care" for this condition. Subjects in the control group do not receive the stress-reduction intervention, but they too are receiving the standard of care medication. The trial is designed to investigate whether the standard of care medication plus the add-on intervention leads to fewer heart attacks than the standard of care medication alone.

The number of heart attacks is determined for each treatment group, and a relative risk ratio is calculated by considering the number of heart attacks in the treatment group as the numerator and the number of heart attacks in the control group as the denominator. If the number of events in each treatment group were to be precisely the same (the likelihood of which is vanishingly small), the value of the risk ratio will be unity, represented here as 1.00. If the number of events in the treatment group is less than that for the control treatment group, the value will be less than 1.00. Conversely, if the number of events in the treatment group is greater than that for the control treatment group, the value will be greater than 1.00.

Imagine that the value of the relative risk ratio is 0.80. This value conveys that, in this single trial, the addition of the stress-reduction program to the standard of care medication led to a 20% reduction in risk of heart attack. To estimate the true but unknown relative risk for the general patient population, confidence intervals (CIs) are placed around this value of 0.80, which in this context is called the relative risk point estimate. Let us calculate a two-sided 95% CI, which can be defined as a range of values that we are 95% confident that will cover the true but unknown population risk ratio. Imagine that the lower and upper limits of the 95% CI are 0.70 and 0.92, respectively. (The calculation of a ratio means that these limits do not fall symmetrically around the point estimate.) The confidence interval provides insight into the likely occurrence of heart attacks in the general population receiving the stress-reduction program. The following statement can now be made:

- The data obtained from this single trial are compatible with as little as an 8% decrease and as much as a 30% decrease in the risk of a heart attack in the general population, and our best estimate is a decrease of 20%.

Consider now a scenario in which the relative risk point estimate is 1.50, and the lower and upper bounds of a two-sided 95% CI placed around this point estimate are 1.35 and 1.68,

respectively. Such data would show that adding the stress-reduction intervention to the standard of care medication actually *increased* the risk of heart attack. The interpretation of such results is as follows:

- The data obtained from this single trial are compatible with as little as a 35% increase and as much as a 68% increase in risk of heart attack in the general population, and our best estimate is an increase in risk of 50%.

Relaxation: Techniques/Therapy

Hiroe Kikuchi
Department of Psychosomatic Research, National Institute of Mental Health, National Center of Neurology and Psychiatry, Tokyo, Japan

Definition

Relaxation techniques/therapy are techniques for reducing stress and inducing relaxation. Relaxation techniques/therapy increase parasympathetic nervous system activity, thereby decreasing the opposing sympathetic nervous system activity such as the fight or flight phenomenon and decreasing arousal. There are a variety of techniques for inducing relaxation. Probably, the most common are variants of Jacobson's progressive muscle relaxation training. Other methods include autogenic training, use of relaxation imagery, biofeedback, and practices derived from meditation and yoga techniques (Jorm, Morgan, & Hetrick, 2008).

With regard to psychiatric illnesses, relaxation techniques/therapy are often used as a competing stimulus during systematic desensitization and as part of a comprehensive intervention strategy for the reduction of anxiety. They are more effective at reducing self-rated depressive symptoms than no or minimal treatment, while data on clinician-rated depressive symptoms are less conclusive. However, they are not as effective as psychological treatment (Jorm et al., 2008). In addition, progressive muscle relaxation training has significant therapeutic efficiency in chronic insomnia in adult patients (Taylor & Roane, 2010).

With regard to physical symptoms or diseases, relaxation techniques/therapy have positive effects on pain reduction (Palermo, Eccleston, Lewandowski, Williams, & Morley, 2010). In addition, they have a mild to moderate effect on reducing hot flushes in women with a history of breast cancer (Rada et al., 2010). Although many studies tried to investigate the effect of relaxation techniques/therapy on primary hypertension, the evidence in favor of causal association between relaxation and blood pressure reduction is weak due to the poor quality of the studies (Dickinson et al., 2008). Therefore, further research is required to investigate the possibility of relaxation on physical symptoms or diseases.

Reliability and Validity

Yori Gidron
Faculty of Medicine and Pharmacy,
Free University of Brussels (VUB), Jette,
Belgium

Definition

These two concepts are the basis for assessment in most scientific work in medical and social sciences. Reliability refers to the degree of consistency in measurement and to the lack of error. There are several types of indices of reliability. Internal reliability (measured by Cronbach's alpha) is a measure of repeatability of a measure. In psychometrics, a questionnaire of, for example, 10 items, is said to be reliable if its internal reliability coefficient is at least 0.70. This reflects approximately the mean correlation between each score on each item, with all remaining item scores, repeated across all items. Methodologically, this reflects a measure of repeatability, a basic premise of science. Another type of reliability is inter-rater reliability, which refers to the degree of agreement between two or more observers, evaluating a patient's behavior, for example. Thus, in the original type A behavior interview, which currently places more emphasis on hostility, researchers provide a measure of inter-rater reliability, reflecting their agreement on an observed behavior. Finally, test-retest reliability refers to stability of a measure over time, for example, over 2 weeks, 1 month, or 4 years. For example, hostility has a strong test-retest reliability over 1 year of $r = 0.85$, $p < .0001$ (Barefoot, Dahlstrom, & Williams, 1983). This reliability can indicate stability of a measure and of the psychological phenomenon being assessed.

Validity of instruments refers to the degree to which instruments assess the construct they aim to measure. To test this, researchers have developed several types of validity indices. Face validity reflects the degree to which items of a scale "appear" to assess the construct they claim to, based on the meaning of items. This can be judged by participants or experts rating the relevance of each item to the construct being investigated. Construct validity refers to the degree to which scores on a scale correlate with scores on other measures of other constructs with which they should be theoretically correlated. For example, a scale of anxiety would be expected to correlate with life events in one's past, the latter being a possible trigger of current anxiety levels. Concurrent validity refers to correlations between scores of two different measures of the same construct, for example, between two anxiety scales. Criterion validity occurs when scores on an instrument predict or correlate with an accepted criterion, for example, anxiety being associated with observed behavioral responses to a stressor. Alternatively, criterion validity can be measured by showing that anxiety scores of a group of patients with clinically high anxiety levels (post-traumatic stress disorder) are higher than those of a healthy control group, also referred to as discriminant validity. Finally, predictive validity reflects the degree to which scores on an instrument predict in time the outcome of people in future. For example, an anxiety scale has predictive validity if it predicts health-care utilization over the next 12 months.

Another type of validity, a very important one, is internal validity. This reflects the confidence a researcher may have in his or her inferences from a study. This can be achieved by choosing

an adequate study design and methodological and statistical control over confounders. However, it also results from close consideration and measurement of all possible variables in a study, from sampling, to reliability and validity of tests, to control over confounders. To the extent that these are achieved, the attribution of observed results to an independent variable or predictor variable may be internally valid. Internal validity is perhaps the outmost important issue in scientific investigation, and a study can be scientifically valid if its internal validity is maintained.

Religion/Spirituality

Stephen Gallagher and Warren Tierney
Department of Psychology, Faculty of Education & Health Sciences, University of Limerick, Castletroy, Limerick, Ireland

Synonyms

Religiosity; Religiousness; Spiritual; Spirituality

Definition

Even though there is much dispute among researchers regarding accurate definitions of spirituality and religion, it is generally accepted that spirituality concerns the exploration for sacred, celestial, or the transcendent side of life, while religion can be defined as a perception, influence, and behavior which emerges from a consciousness of, or alleged contact with, metaphysical entities which are deemed to perform an essential role in human life. Moreover, in contemporary society, the formation of a dichotomy is being witnessed: with spirituality representing the personal, subjective, inner-directed, unsystematic, liberating expression, and religion signifying a formal, authoritarian, institutionalized inhibiting expression. Yet the concept of religion may further be separated into two categories: intrinsic and extrinsic religion. Intrinsic religion is an internalized faith which becomes an innate outlook on life. Extrinsic is focused more on individual practices driven by external motives, such as improved social standing or acceptance. Although religion and spirituality at times appear to be polarized concepts, for the moment, at least, it is impossible to completely segregate the two concepts as the search for the sacred occurs within various faith traditions, and most researchers agree that they are in fact overlapping constructs.

Description

Associations Between Spirituality, Religion, and Health

Historically, it was argued that the study of the natural and explicable phenomena belonged to science whereas the relatively unexplained belonged to religion. This was very pertinent to the field of medicine. Nowadays, however, there is a strong realization that health involves the interaction of mind, body, and more. In fact, health is far more than a physical matter. Much of this realization has been attributed to a substantial body of literature which has accumulated over the last number of decades connecting

spirituality, religion, and communal religious involvement to a variety of health outcomes (Hill & Pargament, 2003; Koenig, 2009; McCullough & Willoughby, 2009; Powell, Shahabi, & Thoresen, 2003). The links between spirituality and health are discussed elsewhere in this encyclopedia (see ▶ Spirituality). Even though the vast majority of studies report a beneficial effect of religion on health, this research has been the subject of considerable controversy. For example, religious involvement is strongly correlated with health-related factors, such as functional status, lifestyle, and social support, which may confound associations between religious observance, beliefs, and health (Sloan, Bagiella, & Powell, 1999). Further, longitudinal studies have found differential stress buffering effects: protective against multiple events but not discrete events (Schnittker, 2001). It could be that religious coping is used as a last resort when individuals feel overwhelmed when dealing with multiple stressful episodes, especially when their personal coping resources fail or prove to be inadequate. However, what adds to this controversy is that the precise mechanisms behind the links between religion and health are not yet clear and are the subject of much research(Powell, Shahabi, & Thoresen, 2003; Seeman, Dubin, & Seeman, 2003).

A number of possible psychological, social, and physiological mediators have been proposed to account for this connection. For example, it could be that prayer may help people deal with unpleasant situations or that faith promotes a positive disposition which facilitates coping. It is also becoming increasingly evident that religious/spiritual coping strategies can be divided into positive (e.g., seeking support from clergy, forgiveness, reappraisal) and negative (e.g., spiritual discontent, pleading for direct intercession, punishing God reappraisal) forms; positive forms typically relate to more positive outcomes, whereas negative religious coping strategies are generally related to more negative outcomes (Hill & Pargament, 2003). Moreover, religious affiliations are associated with the practice of healthy lifestyles and the social aspect of attending religious rituals, i.e., church, promotes social integration, all of which are linked to better health (Sloan & Ramakrishnan, 2006). Further, religious attendance has been found to be inversely related to inflammatory cytokines high interleukin −6 levels (>5 pg/ml), providing supportive evidence of a direct link between religious observance and health (Koenig, et al., 1997); this observed association was somewhat attenuated after controlling for age, sex, race, education, chronic illnesses, and physical functioning, implying that other factors may be driving the observed effects. In addition, the proponents of these links between religion and health would argue that the strongest evidence comes from intervention studies, demonstrating the positive effect of intercessory prayer on cardiovascular health (Townsend, Kladder, Ayele, & Mulligan, 2002). However, in a very recent Cochrane Review, it was found that this particular evidence was rather weak and that trials of this type of intervention should not be undertake, stating that they "would prefer to see any resources available for such a trial used to investigate other questions in health care (Roberts, Ahmed, Hall & Davidson, 2009)." Another issue that needs to be addressed is the differential effects of intrinsic and extrinsic religion on psychological distress. Studies have indicated that intrinsic religious individuals who attend religious services demonstrate reduced anxiety whereas extrinsically motivated individuals who attend services tend to portray anxiety (Koenig, 2009). How these different religious concepts relate to physical health outcomes is still unclear, but the link between psychological distress and ill-health is well established (Roberts, Ahmed, Hall & Davidson, 2009; Rugulies, 2002).

How to Measure Spirituality and Religion

Measuring spirituality and religion has proven to be a very difficult task due to researcher's inability to completely differentiate between religion and spirituality. This inadequacy has unlocked Pandora's Box, due to the paradoxical question: is one measuring/or has one measured spirituality or religion? Or are these religious measurements tapping into other constructs such as social

support? Nonetheless, there are a number of measures available for measuring spirituality (see entry on ▶ Spirituality) and religion: the Religious Involvement Scale (Piedmont, Ciarrochi, Dy-Liacco, & Williams, 2009) is a useful scale to test how involved individuals are in religious activities; the Multi-Religion Identity Measure (Abu-Rayya, Abu-Rayya, & Khalil, 2009) is a scale which can be used accurately in order to distinguish between members of different religions; and the religious coping scale (RCOPE) (Pargament, Koenig, & Perez, 2000) can be used to assess religious coping. If one wants to measure both spirituality and religion, the Assessment of Spirituality and Religious Sentiments ASPIRES (Piedmont, 2004) scale can be used, which has proved to have reliability and discriminant validity. Finally, and more recently, an Implicit Christian Humanist Implicit Association Test (Ventis, Ball, & Viggiano, 2010) has been developed to measure both religion and spirituality which may have stronger behavioral correlates.

Religious Coping

Jennifer Wortmann
Department of Psychology, University of Connecticut, Storrs, CT, USA

Synonyms

Negative religious coping; Religious struggle; Spiritual coping; Spiritual struggle

Definition

Religious coping is religiously framed cognitive, emotional, or behavioral responses to stress, encompassing multiple methods and purposes as well as positive and negative dimensions.

Description

Religion and spirituality translate into coping responses to stress insofar as they serve as available and compelling orienting systems and especially when stressors test "the limits of personal powers" (Pargament, 1997, p. 310). Religion can provide a framework for understanding emotional and physical suffering and can facilitate perseverance or acceptance in the face of stressors. Religious coping encompasses religiously framed cognitive, emotional, or behavioral responses to stress. It may serve many purposes, including achieving meaning in life, closeness to God, hope, peace, connection to others, self-development, and personal restraint (Pargament, 1997). Who uses religious coping depends on individual (e.g., degree of personal religious commitment), situational (e.g., stressfulness of the event), and cultural factors (Harrison, Koenig, Hays, Eme-Akwari, & Pargament, 2001). The outcomes of religious coping depend on the appropriateness of the coping method to the stressor (Pargament, 1997).

Early measures of religious coping were limited in breadth and depth. For instance, Ways of Coping (Lazarus & Folkman, 1984) measures one religious practice: prayer. The COPE (Carver, Scheier, & Weintraub, 1989) assesses religious coping with four items: "I seek God's help," "I put my trust in God," "I try to find comfort in my religion," and "I pray." The RCOPE religious coping scale by Pargament and colleagues expands measurement of religious coping to include methods to find meaning, to gain control, to gain comfort and closeness to God, and to achieve a life transformation (Pargament, Koenig, & Perez, 2000). Measurement of multiple methods of religious coping permits researchers and clinicians to assess specific beliefs, experiences, or practices that differentially relate to health.

Religious coping may be active or passive in nature. In fact, a collaborative religious coping style in which a person considers him or herself partners with God in resolving a problem was found to be more common and more effective than either a self-directing or passive style (Pargament, 1997). Religious coping methods that have been shown to have a generally positive relationship with psychological outcomes (Ano & Vasconcelles, 2005), hence *positive religious coping*, include the collaborative style, benevolent reappraisal of the stressor, and seeking spiritual support from God, clergy, or members of one's religious group. Religious coping is increasingly being researched in the contexts of multiple illnesses, and suspected mechanisms through which religious coping can influence health include relaxation, sense of control, and the promotion of healthy behaviors. Although research has failed to show consistent

relations between positive religious coping methods and physical health, future research may incorporate sophisticated design and proposed psychosocial (e.g., meaning, social support, meditation) and physiological mediation pathways (Park, 2007; Seybold, 2007).

Research has demonstrated more consistent relations between negative religious coping methods and poorer mental and physical health (Ano & Vasconcelles, 2005; Powell, Shahabi, & Thoresen, 2003). Negative religious coping, also known as spiritual struggle, encompasses interpersonal, intrapersonal, and divine categories, including conflict with religious others, questioning, guilt, and perceived distance from or negative views of a higher power (Pargament, 2007). Religious coping may also be a negative force in health if it interferes with receipt of necessary treatments (e.g., passive religious deferral). Although generally less common than positive coping in response to stress, negative religious coping is common in people facing serious or life-threatening illness. As such, researchers have recommended incorporating assessment of positive and negative religious coping in clinical practice to identify those at risk for the negative impacts of spiritual struggles and have begun to develop recommendations regarding and interventions targeted at spiritual struggles (Pargament, 2007).

Religious Practice

▶ Religious Ritual

Religious Ritual

Login S. George and Crystal L. Park
Department of Psychology, University of Connecticut, Storrs, CT, USA

Synonyms

Church attendance; Prayer; Religious ceremony; Religious practice; Religious service; Service attendance

Definition

A religious ritual is any repetitive and patterned behavior that is prescribed by or tied to a religious institution, belief, or custom, often with the intention of communicating with a deity or supernatural power. Rituals may be performed individually or collectively during predetermined times (e.g., praying at specific times of day), elicited by events (e.g., mourning rituals performed after a death), or performed sporadically (e.g., praying at various times throughout the day).

Description

Rituals are an important aspect of religion because they allow believers to express and reaffirm their belief systems. One of the primary purposes of rituals is communication. Rituals communicate or are intended to communicate to self, others, or deities. They convey information regarding the commitments, beliefs, and values of the individuals performing the ritual and link them to the larger religious tradition. They reaffirm the religious frameworks individuals use to conceptualize and understand life and, thus, endow a sense of meaning. Religious rituals also serve other psychosocial functions such as emotional control, social support, and community cohesion. By structuring and prescribing behavior, rituals may ease anxiety and uncertainty and promote stability and understanding in social interactions. It is thought that religious rituals may affect physical and mental health through the psychosocial functions that they serve.

In the context of health, prayer is one of the most common religious rituals examined. Studies of relationships between prayer and health have produced contradictory findings. Some have demonstrated favorable links between the two. For example, a longitudinal study of healthy elderly adults found that prayer was related to reduced mortality rates even after many potential confounds such as demographics, health practices, and social support were controlled for (Helm, Hays, Flint, Koenig & Blazer, 2000). In contrast, cross-sectional studies have found unfavorable relationships between prayer and health such that higher levels of prayer are related to more disability and pain. A possible explanation for this negative relationship is that those who are ill and suffering may turn to prayer as a way to deal with their distress. Prayer may become particularly relied upon when individuals are facing stress or illness in that prayer can be an important coping resource. The contradictory findings regarding prayer and health may also be due to the failure of many studies to examine factors such as frequency and content of prayer. Prayer can be categorized into different types based on its content, and evidence suggests that different types of prayer may have differing relationships with health and well-being. As of now, it seems that the relationship between prayer and health is a complex one and one that is yet to be fully explored or understood.

Numerous studies have also looked at relationships between frequency of service attendance and health. Ample evidence points to a strong positive relationship between the two. For example, a review of the literature concluded that there was a 25% reduction in mortality rates among those who attended religious services even after confounds and risk factors (such as demographics, healthy lifestyle, social support, and depression) were taken into account (Powell, Shahabi, & Thoresen, 2003). A meta-analysis that included data from over 125,000 participants found a similar 25% reduction in mortality rates even after potential confounding variables were taken into account (McCullough, Hoyt, Larson, Koenig, & Thoresen, 2000). Many pathways through which service attendance affects health have been proposed; service attendance may affect health by generating strong positive emotions, encouraging healthy behaviors, and providing access to resources and social support.

Other forms of religious rituals exist besides religious service and prayer, and such forms of rituals may be related to health as well. For example, religious mourning rituals have been postulated to play a role in constructively dealing with grief. Mourning rituals may provide a sense

of mastery and control during a highly stressful and uncertain time by prescribing to individuals what ought to be done. Other collective rituals such as participation in religious festivals or ceremonies may foster social bonding and yield a sense of community and social support. Although it can be reasoned that such forms of rituals may affect health as it is related to many salutary psychosocial functions such as social support and a sense of control, currently there is very little empirical literature linking them to health.

In conclusion, although scholars have theorized that religious rituals serve a wide array of functions such as social cohesion, sense of meaning, emotional control, and personal control, all of which have been shown to be related to better health, very little research has examined the full linkages. With the exception of participation in formal worship services as strongly linked to better health, few solid conclusions regarding links between religious rituals and physical health can be drawn at this point. These questions await further empirical attention.

Religious Social Support

Chad Barrett
Department of Psychology, University of Colorado, Denver, CO, USA

Synonyms

Church-based support

Definition

Religious social support can be described as the social support individuals receive as a result of their religious beliefs and participation in religious activities. Social support refers to the size of one's social network and the perception of belonging to one or more groups. It also includes perceptions of received, provided, and expected emotional and tangible support from one's social network (Cohen, Underwood, & Gottlieb, 2000). Thus, religious social support refers to the emotional and tangible support that one receives, provides, and expects from one's religious

community. It may also refer to the size of one's social network as a result of participation in religious and spiritual activities (Debnam, Holt, Clark, Roth, & Southward, 2011; Krause, Ellison, Shaw, Marcum, & Boardman, 2001). Religious support is a multidimensional construct that has sometimes been operationalized differently across various studies. Most definitions of religious social support include the amount of religious involvement (usually indicated by frequency of attending religious services and related activities). Religious involvement is intended as a proxy measure of the social interaction and supportive relationships that one may form with fellow members of a religious community. Religious social support can be further specified according to type (emotional or spiritual) and source (clergy or laity members) of the support (Debnam et al., 2011). Occasionally, religious support includes a person's perception of emotional and tangible support received from supernatural entities as a result of religious or spiritual beliefs and activities. A four-dimensional model of religious social support has been described in the Brief Multidimensional Measure of Religiousness/Spirituality for Use in Health Research (NIA working group/Fetzer Institute, 1999). The four dimensions are emotional support provided, emotional support received, negative interaction, and anticipated support.

Description

There is a broad literature linking religiosity and spirituality to mental and physical health (George, Ellison, & Larson, 2002; Koenig, 2009; Koenig, McCullough, & Larson, 2001; Oman & Thoresen, 2005). In general, though not always, the large number of studies examining the relationship between religiosity and spirituality and mental and physical health suggest that religious and spiritual activities have a salutary influence on a variety of variables related to mental and physical health. Numerous studies involving participants in a variety of settings, from different ethnic backgrounds, in different age groups, and in different countries, some of which used longitudinal designs or random controlled trials, have found evidence that religious and spiritual activities are mostly related to better coping with stress and less depression, suicide, anxiety, and substance abuse (Koenig, 2009). The positive influence of religion and spirituality goes beyond the mere absence of psychopathology to include greater general happiness, satisfaction with life, and sense of meaning and purpose (Miller & Kelley, 2005). They are also related to better physical health, better health behaviors, and longer survival (George, Ellison, & Larson, 2002; Oman & Thoresen, 2005; McCullough, Hoyt, Larson, Koenig, & Thoresen, 2000; Powell, Shahabi & Thorensen, 2003). People who attend religious services and activities once a week or more tend to have fewer illnesses, recover more quickly from illness, and live longer than those who attend less frequently (George et al., 2002). There is also evidence that they have lower blood pressure and reduced risk of hypertension. Many religious communities encourage health-promoting behaviors. Individuals who attend religious activities tend to engage in more exercise and less smoking and heavy drinking, and they tend to wear their seat belts more often. Further, they are more likely to seek preventative medical care and comply with medical treatment. At least one longitudinal study of over 2,500 community participants spanning 30 years found that people who attended religious services more often were also more likely to adopt and maintain healthy behaviors, such as exercising and avoiding smoking and abusing alcohol (Oman & Thoresen, 2005). At least two reviews found evidence from several large-scale studies that religious involvement is related to lower mortality rates (McCullough et al., 2000; Powell et al., 2003). In both studies, on average, increased religious activity reduced mortality rates by about 25%.

It is likely that the influence religion and spirituality have on mental and physical health is partially mediated by religious social support. Social support in general, (i.e., social support that is not specific to religiously based social support) has often been related to better physical and mental health (Taylor, 2011). Involvement in

religious and spiritual communities seems to provide individuals with opportunities to develop greater social support. Individuals who participate in religious and spiritual communities may have additional, and/or unique, opportunities to benefit from social support. People who regularly attend religious and spiritual activities, compared to those who attend less frequently, typically have larger social networks and engage in more activities in which they provide or receive social support (Ellison, Hummer, Burdette, & Benjamins, 2010; Oman & Thoresen, 2005). Increased participation in religious community activities is associated with larger and more stable social networks and with more perceived social, and emotional, support (George et al., 2002; Strawbridge, Shema, Cohen, & Kaplan, 2001). Further, the quality of religious social support may be better. Members of religious and spiritual communities tend to share similar beliefs, worldviews, values, backgrounds, and experiences. They may also have more opportunities to share intimate moments, significant life experiences, and develop long-term friendships and bonds. They may feel more closely connected as a result of participating in common worship, prayer, services, or social groups and activities. In addition, religious and spiritual teachings that promote prosocial values can encourage and facilitate providing and receiving emotional and tangible support, especially during times of stress (Ellison & George, 1994).

Religious social support may help individuals cope with stress by encouraging healthy coping strategies and may help them construct a sense of meaning and purpose. Religious social support can also provide individuals with a sense of shared burden and comfort. Another way religious social support may influence physically and mentally is by encouraging healthy behaviors. Most religious and spiritual communities encourage their members to abstain from harmful behaviors such as drug and alcohol abuse, smoking, and unsafe sex. Dimensions of religious social support have been related to better eating and exercising habits (Debnam et al., 2011; Oman & Thoresen, 2005; McCullough et al., 2000; Powell et al., 2003). However, the evidence for the mediating role of religious social support is mixed with some studies finding evidence for the mediating role of religious social support and some not finding this (George et al., 2002).

It is also important to note that increased involvement in religious and spiritual communities can sometimes have negative consequences. Religious and spiritual participation can sometimes be a source of stress rather than comfort. Interactions may be more negative than positive. For example, in religious communities where certain things such as divorce or homosexuality are strongly condemned, individuals and families experiencing these issues may encounter a variety of negative interactions with community members. In some cases, religious communities may reinforce unhealthy beliefs and behaviors. They can promote perfectionism, negative self-views, and exacerbate feelings of guilt, worry, and anxiety. They can perpetuate mental illness by interpreting pathological symptoms in religious and moralistic terms. Further, some religious communities may discourage members from seeking and adhering to medical treatment for physical and mental health issues (Exline & Rose, 2005; Miller & Kelley, 2005). Quite often, the negative reality of religious and spiritual activity exists alongside the positive benefits. Thus, religious social support includes both positive and negative elements.

Elements of religious and spiritual activities likely to influence health and mental health include public participation (e.g., attendance at religious services and related activities), religious affiliation (i.e., belonging to religious groups or denominations), private religious practices (e.g., prayer, meditation, reading religious literature), and religious coping (relying on religion to help cope with stressful situations) (George, Ellison, & Larson, 2002).

Religiousness/Religiosity

Stephen Gallagher and Warren Tierney
Department of Psychology, Faculty of Education & Health Sciences, University of Limerick, Castletroy, Limerick, Ireland

Synonyms

Religion; Spirituality

Definition

The terms religiousness/religiosity are used interchangeably but often defined as an individual's conviction, devotion, and veneration towards a divinity. However, in its most comprehensive use, religiosity can encapsulate all dimensions of religion, yet the concept can also be used in a narrow sense to denote an extreme view and over dedication to religious rituals and traditions. This rigid form of religiosity in essence is often viewed as a negative side of the religious experience, it can be typified by an over involvement in religious practices which are deemed to be beyond the social norms of one's faith.

Description

Religiousness/Religiosity and Health

As the use of the concept religiosity has a certain ambiguity in its definition, the lack of clarification can lead to much confusion among researchers. Further, adding to this complexity is the fact that research has found both negative and positive relationships between religiosity and a variety of health outcomes (Miller & Kelley, 2005). Thus, future researchers may need to investigate not only linear patterns, but to test for nonlinear associations between these particular constructs and need to appreciate that religiosity can often be used to represent an extreme view and over dedication to religious rituals and traditions that are positioned outside social norms. Indeed, such obsessive behaviors are frequently viewed as pathological, and perhaps it is these excessive practices that underlie the negative ill-health associations that have been observed. Moreover, some researchers have proposed a bidirectional and interaction model to explain these complex relationships (Erwin-Cox, Hoffman, Grimes, & Fehl, 2007).

Measuring Religiosity/Religiousness

When one is measuring religiosity and religiousness, they are in fact measuring how religious an individual is. The Faith Maturity Scale (Benson, Donahue, & Erikson, 1993) is an 11-item self-report questionnaire which is segregated into two subscales: horizontal and vertical faith maturity. The vertical scale assesses closeness to God, while the horizontal subscale reviews the existent to which faith has motivated an individual to assist another person. Also, religiousness can be measured using a number of scales such as the Religiosity Index, (Piedmont, 2001) and the Religion Schema Scale (Streib, Hood, & Klein, 2010). However, as researchers neglect to consider that religiousness may also denote religiosity, one must analyze specific questions from the scales in order to assess the religiosity of an individual. Similarly, is not yet clear whether these scales allow for assessment of the more extreme aspects of religiosity which have been associated with ill health.

REM Sleep

Salvatore Insana
Western Psychiatric Institute and Clinic, Pittsburgh, PA, USA

Synonyms

Active sleep; Paradoxal sleep; Phasic REM; Tonic REM

Definition

Rapid eye movement (REM) sleep is a behavioral classification of sleep that is characteristic to rapid jerky eye movements and is associated with increased incidence of dream activity. REM is present in humans from birth throughout the life span and is expressed by all terrestrial mammals as well as birds.

Description

Rapid eye movement (REM) sleep is widely known by its shortened acronym "REM" sleep – when pronounced, REM rhymes with "gem." Sleep can be measured with polysomnography (PSG). Polysomnographically measured sleep can be classified into distinct categories that include N1, N2, N3, and REM – the focus of this entry. REM can be classified as defined by the 2007 American Academy of Sleep Medicine sleep scoring manual (Iber, Ancoli-Israel, Chesson, & Quan, 2007) and is similarly classified according to the Rechtschaffen and Kales "classic criteria" (Rechtschaffen & Kales, 1968). REM sleep was given its name due to the rapid and jerky eye movements that occur during this behavioral state. Another common term used to describe REM sleep is "paradoxal sleep" because brain activity during REM sleep has a striking resemblance to that observed during wakefulness, hence the paradox. The term "paradoxal sleep" was coined in the late 1950s by Michel Jouvet, M.D.

REM sleep was discovered and first reported in the early 1950s by Eugene Aserinsky, Ph.D. and his mentor Nithaniel Kleitman, Ph.D. The discovery was made through Aserinsky's doctoral dissertation study, serendipitously, when Aserinsky observed rapid eye movements among his sleeping participants (Aserinsky & Kleitman, 1953). During the late 1950s and early 1960s, William C. Dement, M.D., Ph.D. began researching REM sleep in greater detail (e.g., Dement & Kleitman, 1957), which initiated his to-be legendary career in sleep science, and provided a platform for sleep science to advance. During the 1950s and 1960s era, the groundbreaking discovery of REM sleep lead to the acknowledgment of brain activity during sleep, which countered the conventional wisdom that the brain was inactive during this behavioral state. In sum, the discovery of REM sleep propagated the investigations that built the foundation for the development of modern sleep medicine as it stands today (Dement, 2005).

A characteristic component of REM sleep is an unstructured pattern of low amplitude (4–7 Hz) mixed frequency neurological activity, as measured by electroencephalography. The neurological activity during REM sleep displays sawtooth wave forms or trains of sharp triangular waves that occur at 2–6 Hz. Behavioral and physiological changes occur during REM sleep, including rapid eye movements, poikilothermia, atonia (i.e., low or absent muscle tone), fast bursts of transient muscle activity, shallow irregular breathing, increased heart rate and blood pressure, increased genital blood flow, and increased neurological oxygen and glucose metabolism. Poikilothermia is the loss of thermoregulatory control, resulting in the body temperature gravitating toward the ambient environmental temperature; sweating and shivering also cease. Atonia is when the skeletal musculature essentially enters a state of paralysis, which likely functions to avoid acting out the dreams that typically occur during REM sleep. Transient increases in heart rate, blood pressure, and irregular breathing typically occur during dream content and co-occur with rapid eye movements. Increased genital blood flow leads to erections that are unrelated

to dream content for men and increased vaginal blood flow for women. Dreams typically occur during REM sleep (Dement & Kleitman, 1957); brain activity associated with dreams increases, which propagates increased neurological oxygen and glucose metabolism. Due to the multiple physiological and behavioral expressions during REM sleep, REM sleep can be further subdescribed as phasic or tonic. Phasic is the occurrence of rapid eye movements and muscle twitches, whereas tonic is the more constant state of REM between the phasic events.

Typically, sleep transitions from wake into N1, followed by N2, followed by N3, and then followed by REM – this progressive series is termed a "sleep cycle." Sleep cycles typically occur throughout sleep at approximately 50-min intervals among infants and approximately 90–110-min intervals among adults. Several sleep cycles occur throughout the night, and the time spent in the different sleep stages changes within each sleep cycle. During the first sleep cycle, REM may only last several minutes; REM episodes within each subsequent sleep cycle become progressively longer throughout the night. Thus, typically, the first portion of the night primarily consists of non-REM sleep (i.e., N1, N2, and N3), and the second portion of the night primarily consists of REM sleep.

Although the true function of sleep, and particularly REM sleep, is unknown, to date several functions of REM sleep have been delineated (e.g., Rector, Schei, Van Dongen, Belenky, & Krueger, 2009; Siegel, 2009). Dreams typically occur during REM sleep; although, the purpose of dreaming remains unknown. REM sleep may stimulate the brain during sleep through dreaming. REM sleep appears central to memory formation, where REM sleep and non-REM sleep (N1, N2, N3) complement each other to process and consolidate various memory forms (Diekelmann & Born, 2010; Stickgold & Walker, 2007). REM sleep also appears to be central to emotion regulation (Walker & van der Helm, 2009). Despite the unknown purpose of REM sleep, it appears necessary to obtain. For example, total sleep deprivation, as well as experimentally induced REM sleep deprivation, leads to a compensatory increase in time spent in REM sleep during the following sleep episode, a phenomenon known as REM rebound. Furthermore, REM sleep has been observed among all terrestrial mammals and birds, but not reptiles.

Entering directly into REM sleep from wake, instead of into N1 first, is associated with a sleep disorder called narcolepsy. Several parasomnias are particularly linked to REM sleep, including nightmares, isolated sleep paralysis, and REM sleep behavior disorder. REM sleep disturbances are implicated in and are associated with numerous psychiatric disorders, including depression, schizophrenia, bipolar disorder, and posttraumatic stress disorder.

Human Development: From birth to approximately 6 months post-term, infant sleep patterns are classified into either REM or NREM; during the birth–6-month postterm period, these classifications are also referred to as active sleep and quiet sleep, respectively. Following 6 months post-term, infant NREM sleep patterns become more complex and can be categorized into N1, N2, and N3 sleep stages – in addition to REM sleep. During the first few postterm months, infants spend approximately 50% of time in both REM and NREM sleep. During childhood, the percentage of time spent in REM sleep drops off, levels out to approximately 25% of the entire sleep time, and then gradually decreases across the life span. Across the life span, generally, the percentages of N1 and N2 sleep increase, whereas N3 and REM sleep decrease (Ohayon, Carskadon, Guilleminault, & Vitiello, 2004).

Renin

George J. Trachte
Academic Health Center, School of Medicine-Duluth Campus, University of Minnesota, Duluth, MN, USA

Definition

General Background

Renin is an aspartyl protease secreted primarily from the kidney that raises blood pressure, retains sodium, and produces various changes in gene transcription that are usually associated with pathological damage, particularly to the kidney and heart. Specifically renin cleaves a 10 amino acid peptide (angiotensin I) from a large protein (angiotensinogen) secreted by the liver. The angiotensin I is subsequently modified by removal of two amino acids by angiotensin converting enzyme to form an eight amino acid product, angiotensin II. Angiotensin II is the primary mediator of renin effects. Pathological conditions involving this system include the following: congestive heart failure, myocardial infarction, hypertension, and diabetes mellitus (renal damage). Inhibitors of the system are beneficial in treating these pathologies and include direct renin inhibitors (aliskerin), converting enzyme inhibitors (lisinopril and other "prils"), and angiotensin receptor antagonists (candesartan and other "artans").

Physiological Relevance

The renin-angiotensin system is thought to be important in adaptations to low-salt diets and normal development of the kidneys in utero. Inhibition of the system with converting enzyme inhibitors has resulted in greater fetal mortality and children born with malformed kidneys.

Control of Renin Release

Renin is secreted in response to the following: a drop in pressure in the renal artery, reduced dietary sodium intake, sympathetic nerve activation leading to the stimulation of ß1 receptors, and prostaglandins. Renin release is inhibited by: elevated renal artery pressure, increased sodium consumption, ß receptor antagonists, and atrial natriuretic peptide. The drop in renal artery pressure is the specific stimulus for renin release leading to hypertension in renal artery stenosis. Dietary sodium status is primarily responsible for the daily fluctuations in renin levels. Prostaglandins are the specific stimulus leading to excessive activity of this system resulting in potassium depletion in Bartter's syndrome.

Renin Tissue Localization and Molecular Biology

In addition to the kidney, renin (REN) mRNA is found in the following: adrenal gland, testis, ovary, liver, brain, hypothalamus, salivary gland, adipose tissue and, in lower levels, lung, spleen, thymus, and prostate. The REN genes code for a large 406 amino acid protein (pre-prorenin). The removal of 23 amino acids from the carboxyl terminal results in the formation of prorenin. The final step in the process involves removal of 43 amino acids from the amino terminal to form the 340 amino acid active protein known as renin. Both renin and prorenin are secreted into the circulation. Prorenin can be activated by binding to its receptor even in the absence of conversion to renin. The enzyme converting prorenin to renin has not been identified but is believed to be specific to the kidney because nephrectomized patients or animals contain no renin in their circulation but prorenin is present. Inhibitors of the prorenin receptor have been shown to be beneficial in diabetic nephropathy.

Behavioral Actions of Renin

Renin and other components of the renin-angiotensin system are present in the brain and are believed to impact memory negatively and to exacerbate neurogenic diseases such as Alzheimer's disease and other neurodegenerative disorders.

Reproductive Health

Ulrike Ehlert[1] and Simona Fischbacher[2]
[1]Department of Psychology, University of Zurich, Binzmuehlestrasse, Zurich, Switzerland
[2]Klinische Psychologie und Psychotherapie, Universität Zürich, Zürich, Switzerland

Definition

As a part of general health and development, reproductive health, which refers to the reproductive processes and functions, is essential in adolescence and adulthood and also affects one's well-being beyond the reproductive years. Healthy development of the reproductive system in the fetus and during early childhood is required to achieve reproductive capacity. Reproductive maturity is usually reached after puberty, a phase characterized by biologically based growth and change processes modulated by psychosocial factors. In adulthood, when reproductive capacity is completely developed, a healthy menstrual

cycle and male reproductive functioning are biological requirements for reproduction. Furthermore, individual reproductive goals need to be developed and pursued. For women, the fertile phase ends rapidly with menopause, whereas men usually experience a gradual decrease in fertility with increase in age.

Description

A Biopsychological Approach to Reproductive Health

From a biopsychological perspective, the association between psycho-endocrinological or psycho-immunological factors and reproductive processes is of interest. Deviations from the healthy sex hormone secretion are associated with the development and maintenance of various chronic diseases and modulate neurotransmitter systems associated with psychiatric disorders. On the other hand, infertility and diseases of the reproductive system affect one's psychological well-being and may lead to impairments in social life, work productivity, interpersonal relationships, and sexuality (Stanton, Lobel, Sears, & Stein De Luca, 2002).

Stress is one of the most potent factors affecting reproductive health and is related to several reproductive disorders, such as cycle length disorders, infertility, premenstrual syndrome, or erectile dysfunction. The bidirectional interaction between the hypothalamic-pituitary-adrenal (HPA) axis, as the most prominent stress-associated hormone system, and the hypothalamic-pituitary-gonadal (HPG) axis is well documented. The HPA axis exerts an inhibitory effect on the HPG axis, due to the inhibiting action of corticotropin-releasing hormone (CRH), arginine-vasopressin (AVP), and CRH-induced beta-endorphin release. In addition, cortisol suppresses secretion of the gonadotropin-releasing hormone (GnRH) and the luteinizing hormone (LH), and inhibits ovarian sex steroids (estrogen and progesterone) and testosterone. Sex steroids, on the other hand, have a modulating effect on the HPA axis (Creatsas, Mastorakos, & Chrousos, 2006).

Women's Reproductive Health

Women's reproductive health includes not only reproductive processes, a healthy reproductive system, and reproductive functioning, but also psychological well-being and a safe and satisfying sexual life. The biological basis of women's reproductive health is a healthy and ovulatory menstrual cycle. This entry will give a brief overview on the endocrinological processes of a healthy menstrual cycle.

Endocrinology of female reproduction and the menstrual cycle: The most important physiological function of the hypothalamic-pituitary-ovarian (HPO) axis is the control of reproduction. This hormonal system includes the hypothalamic GnRH, which is controlled by the GnRH-pulse generator, the pituitary gonadotropes, and sex-hormones produced by the ovaries. The menstrual cycle can be divided into three successive phases: the follicular phase, the ovulatory phase, and the luteal phase. Menstrual bleeding marks the first day of the follicular phase and occurs after the decrease in levels of progesterone and estrogen at the end of the previous cycle. At the beginning of the follicular phase, the follicle-stimulating hormone (FSH) stimulates the development of several follicles, resulting in a slow increase in a woman's estrogen level. As the estradiol level increases, its negative feedback on the pituitary inhibits secretion of FSH; consequently, the FSH level decreases. Shortly before ovulation occurs, maturation of the dominant follicle and the corresponding peak in estrogen level lead to a positive feedback on LH, generating a preovulatory LH surge. This surge causes the follicle to swell and rupture. Ovulation usually occurs after the LH surge. The following luteal phase is characterized by the formation of the corpus luteum and its production of progesterone and estrogen, which help to prepare the endometrium for implantation and maintenance of pregnancy. High progesterone level exerts negative feedback on the GnRH pulse frequency, and consequently, FSH and LH secretions decrease. Lacking stimulation by FSH and LH, the corpus luteum regresses after approximately 14 days. The following decline in estrogen and progesterone levels remove the negative

feedback control on FSH, and its level increases again to initiate the next menstrual cycle.

The first day of menstrual bleeding is counted as the beginning of the menstrual cycle, which lasts until the day before the next onset of menses. Between the ages of 20 and 40 years, the average cycle length ranges from 27 to 30 days. Whereas the follicular phase can vary in length (13–15 days), the luteal phase lasts approximately 14 days, correlating with the life span of the corpus luteum. Menstrual cycle lengths vary most after menarche and before menopause, mainly because of anovulatory cycles (Rees, Hope, & Ravnikar, 2005).

Women's Reproductive Disorders

Reproductive health is influenced by a number of different factors, such as age, genetics, lifestyle, and exposure to environmental toxins. Thus, women's reproductive health not only includes the healthy aspects of reproduction but also diseases and conditions that negatively affect the female reproductive system. Reproductive disorders, defined as abnormalities in the reproductive system, reduce reproduction and often affect overall health, psychological well-being, and sex life. This section will provide a brief outline of selected menstrual cycle–related reproductive disorders from the perspective of behavioral medicine.

Menstrual Cycle–Related Disorders

Cycle Length Disorders and Bleeding Disorders: Cycle length disorders and bleeding disorders are deviations from normative patterns of menstrual functioning in terms of menstruation frequency or bleeding pattern. Cycle length disorders and bleeding disorders are often associated with anovulatory cycles and infertility. The most common are oligomenorrhea, amenorrhea, menorrhagia, and spotting or breakthrough bleeding. Oligomenorrhea is defined as infrequent menstruation, with 5–9 periods within 1 year; amenorrhea is the absence of a menstrual period. Primary amenorrhea (or the absence of a menstrual period until the age of 16) is a relatively rare disorder, whereas secondary amenorrhea (i.e., the absence of a menstrual period for 3 or more months) affects about 3% of women during the reproductive years (Rees et al., 2005). Menorrhagia is defined as prolonged and/or abnormally heavy periods, with a blood loss of more than 80 ml/period. Spotting or breakthrough bleeding usually affects young or perimenopausal women. Cycle length disorders or bleeding disorders can have organic, endocrine, or psychosocial causes. Exposure to chronic stress or traumatic events seems to influence the hypothalamic pulse generator, leading to a disturbance of reproductive function. Behavioral factors like restraint eating or excessive exercise may contribute to the development of menstrual disorders. In addition, there is a close association between eating disorders, such as anorexia nervosa or obesity, and cycle length disorders (Creatsas et al., 2006).

Dysmenorrhea: Dysmenorrhea is defined as pelvic pain associated with the bleeding phase of the menstrual cycle and can be classified as either primary or secondary, depending on the absence or presence of an identifiable pelvic pathology. Painful cramping is felt in the lower abdomen or back area and is often accompanied by somatic or psychological symptoms, for example, headache, nausea, vomiting, dizziness, restlessness, fatigue, and depressed mood. Dysmenorrhea often interferes with daily activities and may result in absenteeism from school or work (Stanton et al., 2002). The cause of dysmenorrhea can be either organic (e.g., endometriosis) or functional (associated with excessive production of prostaglandines). Studies have shown that affected women show a learning history of enhanced body vigilance and anticipated pain-avoidance behavior. The widely used therapy options for dysmenorrhea are nonsteroidal anti-inflammatory drugs (NSAIDs) to inhibit prostaglandin production and oral contraceptives to suppress ovulation. Pain relief can also be achieved by behavioral therapy methods, such as relaxation techniques or an increase in (physical) activity.

Premenstrual Syndrome and Premenstrual Dysphoric Disorder: Up to 90% of women of reproductive age experience some degree of premenstrual symptoms. A smaller group of women

report symptoms meeting criteria of premenstrual syndrome (PMS), and less than 10% of women are classified as having premenstrual dysphoric disorder (PMDD). According to the *Diagnostic and Statistical Manual of Mental Health Disorders* 5th edition (in development process; www.dsm5.org), indications of PMDD include depressive symptoms (decreased interest in usual activities, depressed mood, self-deprecating thoughts, difficulty concentrating, hopelessness, affective lability, and change in sleep and appetite), anxiety symptoms (feeling of tension or anxiety, irritability or anger, and feeling overwhelmed), and physical symptoms (bloating, breast tenderness, and joint or muscle pain). Symptoms begin in the late luteal phase and remit after the onset of the follicular phase. Women suffering from PMDD often experience impairment of work productivity and interpersonal relationships and increased healthcare utilization. Although the etiology of PMS/PMDD has not been definitely established, studies suggest that the cause of PMS/PMDD is allopregnanolone and $GABA_A$ receptor dysfunction, serotonin abnormalities, and a special sensitivity to the withdrawal or fluctuation of estrogen and progesterone (Freeman, 2003). Depending on the predominant symptoms, different treatment options seem to be effective: oral contraceptives, stress management training, exercise, dietary regulation, vitamins, herbal preparations, cognitive behavioral therapy (CBT), and selective serotonin reuptake inhibitors (SSRIs) (Rapkin, 2003).

Endometriosis: Endometriosis is a common gynecological condition that affects women of reproductive age. It is a condition in which extrauterine, glandular, and stromal endometrial-like tissue grows in physiologically abnormal locations, often within the fallopian tubes, on the outside of the tubes and ovaries, or on the surface of the uterus and intestines. These cells are influenced by monthly hormonal changes; they build up during the menstrual cycle and are shed as levels of sex steroids decrease. Endometriosis is associated with several symptoms, including chronic pelvic pain, dysmenorrhea, menstrual disorders, infertility, dyspareunia (painful intercourse), and dysuria (painful or difficult urination). The exact cause of endometriosis remains unknown; several factors have been suggested, for example, the presence of estrogen, retrograde menstruation, hereditary factors, immune system function, and environmental influence. In addition, discrepancies between the reported location of pain and endoscopic findings make it difficult for women and their gynecologists to handle the symptoms. Affected women present greater susceptibility to mood disturbances, and depressive or anxiety symptoms may play a role in the maintenance of pelvic pain (Gao et al., 2006).

Polycystic Ovary Syndrome: Polycystic ovary syndrome (PCOS) is one of the most common endocrine disorders, affecting about 5–10% of women of childbearing age. Symptoms are heterogeneous and include oligo- or anovulation, biochemical or clinical hyperandrogenism (hirsutism, acne, and alopecia), polycystic ovaries, hyperinsulinemia, infertility, and obesity. The exact etiology has not yet been clarified, but considerable knowledge of the underlying pathophysiologic mechanism and management has been gained. Various lines of evidence suggest a genetic component, but the candidate genes have yet to be identified. Several hypotheses have been proposed to explain the pathogenesis of PCOS:

(a) An alteration in LH pulse frequency and amplitude, resulting from an increased frequency of GnRH pulses and leading to increased androgen synthesis in the theca cells within the ovary
(b) Hyperinsulinemia, resulting from insulin resistance and acting synergistically with LH to stimulate ovarian testosterone production and decrease serum sex hormone–binding globulin (SHBG) concentrations
(c) A primary defect of sex steroid synthesis, leading to increased androgen production and anovulation

The treatment of PCOS depends on the predominant symptoms and the women's stage of life (Jones, Hall, Balen, & Ledger, 2008). The management (e.g., lifestyle management and exercise) of PCOS is directed toward improving the woman's health-related quality of life.

A growing body of evidence suggests that affected women are at increased risk for cardiovascular disease, type II diabetes mellitus, dyslipidemia, metabolic syndrome, and affective disorders (Azziz, 2007).

Reproductive Health Issues Not Related to the Menstrual Cycle

The following disorders are not related to the endocrinological processes of the menstrual cycle but to female sexual health.

Vulvodynia: Vulvodynia is defined as vulvar discomfort (burning, irritation, or sharp pain) often accompanied by sexual dysfunction and affective distress in the absence of anatomic or neurologic findings. Many factors have been proposed to be possible causes (e.g., genetic, immune, or hormonal factors), yet the etiology remains unknown. Comorbidity with psychosomatic disorders, such as irritable bowel syndrome or fibromyalgia, points to a potential psychosomatic cause. Vulvar discomfort affects one's psychological well-being, relationship quality, and sexuality; however, only a few randomized controlled studies have been conducted to study vulvodynia. Apart from numerous medical treatment options (including topical, oral, and injectable medications), biofeedback and relaxation techniques are helpful, especially when vaginismus is concomitant. There is growing evidence that CBT for pain management reduces pain severity and improves sexual functioning in women suffering from vulvodynia.

Pruritus Vulva: Pruritus vulva is characterized by severe itching of the external female genitalia. It can be caused by infections, systemic diseases, or mechanical stimulation. Scratching, which relieves the physical discomfort, may eventually lead to chronic painful sensations in the vulva area. Therapeutic interventions, such as psychoeducation, diverting attention, and development of new coping skills, seem to be promising approaches.

Other Common Reproductive Diseases/Disorders

- Ovarian cancer
- Cervical cancer
- Neoplasia and dysplasia of the cervix
- Uterine cancer
- Sexually transmitted diseases
- Pelvic inflammatory disease/pelvic pain
- Ovarian cysts
- Benign/malignant breast ailments
- Medical complications during gestation
- Low birth weight
- Reduced fertility/infertility

Male Reproductive Health

The endocrinology of male reproduction and a healthy reproductive system are biological requirements for successful reproduction and an important part of overall health in men. The following section will describe the endocrinology of male reproduction and the healthy male reproductive system.

Endocrinology of Male Reproduction and the Male Reproductive System: The male morphologic reproductive system includes the hypothalamic-pituitary-testicular (HPT) axis, penis, scrotum, epididymis, vas deferens, accessory glands, seminal vesicles, prostate, and urethra. The testes have two important functions: production of sperm and synthesis of androgen (testosterone). Both functions are regulated by an endocrine feedback mechanism of the hypothalamus and the pituitary. The pulsatile hypothalamic release of GnRH causes the secretion of FSH and LH. Whereas FSH primarily acts on Sertoli cells to facilitate spermatogenesis, LH acts on Leydig cells in the testicular interstitium to stimulate steroidogenesis, particularly of testosterone. Testosterone is necessary for spermatogenesis, and together with inhibin (which is secreted by the Sertoli cells), it downregulates LH and FSH release via a negative feedback loop (Nieschlag & Behre, 2001).

Male Reproductive Disorders

The above-mentioned endocrinological functioning of male reproduction describes healthy male reproduction. However, male reproduction can be diminished by a variety of diseases and conditions. In the following section, selected male reproductive disorders will be discussed.

Hypogonadism: Primary or secondary hypogonadism is a defect of the testes, resulting in inadequate production of androgen (causing androgen deficiency) and germ cells. Primary hypogonadism is caused by abnormal testicular function. Reasons for primary hypogonadism include genetic disorders (e.g., Klinefelter's syndrome), viral orchitis, and the influence of toxins, among others. Secondary hypogonadism results from a malfunction in the hypothalamus or pituitary gland, which inhibits secretion of pituitary hormones. Symptoms of hypogonadism can be observed in the developing fetus (e.g., improperly formed external genitals), during puberty (e.g., absence of testicular growth and secondary sexual characteristics), and adulthood (e.g., decreased fertility). Hypogonadism is associated with loss of libido, erectile dysfunction, concentration problems, decreased interest in activities, depression, irritability, sleep disorders, loss of muscle strength, and loss of bone density. The most commonly used therapy for hypogonadism is testosterone replacement therapy (Nieschlag & Behre, 2001).

Erectile Dysfunction: Erectile dysfunction is defined as the "consistent inability to achieve or maintain an erection sufficient for satisfactory sexual performance." The prevalence rate ranges from 7% for men aged between 18 and 29 years to 18% for men aged between 50 and 59 years. The cause of erectile dysfunction can be organic or psychogenic. Several risk factors have been detected, including cardiovascular disease, hypertension, smoking, stress, and alcohol or drug abuse. Psychosocial distress, relationship problems, depression, and performance anxiety seem to be potential psychosocial causes. The management of erectile dysfunction includes lifestyle modification, medication (sildenafil citrate), psychotherapy, and surgery. There is evidence that psychotherapy improves erectile functioning, interpersonal assertiveness, and relationship satisfaction and reduces anxiety in men suffering from erectile dysfunction (Nieschlag & Behre, 2001).

Chronic Prostatitis/Chronic Pelvic Pain Syndrome: Chronic prostatitis/chronic pelvic pain syndrome (CP/CPPS) is characterized by pain in the pelvis or perineum, which may be accompanied by ejaculatory disturbances, dysuria, fatigue, low libido, and erectile dysfunction. Chronic prostatitis/chronic pelvic pain syndrome can result either from a bacterial infection (5–10% of all cases) or may not be associated with an identifiable cause, which is the most common type of CP/CPPS. Several different causes have been suggested (including immunological, neurological, endocrine, and psychological causes), yet the actual cause remains unknown. Recently published studies have shown that several traditionally used medications (antimicrobials, anti-inflammatories, and alpha-blockers) do not significantly ameliorate symptoms of CP/CPPS (Tripp, Nickel, Landis, Wang, & Knauss, 2004). Affected men often report helplessness, catastrophic thinking about pain, pain-contingent resting for coping with pain, and a low perceived control over pain. There is primary evidence that psychotherapy, which focuses on decreasing negative thoughts and emotional responses related to pain while building up self-management skills, is predictive of positive treatment outcomes for patients with CP/CPPS (Nickel, Mullins, & Tripp, 2007).

Other Common Reproductive Diseases/Disorders

- Infertility
- Sexually transmissible diseases
- Testicular cancer

Reproductive Health in Middle-Aged and Elderly Men

Whereas women show an unavoidable clear cessation of reproductive capacity, men usually maintain fertility through old age. Similar to women, men may also experience physical and psychological symptoms due to changing concentrations of steroid hormones from midlife onward. Age-related decline in insulin, growth hormone, thyroid hormones, aldosterone, melatonin, and progesterone has been demonstrated. Cortisol, on the other hand, increases with advancing age. Testosterone and bioavailable testosterone show a decline of 35–50% between

the ages of 20 and 80 years, whereas the LH level increases slightly with age. In addition to age-related variations in hormone concentrations, loss of circadian rhythm of LH and testosterone levels has been demonstrated. Furthermore, sex hormone–binding globulin (SHBG) increases with age, leading to reduced bioavailable testosterone (Hermann, Untergasser, Rumpold, & Berger, 2000).

Partial Androgen Deficiency in Aging Men: If decline in testosterone levels is associated with symptoms of androgen deficiency, the condition is called andropause, androgen deficiency in aging men, or partial androgen deficiency in aging men. The incidence and prevalence of androgen deficiency (or unequivocally low serum testosterone levels) in middle-aged men and elderly men are difficult to determine, particularly because of controversial diagnostic criteria and because some of the symptoms are also experienced by normal aging men. Androgen deficiency is associated with symptoms similar to those experienced by menopausal women or men suffering from hypogonadism. Several studies have indicated that testosterone replacement therapy can improve many of these parameters in middle-aged and elderly men. However, the risks of testosterone replacement therapy (e.g., cardiovascular disease) have not been fully assessed.

Other Age-Associated Disorders: Several age-associated histomorphological alterations of the testes have been observed. Age seems to have a negative impact on spermiogenesis, and there is an association between chromosomal abnormalities in spermatozoa and age. One of the most common age-associated morbid changes is prostate hyperplasia (benign enlargement of the prostate); it is sometimes accompanied by erectile dysfunction, which affects quality of life and can cause mood disorders and relationship problems. The major risk factor for erectile dysfunction is age, with an incidence rate of 5–15% for complete impotence and a prevalence of 52% (of erectile dysfunction of any grade) in men between the ages of 40 and 70 years.

Summary

As a part of general health, reproductive health, which refers to the processes and functions of the reproductive system, is essential across the life span. From a biopsychological perspective, a close association between the endocrinology of the reproductive system and psychosocial well-being is of interest. Normal and healthy functioning of the reproductive system and processes is one of the biological fundaments of psychosocial well-being. Nevertheless, reproductive health includes the diseases, disorders, and conditions that affect the functioning of the male and female reproductive system, their sexual life, and mental health.

Cardiovascular Safety, Quintiles, Durham, NC, USA

Synonyms

Study methodology

Definition

Research methodology falls in between study design (including the design of a clinical trial) and data management and analysis. It is concerned with the acquisition of optimum quality data.

Three factors are of central importance in determining the attainment of statistical significance:

1. Variation *between* the two sets of data (one receiving the behavioral intervention of interest, the test treatment group, and one receiving a control treatment, the control treatment group). This is between-groups variation.
2. Variation *within* the two sets of data, or within-groups variation.
3. The total number of subjects participating in the study (the sum of subjects in each treatment group), sometimes expressed as the size of the trial.

The following statements can then be made for each of these factors, assuming in each case that the other two factors remain constant:

- The greater the between-groups variation (operationalized as the greater the difference between the group means, i.e., the greater the

treatment effect), the more likely it is that the difference will attain statistical significance.
- The greater the within-groups variation, the less likely it is that the difference will attain statistical significance.
- The greater the number of subjects participating in the trial, the more likely it is that the difference will attain statistical significance.

Notice that two of these three factors address variation. Consider the first statement, which is intuitively the most straightforward. The larger the treatment effect, the more likely it is to attain statistical significance. That is, all other factors being constant, the greater the treatment's efficacy the more likely it is that compelling evidence for the use of the new treatment is provided.

The influence of the treatment can be considered a systematic influence. It is the signal in which we are interested. In contrast, in the present context, the within-groups variation can be regarded as nonsystematic variation, or the noise against which we desire to detect the signal. This noise has two components: biological variation and random error. Since we all have unique biological systems, including those pertinent to a treatment's influence on the body (a statement that is true for identical twins and other identical births given the gene-environment interactions they experience), biological variation is inevitable and perfectly normal.

In contrast, random error can be addressed. Indeed, minimizing random error is a key focus of research methodology. There are multiple instances where such error can occur, with the following being just a few examples:
- Administering the wrong behavioral treatment to a subject on one or more occasions during the trial.
- Employing measurement equipment that is substandard (e.g., blood pressure monitors).
- Conducting blood pressure measurements in an inconsistent manner (e.g., using the dominant arm sometimes and the nondominant arm at others).
- Recording a measurement incorrectly.
- Misplacing data.

Optimum quality research methodology contributes to optimum quality data. All researchers must strive to the greatest extent possible to execute their role in a study flawlessly to reduce random error, thus allowing the trial the best opportunity of accurately assessing the test treatment's characteristics.

Definition

Voluntary decision to engage in a process of *organized scientific inquiry (research)*.

Description

The conduct of human subjects research relies on the voluntary participation of persons in research studies. The design of a particular study and definition of the population of interest will define which person or populations will be sought for recruitment into a research study. The decision to participate in a research study begins with a process known as informed consent. Informed consent is referred to as a process because continued review and education must be offered throughout every stage of participation in a study, and consent to continue participation is ongoing.

Through this process, participants are continually informed about the requirements of their participation, any known risks associated with participation, and any potential benefits (to themselves or to a larger community) that may result from their participation. Prior to the start of research projects, an institutional review board will review the risks and benefits of proposed research from a scientific and human subject's perspective. However, before actually enrolling in a research study, every participant (or legally authorized representative, in the event the participant cannot consent on his/her own behalf) should understand the potential risks and benefits to the individual associated with participation in the research. The risks and benefits of participation must be explained completely to all potential participants and, ideally, the participant communicates a thorough understanding of the research procedures, risks, and benefits prior to providing initial consent. In some cases, not all the risks of participation may be known. It is not uncommon for researchers to include a statement in the consent form advising potential participants that there may be unknown risks to participation.

Examples of some of the risks involved in research participation may include physical injury, as may occur when testing the safety of a new drug or medical device, or psychological injury, such as the diagnosis of a mental health problem during testing or data collection. There may also be a financial cost associated with research participation, such as treatment of research related illnesses or injuries not covered by the research study or the participant's medical insurance. However, generally speaking, the most common risk encountered is the breach of confidential information collected during the course of participation in human subjects research. The Health Insurance Portability and Accountability Act of 1996 (HIPAA) has had a significant impact on the way all protected health information (PHI) is collected and stored in both clinical and research arenas; therefore, researchers are required to make provisions to safeguard an individual's health information collected as part of their research participation (U.S. Department of Health & Human Services [DHHS], 2011).

Examples of some of the benefits of research participation may include direct physical benefit, such as relief from disease symptoms from the use of an experimental drug or other intervention. Psychological benefits may evolve through a targeted mental health intervention. Often, subjects will agree to participate in research with the knowledge that there may be no direct benefit to self but that they are making a contribution to science and therefore the greater good of society. Some research studies offer direct financial compensation for participation, but this practice causes concern regarding the potential for payment to unduly influence participation and thus obscure risks, impair judgment, or encourage misrepresentation (Grady, 2005). The research application and consent form should state how any risks will be minimized, and the institutional review board or regulatory body overseeing research should carefully evaluate the research study protocol to ensure that overall, benefits outweigh the risks.

Research to Practice Translation

Bonnie Spring, Alex Pictor, Andrew DeMott, Molly Ferguson and Arlen C. Moller
Department of Preventive Medicine, Feinberg School of Medicine, Northwestern University, Chicago, IL, USA

Synonyms

Dissemination and implementation; Knowledge translation; Translational research

Definition

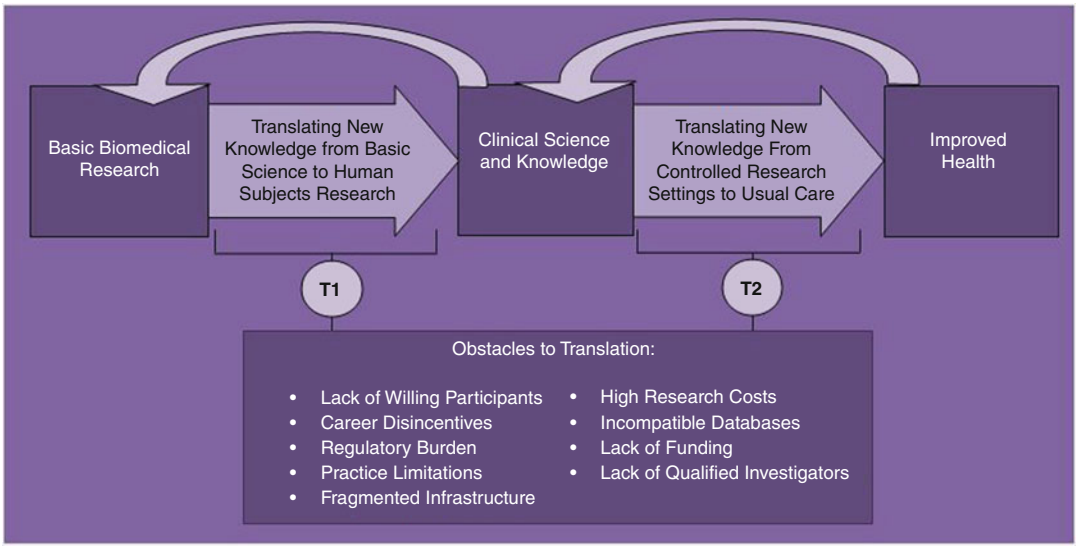
Research to practice translation is the process of adapting principles and findings from scientific investigation in order to apply them in real world practice (Sung et al., 2003; Woolf, 2008). The translational process typically proceeds through a series of phases: T1 (translation of fundamental research findings to develop new practical applications), T2 (adaptation of efficacious treatments into a form that is effective in usual practice settings), and T3 (dissemination and implementation of research-tested interventions so that they are taken up widely by care systems and become usual practice). Although T1, T2, and T3 are all part of research to practice translation, the phrase connotes an emphasis on the later stages, particularly T3. The problem addressed is the slow and incomplete uptake of scientific discoveries into clinical and public health practice. Barriers that impede translation include lack of resources for practitioner training, resistance to change, competing institutional priorities, and lack of infrastructure to support new practices.

Description

Background

A bifurcation between basic and applied research has characterized US science policy since the mid-1940s. In the wake of World War II, Vannevar Bush, Science Advisor to President Franklin D. Roosevelt, wrote an advisory entitled "Science: The Endless Frontier." In it, he advocated for major federal investment in basic science research as the engine that would drive the post-war economy. Bush drew a distinction between basic research, motivated fundamentally by curiosity and a quest for understanding, versus applied research, motivated by the need to solve practical problems. He contended that new insights from basic research are the prime mover of technological and medical progress. Because major advances result from discoveries in remote, unexpected scientific domains, it is virtually impossible to predict which basic scientific inquiries will produce major advances. Consequently, Bush aimed to protect unfettered, curiosity-driven pursuit of scientific understanding from being constrained by worries about whether the knowledge to be gained had any practical use. Arguing that industrial and medical progress would stagnate if basic research were neglected, he succeeded in prompting major federal investment in basic research, including creation of what was to become the National Science Foundation.

Over the next half century, it gradually became apparent that the insights emerging from basic science research were not being translated into practical applications. An analysis by Balas and Boren (2000) indicated that, even after 17 years, only 14% of research knowledge is adopted into practice. By 2001, the Institute of Medicine (IOM) used the term "chasm" to describe the gap between scientific knowledge and actual clinical practice. There was also growing realization that Vannevar Bush's contention that "applied research invariably drives out pure" drew too sharp a dichotomy. In a 1996 book entitled, *Pasteur's Quadrant*, Donald Stokes presented a fourfold table, whereby research could be either low or high on both quest for fundamental understanding and considerations about use. Stokes argued that the most generative, valuable research falls into *Pasteur's Quadrant*, inspired simultaneously *both* by the need to solve a practical problem *and* by curiosity to understand how nature works. A consequence of these



Research to Practice Translation, Fig. 1 Translating basic biomedical research into clinical practice and improved health outcomes (Adapted from Sung et al. (2003))

realizations has been some realignment of budget allocations at the National Institutes of Health (NIH) to support greater investment in translational and applied research. In fiscal year 1998, the NIH allocated 31% of its budget to applied research and 57% to basic science (Institute of Medicine [IOM], 1998). By fiscal year 2007, the amount allocated to applied research was 41%, increasing to 46% by fiscal year 2010 (National Science Board, 2004).

New Research Approaches to Facilitate Translation

In 2003, the Institute of Medicine's Clinical Round Table presented a schema to conceptualize blockades within the translational pipeline (Sung et al., 2003). The identified obstacles are shown in Fig. 1 (adapted from Sung et al., 2003).

Although T1 translation remains a concern, attention has focused increasingly on blockages later in the pipeline. There has been major federal investment in Comparative Effectiveness Research to address a T2 blockade: determining which treatments work best in usual practice, as contrasted with research settings. Moreover, a further translational phase (T3 – Implementation) has been recognized, acknowledging the need to overcome system-level obstacles that impede uptake of best research-tested practices into institutions and health care systems (Westfall, Mold, & Fagnan, 2007) (see also entry on "▶ Translational Behavioral Medicine"). Practice-Based Research and Community-Based Participatory Research (CBPR) are two research approaches now being applied to learn how to overcome implementation barriers (Woolf, 2008).

An insight that is driving attention toward later phase translation is the desire to scale evidence-based interventions to bring their benefits to more of the population. A highly efficacious treatment available to very few will have less public health impact than a less effective treatment available to many (Glasgow, Klesges, Dzewaltowski, Estabrooks, & Vogt, 2006). Stated differently, population level impact is the product of efficacy and reach (Abrams et al., 1996).

Comparative Effectiveness Research

The U.S. Agency for Health Research and Quality (AHRQ) defines Comparative Effectiveness Research (CER) as the conduct and synthesis of research that compares the benefits and harms of

different strategies to prevent, diagnose, treat, and monitor health conditions in "real world" settings. CER is a T2 research strategy that addresses practitioners' need to know the relative merits of the treatment options available to them. CER takes two main forms: (1) systematic evidence reviews that evaluate benefits and harms of treatment options for different groups of people on the basis of preexisting research and (2) new studies that generate evidence about the effectiveness of health care practices in usual practice. The most common CER methodologies have been Randomized Controlled Trials (RCTs) (60% of total CER), followed by systematic reviews (14%), and retrospective observational studies (6%). The most common CER interventions have been: pharmacological (34% of total CER), delivery system (20%), and behavioral (16%) (Department of Health and Human Services [DHHS] & Federal Coordinating Council for Comparative Effectiveness Research, 2009).

Implementation Research

The aim of T3 or Implementation Research (IR) is to learn how to overcome barriers that limit the uptake of evidence-based practices into usual care. A core insight is that "If we want more evidence-based practice, we need more practice-based evidence" (Green & Kreuter, 2005). A common implementation barrier is that few practitioners appreciate being admonished by academic researchers for not following scientific practices. Practitioners note that translational processes need to be bidirectional, so that an understanding of the practice context informs the genesis of relevant research.

Practice-Based Research

Because primary care is the gateway health care provider for most of the population, it offers a major channel to deliver evidence-based care to the public. In 1999, Congress enabled the AHRQ to establish Practice-Based Research Networks (PBRNs) that engage groups of experienced, practicing clinicians in framing research questions whose answers could improve the practice of primary care (Green & Hickner, 2006). By helping practices collaborate to address quality improvement questions with rigorous research methods, AHRQ hopes the PBRN can produce research findings that are immediately relevant to the clinician and readily assimilated into everyday practice.

Community-Based Participatory Research

Community-Based Participatory Research (CBPR) steps beyond the clinical practice to engage the entire community as a co-equal partner in research collaboration. Guided by a core set of values, CBPR builds on community strengths and resources, facilitates collaboration, co-learning, and capacity building, and balances research with long-term commitment to action that benefits the community and eliminates disparities (Israel, Schulz, Parker, & Becker, 2008). A guiding principle of CBPR is that culture, religious values, and economic factors specific to a community are integral to any decision about best practices.

Educating Researchers and Practitioners About Translation

Because research to practice translation is still an evolving field, efforts to educate researchers and practitioners about this area will continue to play a role in improving healthcare. Several training resources are available. First, the NIH Office of Behavioral and Social Science Research (OBSSR) offers a 5-day residential summer training institute on Dissemination and Implementation Research in Health (http://conferences.thehillgroup.com/OBSSRinstitutes/TIDIRH2011/index.html) Another OBSSR-funded resource that can be accessed remotely and free of charge is the Evidence-Based Behavioral Practice (EBBP) site available at www.ebbp.org. Among the interactive online learning modules available at ebbp.org are several dedicated to: (a) shared decision making with communities, (b) stakeholder perspectives about research and evidence-based practice, and (c) implementation. Finally, a third set of resources involve several new scholarly journals: *The Journal of Translational Medicine* (2003), *Science: Translational Medicine* (2009), and *Translational Behavioral Medicine* (2011).

Resilience

Judith Carroll[1] and Chris Dunkel Schetter[2]
[1]Cousins Center for Psychoneuroimmunology, University of California, Los Angeles, CA, USA
[2]Department of Psychology, UCLA, Los Angeles, CA, USA

Synonyms

Adaptation; Hardiness; Personal growth; Psychological thriving; Recovery

Definition

Resilience is a process of "bouncing back" or recovering quickly from adversity, and is not considered a trait disposition. As a dynamic process, resilience involves sustaining psychological functioning during stress, recovering from stressors as rapidly as possible to resume normal functioning, and, in some cases, experiencing psychological growth in the aftermath (Zautra, Arewasikporn, & Davis, 2010). One could think

of a person's resilience as akin to a trampoline with the forces jumping on it as various stressful demands and the strength of the trampoline as the degree of resilience. In this scenario, a major stressor would be a substantial force pressing down on the trampoline, which may or may not cause permanent damage to the trampoline and allow it to remain resistant to stress. In essence, resilience is a process by which a person is able to appraise stressful circumstances in an accurate and constructive way. It involves cognitions, behaviors, and resources that are available or learned and that can support coping and growth from the stressful or traumatic experience. Although traditionally studied in the context of traumatic or major stressful life events such as major illnesses, childhood adversity, or loss of a loved one, resilience can also be examined in the context of chronic stressors – constant or recurrent demands – that are known to have a pronounced biological impact on health (Schneiderman, Ironson, & Siegel, 2005). In these circumstances, individuals often experience psychological and physiological exhaustion if their resources are inadequate to cope with stressful demands over the long term. Inversely, a person who has strong resilience resources can sustain normal functioning in the face of chronic stress. Dunkel Schetter and Dolbier (2011) developed a taxonomy of resilience resources at the individual level to foster comprehensive assessments of resilience in research that are pertinent to behavioral medicine. This taxonomy involves individual difference resources (i.e., positive affectivity, optimism), self and ego-related resources (i.e., self-efficacy, self-esteem), interpersonal/social resources (i.e., social support, social networks), worldviews and cultural beliefs (i.e., religiosity, life purpose, collectivism), behavioral and cognitive skills (emotion regulation, problem solving skills), and endowed or acquired resources (i.e., intelligence, health behaviors). Similarly, the American Psychological Association (APA, 2012) has described key factors that foster the development of resilience, including developing self-worth and self-efficacy, meaning making and positive cognitions, constructive coping, emotion regulation, social support, self-care behaviors (e.g., getting exercise, eating well, sleeping), expressive writing, spirituality, and meditation (www.apa.org). While much remains to be learned about resilience, scientific understanding has grown substantially in the wake of major disasters in the last decade.

Resilience: Measurement

Susanne Fischer
Department of Psychology, Clinical Biopsychology, Philipps-University of Marburg, Marburg, Germany

Synonyms

Hardiness; Resiliency; Sense of coherence – measurement

Definition

Resilience is defined as the capability of successfully restoring, sustaining, or enhancing adaptive competences in the face of significant adversity.

Description

Several core elements are part of the definition of resilience: (a) Occurrence of a stressor is an essential antecedent of resilience. (b) There is a beneficial outcome as a consequence of negative experiences. (c) A life span perspective is required, encompassing varying trajectories such as short-term recovery, delayed reactions, and chronic dysfunction (Bonanno, 2004; Bonanno & Mancini, 2008). Despite general consent on these conceptual core elements, there are ambiguities in defining type, severity, and frequency of stress experience as well as domain and level of possible subsequent competence.

Regarding *stress experiences*, operationalization usually depends on individual study aims and populations of interest. This results in numerous highly heterogeneous measurements of stressors. In studies on children and adolescents, focus is on socioeconomic deprivation as a variant of prolonged stress or aversive early life events (such as childhood trauma), whereas isolated critical life events or traumatization occurring during the adult life span are subject of numerous studies in adults. Most of these studies adopt self-report measurement approaches using structured interviews or administering checklists and questionnaires to retrospectively assess negative experiences. These subjective measures may be complemented by biological parameters, such as brain activity as well as endocrinological, autonomic, or immunological parameters which may constitute valuable indicators of often long-lasting physiological changes in stress-response systems precipitated by adverse experiences (McEwen, 2008).

In order to measure *adaptive competences* after previous exposure to stress, researchers examining children and adolescents often generate composite indices across multiple behavioral domains of functioning (e.g., school or recreational activities). Also, achievement of developmental milestones can be used as a measurement of successful adaptation (Atkinson, Martin, & Rankin, 2009). These measurements commonly rely on evaluations and ratings provided by parents or teachers. In contrast, studies investigating adults are mostly designed within a clinical context. As a consequence, definition of resilience usually equals absence of somatic symptoms, physical illness, psychological distress or psychopathology, and measurement of resilience is reflected by this. The assessment of physical and mental well-being usually relies on experiential statements made by the individual under investigation himself or herself (Atkinson, Martin, & Rankin, 2009).

Several psychometric instruments have been developed on the basis of rather comprehensive theoretical conceptualizations, such as sense of coherence (Antonovsky, 1979), hardiness (Kobasa, 1979), or ego-resiliency (Block & Block, 1980). Apart from these broader concepts, a number of more specific characteristics have been commonly associated with resilience: cognitive flexibility, internal locus of control, self-efficacy, positive affectivity, optimism,

self-esteem, active coping, and social support, among many others (Earvolino-Ramirez, 2007; Mancini & Bonanno, 2009). At present, a number of self-report questionnaires assessing at least some of these characteristics have gained considerable attention (Ahern, Kiehl, Sole, & Byers, 2006; Windle, Bennett, & Noyes, 2011). Prominent examples (in terms of good psychometric properties and/or international use in empirical studies) are the Resilience Scale (RS; Wagnild & Young, 1993), the Connor-Davidson Resilience Scale (CD-RISC; Connor & Davidson, 2003), and the Resilience Scale for Adults (RSA; Friborg, Hjemdal, Rosenvinge, & Martinussen, 2003). The RS was developed based on interviews with community-dwelling older women after experience of critical life events, conceptualizing resilience as an individual trait. Principal component analysis of the 25 items revealed two factors labeled "personal competence" and "acceptance of self and life." The scale has been employed in population-based as well as clinical contexts. The CD-RISC, by contrast, predominantly consists of questions addressing stress-coping behavior. A preliminary validation study conducted by the authors yielded a structure of five factors based on the 25 items of the test. Application of the instrument has so far mostly been limited to clinical trials. Finally, the RSA incorporates items on external protective resources such as social support. Overall, five dimensions were empirically found to adequately describe the resilience concept as suggested by the authors, namely, personal competence, social competence, family coherence, social support, and personal structure. The scale has been used in studies in both healthy participants and patient samples.

While resilience has been traditionally examined using psychometric assessments, more recent research has sought to evaluate the biological underpinnings and physiological correlates of resilience in both animals and humans (Charney, 2004; Cicchetti & Blender, 2006; Feder, Nestler, & Charney, 2009; McEwen, 2008; Stein, 2009; Yehuda, Flory, Southwick, & Charney, 2006). Studies in this area of research usually utilize experimental designs directed at exploring the dynamic biological processes involved in the promotion of general well-being, with the goal of identifying genetic, neuronal, and physiological mechanisms in resilient humans. Research incorporating multidisciplinary approaches and addressing the role of biopsychosocial mechanisms of resilience holds substantial promises for a better understanding of how individuals are capable of thriving in the face of adversity.

Resiliency

► Resilience: Measurement

Resistance Training

Roland Thomeé
Department of Rehabilitation Medicine, Sahlgrenska University Hospital, Öjersjö, Göteborg, Sweden

Definition

Resistance training has an impact on many-body systems such as the muscular, respiratory, skeletal, and neural, but also the immune, endocrine, and metabolic (Deschenes & Kraemer, 2002).

Description

Resistance training has been used for a very long time. There is documentation from 700 B.C. of the very strong Bybon in Greece lifting a 140 kg rock over his head with only one hand. The legendary Milon from Italy lifted a new born calf every day until the calf was a full-grown bull. This is the first documentation of progressive resistance training (Fry & Newton, 2002). Among the pioneers in research on resistance training Thomas L. De Lorme needs to be mentioned. In 1946 he presented a method for resistance training using the one repetition maximum (1RM) (De Lorme, 1946). This concept is still widely used today describing the intensity used in resistance training programs.

In order to achieve the desired response on the body it is important to understand the basic principles of resistance training. Resistance training can, according to the American Sports Medicine Institute (http://www.asmi.org/), be defined as a gradual overload of the musculoskeletal system resulting in improved capacity. In general resistant training is often synonymous with strength training. Depending on the design the resistance training program can result in improved muscle strength, muscle volume, muscle power, or muscle endurance. Motor control can improve with better balance, coordination, and technique. Also tendons, ligaments, articular cartilage, and bones

can improve their capacity as a result of resistance training (Deschenes & Kraemer, 2002).

There are several methods available and various effects of the resistance training program are achieved depending on the frequency, intensity, and volume of the training (Wernbom, Augustsson, & Thomee, 2007). The program needs to specify the number of weeks of training, the number of training sessions performed per week, the number of exercises used for each muscle group, the number of sets and repetitions used for each exercise, and how long time of rest is given in between sets and exercises. For general strength training it can be recommended that the program consists of two session per week, two exercises per major muscle group, two to three sets of 8–12 repetitions per exercise with 30 s of rest in between sets and exercises (Haskell et al., 2007). In order to improve muscle power, i.e., the ability to produce a high force rapidly, a moderate load moved as fast as possible is recommended. For muscular endurance the number of repetitions should exceed 20 and the rest between sets and exercises decreased to a minimum (Wernbom et al., 2007).

One mode of strength training can be classified as dynamic external resistance, including free weights and weight machines, where the resistance is moved through the range of motion of the joint. Another mode can be classified as accommodating resistance, for example, isokinetic (the speed of movement is constant and the resistance offered by the machine accommodates to the applied force through the whole range of motion). A third mode can be classified as isometric resistance where no movement occurs during muscle force development. For the first two modes one usually differs concentric from eccentric muscle action. In a concentric muscle action the muscle shortens while developing force and in the eccentric muscle action the muscle lengthens while developing force. There is no evidence as of now for the superiority of any mode and/or type of muscle action over other modes and types (Wernbom et al., 2007). Given sufficient frequency, intensity, and volume of work, all three types of muscle actions can induce significant increased muscle volume at an impressive rate.

Respiratory Sinus Arrhythmia

Randall Steven Jorgensen
Department of Psychology, Syracuse University, Syracuse, NY, USA

Synonyms

Heart rate variability (HRV)

Definition

In mammals, heart rate (HR) ordinarily accelerates during inspiration and decelerates during expiration, and the tenth cranial nerve (i.e., vagus nerve) exerts a profound influence on this heart rate

variability (HRV). This oscillation of R-wave (the sharp upward spike of the QRS complex associated with the contraction of the heart) to R-wave intervals (RRI) is a cardiorespiratory phenomenon called respiratory sinus arrhythmia (RSA); since RRI, which are inversely related to moment-to-moment HR, reflect vagal stimulation, noninvasive measures of RSA are commonly used to estimate autonomic cardiovascular control (Grossman & Taylor, 2007). The "peak to valley" time-domain estimate, usually quantified in milliseconds (ms), corresponds to the inspiratory-expiratory difference in RRI. For estimates based on spectral analysis and other frequency-domain approaches, RRI variation is estimated within the respiratory frequency range (.15–.4 Hz); to reflect statistical units of variance, ms^2 is commonly used. For steady-state conditions (viz., respiratory parameters, momentary physical activity, metabolic activity, and autonomic tone remain nearly constant), these estimates are almost perfectly correlated (Grossman and Taylor). These noninvasive measures' covariation with cardiac vagal tone, however, can be confounded by such factors as respiratory rate and volume, changes in physical and metabolic activity, body weight, age, and sympathetic nervous system tone; this confounding is more pronounced in between-group designs (e.g., high blood pressure vs. normal blood pressure groups) than within-subject designs (e.g., examining within-person changes in RSA following atropine administration) (Grossman & Taylor, 2007).

The vagus has been posited to be a key factor in emotional regulation and health (Thayer & Lane, 2009). Researchers, therefore, have used noninvasive measures of HRV and RSA to predict health and psychological well-being. These ostensible markers of cardiac vagal tone are reported to covary with cardiovascular disease, anxiety, depression, and childhood behavior disorders (Berntson, Cacioppo, & Grossman, 2007; Thayer & Lane, 2007). Even when the predicted associations are revealed, the (a) correlational designs; (b) paucity of multivariate/multilevel studies cutting across anatomical, physiological, and behavioral domains; and (c) inadequate controls of confounds (e.g., bodily motion and respiration rate) make interpretation of underlying causal and multiply determined pathways ambiguous (Berntson et al., 2007). At minimum, it is important to take into account and address the confounding variables discussed earlier (for guidelines, see Grossman & Taylor, 2007).

Retrospective Study

Jane Monaco
Department of Biostatistics, The University of North Carolina at Chapel Hill, Chapel Hill, NC, USA

Definition

A study in which the outcome of interest has already occurred when the study initiated is commonly referred to as retrospective study.

Some investigators have used the terms retrospective and case control interchangeably. This usage is misleading since study designs other than case-control studies can be retrospective. For example, in a retrospective cohort study (Okasha, McCarron, McEwen, & Davey Smith, 2002) examining the relationship between body mass index (BMI) during early adulthood and cancer death, both the exposure and the outcome had occurred at the initiation of the study. University students' weight and height information was obtained from annual physical records at the University of Glasgow health service from 1948 to 1968. Cancer mortality was determined based on a central registry in Scotland that identifies the cause of death (National Health Service Central Register). Subjects with BMI in the highest quartile were found to be at higher risk of cancer death than individuals in the lowest BMI quartile.

In a retrospective study, data may be collected based on clinical records, employment records, or memory. These retrospective data can be more prone to bias, such as recall bias, than prospective designs studying the same association.

Some investigators may also use the term "retrospective" in a different way, referring to the timing of the measurements of the exposure and outcome; studies in which the exposure is measured after the outcome is measured can be referred to as retrospective (Rothman & Greenland, 1998, pp. 74–75).

Rheumatoid Arthritis: Psychosocial Aspects

Toshihide Hashimoto
Department of Rehabilitation, Graduate School of Medicine, Gunma University, Maebashi, Gunma, Japan

Synonyms

RA

Definition

Rheumatoid arthritis is a chronic, systemic, progressive inflammatory disease characterized by swelling, pain, and deformity of the joints. It affects not only synovial joints but also many tissues and organs of the body.

Description

Rheumatoid Arthritis (RA)

RA affects about 0.5–1.0% of the general population. The prevalence shows similarity by region and race worldwide. Women are afflicted two to three times more often than men. Individuals between 40 and 60 years of age are most liable to RA, but people at any age can be affected. Although the cause of RA has not been fully elucidated, the abnormal autoimmune response which attacks the body's own tissue plays a major role in the onset and progression of RA.

The first symptoms of RA generally occur in the smaller joints (e.g., finger or wrist joints) and gradually spread symmetrically to the larger joints (e.g., elbow or knee joints). In affected joints, inflammation first occurs in the synovial membrane. Abnormal synovium, called "pannus," multiplies gradually and results in cartilage damage and bone erosion and eventually the destruction of the joints. Consequently, RA patients suffer from joint symptoms such as pain, swelling, stiffness, deformity, and restriction of motion.

In addition, inflammation involved in RA may affect various organs, including fibrosis or pleuritis in the lungs, pericarditis or cardiovascular disease in the heart, osteoporosis in the bones, vertebral malalignment or subluxation in the cervical spine, and rheumatoid nodules in the skin. RA patients also experience some general symptoms due to chronic inflammation, such as anemia, fatigue, low-grade fever, sleep disorder, and lack of appetite.

Such symptoms cause multiple joint pains, physical disability, and various comorbidities in RA patients. As a result, many RA patients experience loss of income, loss of recreational and social activities, and disability in doing housework and taking care of children. These physical and social disabilities are likely to disturb interpersonal relationships and lead to psychological disorders. Depression and anxiety have also been known to cause increased pain and other RA-related symptoms (Firestein, 2009; Harris et al., 2009).

Psychological Distress of RA Patients

Depression is significantly more common among RA patients than healthy individuals. The prevalence of depression in patients with RA varies from 20% to 40%. This varying range may be due to both the RA patient population and the evaluation method of depression. RA-related symptoms (i.e., fatigue, sleep disturbance, or loss of appetite) correspond to physical symptoms of patients with general depression. When prevalence is measured satisfactorily independent of the severity of RA symptoms, it is more likely to be about 20%. This figure is presumed to be similar to those of other chronic conditions and two or three times higher than that of the general population.

Many factors have been associated with depression of RA patients. In terms of RA-related symptoms, the increase in subjective self-reported pain, fatigue, and physical disability is likely to lead to a more depressive state. The causal relationship between pain, fatigue, disability, and depression is complex and considered multidirectional. On the other hand, disease

factors that are indices of inflammation (e.g., C-reactive protein (CRP), erythrocyte sedimentation rate (ESR), swollen joint count, grip strength, and radiological status) are generally not associated with depression.

Recently, psychosocial factors have been emphasized as important variables associated with depression. Generally, increased depression of RA patients is related to being female, younger age, lower income, less employment, greater work disability, more social stress, less social support, dysfunctional familial background, maladaptive coping strategy, and distorted cognition.

In clinical practice, objective clinical variables (CRP, ESR, or joint count) and subjective patient-reported physical symptoms are regarded as important indices of treatment effects. However, clinicians do not tend to pay close attention to mood states of RA patients. Depressed RA patients may not verbally express their emotion, because they judge that their emotional and physical conditions are a part of their RA symptoms. Accordingly, depression in RA patients is most likely underestimated by clinicians. All health-care professionals should thus try to observe whether RA patients have latent depression (Sheehy, Murphy, & Barry, 2006; Travis, 2008).

Relationship Between RA-Related Symptoms and Psychosocial Factors

Pain, fatigue, and physical disability are RA-related symptoms that need to be addressed by all health-care professionals. Pain is the most common and basic symptom in RA patients. Fatigue is also common and the most burdensome symptom. The prevalence of fatigue ranges greatly from 40% to 80%, most likely because the definition and method of measurement are not uniform. Fatigue is perceived as a frustrating or exhausting state, impacts every situation of life, and persists for a long time. Pain, fatigue, and physical disability influence psychological well-being and social participation of RA patients. Moreover, psychosocial factors, e.g., perception of symptoms, self-efficacy, coping strategy, social stress, and social support, play important roles in modifying the process and outcome of RA-related symptoms and psychological distress.

Perception of symptoms is an individual belief in how RA will influence oneself, how long RA will last, whether RA can be controlled, and what the outcomes of RA are. RA patients with negative beliefs, such as "catastrophizing" (the tendency to focus on symptoms and predict extremely negative outcomes) or "helplessness" (the belief that nothing can be done by oneself to deal with symptoms), may demonstrate increased symptoms and poor psychological well-being. On the other hand, self-efficacy (the confidence in one's ability to accomplish sufficiently a desired outcome) and an adaptive coping strategy (the suitable and effective process to deal with stresses and difficulties of life) are considered to improve symptoms and psychological distress.

All health-care professionals should make efforts to inform RA patients of the cause, treatment, clinical course, and result of RA at the early stage of their disease before they have poor perception of symptoms and acquire maladaptive coping strategies. In patients who have already experienced physical and psychological distress, several interventions (e.g., cognitive behavioral therapy, patient education, and physical exercise) have been implemented, but the evidence of these interventions has not been clarified. All health-care professionals should take note of any psychological distress of RA patients, accurately evaluate the patients' social stress and social support, and provide them with information about available care and support, in order to promote better self-efficacy and more adaptive coping strategies (Backman, 2006; Repping-Wuts, van Riel, & van Achterberg, 2009; Sheehy et al., 2006; Travis, 2008).

Relevance to Clinical Practice

In the past decade, drug treatment of RA has improved greatly. Disease-modifying antirheumatic drugs (DMARDs) and biological DMARDs (drugs to block or modify the effect of factors of the immune system, such as cytokines and lymphocytes) have been introduced to RA patients at the early stage. These new medications effectively reduce inflammation of RA and prevent the advancement of joint erosion and deformities. These drug therapies have

possibility of reducing not only pain but also fatigue or depression. As a result, the clinical course of RA could change significantly, leading to a decrease in the number of patients who suffer from fatigue and depression in the future.

However, such medications have several problems, including potential side effects (e.g., infection or blood disease), ineffectiveness for some patients, and high cost of treatment. Some, but not all, RA patients are expected to benefit from these medical advancements in RA, and they will probably experience new psychosocial problems. Health-care professionals need to further examine psychosocial factors that accompany new therapies to evaluate both the positive and negative influences on patients (Genoves, 2009; Saag et al., 2008; Smolen et al., 2010).

Rief, Winfried

Alexandra Martin
Friedrich-Alexander University Erlangen-Nürnberg; University Hospital, Erlangen, Germany

Biographical Information

Winfried Rief was born in Ellwangen, Germany, on May 12, 1959. He is married to Sabine and has

a son. Rief studied physics at the University of Karlsruhe, Germany (1978–1979), and psychology at the University of Trier, Germany (1979–1984), receiving a Diploma in psychology in 1984. His doctoral thesis presented EEG-based research about "Visual Information Processing in Chronic Schizophrenics" and led to the awarding of the Ph.D. degree at the University of Konstanz in 1987.

Rief completed postgraduate training in cognitive-behavioral therapy (1988) and is a licensed Psychological Psychotherapist. He gained excellent clinical experiences and was Head of the psychology department at the Roseneck Hospital in Prien (1989–2000), a behavioral medicine center specialized in the inpatient treatment of eating disorders, anxiety, somatoform disorders, and other conditions, which is affiliated with the Medical Faculty of the University of Munich. He accomplished the "Habilitation" – the regular German academic qualification for professorship – at the University of Salzburg, Austria in 1994.

Rief was appointed as Professor of Clinical Psychology and Psychotherapy at the University of Marburg, Germany, in 2001 and since then has chaired the division for clinical psychology. He is also Head of the Outpatient Clinic for Psychological Interventions and Head of the postgraduate training program in cognitive-behavior therapy. He has been an invited guest professor for research visits at the University of Auckland Medical School, New Zealand (2002), Harvard Medical School Institute of Psychiatry (2004), and at the University of California, San Diego, Department of Psychiatry (2009).

Rief is an active participant in many professional organizations. He was President of the German Society of Behavioral Medicine and Behavior Modification (DGVM; 2001–2005). He served as Member and as Chair of the speaker group of the section for "Clinical Psychology and Psychotherapy" in the German Psychological Society (Fachgruppe Klinische Psychologie und Psychotherapie in der Deutschen Gesellschaft für Psychologie DGPs; 1996–1998; 2005–2008). He was one of the founding members of the German Society of Biofeedback, and later served as President in this organization (DGBFB 2000–2004). He organized many national and international scientific meetings, for example, the "International Symposium on Somatoform Disorders" (co-sponsored by the Division of Mental Health of the World Health Organization; Prien, 1997), the Congress of the German Society of Behavioral Medicine (Prien, 1999, co-organized with Prof. Dr. Manfred Fichter), the International Congress "Somatoform Disorders" (Marburg 2002), the International Congress of Behavioral Medicine (Mainz 2004, co-organized with Prof. Dr. Wolfgang Hiller), and the Annual Meetings of the German Society of Biofeedback (2001, 2007). Rief is recipient of the Biofeedback Foundation of Europe Award for Excellent Scientific Contribution (2004).

Rief has been appointed as reviewer for several research funding organizations, including the Deutsche Forschungsgemeinschaft (DFG) (German Research Foundation), Swiss National Fonds (SNF), NIHR Biomedical Research Center for Mental Health, and the Institute of Psychiatry/King's College London. In 2011, he was elected as coordinator for DFG grants in the field of clinical and health psychology in Germany. He currently serves or has served as an editorial board member in several scientific journals (*Behavioural and Cognitive Psychotherapy; British Journal of Health Psychology;Cognitive Behaviour Therapy; Current Opinion in Psychiatry; Psychology and Health; Psychotherapie in Psychiatrie, Psychosomatik und Klinischer Psychologie; Verhaltenstherapie; Zeitschrift für Psychiatrie, Psychologie und Psychotherapie ZPPP*).

Major Accomplishments

Rief is a world-leading scientist in the field of *somatoform disorders*. For more than 20 years, his research has considerably advanced the knowledge about epidemiology, etiology, and effective treatments of somatoform disorders. He has shown that medically unexplained symptoms are not only prevalent in medical settings, but also common in the general population. With the Screening for Somatoform Symptoms (SOMS) he and Professor Wolfgang Hiller

provided a reliable and valid instrument to assess somatoform syndromes that are associated with considerable distress, disability, and health care utilization. One of his most recent research projects (funded by a DFG grant) aimed to investigate course and classification of medically unexplained physical complaints in the general population. Against the background of current proposals to improve the classification of somatoform disorders and related syndromes in the Diagnostic and Statistical Manual of Mental Disorders DSM-5 and the International Classification of Diseases ICD-11, Rief and colleagues were the first who tested the most prominent classification proposals (such as the Complex Somatic Symptom Disorder). Their results showed that classification criteria that include positive psychological features (such as somatic illness attribution and illness behavior) are advantageous in identifying people with health care needs and disability as compared to approaches that focus simply on symptom count and the absence of sufficient medical explicability (Rief, Mewes, Martin, Glaesmer, & Braehler, 2011). Based on his expertise in the classification of somatoform disorders Rief was appointed as an ICD-11 representative of the International Association for the Study of Pain IASP to coordinate revision proposals for pain diagnoses, and he was Member of the Expert Conference on Somatic Presentations of Mental Disorders (Task: Preparation of classification criteria for ICD-11 and DSM-V) under the auspices of the American Psychiatric Association (APA), the National Institute of Health (NIH), and the World Health Organization (WHO) 2006).

Rief has always been interested in processes that contribute to etiology and maintenance of somatoform disorders. He demonstrated the roles of cognitive processes such as symptom interpretation and memory biases (Rief, Heitmüller, Reisberg, & Rüddel, 2006), of illness behaviors, and especially of neurobiological and psychoneuroimmunological processes in somatoform disorders (Rief & Barsky, 2005; Rief & Broadbent, 2007).

Rief and his colleagues conducted a number of randomized clinical trials to evaluate the effects of different intervention strategies in somatoform syndromes (all funded by research grants from the DFG, the Federal Ministry of Education, Research BMBF Germany, and others). These studies demonstrated, for example, that a cognitive-behavior group–based inpatient treatment is effective in somatoform disorders, and that even a minimal intervention program designed for subjects in primary care results in symptom improvement. The evaluation of a special training program for general practitioners to improve management of patients with unexplained physical symptoms showed a reduction in health care utilization, but appeared not to be sufficient to improve disability in patients. Rief will continue to develop psychological treatments further to enhance their clinical effects in somatoform disorders.

Placebo effects and placebo and nocebo mechanisms are one of Rief's most recent research fields (Rief, Avorn, & Barsky, 2006). He has published meta-analytical results showing that close to 70% of positive effects of antidepressants are already reported for the placebo group. In line with his interest in the development of somatic symptoms, he was able to show that expectation of side effects results in higher side effect rates in clinical trials. Consequently, many subjects discontinuing drug intake because of side effects were shown to be in the placebo group. He is the spokesperson of a German Research Unit "Expectation and conditioning as basic mechanisms of placebo and nocebo effects," which covers eigth subprojects on placebo and nocebo mechanisms (total budget about 2.7 Mio. EUR; local budget for Rief's work is 640,000,– EUR). Together with colleagues of this research unit, he has published new proposals for study design in clinical trials (Rief, Bingel, Schedlowski, & Enck, 2011).

Rief's breadth of research interests in the field of behavioral medicine is demonstrated by additional studies he has conducted in obesity (e.g., BMBF grants' "Counseling of obese patients including genetic findings" and "Psychosocial, legal, and ethical aspects of genetic and molecular obesity research"), cancer (Rief et al., 2011), tinnitus (e.g., DFG grant "Psychophysiological

aspects and treatment of chronic tinnitus" (Weise, Heinecke, & Rief, 2008), chronic pain, CBT in schizophrenia, side effect assessment in clinical trials, and public health issues. In international projects, he has collaborated with distinguished members of Harvard Medical School (A. Barsky), UCSD (J. Dimsdale), Auckland Medical School (K. Petrie), and many others. His current publication record includes more than 300 publications in peer-reviewed journals, 15 books and co-edited books, and numerous book sections.

Risk Factors and Their Management

Bernt Lindahl
Occupational and Environmental Medicine, Department of Public Health and Clinical Medicine, Umeå University, Umeå, Sweden

Definition

The term "risk factor" describes factors that are associated with an increased risk of developing a disease but that are not sufficient to cause the disease. In this topic, risk factors for our most important noncommunicable diseases, such as cardiovascular disease (CVD), type 2 diabetes, and certain forms of cancer, are discussed. Special emphasis is on explaining the link between an individual's choice of lifestyle (behaviors) and these diseases. This link is called "the metabolic syndrome" and can be described as a group of risk factors that occur together, are modifiable by lifestyle change, and increase the risk for CVD

and diabetes. Some implications of this lifestyle metabolic syndrome association may also be drawn to other diseases, such as dementia and depression. Management of these cardiometabolic risk factors is primarily behavior modification or long-term lifestyle change. Often, the lifestyle treatment needs to be complimented by pharmacologic treatment for some specific risk factors, such as LDL-cholesterol and high blood pressure.

Description

Risk Factors

During the last four decades, it has been said that three risk factors, often called the traditional risk factors, could explain 50% of the risk of getting an acute heart attack or an acute myocardial infarction (AMI). The three risk factors were smoking, serum cholesterol, and blood pressure. In 2004, the Interheart study was published, and this worldwide case–control study found nine modifiable risk factors to explain 90% of the risk of getting AMI (Yusuf et al., 2004). The study compared 15,000 cases of AMI with the same number of controls without having AMI. They found that smoking and lipid disorder, mainly high total and LDL-cholesterol, were the most powerful of these nine risk factors. The others were blood pressure, diabetes, abdominal obesity, psychosocial factors, physical activity, fruit and vegetables, and alcohol consumption. The last three of these risk factors were in reality protecting factors, since a higher level of physical activity, fruit and vegetables, and alcohol were associated with a lower rate of AMI. The strength of this worldwide study is that the risk factor pattern for AMI was the same among men and women, between different geographical regions of the world and also between different racial or ethnic groups (Yusuf et al., 2004).

Smoking

Smoking is perhaps the most important risk factor for cardiovascular disease (CVD), and if one was to be confronted with a patient with CVD and several other risk factors, who still was a smoker, the foremost advice would be to discuss how to stop smoking (Burell & Lindahl, 2008). The consequences of smoking and how to work with tobacco and smoking cessation will be dealt with elsewhere.

Lipids

Disturbances in blood lipids are strong risk factors for atherosclerosis and cardiovascular disease, such as coronary heart disease, stroke, and peripheral artery disease. There are two main forms of lipids in the blood: cholesterol and triglycerides. Total cholesterol can be subdivided into low density lipoprotein (LDL)-cholesterol, sometimes called bad cholesterol since it increases the risk of cardiovascular disease, and high density lipoprotein (HDL)-cholesterol, sometimes called good cholesterol since it reduces the risk of cardiovascular disease (Faergeman, 2008). As a rule of thumb, in order to avoid atherosclerosis and risk of CVD, an individual's total cholesterol should be below 5 mmol/L, LDL-cholesterol below 3 mmol/L, triglycerides below 2 mmol/L, and HDL-cholesterol above 1 mmol/L. For some individuals, the lipid goals need to be even more advanced. In secondary prevention, for instance, when you already have had one heart attack and you want to prevent another one, the aim for the LDL-cholesterol level may be below 2.5 mmol/L or 2.0 mmol/L. All patients with cardiovascular disease, diabetes, and familial high cholesterol belong to this group of individuals (Faergeman, 2008).

Obesity, Insulin Resistance, and the Metabolic Syndrome

Obesity has long been the main modifiable risk factor for type 2 diabetes, and during the last decade, a nearly explosive growth over the world of both obesity and diabetes has been demonstrated. This development has mostly been attributed to developed countries, but has also increasingly been found in many developing countries (Barnett & Kumar, 2004; Björntorp, 2001). Obesity is often defined as a condition of excessive fat accumulation in adipose tissue to the extent that health may be impaired and is the result of an imbalance between energy intake and

expenditure (Björntorp, 2001). If an individual consumes more energy than he/she spends, fat tissue will accumulate, and obesity may follow. According to the World Health Organization (WHO), obesity is defined as a body mass index (BMI) of 30 kg/m^2 or more. Although obesity per se is a strong risk factor for diabetes and CVD, it was discovered already in the beginning of the 1950s that the male form of obesity having most of the fat deposit localized around the waist, i.e., abdominal obesity, was an even stronger risk factor (Barnett & Kumar, 2004; Björntorp, 2001). A waist circumference of 94 cm (37 in.) in men and 80 cm (32 in.) in women has been shown to increase the risk of getting diabetes and CVD, and this risk is further increased with a waist of 102 cm (40 in.) or above in men and 88 cm (35 in.) or above in women. The first level could be seen as an alerting zone, i.e., an obligation to inform the individual about the increased risk and discuss possible solutions. The second level is often called "an action level," implying that these individuals really ought to be offered inclusion in a lifestyle program (Björntorp, 2001).

Portal-Visceral Hypothesis and Insulin Resistance

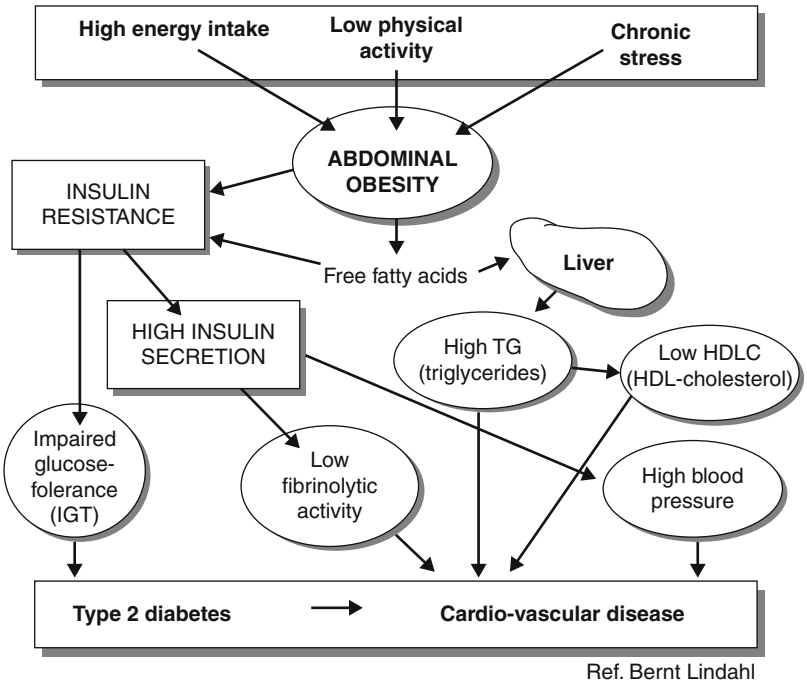
Several of the nine modifiable risk factors from the Interheart study are highly correlated to each other, i.e., they are more often than by chance found together in the same individual. As shown in Fig. 1, low physical activity in combination with high energy intake and sustained psychosocial stress will increase the risk of developing obesity and especially abdominal obesity. A large amount of abdominal fat, which is more metabolically active than subcutaneous fat, will release large amounts of fatty acids to the blood circulation. Large amounts of free fatty acids at muscular level will reduce the uptake of glucose due to a subnormal insulin action. A state of insulin resistance will follow, which may be defined as a state in which a given concentration of insulin produces a less than expected biological effect. The small increase in glucose concentration in the circulation that will follow will in turn increase the secretion of insulin from the beta cells in the pancreas. Glucose uptake at muscular level will be restored, despite that insulin resistance still exists. However, the price to pay is a larger than normal insulin secretion. This could go on for years with increasing body weight, waist circumference, insulin resistance, and high beta cell activity. The long-term problem is that the beta cells get exhausted and lose their ability to produce insulin (Kumar & O'Rahilly, 2005).

In the beginning of such a development, the amount of insulin secreted is not high enough to take care of the carbohydrates after a meal and plasma glucose often rises to levels beyond the normal. This is called a state of impaired glucose tolerance (IGT), and without a lifestyle change, this state will worsen to type 2 diabetes in about 50% of the cases within a 10-year period. IGT is a reversible state, and much attention in primary prevention of type 2 diabetes has been devoted to find and to treat this group of high-risk individuals. Impaired glucose tolerance (IGT) as well as impaired fasting glucose (IFG), i.e., having a higher than normal plasma glucose in the fasting state but not after a meal, may be called prediabetic states (Ganz, 2005; Kumar & O'Rahilly, 2005).

Other effects of insulin resistance and high insulin secretion are the appearance of risk factors such as high blood pressure and a specific lipid disturbance, characterized by high levels of triglycerides and low levels of HDL-cholesterol. This lipid combination is relatively common and considered to be a strong risk factor for CVD. The combination of these multiple risk factors for diabetes and cardiovascular disease is called "the metabolic syndrome" (Fig. 1). Other names for this risk state are syndrome X, the deadly quartet, or the insulin resistance syndrome. The description above is based upon the portal-visceral hypothesis for the mechanism of developing insulin resistance. However, other mechanisms have also been discussed (Kumar & O'Rahilly, 2005).

Adipose Tissue as an Endocrine Organ

During the last 15 years, our knowledge of fat tissue has changed tremendously, from being just a reservoir for energy to being the largest endocrine organ in the body. The handling of energy intake and expenditure and of hunger and satiety



Risk Factors and Their Management, Fig. 1 The metabolic syndrome: the link between lifestyle, type 2 diabetes, and cardiovascular disease

as well as effects on blood pressure and inflammatory systems are regulated, at least in part, by hormones or hormone-like substances (adipokines) produced and secreted from fat cells in adipose tissue (Kumar & O'Rahilly, 2005).

Ectopic Fat Accumulation

A third possible mechanism for the development of insulin resistance and increased risk for diabetes is "ectopic fat" accumulation. The definition of ectopic fat is that it is accumulation of fat cells in other tissues than adipose tissue. It has been shown that ectopic fat in liver and muscle tissues is associated with central (liver) and peripheral (muscles) insulin resistance, and accumulation of fat droplets in the neighborhood of the beta cells in the pancreas has been associated with a disturbance in insulin secretion (Kumar & O'Rahilly, 2005).

Type 2 Diabetes and Cardiovascular Disease

From population studies, using different metabolic syndrome definitions, as much as 20–25% of the adult population has been found to have a metabolic syndrome. Besides having the risk of developing diabetes, the risk of getting CVD is two- to threefold higher among those with the metabolic syndrome. Today, type 2 diabetes, due to its strong correlation with CVD (macrovascular complications of diabetes), is by many considered to be in its essence a cardiovascular disease, and among diabetes patients, there is a three- to fourfold increased risk for CVD. Importantly, much points to the fact that the CVD risk already starts to rise when the individuals start to accumulate body fat and is clearly increased in the state of the metabolic syndrome, and even more so in impaired glucose tolerance. In other words, the risks of developing type 2 diabetes and cardiovascular disease should be seen as parallel phenomena, and not as a simple case of diabetes being followed by CVD (the "common soil" hypothesis). This has of course large implications on when in this process of development it is optimal to start the prevention or treatment of these risk states or diseases (Ganz, 2005; Kumar & O'Rahilly, 2005).

The strong association between diabetes and CVD could also be demonstrated from another point of view. In a recent Swedish study on acute myocardial infarction patients submitted to

hospital care and followed up 3 months later with among other things an oral glucose tolerance test, it was demonstrated that only 35% of the AMI patients had normal glucose concentrations. A majority of the cases (65%) had either unknown diabetes or prediabetes (Norhammar et al., 2002).

Other Related Diseases

The same kind of reasoning as above, using the same risk factor pattern, has also given rise to implications for other types of diseases (outcomes), such as certain types of cancers (mainly breast, colon, and prostate), dementia, and depression. However, our knowledge is much more limited in this area of research.

Management of Risk Factors

Behavior Modification and Long-Term Lifestyle Change

As discussed above, in reality, many of our most important risk factors for noncommunicable diseases, such as type 2 diabetes and cardiovascular disease as well as certain forms of cancer, dementia, and depression, are the same and are also associated with each other in a complex pattern of interrelationships, such as in the metabolic syndrome (Fig. 1). An individual's choice of lifestyle will have great impact on these relationships, and the metabolic syndrome may be seen as the link between the lifestyle of an individual and the risk to develop type 2 diabetes and cardiovascular disease for that individual. Of course, heredity also influences many of these interrelationships, but this is a risk factor that, at least today, is unmodifiable. Behavior modification inducing long-term lifestyle change with increased physical activity and a lowered energy intake, often based upon a low-fat high-fiber diet, and sometimes also the inclusion of stress management techniques in the lifestyle change, has been the standard for an intensive lifestyle change program. Studies using this approach often achieve a weight loss of 5–10% of the initial body weight (Barnett & Kumar, 2004; Burell & Lindahl, 2008; Ganz, 2005). Although, this is a relatively modest weight loss for someone having obesity, it has been shown to generate large beneficial effects on the metabolism. However, it seems crucial that the weight loss is achieved by a lifestyle change. An intensive lifestyle program induces a multitude of effects that protect against both cardiovascular disease and type 2 diabetes. In the Finnish Diabetes Prevention Study (DPS), a weight loss difference between the intensive lifestyle group and the control group of 2.7 kg after 2 years resulted in a reduction of diabetes development of 58% at the 3-year follow-up (Tuomilehto et al., 2001).

Effects of Physical Activity

There is a strong inverse relationship between physical activity, type 2 diabetes, and cardiovascular disease, and the evidence for this relationship must be considered as solid (Burell & Lindahl, 2008). Furthermore, a large body of evidence examining the effects of physical activity on cardiovascular risk factors has also documented beneficial effects, mainly a lowering of blood pressure and a less atherogenic lipid profile. A paradigm shift concerning physical activity was launched in 1995, proclaiming that even less intensive and shorter bouts of physical activity may have health promoting effects (Pate et al., 1995). It was shown that a dose corresponding to an energy expenditure of 1,000 kcal per week significantly lowered all-cause mortality by 20–30%, and CVD mortality possibly even more. This level of energy expenditure corresponds to about 30 min of moderately intensive physical activity each day, i.e., brisk walks, bicycling, and swimming. An updated version of this physical activity statement was published in 2007 (Haskell et al., 2007).

Effects of a Healthy Diet

In the last decade, our understanding of how nutrients and foods promote cardiac health or increase the risk for diabetes and cardiovascular disease has grown substantially, but the search for an optimal composition of food intake is far from over. Diets that are higher in monounsaturated fatty acids, fiber, and low glycemic foods (slow carbohydrates) appear to improve insulin resistance, blood glucose, and blood lipids. Additionally, three food intake strategies to prevent

cardiovascular disease have been suggested. First, to increase intake of unsaturated fats and decrease intake of saturated and trans-fats, second, to increase intake of omega-3 fatty acids, and last, to increase consumption of fruits, vegetables, nuts, and whole grains (Hu & Willett, 2002).

Adherence to a Long-Term Lifestyle Change

Two key features of such an intensive lifestyle program in order to achieve adherence are goal-setting and self-monitoring. The goals should be realistic, measurable, concrete, and engaging, and there should be both short- and long-term goals. Simple ways of self-monitoring key behaviors, such as food intake and physical activity, should also be included in such a lifestyle program (Burell & Lindahl, 2008; Ganz, 2005).

Management of Specific Risk Factors: High LDL-Cholesterol and High Blood Pressure

In addition to a comprehensive lifestyle program, some specific risk factors need to be treated with medications, either because the lifestyle program is insufficient to handle the risk factor in an optimal way or because healthy lifestyle change does not impact enough on the risk factor in question. In order to lower LDL-cholesterol, lipid-modifying drugs, especially use of statins, are the standard treatment in cases with familial high cholesterol levels and in patients with cardiovascular disease and type 2 diabetes (Faergeman, 2008). In order to control high blood pressure, a lifestyle change is often not enough, and the use of antihypertensive drugs is customary.

Risk Perception

Catherine Darker
Public Health & Primary Care, Trinity College, The University of Dublin, Dublin, Ireland

Synonyms

Risk aversion; Risk taking

Definition

Risk perceptions are beliefs about potential harm or the possibility of a loss. It is a subjective judgment that people make about the characteristics and severity of a risk.

Description

The degree of risk associated with a given behavior is generally considered to represent the likelihood and consequences of harmful effects that result from that behavior. To perceive risk includes evaluations of the probability as well as the consequences of an uncertain outcome. There are three dimensions of perceived risk – perceived likelihood (the probability that one will be harmed by the hazard), perceived susceptibility (an individual's constitutional vulnerability to a hazard), and perceived severity (the extent of harm a hazard would cause). Risk perceptions are central to many health behavior theories. For example, models that have been developed specifically to predict health behavior such as the health belief model (Rosenstock, 1966), protection motivation theory (Rogers, 1975), and the self-regulation model (Leventhal, Meyer, & Nerenz, 1980) all contain constructs that explicitly focus on risk perceptions. In addition, other models such as the theory of reasoned action (Fishbein & Ajzen, 1975), the theory of planned behavior (Ajzen, 1985), and social cognitive theory (Bandura, 1977) also include perceptions of risk indirectly via other constructs.

Biases and Heuristics in Risk Assessment

The estimation of risk tends to be a complex process that depends on factors such as the context in which the risk information is presented, the way the risk is being described, and also on personal and cultural characteristics. Tversky and Kahneman (1973) proposed that when faced with the difficult task of judging risk, people use a limited number of strategies, called heuristics, to simplify these judgments. These heuristics can be useful shortcuts for thinking, but they may lead to inaccurate judgments in some situations in which case they become cognitive biases. There are three broad biases that can affect risk perceptions and these are the availability heuristic, the representativeness heuristic, and anchoring and adjustment heuristic.

Availability heuristic is a phenomenon in which people predict the frequency or likelihood of an event, or a proportion within a population, based on how easily an example can be brought to mind (Tversky & Kahneman, 1973). Representativeness heuristic is an occurrence in which individuals assess the frequency of a particular event based solely on the generalization of a previous similar event (Gilovich, Griffin, & Kahneman, 2002). Anchoring and adjustment heuristic is a phenomenon in which people start with one piece of known information, known as an anchor, and then adjust said information to create an estimate of an unknown risk (Epley & Gilovich, 2006).

Psychometric Paradigm of Risk Assessment

The "psychometric paradigm" developed by Slovic, Fischhoff, and Lichtenstein was a landmark in research about public attitudes toward risks (Fischhoff, Slovic, & Lichtenstein, 1983; Fischhoff, Slovic, Lichtenstein, Read, & Combs, 1978; Slovic, Fischhoff, & Lichtenstein, 1980, 1982, 1985). These studies demonstrated that the public is not irrational. Ordinary people simply use a broader definition of "risks" than experts when making their judgments about which ones are of most concern to them. "Experts" base their risk ratings on the expected number of fatalities. "Lay people," in contrast, have a richer definition of risk. This incorporates a number of more qualitative characteristics such as "voluntariness" (whether people have a choice about whether they face the risk), "immediacy of effect" (the extent to which the effect is immediate, or might occur at some later time), and "catastrophic potential" (whether many people would be killed at once). Slovic et al.(1985) identified and analyzed 18 characteristics of this kind using factor analysis and found that they could be resolved into three factors broadly defined as "dread," "unknown," and "exposure." Further,

high perceived risk, and hence a desire for societal regulation, was associated.

Research within the psychometric paradigm turned to focus on the roles of affect, emotion, and stigma in influencing risk perception. Psychometric research identified a broad domain of characteristics that may be condensed into three high order factors: (1) the degree to which a risk is understood, (2) the degree to which it evokes a feeling of dread, and (3) the number of people exposed to the risk. A dread risk elicits visceral feelings of terror, uncontrollability, catastrophe, and inequality. An unknown risk is new and unknown to science. The more a person dreads an activity, the higher its perceived risk and the more that person wants the risk reduced (Slovic et al., 1982).

Risk taking

Definition

Risky behavior or risk-taking behavior is defined according to Trimpop (1994) as "any consciously, or non-consciously controlled behavior with a perceived uncertainty about its outcome, and/or about its possible benefits, or costs for the physical, economic or psycho-social well-being of oneself or others." In addition to this broad definition, there are other definitions of risky behavior depending on the field of research. While in the economic view, risk is defined in terms of the variability of possible monetary outcomes, in the clinical literature, the risk is generally defined as exposure to possible loss or harm (Schonberg, Fox, & Poldrack, 2011). Turner et al. (2004) described risk-taking behavior further as either a socially unacceptable volitional behavior with a potentially negative outcome in which precautions are not taken, such as speeding, drinking and driving, drugs abuse, unprotected sex, . . ., or a socially accepted behavior in which the danger is recognized (climbing, competitive sports,. . .). This description is important when looking at the relation between risk-taking behavior and injuries. It has been shown that risk-taking behavior is associated with an increased chance of sustaining an injury. However, this relation was not shown in the case of high-skilled, risk-taking sports (Turner, McClure, & Pirozzo, 2004). Risky behavior can be a direct consequence and manifestation of a risk-taking personality or of sensation-seeking personality. These can be reliably assessed by various existing questionnaires. In behavior medicine, risk behavior is an important factor to consider, since it is a predictor of various adverse health outcomes. In the domain of driving, risky behaviors, such as excessive speeding or driving under the influence of alcohol, are known predictors of traffic accidents (Jonah, 1997), one of the 10 leading causes of mortality worldwide. In infectious diseases, risky behavior in the form of unprotected sex or having multiple partners often co-occurs (Biglan et al., 1990) and can increase the risk of HIV/AIDS, a leading cause of death in Africa. Thus, identifying people likely to perform risky behaviors and developing and testing interventions to prevent risky behaviors are crucial for contributing to prevention of diseases and adverse health outcomes at the individual and social levels.

Coding RNA; Messenger RNA; mRNA; Noncoding RNA; Ribosomal RNA; rRNA; Transfer RNA; tRNA

Definition

Ribonucleic acid (RNA) is a chain of multiple nucleotides (a polynucleotide) consisting of a molecule of sugar (ribose), a molecule of phosphoric acid, and a nucleic base (uracil, cytosine, guanine, or adenine). In contrast to DNA, RNA is normally single-stranded. Its main function within the cell is the conversion of the genetic information into proteins, i.e., gene expression. There are different RNA molecules exerting different functions, the so-called coding and noncoding RNA. Coding RNA, also called messenger RNA (*mRNA*), copies information from the DNA and carries this information to the ribosome, the cell organelle where protein synthesis takes place. There are different forms of noncoding RNA with transfer RNA and ribosomal RNA being the most important. Transfer RNA (*tRNA*) molecules take amino acids and transport them to the ribosome. Ribosomal RNA (*rRNA*) is the fundamental part of the ribosome and catalyzes protein synthesis.

Research has demonstrated that various types of stressors modulate RNA. For instance, social isolation, chronic stress, and low socioeconomic status are associated with immunological impairment mediated via alterations in immune-related RNA expression. In contrast, there is also evidence for an RNA-regulating effect of positive psychological states.

Robert Wood Johnson Foundation

Stephanie Ann Hooker
Department of Psychology, University of Colorado, Denver, CO, USA

Basic Information

The Robert Wood Johnson Foundation (RWJF) is one of the world's largest private philanthropic foundations, with a mission of improving public health in the United States. Upon his death, Robert Wood Johnson II (of Johnson & Johnson Services Inc.) dedicated virtually all of his fortune to establish this foundation.

The RWJF funds projects that are "innovative" and have "measurable impact" in seven different program areas. These program areas include childhood obesity, coverage (health care), human capital (preparation of health professionals), pioneer (innovative health-related technologies), public health, quality/equality (health care), and vulnerable populations. Within these seven program areas, the RWJF funds a variety of different types of projects including service demonstrations, gathering and monitoring of health-related statistics, public education, training and fellowship programs, policy analysis, health services research, technical assistance, communications activities, and evaluations. In 2009, the RWJF funded $350 million in grants, and approximately 20% of the funding was dedicated to research-related projects.

Major Impact on the Field

The RWJF seeks to better society and the lives of Americans through its philanthropic contributions. Some notable past efforts include the creation of the 911 emergency response system across the United States; the introduction of new methods for the research, prevention, and treatment of tobacco use; and the establishment of the field of end-of-life/palliative care.

Each year, the RWJF publishes a book entitled *To Improve Health and Health Care: The Robert Wood Johnson Foundation Anthology*. The book focuses on approximately 10 different topics every year and describes why the foundation funded certain topics, what the program activities were, what was accomplished, how the program fits with RWJF, and what lessons were learned. The most recent volume (XIV) focused on health and health care of vulnerable populations. This anthology is one way the foundation examines its impact on public health, and it is available on the foundation's website.

Rumination

Yori Gidron
Faculty of Medicine and Pharmacy, Free University of Brussels (VUB), Jette, Belgium

Definition

Rumination is both a state and trait tendency to focus on negative events, emotions, and

symptoms, their occurrence, causes, and consequences (Nolen-Hoeksema, 1991; Rydstedt, Cropley, & Devereux, 2011). Multiple conceptualizations of rumination exist, each having its own measure, and tested in different contexts. The majority of research has tested and shown rumination to play a key role in the onset and maintenance of depression. However, some research also shows that it causes and maintains distress in physically ill patients (see review by Soo, Burney, & Basten, 2009). Rumination is a marker of poor adaptation, since it is thought to prolong one's psychophysiological response to a stressor even long after it has ended. In a review of this domain, Brosschot (2010) views rumination as part of perseverative cognitions, where people have a sustained cognitive representation of past stressors, beyond their mere existence. Brosschot also contends that much of the effects of rumination could also be unconscious, even impacting one's well-being during sleep. Furthermore, rumination is thought to mediate the association between stress and one's psychophysiological responses. Rumination, which amplifies one's failure to achieve goals, can be contrasted with more constructive self-reflection which is more distant and less immersed in one's experiences. Supporting this, among people moderately high on rumination, promotion failure predicted depressive symptoms. In contrast, among people high on self-reflection, promotion failure was not predictive of severe increases in depressive symptoms (Jones, Papadakis, Hogan, & Strauman, 2009). Looking at physiological indices of stress, Rydstedt et al. (2011) found that rumination interacted synergistically with job ambiguity (a known stressor) in relation to morning cortisol in British workers. As such, rumination amplified the effects of job ambiguity on a physiological marker of stress, namely, morning cortisol. Thus, rumination amplifies and worsens the impact of negative events, both in terms of their "duration," and in terms of their possible psychophysiological consequences. Some research shows that meditation can reduce levels of rumination, and this requires further research.

Definition

Behavioral medicine research is increasingly being influenced by theoretical models that explain individual differences in behavior and disease risk as a function of interrelated biological, behavioral, social, and contextual forces. This multi-level theoretical approach follows technical innovations that have made measuring the activity of many biological systems straightforward, portable, and cost efficient. Saliva, in particular, has received attention as a biospecimen; sample collection is perceived as feasible, cost-efficient, and safe, and salivary assays as reliable and accurate (see Table 1). A single oral fluid specimen can provide information about a range of physiologic systems, chemical exposures, and genetic variability relevant to basic biological function, health, and disease. The purpose of this review is to provide a road map for investigators interested in integrating this unique biospecimen into the next generation of studies in behavioral medicine.

Description

Oral fluid as a biospecimen: "Saliva" is a composite of oral fluids secreted from many different glands. The source glands are located in the upper posterior area of the oral cavity (*parotid gland* area), lower area of the mouth between the cheek and jaw (*submandibular gland* area), and under the tongue (*sublingual gland* area). There are also

Salivary Biomarkers, Table 1 Perceived advantages of oral fluids as a research specimen compared to serum

"Minimally invasive"	Considered "acceptable and noninvasive" by research participants and patients
	Collection is quick, non-painful, uncomplicated
"Safety"	Reduces transmission of infectious disease by eliminating the potential for accidental needle sticks
	CDC does not consider saliva a class II biohazard unless visibly contaminated with blood
"Self-collection"	Allows for community- and home-based collection
	Enables specimen collection in special populations
"Economics"	Eliminates the need for a health care intermediary (e.g., phlebotomist, nurse)
	Resources for collection and processing samples are of low cost and available
"Accuracy"	Salivary levels of many analytes represent the "free unbound fraction" or biological active fraction in the general circulation

Source: US Department of Health and Human Services (2000)

many minor secretory glands in the lip, cheek, tongue, and palate. A small fraction of oral fluid (i.e., crevicular fluid) comes from serum leakage, either from the cleft area between teeth and gums, or from mucosal injury or inflammation. In the presence of significant mucosal or epithelial inflammation, however, serum constituents may contribute substantially to oral fluids. Each secretory gland produces a fluid that differs in volume, composition, and constituents. Oral fluid is water-like in composition and has a pH (acidity) between 6 and 9; it has minimal buffering capacity, so substances placed in the mouth can change salivary acidity very quickly.

An understanding of how a given analyte makes its way into oral fluid is key to interpreting individual differences in that analyte, as well as its association with outcomes of interest. Many of the salivary analytes of interest in biobehavioral research are serum constituents (e.g., steroid hormones). Serum constituent analytes are transported into saliva either by *filtration* between the tight spaces between acinus or duct cells in the salivary glands, or by *diffusion* through acinus or duct cell membranes. In contrast, some analytes found in oral fluids are synthesized, stored, and released from the granules within the secretory cells of the salivary glands (i.e., enzymes, mucins, cystatins, histatins). Still others are components of humoral immunity (antibodies, complement) or compounds (cytokines) secreted by immune cells (neutrophils, macrophages, lymphocytes). In addition to these analytes, saliva contains sufficient cellular material to obtain high quantity and quality DNA (Zimmerman, Park, & Wong, 2007).

The *rate* of saliva secretion can significantly influence levels of salivary analytes produced locally in the mouth (e.g., alpha-amylase (sAA), secretory IgA) as well as those that migrate into saliva from blood by filtration (e.g., dehydroepiandrosterone-sulfate and other conjugated steroids) (Malamud & Tabak, 1993). Oral fluid secretion is influenced by many factors, including the day-night cycle, chewing movement of the mandibles, taste and smell, medications that cause dry mouth, as well as medical conditions and treatments that affect salivary gland function (e.g., radiation therapy, Sjögren's syndrome). It is important to note, therefore, that for analytes influenced by flow rate, the measured concentration or activity of the analyte (e.g., U/mL, pg/mL) must be multiplied by the flow rate (mL/min). The resulting measure is expressed as *output as a function of time* (e.g., U/min, pg/min).

Sample Collection: Even under normative-healthy conditions, more than 250 species of bacteria are present in oral fluids (Paster et al., 2001). During upper respiratory infections, oral fluids are highly likely to contain agents of disease. Oral fluid specimens should, therefore, be handled with *universal precautions* when used in research and diagnostic applications.

Saliva collection devices have historically involved cotton-based absorbent materials. Placed in the mouth for 2–3 min, oral fluids rapidly saturate the cotton; fluids are subsequently recovered by centrifugation or compression.

Most of the time, this approach is convenient, simple, and time-efficient. However, when the sample volume is small, the specimen can be diffusely distributed in the cotton fibers, making sample recovery problematic (Harmon, Hibel, Rumyansteva, & Granger, 2007). The process of absorbing oral fluid with cotton and other materials also interferes with several salivary immunoassays (Groschl & Rauh, 2006). Further, where in the mouth oral swabs are placed may affect the measured levels or activity of some salivary analytes (e.g., Beltzer et al., 2010). Standardizing swab placement instructions and monitoring compliance can minimize this threat to measurement validity.

In early studies, saliva flow was often stimulated using techniques that involved chewing or tasting various substances (e.g., gums, waxes, sugar crystals, powdered drink mixes). When not used minimally and/or consistently, some of these methods may change immunoassay performance (Granger et al., 2007). Indirectly, stimulants also influence levels of salivary analytes that depend on saliva flow rate (SIgA; dehydroepiandrosterone-sulfate (DHEA-S); Neuropeptide Y (NPY); Vasoactive Intestinal Peptide, (VIP)). Researchers are advised to avoid these techniques.

Collecting *whole saliva* by "passive drool" (Granger et al., 2007) is an alternative collection approach that minimizes many of the threats to validity described above. Briefly, participants imagine they are chewing their favorite food, slowly moving their jaws in a chewing motion, and allowing oral fluid to pool in their mouth. Next, they gently force the specimen through a short plastic drinking straw into a vial. The advantages of this procedure include the following: (1) A large sample volume may be collected relatively quickly (3–5 min). (2) Target collection volume may be confirmed by visual inspection in the field. (3) The fluid collected is a pooled specimen mixture of the output from all salivary glands. (4) The procedure does not introduce interference related to stimulating or absorbing saliva. (5) Collection materials are of very low cost. (6) Samples can be aliquoted and archived for future assays.

Blood Leakage into Oral Fluid: Blood poses a threat to the validity of salivary analyte measurements because most analytes are present in serum in much higher levels (10–100-fold) than in saliva. Specifically, to meaningfully index *systemic* (vs oral) biological activity, analyte levels in saliva must be highly correlated with levels measured in serum. This serum-saliva association depends, in part, on circulating molecules being appropriately and consistently transported into oral fluids (Malamud & Tabak, 1993). When the integrity of diffusion or filtration is compromised (e.g., through blood leakage directly into salivary fluid), the level of the serological marker in saliva will be affected. Blood leakage into oral fluid is more common among individuals with poor oral health (i.e., open sores, periodontal disease, gingivitis), certain infectious diseases (e.g., HIV), and tobacco users. Samples visibly contaminated with blood present varying degrees of yellow-brownish hue. Kivlighan and colleagues (2004) have proposed a five-point Blood Contamination in Saliva Scale (BCSS) that rates contamination from one (no visible color) to five (deep, rich, dark yellow or brown). Under healthy conditions, BCSS ratings ($N = 42$) averaged 1.33 ($SE = .08$); after microinjury caused by vigorous tooth brushing, ratings averaged 2.42 ($SE = .19$).

Particulate Matter and Interfering Substances: As noted above, items placed in the mouth can influence the integrity of oral fluid samples. Food residue in the oral cavity may introduce particulate matter in samples, change salivary pH or composition, and/or contain substances (e.g., bovine hormones, active ingredients in medications, enzymes) that cross-react with assays. Accordingly, research participants should not eat or drink for 20 min prior to sample donation. In the event that they do eat in this time window, participants should rinse their mouths with water. Importantly, however, they must wait at least 10 min after rinsing before a specimen is collected to avoid artificially lowering estimates of salivary analytes. Access to food and drink should be carefully planned and scheduled when study designs involve repeated sample collections over long time periods.

Sample Handling, Transport, and Storage: Typically, once specimens are collected, they should be kept cold or frozen. Refrigeration prevents degradation of some salivary analytes and restricts the activity of protolytic enzymes and growth of bacteria. Conservatively, it is recommended that samples be kept frozen. At minimum, samples should be kept cold (on ice or refrigerated) and frozen later on the day of collection. Repeated freeze-thaw cycles should be avoided. DHEA, estradiol, and progesterone are very sensitive to freeze-thaw, whereas DNA, cortisol, testosterone, and sAA are robust (up to at least three cycles). Freeze-thaw cycles should be considered in the context of plans to aliquot and archive frozen samples for future assays. It should also be noted that some salivary analytes (e.g., neuropeptides) may require specimens be collected into prechilled storage vials (Carter et al., 2007) or treated with neuropeptidase inhibitors (e.g., EDTA, aprotinin) to minimize degradation (Dawidson, Blom, Lundeberg, Theodorsson, & Angmar-Mansson, 1997). For large-scale national surveys, investigators working in remote areas, or patients collecting samples at home, freezing and shipping these frozen samples can be logistically complex and cost-prohibitive. In such circumstances, the impact of the handling and storage conditions should be documented by pilot work, or alternative biospecimens should be considered.

Medications: As noted above, many medications can indirectly affect some analytes by reducing salivary flow (e.g., diuretics, hypotensives, antipsychotics, antihistamines, barbiturates, hallucinogens, cannabis, and alcohol). Further, the condition for which the medication is prescribed or taken may itself directly influence analyte levels or activity (Granger, Hibel, Fortunato, & Kapelewski, 2009). Few behaviorally oriented studies involving salivary analytes comprehensively document medication usage. Further, a lack of normative data coupled with wide individual variation in salivary analyte levels makes it impractical to identify improbable values due to medication use (unless the value is not physiologically plausible).

Medications that are applied intranasally, inhaled, or applied as oral topicals (e.g., teething gels) are of particular concern. Residue in the oral cavity left by these substances may change saliva composition and/or interfere with antibody-antigen binding in immunoassays. The name, dosage, and schedule of all medications taken (prescription and nonprescription) within 48 h should be recorded and used to statistically evaluate the possibility that medication use is driving analyte-outcome relationships.

Assays for Salivary Analytes: Immunoassays are the main laboratory techniques employed to assess levels and activity of salivary analytes. Most immunoassays share two basic steps. Antibodies prepared against a specific salivary analyte are coated to the bottom of a microtiter plate well; these antibodies are used to capture the target molecules. Conversely, antigens may be coated to the wells to capture antibodies present in the sample. Most modern assays employ a labeling design known as enzyme immunoassay (EIA), which uses enzymes coupled to antigens or antibodies (i.e., the enzyme conjugate). To measure salivary cortisol, for instance, antibodies to cortisol are fixed to the plastic surface of a microtiter well. The specimen and a cortisol-enzyme conjugate are added into the well and incubated. During the incubation, cortisol from the sample and the cortisol-enzyme conjugate compete for available antibody-binding sites. The well is then rinsed to remove unbound materials. Next, a substrate is added that reacts with the enzyme conjugate to produce a color. The degree of color in each reaction well is measured in units of optical density (OD). The more cortisol in the sample, the lower the amount of cortisol-conjugate that is bound to the plate, and the lower the OD in that reaction well. To determine concentrations of cortisol in the unknown samples, samples with known concentrations of cortisol (standards) are analyzed as part of each assay. Results from the standards are used to establish a calibration curve from which concentration/volume units can be interpolated from OD.

Operationalizing Individual Differences: A "basal level" is the level or activity of an analyte that represents the "stable state" of the host during a resting period. One approach to assessing "basal" levels is to sample early in the

morning before the events of the day are able to contribute variation. However, day-to-day variability differs across salivary analytes depending on a number of factors including inherent variation in the production/release of the analytes, rate of their metabolism/degradation, and their sensitivity to environmental influences. Therefore, a single time-point measure of salivary analytes (other than invariant genetic polymorphisms) is unlikely to yield meaningful insight into an individual's true "basal level." The reliability of "basal" estimates of salivary analytes can be enhanced by sampling at the same time of day across a number of days, then aggregating (by averaging assay results or physically pooling specimens) across days.

Most salivary biomarker/analyte studies have involved a reactivity/regulation paradigm; this approach uses repeated samples to evaluate time-dependent changes in analytes (i.e., cortisol, sAA) in response to (or in anticipation of) a discrete event. The number of samples collected depends on the research question and logistical and practical issues (e.g., participant's tolerance for sampling burden). The optimal design for the measurement of salivary cortisol and sAA reactivity and regulation involves a pre-pre-[task]-post-post-post sampling scheme with samples collected on arrival to the lab (after consent) immediately before the task, then again immediately, 10-, 20- and 40-min post-challenge. Although some studies have yielded consistent mean-level differences in the patterns of cortisol response following a stressful or novel event, there are more often significant individual differences in stress-reactivity. Some individuals exhibit unexpected patterns of change (or no change), as well as continuously increasing or decreasing analyte levels over time.

An important component of variability in salivary analyte levels, both within and between individuals, is the diurnal rhythm. Most salivary hormone levels (e.g., cortisol) are high in the morning, decline before noon, and then decline more slowly in the afternoon and evening hours (Nelson, 2005). By contrast, levels of sAA show the opposite pattern with low levels in the morning and higher levels in the afternoon (Nater, Rohleder, Scholtz, Ehlert, & Kirschbaum, 2007). The nonlinear nature of these patterns requires multiple sampling time points to create adequate statistical models. A typical sampling design for salivary cortisol would involve sampling immediately upon waking, 30-min post-waking, midday (around noon), in the late afternoon, and immediately prior to bed.

Many analytical techniques have been used to model individual differences in diurnal rhythm including mean levels, evaluating the awakening response, and calculating summary measures of analytes over time (e.g., area under the curve, Pruessner, Kirschbaum, Meinlschmid, & Hellhammer, 2003). Another approach, growth curve modeling (McArdle & Bell, 2000), has recently gained popularity for a number of reasons. Briefly, growth models allow the level and slope of the diurnal rhythm to be examined in the same model and their distinct effects on predictors can be evaluated; they minimize the impact of error or noise in measured values; and the presence of individual differences in the diurnal rhythm can be statistically tested (e.g., McArdle & Bell, 2000).

Another analytical approach, hierarchical linear modeling (HLM) allows investigators to estimate values across the day for an individual, based on several samples (Bryk & Raudenbush, 1992). Then, deviations from these expected values can be predicted from momentary states and feelings (e.g., mood states) about activities reported at that time of day. Documenting everyday events and emotions that help explain changes in analyte levels or activity across a time period of interest may strengthen causal inference when paired with samples across multiple days. For example, in studies focusing on cortisol, samples are collected approximately 20 min after a diary entry. Computerized handheld devices have made self-assessments quite feasible.

Analytes in Saliva of Interest to Behavioral Medicine: To date, most biobehavioral research has focused on a small number of salivary analytes, that is, cortisol, testosterone, DHEA, and sAA. In fact, however, the salivary proteome has recently been characterized, and includes

Salivary Biomarkers, Table 2 Salivary analytes of potential interest to biobehavioral research

Endocrine		
Aldosterone	Estradiol, Estriol, Esterone	
Androstenedione	Progesterone; 17-OH Progesterone	
Cortisol	Testosterone	
Dehydroepiandrosterone, and -sulfate	Melatonin	
Adiponectin, leptin, ghrelin	Oxytocin, Vassopressin	
Immune/inflammation		
Secretory immunoglobulin A (SIgA)	Beta-2-microglobulin (B_2M)	
Neopterin	Cytokines	
Soluble tumor necrosis factor receptors	C-reactive protein (CRP)	
Autonomic nervous system		
Alpha-amylase (sAA)	Neuropeptide Y (NPY)	
Vasoactive intestinal peptide (VIP)	Chromogranin A	
Nucleic acids		
Human genomic	mRNA	
Mitochondrial	Microbial	
Bacterial	Viral	
Antibodies specific for antigens		
Measles	Hepatitis A	Herpes simplex
Mumps	Hepatitis B	Epstein-Barr
Rubella	Hepatitis C	HIV
Pharmaceuticals/environmental chemicals		
Cotinine	Alcohol	Pesticides
Meth-, amphetamine	Lithium	Metals
Methadone	Cocaine	Opiods
Marijuana (THC)	Caffeine	Phenytoin
Bisphenol-A (BPA)	Barbituates	

Sources: Cone & Huestis (2007); Malamud & Tabak (1993); Tabak (2007); US Department of Health and Human Services (2000)

more than 1,000 analytes (Hu, Loo, & Wong, 2007). These analytes provide information about the following: (1) systemic body processes, (2) local oral biology, (3) surrogate markers of physiological activity, (4) antibodies, (4) medications and environmental exposures, and (5) genetic factors. Each category of analyte is briefly discussed below and summarized in Table 2.

The first group of analytes is present in saliva because oral fluid represents an ultra-filtrate of analytes found in the bloodstream (i.e., serum constituents). Because of high serum-saliva correlations, measuring these analytes in saliva enables investigators to make interferences about systemic physiological states. Adrenal and gonadal hormones are exemplars of this category of salivary markers (e.g., see Table 2).

Most analytes in oral fluid are produced locally in the oral cavity and are secreted from salivary glands. While individual differences in these salivary analytes may reflect systemic processes, a major contributor is local oral biology (e.g., local inflammatory processes, oral health and disease). Many salivary immune and inflammatory markers such as neopterin, beta-2-microglobulin, cytokines, and C-reactive protein (see Table 2) fall into this category. Markers in this group may be less interesting to investigators outside the fields of oral biology and oral health.

A third group of salivary analytes is produced locally by salivary glands, but the levels vary predictably with systemic physiological activation. For example, sympathetic nervous system activation affects the release of catecholamines from nerve endings, and these compounds' action

on adrenergic receptors influences the activity of the salivary glands. For instance, salivary alpha-amylase is considered a *surrogate marker* of ANS activation, as are salivary measures of neuropeptide Y and vasoactive intestinal peptide.

Antibodies to specific antigens (e.g., HIV antibodies) comprise another group of salivary analytes. Table 2 offers several additional examples. Antibodies in oral fluids reflect an individual's immunological history and pathogen/microbe exposure. Further, depending on the specific antibody measured, they may reflect local and/or systemic immune activity. To date, relatively few biobehavioral studies have taken advantage of the information provided by salivary antibodies.

A variety of pharmaceuticals, abused substances, and environmental contaminants can be quantitatively monitored in oral fluids (see Table 2). One example is bisphenol-A (BPA) – a constituent of polycarbonate plastic and epoxy resins used in water bottles, baby bottles, and food containers that may leach into food and drink. Daily BPA exposures below the US Human Exposure limit (50 ug/kg/day) have been linked to permanent changes in genitalia, early puberty, and reversal of sex differences in brain structure (Maffini, Rubin, Sonnenschein, & Soto, 2006).

A final group of analytes has been made possible by recent technical advances allowing high quantity and quality DNA to be extracted from whole saliva (Zimmerman et al., 2007). Saliva samples collected to assess individual differences in salivary analytes, and biomarkers can yield reliable and valid information about genetic polymorphism.

Conclusion and Future Directions: As the gateway to the body, the mouth senses and responds to the external world, and reflects what is happening inside the body. Oral fluids provide insight into environmental exposures and contaminants, and serve as an early warning system for disease and infection. Genetic analyses using oral fluids can help explain individual differences, predict outcomes of medical treatments, and identify polymorphisms that affect disease risk and resilience. As the number of substances that can be reliably measured in saliva increases, oral fluid may become an increasingly attractive alternative to collecting blood. The wealth of information provided by salivary analytes has the potential to greatly enrich behavioral medicine research.

Salt, Intake

Kelly Flannery
School of Nursing, University of Maryland Baltimore, Baltimore, MD, USA

Synonyms

Sodium; Sodium chloride

Definition

Salt is a dietary element made up of sodium and chlorine (U.S. National Library of Medicine & National Institutes of Health, 2011a).

Description

A majority (90%) of sodium consumed comes from salt (Centers for Disease Control & Prevention, 2011). The body needs a small amount of sodium for fluid regulation, nerve impulse transmission, and muscle function. The kidneys are responsible for retaining sodium (if body stores are low) or excreting sodium through urine (if body stores are too high). However, if the kidneys do not excrete enough sodium the excess sodium will accumulate in the blood. This can lead to high blood pressure, from an increase in fluid volume in the arteries, ultimately putting additional stress on the heart (Mayo Clinic, 2011a; U.S. National Library of Medicine & National Institutes of Health, 2011a).

Recommendations

There are no specific sodium recommendations for those under 18 years of age. However, it is suggested these individuals consume a moderate intake of sodium (U.S. National Library of Medicine & National Institutes of Health, 2011b). There are two different recommendations for adult sodium intake based on specific characteristics. African-Americans, people with diabetes, people with high blood pressure, people with chronic kidney disease, and anyone over the age of 51 are more susceptible to blood pressure elevation from sodium; therefore, these individuals should limit sodium intake to less than 1,500 mg of sodium a day. The remaining American population should consume less than 2,300 mg of sodium a day. However, the general population will benefit by reducing their sodium to less than 1,500 mg a day (U.S. Department of Agriculture, & U.S. Department of Health and Human Services, 2010). In fact, the American Heart Association recommends the general public reduce their sodium intake to no more than 1,500 mg per day (American Heart Association Presidential Advisory, 2011). In addition, those with certain diseases (e.g., cirrhosis and congestive heart failure) may be recommended lower sodium intake levels by their primary care providers (U.S. National Library of Medicine & National Institutes of Health, 2011b).

A half of a teaspoon of salt is approximately 1,200 mg of sodium and one teaspoon of salt is approximately 2,300 mg of sodium (American Heart Association, 2011). More than 85% of Americans consume 2,300 mg of sodium or more a day; the average intake of sodium for Americans over 2 years of age is 3,400 mg per day (Centers for Disease Control & Prevention, 2011; U.S. Department of Agriculture, & U.S. Department of Health and Human Services, 2010). Diets high in sodium have been associated with an increased risk for high blood pressure, heart disease, and stroke (American Heart Association, 2011). Generally, when salt intake is reduced it only takes a few weeks for blood pressure to decrease (Centers for Disease Control & Prevention, 2011).

Identifying Sources of Sodium

Most foods naturally contain sodium (U.S. National Library of Medicine & National Institutes of Health, 2011b); however, this form of sodium only accounts for about 12% of daily sodium intake. An additional 11% of sodium intake comes from cooking at home and adding salt while eating. A majority (77%) of the sodium Americans consume comes from processed foods, foods bought at stores, packaged foods, and foods cooked at restaurants (Centers for Disease Control & Prevention, 2010). Sodium is added to foods to act as a preservative, cure meat, retain moisture, and enhance color and flavor (American Heart Association, 2011; U.S. Department of Agriculture, & U.S. Department of Health and Human Services, 2010). When food and beverages were grouped in 96 categories, the top six categories that contributed the most sodium to Americans' diets included yeast breads, chicken and chicken mixed dishes, pizza, pasta and pasta dishes, cold cuts, and condiments (National Cancer Institute, 2010).

Reading food labels is important for determining sodium intake because milligrams of sodium in food can vary even for the same type of food. For instance, a slice of frozen pizza can range from 450 to 1,200 mg of sodium (Centers for Disease Control & Prevention, 2011). However, caution should be used reading the %DV (daily value) on the food label because the percentage is based on 2,400 mg, which is 100 or 900 mg higher than the recommended daily sodium intake depending on recommended group (U.S. Department of Agriculture, & U.S. Department of Health and Human Services, 2010; U.S. Food and Drug Administration, 2011). Food packaging messages can be confusing (Centers for Disease Control & Prevention, 2011). For example, a package message titled unsalted or no salt added simply means no salt was added while processing the food; yet, reading the label is important because some of the ingredients may contain sodium (Mayo Clinic, 2011b). Additionally, looking at the ingredients list can help determine if sodium was added. Sodium is sometimes called different names; some examples include baking soda, monosodium

glutamate, and sodium nitrite (U.S. National Library of Medicine & National Institutes of Health, 2011b; Mayo Clinic, 2011b).

Methods for Reducing Sodium

Some methods for reducing the amount of sodium consumed can include (Mayo Clinic, 2011b; National Heart, Lung and Blood Institute, n.d.; National Library of Medicine & National Institutes of Health, 2010; U.S. Department of Agriculture, & U.S. Department of Health and Human Services, 2010; American Heart Association, 2011):

- Following specific heart-healthy diets (e.g., dietary approaches to stop hypertension, which is also called the DASH diet)
- Eating fresh foods
- Using food labels to purchase items low in sodium
- Ordering lower sodium items when eating out
- Using healthy salt substitutes to replace salt

Salutogenesis

Sefik Tagay
Department of Psychosomatic Medicine and Psychotherapy, University of Duisburg-Essen, Essen, North Rhine-Westphalia, Germany

Synonyms

Hardiness; Resilience; Self-efficacy; Sense of coherence

Definition

The medical sociologist Aaron Antonovsky (1923–1994) introduced the term "salutogenesis" which derives from the Latin "salus = health" and the Greek "genesis = origin." Antonovsky was mainly interested in the question of what creates

and what sustains health rather than explaining the causes of disease in the pathogenic direction (Antonovsky, 1979, 1987, 1993). In his salutogenetic model, he described health as a continuum between total ease (health) and total disease rather than a health-disease dichotomy. Therefore, his most important research question was: What causes health (salutogenesis)? (rather than what are the reasons for disease (pathogenesis)). The core concepts of salutogenesis show great conceptual overlap with the theory of "hardy personality" (Kobasa, 1979, 1982), the theory of "self-efficacy" (Bandura, 1977), and with the theory of "resilience" (Werner & Smith, 1982).

The central terms of the salutogenetic theory are sense of coherence (SOC) and general resistance resources (GRRs). Antonovsky postulates that the status of health and well-being depends on these personal and environmental resources (Antonovsky, 1979, 1987).

Description

Sense of Coherence (SOC)

Sense of coherence explains why humans in stressful situations stay well and are even able to improve their physical, mental, and social well-being. Antonovsky (1993) suggested that SOC depicts a stable and long-lasting way of looking at the world. He postulated that SOC is mainly formed in the first three decades of life and then becomes relatively stable.

Antonovsky defined SOC as a:

"Global orientation that expresses the extent to which one has a pervasive, enduring though dynamic feeling of confidence that (1) the stimuli, deriving from one's internal and external environments in the course of living are structured, predictable, and explicable; (2) the resources are available to one to meet the demands posed by these stimuli; and (3) these demands are challenges, worthy of investment and engagement" (Antonovsky, 1987, p.19).

The SOC consists of three dimensions (Antonovsky, 1987) as follows:

1. *Comprehensibility (cognitive component)*: The internal and external environments are interpreted as understandable, consistent, structured, and predictable.
2. *Manageability (behavioral component)*: Individuals consider resources to be personally available to help them cope adequately with demands or problems.
3. *Meaningfulness (motivational component)*: This dimension refers to the extent to which a person feels that life makes sense, and that problems and demands are worth investing energy in. Additionally, it determines whether a situation is appraised as challenging, and whether it is worth making commitments and investments in order to cope with it.

According to Antonovsky (1987) the third component is the most important aspect of SOC.

General Resistance Resources (GRRs)

The general resistance resources (GRRs) are biological and psychosocial factors that make it easier for people to perceive their lives as predictable, controllable, and understandable. Typical GRRs are money, intelligence, social support, self-esteem, ego-strength, healthy behavior, traditions, and culture. These types of resources can help the person to deal in a better way with the challenges of life. In general, the GRRs lead to life experiences that promote a better SOC (Antonovsky, 1987).

Measuring Sense of Coherence

With the Sense of Coherence (SOC) Scale, there is only one instrument that measures sense of coherence worldwide. Antonovsky (1987) developed the SOC as a self-report questionnaire with Likert-type items; higher scores indicate a better SOC. This instrument exists in a long form (SOC-29) and in a short form (SOC-13). In the long form, 11 items refer to "comprehensibility," 8 items refer to "meaningfulness," and 10 items refer to "manageability." The SOC scale is a reliable, valid, and cross-culturally applicable instrument. SOC seems to be a multidimensional concept rather than a unidimensional one (Eriksson & Lindström, 2005). By 2007, the SOC questionnaire has been used in at least 44 languages all over the world (Singer & Brähler, 2007).

Sense of Coherence and Health (Empirical Evidence)

Empirical evidence shows a strong association between SOC and mental health. A large number of studies consistently reveal a negative relationship of SOC with depression, anxiety, and posttraumatic symptoms (Antonovsky, 1993; Eriksson & Lindström, 2007; Tagay, Erim, Brähler, & Senf, 2006; Tagay, Mewes, Brähler, & Senf, 2009). In a recent review, Eriksson and Lindström (2007) synthesized empirical findings on SOC and examined its capacity to explain health and its dimensions. SOC was strongly related to perceived health. The stronger the SOC, the better the perceived health in general. This relation was manifested in study populations regardless of age, sex, ethnicity, nationality, and study design. Therefore, numerous authors assert that there is substantial empirical support for the idea that SOC promotes health. A strong SOC is associated with successful coping with the inevitable stressors that individuals encounter in the course of their daily lives, and therefore, with better outcomes (Antonovsky, 1993; Eriksson & Lindström, 2007). All in all, SOC seems to have a main, moderating, or mediating role in the explanation of health, and it seems to be able to predict health (Schnyder, Büchi, Mörgeli, Senky, & Klaghofer, 1999; Tagay et al., 2011).

Sample Size Estimation

J. Rick Turner
Cardiovascular Safety, Quintiles, Durham, NC, USA

Synonyms

Sample-size calculation; Sample-size determination; Study size

Definition

Sample-size estimation is the process by which a researcher decides how many subjects to include in a given clinical trial. Sample-size estimation is a critical part of the design of clinical trials, and, like all design issues, this must be addressed in the study protocol before the trial commences.

Description

Many sources use the terms sample-size determination or sample-size calculation when discussing this issue. The term sample-size estimation emphasizes that deciding on the sample size that will be employed in a clinical trial is a process of estimation that involves both statistical and clinical informed judgment and not a process of simply calculating the "right" answer. It is true that mathematical calculations are made in this process, and, for a given set of values that are placed into the appropriate formula in any given circumstance, a precise answer will be given. However, the values that are placed into the formula are chosen by the researcher.

Some of the values that need to be entered into the formula are typically chosen from a standard set of possibilities, with the researcher deciding which of several generally acceptable values is best suited for the intentions of a given trial. Other values are estimates based on data that may be available in existing literature or may have been collected in an earlier trial. These include the estimated treatment effect and the variability associated with the estimated treatment effect.

The likelihood of a successful outcome (at least from the point of view that "success" means obtaining a statistically significant result) can be increased by increasing the sample size. When designing a study, the researcher wants to ensure that a large enough sample size is chosen to be able to detect an important difference that does in fact exist. It is certainly possible that a trial can fail to demonstrate such a difference simply because the sample size chosen was too small. Therefore, it might appear reasonable to think that a very big sample size is a good idea. However, increasing the sample size increases the expenses, difficulties and overall length of a trial. Somewhere, for each researcher and each study, an acceptable sample size needs to be chosen that balances the likelihood of a statistically significant result with the cost and time involved in conducting the clinical trial.

Several variables need to be considered in the process of sample-size estimation. The values of these variables in any given case can be chosen by the researcher based on several considerations. Relevant terms include:

- Type I errors and Type II errors. A Type I error occurs when a significant result is "found" when it does not really exist, and a Type II error occurs when one fails to find a significant difference that actually exists.
- The probability of making a Type I error, α. This is also the level of statistical significance chosen, typically 0.05, but it is possible to choose 0.01 or even more conservative values.
- The probability of making a Type II error, β. A probability value must be between 0 and 1: therefore, β will be between 0 and 1.
- Power, calculated as $1 - \beta$. Since the probability represented by β will be between 0 and 1, power will also be between 0 and 1 since it is defined as $1 - \beta$. The power of a statistical test is the probability that the null hypothesis is rejected when it is indeed false. Since rejecting the null hypothesis when it is false is extremely desirable, it is generally regarded that the power of a study should be as great as practically feasible.

Sample-size estimation can be performed for any study design. In each case, the respective formula will be used to estimate the sample size required. For the formula used in the type of study design discussed in some entries in the Methodology section (i.e., a comparison of a new behavioral medicine treatment or intervention with an existing one), each of the variables we have discussed will have certain influences on the sample size, N, that will be given by the formula. These influences, i.e., their relationships with

N given that all of the others remain the same, can be summarized as follows:

- The smaller the chosen value of α, the larger the value of N that will be given.
- The smaller the chosen value of β, the larger the value of N that will be given. This is because power is defined as 1 − β. As β decreases, power increases; as power increases, the larger the value of N that will be given.
- The larger the standardized effect size, the smaller the value of N that will be given. The standardized treatment effect is the estimated treatment effect divided by the variability associated with it.

Sarcopenia

Oliver J. Wilson and Anton J. M. Wagenmakers
School of Sport and Exercise Sciences, University of Birmingham, Edgbaston, Birmingham, UK

Synonyms

Anabolic resistance; Disuse atrophy; Skeletal muscle atrophy

Definition

Sarcopenia is the progressive involuntary loss of skeletal muscle mass, strength, and function with age. Sarcopenia is derived from Greek "sarx" and "penia," literally meaning "loss of flesh."

Description

The global population aged 60 years or older is expected to double from 600 million in the year 2000 to 1.2 billion by 2025 and reaching nearly 2 billion by 2050 (United Nations, Department of Economic & Social Affairs, 2002). In the UK, the number of people aged >65 years will nearly double 61% from 10 million in 2010 to 19 million by 2050 (Office of National Statistics, 2012). However, a healthy life expectancy does not follow in parallel, suggesting that the global population is living longer with detrimental aging-related diseases such as the metabolic syndrome, type 2 diabetes, cardiovascular disease, and inflammatory diseases (WHO, 2008). A common result of the aging process is the loss of an independent lifestyle. Although the causes are varied, an important contributor is the loss of mobility and the associated risk of accidental falls. At present, 30% of people aged >65 years fall each year in the UK, and the estimated annual cost to the National Health Service in the UK is £1 billion. Consequently, meeting the future demand and associated costs of aging will prove challenging for health-care provision.

A key contributor to the increased risk of accidental (fatal) falls, dependency, and self-reported disability is sarcopenia, the progressive involuntary loss of skeletal muscle mass, strength, and function with age. Sarcopenia is derived from Greek "sarx" and "penia," literally meaning "loss of flesh." It is estimated that 20% of 70-year-olds and 50% of people aged 80 years and over have sarcopenia (Narici & Maffulli, 2010). The loss of muscle mass and strength with age is evident even in those who engage in regular aerobic or resistance exercise. Sarcopenia is more notable in lower than upper limbs and is generally more prevalent in women than men.

Sarcopenia, Table 1 Summary of the potential mechanisms underpinning sarcopenia

Whole body
Reduced physical activity and muscle disuse
Loss of motor neurons
Reduced growth hormone and insulin-like growth factor-I production
Chronic pro-inflammatory state
Increased glucocorticoid production and receptor activity
Malnutrition
Muscular
Reduced number and proliferative capacity of skeletal muscle satellite cells
Mitochondrial DNA mutations and apoptosis
Increased intracellular production of glucocorticoids
Impaired insulin mediated increase in (micro)vascular blood flow
Blunting of the effects of insulin and amino acids on muscle protein synthesis
Poor transcriptional responses of muscle to exercise and nutrition

It is also highly associated with osteoporosis and hip fractures in women. Consequently, the higher life expectancy in women coupled with the higher prevalence of sarcopenia means women are more likely than men to spend their final years of life receiving institutionalized care (Narici & Maffulli). The genesis of sarcopenia can be attributable to physical inactivity, inadequate nutrition, and a chronic pro-inflammatory state among other factors (Table 1).

Sarcopenia can be masked by weight stability due to a concomitant increase in fat mass. However, the prolonged accumulation of fat mass can lead to obesity, resulting in "sarcopenic obesity." This presents further complications as excess fat mass which, in association with chronic low-level pro-inflammatory cytokines, can result in the development of insulin resistance in a variety of tissues. These include the endothelium of the microvasculature and skeletal muscle, leading to periods of hyperglycemia, hyperlipidemia, and the development of non-insulin-dependent diabetes mellitus (type 2 diabetes) and cardiovascular disease (Wagenmakers, van Riel, Frenneaux, & Stewart, 2006).

Aging Muscle

In young lean adults, skeletal muscle mass accounts for nearly 60% of total fat-free body mass but accounts for just 45% in elderly individuals. The loss of muscle cross-sectional area is ~40% between 20 and 60 years of age, with men demonstrating greater decreases in muscle mass than women. Consequently, there is a corresponding reduction in knee extensor muscle strength between 20% and 40% in both groups and up to 50% in those aged >90 years. There is also a loss of muscle power, declining at a greater rate than the loss of muscle strength.

The loss of muscle mass is linked to whole muscle and individual muscle fiber atrophy. Aging slow-twitch type I fibers atrophy in size to about 75% of younger individuals, but fast twitch type II fibers but fast twitch type II fibres atrophy in size to about 43% of their younger counterparts (Andersen, 2003). Further changes include the infiltration of fat and connective tissue within the muscle, fiber necrosis, fiber-type grouping, and a reduction in type 2 fiber satellite cell content (Koopman & van Loon, 2009).

A reduction in the oxidative capacity of skeletal muscle is also observed with age and is likely attributable to a reduction in mitochondrial content and/or function. This results in poor endurance and increased fatigability, compromising the ability to live an independent lifestyle. Poor oxidative capacity is also mechanistically linked to the development of insulin resistance and type 2 diabetes.

Protein Metabolism in the Elderly

The maintenance of muscle mass depends on the balance between muscle protein synthesis (MPS) via anabolic stimuli (feeding, muscle contraction, anabolic hormones) and muscle protein breakdown (MPB) via catabolic stimuli (fasting, disuse, pro-inflammatory cytokines). Where muscle protein synthesis exceeds protein breakdown, hypertrophy occurs, whereas the reverse is true for muscle atrophy. Sarcopenia is therefore associated with a removal of

anabolic stimuli, an increase in catabolic stimuli, or a combination of the two.

Early studies suggested basal MPS rates were lower in the elderly compared with young, but when the results are extrapolated across a year, a substantial loss in muscle mass will occur that far exceeds the modest decline observed with healthy aging. It is now generally accepted that in healthy physically active elderly individuals, rates of basal MPS and MPB equal that of younger individuals (Koopman & van Loon, 2009). Instead, sarcopenia might be the result of a blunted response to anabolic stimuli, termed "anabolic resistance" (Rennie et al., 2010).

The ingestion of amino acids and/or protein increases plasma insulin concentrations which independently and additively stimulates MPS and inhibits MPB, leading to a positive net protein balance. However, some studies suggest the anabolic response to ingested essential amino acids is blunted in the elderly compared with young controls (Rennie et al., 2010). Interestingly, some studies have suggested that by increasing the leucine content of the meal, it is possible to increase elderly MPS further (Rennie, 2005).

The current recommended daily allowance (RDA) for habitual protein intake in the elderly is 0.8 g/kg body mass per day, but this might not be sufficient for optimizing exercise-induced gains in muscle mass. It has been suggested that increasing the daily dietary intake of protein (and thus amino acid availability) beyond the RDA might overcome the anabolic resistance and further increase exercise-induced gains in muscle mass. However, when daily protein intake was set at either 0.9 g/kg body mass (adequate) or 1.2 g/kg body mass (moderately high) during a 3-month resistance training study, the gains in exercise-induced muscle mass did not differ between the high and low dose (Koopman & van Loon, 2009).

At the molecular level, the anabolic resistance to plasma insulin and amino acid availability might be attributed to an age-associated reduction in the content, phosphorylation, and activity of key insulin-signaling proteins within the Akt-mTOR pathway (Rennie, 2005). These defects may contribute toward sarcopenia by impairing the sensing and transduction of insulin and/or amino acid-dependent signaling, thereby limiting the stimulation of MPS and inhibition of MPB.

Resistance Training in the Elderly

Resistance exercise training is a potent stimulator of MPS, leading to increased muscle mass and strength in the young and the elderly, frail elderly, and in older individuals presenting with comorbidities. Indeed, the elderly respond to resistance programs training with similar relative gains in limb muscle mass, size, strength, and power as the young. Resistance training therefore offers an effective strategy to counteract sarcopenia and improve functional muscle capacity.

The American College of Sports Medicine (ACSM) Position Stand for Exercise and Physical Activity in Older Adults (Chodzko-Zajko et al., 2009) recommends progressive resistance training at least 2 days per week using 8–10 exercises involving the major muscle groups over 8–10 repetitions. However, even a single weekly bout of resistance training has been shown to increase muscle strength in elderly individuals. After a 3-month resistance training program, an increase in muscle strength of more than 100% has been reported in the elderly with similar relative improvements in muscle strength observed in men aged 90 years and older. This is associated with an increase in muscle cross-sectional area attributable to hypertrophy of type I and type II fibers (Burton & Sumukadas, 2010).

Gains in muscular endurance ranging from 34% to 200% have also been reported after completing moderate to high-intensity resistance training (Chodzko-Zajko et al., 2009). This likely stems from an increase in mitochondrial number, size, and function and has the result of improving skeletal muscle insulin sensitivity and glucose uptake (Dela & Kjaer, 2006).

Conclusion

A growing global population of elderly individuals presents a number of health-care challenges

that will strain health-care provision and increase socioeconomic costs. The development of sarcopenia contributes to the increased risk of falls, fractures, poor mobility, and a reduced ability to lead an independent lifestyle. The resulting reduction in physical activity contributes to the development of insulin resistance, type 2 diabetes, hypertension, and cardiovascular disease. Although aging skeletal muscle can respond to protein intake, peak rates of MPS are blunted compared with the young, suggesting an anabolic resistance, and this may contribute to sarcopenia. However, resistance exercise is a potent stimulator of MPS, and progressive resistance training results in improved muscle mass, strength, and metabolic health.

Scale Development

Yori Gidron
Faculty of Medicine and Pharmacy,
Free University of Brussels (VUB), Jette,
Belgium

Definition

Scale development is an essential stage in the assessment of constructs and variables in behavior medicine, and in any social and biomedical

science. Scales are used for assessment of self-reported variables including mood, daily disability, various types of symptoms, adherence to recommended diet, etc. Though there is no explicit "rule" for the stages of scale development, certain steps need to be included for claiming that a scale is reliable and valid. The reliability of a scale is very important and refers to its repeatability and lack of measurement error. This is tested by internal-reliability tests (Cronbach's α) and by a test-retest reliability of scores over time. Validity is an essential aspect of a scale and refers to the extent to which it measures what it claims to measure. This is tested by several manners including "face validity," concurrent validity, construct validity, and criterion validity. When developing a scale, it is essential to have a clear definition of the concept it refers to. Thus, for example, an anxiety scale should not have items assessing depression since these are not the same construct. After choosing an acceptable definition for the construct, a group of "experts" on the construct meets to provide items or even topics related to the construct, from which the researcher creates items. The chosen items will reflect the most common topics or items suggested by the expert panel. The panel can be experts from the field (psychologists, physicians, etc.) and patients who experienced the issue under investigation, thus reflecting experienced "experts." Then, the investigator can ask another group of experts or patients to rate the relevance of each item to the construct, reflecting face validity. The items with a mean relevance above a chosen criterion will be selected for the preliminary scale. Next, the researcher administers the scale to a larger sample, with theoretically relevant additional tests. This will enable to test the internal reliability, concurrent validity against another scale assessing the same construct, and the construct validity against scales assessing theoretically related constructs. Finally, an acceptable criterion (e.g., ill vs. healthy sample) will enable to test the scale's criterion validity. Predictive validity can also be tested by examining whether the scale's scores predict a certain event or outcome in future, beyond the effects of known confounders. These steps are needed for scale development, to verify a scale's reliability and validity, for use in research and clinical evaluations.

Schneiderman, Neil

Neil Schneiderman
Department of Psychology, Behavioral Medicine Research Center, University of Miami, Coral Gables, FL, USA

Biographical Information

Neil Schneiderman

Neil Schneiderman was born in Brooklyn, New York, on February 24, 1937. He has been married to his wife Eleanor since 1960 and is the father of three children and grandfather of five. Schneiderman received his A.B. degree from Brooklyn College, spent 2 years in the US Army, earned his Ph.D. degree in Psychology from Indiana University, and received postdoctoral training in neurophysiology and neuropharmacology in the Physiological Institute of the University of Basel, Switzerland. Schneiderman was appointed as assistant professor at the University of Miami, Coral Gables, Florida, in 1965, rising through the ranks to become professor in 1974. He subsequently received secondary appointments as professor of Medicine, Psychiatry and Behavioral Sciences, and Biomedical Engineering. In 1989, he was awarded an endowed chair as the James L. Knight Professor of Health Psychology. Since 1986, he has served as the director of the Division of Health Psychology in the Department of Psychology and as director of the University of Miami Behavioral Medicine Research Center. He also served extensively as chair of the NIH-funded University of Miami General Clinical Research Center Advisory Committee. Schneiderman has directed pre- and postdoctoral NIH training grants involving cardiovascular disease from the National Heart, Lung, and Blood Institute (NHLBI) since 1979 and HIV/AIDS from the National Institute of Mental Health (NIMH) since 1993.

Schneiderman was the second editor in chief of the journal *Health Psychology* before becoming founding editor in chief of the *International Journal of Behavioral Medicine*. Within the NIH, he served as a member of the Biopsychology Study Section, NHLBI Research Training Review Committee, and NIMH Health Behavior and Prevention Review Committee. In the American Psychological Association (APA), he was chair of the Board of Scientific Affairs and is a fellow in the Divisions of Experimental Psychology (3), Behavioral Neuroscience and Comparative Psychology (6), and Health Psychology (38) as well as a former president of Division 38. A founding fellow of the Academy of Behavioral Medicine Research, Schneiderman later served as president of that organization. Schneiderman also served as president of the International Society of Behavioral Medicine (ISBM). He is a fellow of the Society of Behavioral Medicine and of the American College of Clinical Pharmacology. He is also the recipient of the APA Distinguished Scientific Contribution Award (1994), Society of Behavioral Medicine Distinguished Scientist Award (1997), and ISBM Outstanding Scientific Achievement Award (2004).

Major Accomplishments

Schneiderman's first two empirical research articles were published in *Science* in 1962. Written with his academic mentor, Isadore Gormezano, the papers described animal models of eyelid and nictitating membrane Pavlovian conditioning in rabbits. These preparations were suitable for concomitantly studying behavioral and neurophysiological processes in conscious, minimally restrained animals. Subsequently, Schneiderman added heart rate conditioning to the repertoire of animal models, and for the next several decades, he and his colleagues traced neuronal pathways involved in Pavlovian conditioning of cardiovascular responses in rabbits. This began with identifying the cells of origin of vagal cardioinhibitory motoneurons in the rabbit medulla, using histochemistry, microstimulation, and single neuron extracellular electrophysiological recordings, and continued with mapping the central nervous system pathways that mediated conditioned and unconditioned cardiovascular adjustments. The study of central nervous system pathways mediating differentiated patterns of cardiovascular adjustments also led Schneiderman and his colleagues including Marc Gellman, Barry Hurwitz, Maria Llabre, and Pat Saab to conduct an important series of psychophysiological studies in humans. They described differentiated patterns of neurohormonal and cardiovascular responses to separate behavioral stressors as a function of race, gender, and hypertensive status. These responses were also shown to be influenced by such psychosocial factors as harassment and hostility. In recent years, Schneiderman has

collaborated with Philip McCabe, Armando Mendez, and other Miami scientists in documenting the psychosocial prevention of atherosclerosis progression in a rabbit model of coronary artery disease.

Because of Schneiderman's interest in relationships among biological regulation, psychosocial factors, and disease processes, it was not surprising that he also joined with colleagues including MaryAnn Fletcher, Gail Ironson, and Nancy Klimas relatively early in the HIV/AIDS epidemic to study relationships between psychosocial variables and endocrine-immune regulation in HIV infected patients, when AIDS was beginning to ravage the Miami community. This, in turn, led Schneiderman, Michael Antoni, and their collaborators to begin to use group-based cognitive behavior therapy and relaxation training in randomized controlled trials to influence psychosocial, endocrine, and immune factors and even to reduce HIV viral load to undetectable levels in patients who were failing their regimen of highly active antiretroviral drugs.

Schneiderman's broad research experience, including intervention studies with clinical patients, prepared him to serve as principal investigator of the Miami Field Center for the NIH/NHLBI "Enhancing Recovery in Coronary Heart Disease Patients (ENRICHD)" randomized trial. The trial compared cognitive behavior therapy and usual care in post-myocardial infarction patients. Although that trial produced null results in terms of morbidity and mortality, Schneiderman and colleagues conducted a secondary analysis that suggested that the trial appeared to decrease morbidity and mortality in White men, but not in women or minority patients. Based on the supposition that the null result in the ENRICHD trail was due to the protocol not being sufficiently tailored to women, Schneiderman joined with Kristina Orth-Gomér and other Swedish colleagues to conduct the "Stockholm Women's Intervention Trial for Coronary Heart Disease (SWITCHD)." This trial, which used group-based cognitive behavior therapy and relaxation training in women previously hospitalized for myocardial infarction or coronary revascularization, showed a significant decrease in mortality rate for the intervention compared with a usual care group. Similar results have now also been reported by others.

In addition to Schneiderman's contributions in basic science and in clinical trials research, he has been actively involved in population-based observational studies such as those with Ronald Goldberg and Jay Skyler. As the principal investigator of the Miami Field Center of the NIH/NHLBI multicenter Hispanic Community Health Study/Study of Latinos, Schneiderman and his colleagues in Miami, including Frank Penedo and David Lee, as well as investigators in the Bronx, Chicago, and San Diego are characterizing the health status and disease burden of Hispanic adults living in the United States, describing the positive and negative consequences of immigration and acculturation in relation to lifestyle and access to health care and assessing likely causal factors of disease in this diverse population. The study has been examining 16,000 Hispanic men and women who have now completed a rigorous 6.5-h baseline exam and participated in an overnight sleep study. Longitudinal follow-up is currently documenting the incidence of acute myocardial infarction, heart failure, resuscitated cardiac arrest, cardiac revascularization, stroke, transient ischemia attack, asthma, and mortality. In summary, Schneiderman's major contributions have been in terms of basic science, population-based observational studies, and randomized clinical trials.

Screening

Yori Gidron
Faculty of Medicine and Pharmacy, Free University of Brussels (VUB), Jette, Belgium

Definition

Screening refers to the process of surveying a population or sample of a population, in the attempt to identify people at risk for or with a given health condition. Screening is a crucial part of epidemiology, as it informs about the prevalence and risk factors of various health conditions in a population. Furthermore, screening is crucial for preventive medicine, since it enables to identify people who may benefit from primary, secondary, or tertiary interventions. Screening for primary prevention reflects identifying people without a risk factor (e.g., hypertension, depression), to prevent the risk factor and subsequent illnesses. Screening for secondary prevention could be among people with a risk factor, to prevent an illness. And screening for tertiary prevention would be done to prevent relapse or mortality in people already ill (e.g., after a first myocardial infarction). Screening could be in relation to psychosocial factors such as hostility or anxiety, behavioral risk factors of disease such as smoking or excessive alcohol drinking, and for genetic profiles. For implementing screening tests in clinical use to reliably predict disease risk, it is crucial to know the relative risk for a disease in people high and low on a screening risk factor as well as the correct value of "false positives" (Wald & Morris, 2011). It is of outmost importance to identify the criteria or cutoffs for screening in clear, precise, and operational manners (e.g., smoking more than 10 cigarettes/day, depression score above 10 on the Center for Epidemiological Studies Depression scale). Screening then enables either to study specific sub-populations at risk for health conditions, or for treating them. One important criterion for screening tests is their accuracy. A test is thought to be 95% accurate if in 95% of the times it predicts correctly who has a disease (sensitivity) and if 95% of the time it predicts correctly who does not have a disease (specificity). Screening also enables to increase one's therapeutic and statistical effects, since by excluding people below a certain cutoff, researchers can prevent a "floor effect" of therapeutic effectiveness. The cutoffs used to screen are a function of previously defined cutoffs from research or clinical studies, a function of how severe a risk the researchers aim to indentify, and the available therapeutic resources that can be allocated for treating the "screened in" subpopulation later. Furthermore, in randomized-controlled trials (RCT), the more strict screening criteria are, the longer could be the trial's duration as the sought patient profile becomes more rare. Thus, the screening criteria are a function of the research question and available resources for such screening and subsequent treatment, and this is a vital part of clinical epidemiology and research and of therapeutic interventions.

Screening, Cognitive

Richard Hoffman
Academic Health Center, School of Medicine-Duluth Campus University of Minnesota, Duluth, MN, USA

Synonyms

Cognitive impairment tests; Cognitive status tests; Dementia screening tests; Mental status examination

Definition

Cognitive screening is a brief, performance-based assessment of one or more domains of neurobehavioral or cognitive functioning. These assessments typically are completed using standardized cognitive screening tests that can be completed at bedside or in the clinic in 20–30 min or less, often accompanied by interview information elicited from family members or other informants who know the examinee well and can comment on their observations about the examinee's behaviors or changes in their behaviors.

Description

Cognitive screening tests are very commonly used in behavioral medicine, neuropsychiatry, and primary care medicine. Surveys indicate that cognitive screening instruments are used by over 50% of practitioners in neuropsychiatry and such tests have become a mainstay in the practice of medicine over the course of the last 35 years. Because cognitive screening tests are brief and require a minimum of specialized testing equipment, they can in most cases be administered at bedside, in a busy clinic, or in the emergency department and serve to identify those patients who might benefit from more extensive workups, including neuroimaging, metabolic assays, and blood work, or more extensive neuropsychological testing. Cognitive screening tests are used as one central component in the initial differential diagnosis of delirium versus dementia and are perhaps most frequently used in the initial screening for dementias and mild cognitive impairment (MCI), both of which are underdiagnosed in their earliest stages in primary care practice due to the subtlety of their initial presenting symptoms.

Changes in cognitive functioning are frequently seen as a consequence of a number of neurological and general medical diseases, prominently including dementias and degenerative diseases of the cerebral cortex and subcortical regions of the brain. In addition to central nervous system diseases, cognition may also be affected by other systemic diseases, including respiratory, cardiovascular, and renal diseases as well as some infectious diseases, diseases of the liver and pancreas, nutritional deficiencies, metabolic diseases and diabetes, adverse effects of medications, and exposure to toxic substances. Judicious use of cognitive screening instruments can provide evidence to suggest an underlying medical disorder heretofore undiagnosed and may help guide the use of medications and medication dosages, as well as provide information that may prompt the treatment of reversible conditions, such as reversible dementias and pseudo-dementias.

In neuropsychiatry, cognitive screening tests can help detect deficits associated with disorders

that are commonly missed in a standard psychiatric intake interview, especially in emergency room settings, including patients who present with mild disorientation or evidence of possible substance abuse. In addition, many primary psychiatric disorders have significant effects on cognition, such as affective disorders and schizophrenia, and some focal neurological disorders such as focal strokes, neoplasias, and seizure disorders may have combined cognitive and affective sequelae.

Among the most commonly used and well-researched brief cognitive screening tests are the Mini-Mental State Examination (MMSE), the Cognitive Capacities Screening Examination (CCSE), and the Short Portable Mental Status Questionnaire (SPMSQ), but there are numerous cognitive screening tests available to practitioners at the present time and these are listed in Table 1. Although there is considerable variability in the component sections of the cognitive

screening tests listed in Table 1, in general each contains some assessment of orientation (does the patient know who they are, where they are, and know the day and date), attention and concentration, language skills, memory and immediate recall of verbal information, and visuaospatial or drawing/copying skills. Most cognitive screening tests are designed to be completed within 10 min or less. The BIMC, the ACE-R, the CASI, the Cognistat, the RBANS, the HSCS, and the CAMCOG-R contain more extensive subtests and may require up to 30 min to complete. The Mattis Dementia Rating Scale requires 20–45 min to complete and provides assessment of attention, initiation perseveration, visuospatial construction, reasoning, and memory.

Since 1988, there have been several cognitive screening tests designed to be administered by phone, typically used in epidemiological studies as more extensive follow-up instruments after an initial administration face-to-face of a brief screening instrument such as the MMSE or the SASSI. Five such instruments are listed in Table 1.

Also listed in Table 1 are three guided interview or informant-based cognitive screening instruments which are designed to document information from family members or caregivers of patients regarding observed cognitive decline, changes in behavior, or – in the case of the Deterioration Cognitive Observee (DECO) instrument – changes in activity level, long-term memory, short-term memory, visuospatial processing, and new skill learning. Although these can be used as stand-alone measures, they are perhaps best used to complement the findings from cognitive screening tests directly administered to the patient in question.

There is now considerable interest in the development of cognitive screening tests for specific at-risk populations, and recent examples include two cognitive screening tests designed to detect the early signs of AIDS-related dementia in AIDS patients (the High Sensitivity Cognitive Screen test and the HIV Dementia Scale) and a recently developed test to screen for post-concussion cognitive changes, the Immediate Post-Concussion Assessment and Cognitive Testing (ImPACT).

With the aging of the population has come an increased interest in cognitive screening in geriatric populations and the increased need to identify early signs of dementia and early signs of mild cognitive impairment, especially as new treatments are developed that are capable of modifying the progression of dementias. In primary care medicine, the standard of practice in the very near future may well include cognitive screening of all patients over the age of 75 in addition to screening of all younger patients when there is a reason to suspect cognitive impairment.

Seasonal Affective Disorder

Kathryn A. Roecklein and Patricia M. Wong
Department of Psychology, University of Pittsburgh, Pittsburgh, PA, USA

Synonyms

Bipolar disorder, with seasonal pattern; Major depressive disorder, with seasonal pattern

Definition

The most common presentation of seasonal affective disorder (SAD) is recurrent depressive episodes in winter followed by spring remission (Rosenthal et al., 1984). SAD is diagnosed according to the American Psychiatric Association not as a separate disorder, but rather as a course specifier to describe the pattern of depressive episodes in patients meeting criteria for major depressive disorder, or bipolar I or II disorder (American Psychiatric Association [DSM-IV-TR], 2000). Criteria for the seasonal specifier include (1) recurrence of major depressive episodes at a specific time of year; (2) full remission (or change to mania/hypomania) from depression also recurring at a specific time of year; (3) at least two major depressive episodes meeting criteria 1 and 2 within the last 2 years, with no occurrence of nonseasonal depression within the same period; and (4) experiencing a greater number of major depressive episodes meeting SAD criteria than that of nonseasonal depression throughout the individual's lifetime (American Psychiatric Association [DSM-IV-TR], 2000).

Description

Epidemiology. SAD is characterized by depressed mood, anhedonia, and fatigue, as well as higher rates of appetite increase, weight gain, and hypersomnia compared to nonseasonal major depression (Magnusson & Partonen, 2005). Ten to twenty percent of patients with depression seeking outpatient treatment have a seasonal pattern of recurrences, and SAD accounts for 10–22% of all unipolar and bipolar mood disorders (Roecklein, Rohan, & Postolache, 2010). A notable characteristic of sleep in SAD is that, in contrast with the predominance of insomnia in nonseasonal depression, a majority of individuals with SAD experience hypersomnia (68–80%; e.g., Rosenthal et al., 1985). Given that seasonality, the tendency to vary in mood and behavior across the seasons (Kasper, Wehr, Bartko, Gaist, & Rosenthal, 1989; Rosen et al., 1990), is normally distributed, a range of mild to severe seasonal changes are likely to occur in behavioral medicine research and practice.

Etiology. Etiological models propose that seasonal changes in the environment, being light levels or other conditioned cues, trigger onset in fall or winter (Rohan, Roecklein, & Haaga, 2009; Sohn & Lam, 2005). Lewy, Sack, Miller, and Hoban (1987) proposed that winter changes in day length lead to a delay in internal circadian rhythms relative to clock time or other rhythms like sleep and wake. Wehr et al. (2001) proposed that winter changes in day length are encoded by nocturnal melatonin release duration as a "circadian signal of change of season," leading to behavioral and physiological changes in humans similar to those of seasonally breeding mammals. Transforming environmental light levels to neural signals is mediated by a retinal pathway to the central clock, and this pathway could be differentially sensitive across individuals, leading some to be vulnerable to insufficient input in winter (Hebert, Dumont, & Lachapelle, 2002). These circadian and retinal hypotheses may interact with one another, as well as with the monoamine hypothesis (i.e., serotonin and dopamine) and cognitive behavioral mechanisms (Rohan et al., 2009).

Treatment. The recommended first-line treatment for SAD is light therapy, while antidepressants are also commonly used (Lam & Levitt, 1999). Light therapy typically requires daily exposure to 10,000-lux of white or full-spectrum fluorescent light for at least 30 min, although efforts to refine the wavelength and reduce

duration are being tested clinically. Among antidepressants, Bupropion XL is the first FDA-approved drug for the treatment of winter depression. A double-blind, placebo-controlled, multisite trial testing Bupropion XL on adults with a history of SAD demonstrated that the overall proportion of depression recurrences following treatment was lower for those taking Bupropion (16%) than for those using a placebo (28%; Modell et al., 2005), although the low rate of recurrence indicates a significant placebo response. In addition, cognitive behavioral therapy is as effective as light therapy for acute treatment during a depressive episode, and has prophylactic effects 1 year later in reducing the risk of a subsequent episode (Rohan et al., 2004). Given that multiple empirically validated treatments are available, detecting seasonal patterns in clinical settings can improve patient outcomes.

Implications for behavioral medicine. Seasonal variations in mood and behavior are relevant to Behavioral Medicine research and clinical practice. Such implications can be divided into specific biopsychosocial components including biological characteristics (e.g., genetic risk for seasonality, neurotransmitter and neurohormonal seasonal fluctuations), behaviors (e.g., seasonal changes in physical activity, sleep, substance use, and eating behavior), and social factors (e.g., seasonal changes in social activity rhythms). Candidate behavioral mechanisms in SAD include behavioral disengagement (i.e., lack of response-contingent positive reinforcement) as well as emotional and psychophysiological reactivity to light and seasonal visual stimuli. Several biological mechanisms in SAD have also been proposed (Rohan et al., 2009). The circadian phase shift hypothesis suggests that in the fall and winter months, the timing of different circadian rhythms (e.g., melatonin release, sleep-wake cycle) is out of phase, or desynchronized from other rhythms and/or environmental factors (e.g., dusk/dawn cycle). Another hypothesis is that individuals with SAD have retinas that are less sensitive to light; low environmental light levels in the winter then lead to subthreshold levels of light information transmitted to the brain. The photoperiodic hypothesis proposes that some individuals with SAD maintain biological mechanisms to track changes in photoperiod, a circadian signal of change between seasons, evidenced by individuals with SAD who demonstrate a longer duration of nocturnal melatonin release in the winter months. Rohan et al. (2009) proposed that behavioral and cognitive mechanisms contribute to a psychological vulnerability that, when integrated with biological vulnerabilities, may explain the onset, maintenance, or remission of SAD. Although these separate mechanisms have been shown to play a role in SAD, it is not yet clear if these factors are mechanistic in the cause or maintenance of the disease.

Secondhand Smoke

Susan J. Bondy
Dalla Lana School of Public Health, University of Toronto, Toronto, ON, Canada

Synonyms

Environmental tobacco smoke; Involuntary exposure to tobacco smoke; Passive smoking

Definition

The exposure to, and effects of, inhalation of cigarette smoke by an individual other than the active smoker. The term is also applied, more specifically, to smoke exhaled by an active smoker that remains in the environment.

Description

Secondhand smoke includes sidestream smoke from the end of a lit cigarette and exhaled smoke (United States Department of Health and Human Services, 2006, 2010; World Health Organization International Agency for Research on Cancer, 2004). Harmful components identified specifically in cigarette smoke measured in the air include gases (e.g., carbon monoxide), droplets, and respirable particles which result from the release, combustion, and partial combustion of the tobacco leaves and cigarette paper, as well as flavorants, additives, and other chemicals introduced at agricultural, manufacturing, or packaging stages (California Environmental Protection Agency, 2005a). Secondhand smoke, has been shown to contain elevated levels of a large number of known and probable human

carcinogens as well as many other toxins with proven causal links to human health conditions (California Environmental Protection Agency, 2005b; Institute of Medicine 2010; United States Department of Health and Human Services, 2010; United States Environmental Protection Agency, Office of Research and Development, Office of Health and Environmental Assessment & U.S. EPA, 1992; World Health Organization International Agency for Research on Cancer, 2004). It has been estimated that, in 2004, one third of all children and nonsmoking adults worldwide were exposed to secondhand smoke, and that this avoidable exposure was responsible for over 600,000 premature deaths or 1% of all deaths (Oberg, Jaakkola, Woodward, Peruga, & Pruss-Ustun, 2010). As with active smoking, there is no confirmed risk-free level of exposure to secondhand cigarette smoke (United States Department of Health and Human Services, 2006, 2010).

Concentrations of secondhand smoke (and resulting levels of toxic exposure) vary widely and are influenced by: the number of cigarettes and rate of active smoking; the time elapsed since cigarettes were lit and extinguished; the volume of the affected air space; ventilation, air exchange rates, and direction of air flow; and the duration of exposure (California Environmental Protection Agency, 2005a). Air concentrations in occupational and private settings, where smoking is permitted, often exceed occupational safety standards for specific agents, and biomarker levels in heavily exposed nonsmokers can overlap levels observed in active smokers (California Environmental Protection Agency, 2005b; United States Department of Health and Human Services, 2006). Exposure levels in outdoor settings can vary from negligible to concentrations similar to indoor levels if the passive smoker is exposed to the stream of smoke (Institute of Medicine, 2010).

Measuring exposure for research, surveillance, and program evaluation may be achieved through air sampling or use of markers of human exposure in biological samples. Air monitoring assesses for concentrations for one or more specific component of tobacco smoke or respirable particulates of specific sizes (Institute of Medicine, 2010; United States Department of Health and Human Services, 2006). The most widely used biomarkers include exhaled carbon monoxide, and cotinine (a metabolite of nicotine) in saliva, urine, or blood samples. Other biomarkers used in research include, metabolites other than cotinine and concentrations of known carcinogens, as well as through use of other biological media (e.g., testing for accumulated cotinine and nicotine in hair samples from exposed individuals, even newborns as an indication of late prenatal exposure).

Over 40 years of evidence exists on the adverse health effects caused by passive smoke exposure. This evidence has been summarized in prominent reports by international health agencies including International Agency for Research on Cancer (IARC) (International Agency for Research on Cancer, 2004, 2009), the Office of the United States Surgeon General (United States Department of Health and Human Services, 2006, 2010), and others (California Environmental Protection Agency, 2005b; Institute of Medicine, 2010). The major classes of health effects linked to passive smoking include cancers, respiratory disorders, cardiovascular diseases, reproductive effects, and adverse effects on pre-and postnatal growth and development.

Carcinogenic effects of passive smoking can be expected to be consistent with those for active smoking (International Agency for Research on Cancer, 2004), and for both, the increased risk is dose-dependent. Secondhand smoke has a confirmed causal role in the development of lung cancer in exposed nonsmokers (California Environmental Protection Agency, 2005b; International Agency for Research on Cancer, 2004; United States Department of Health and Human Services, 2006) and is suggested to increase the risks of nasal and nasopharyngeal cancers in adults (California Environmental Protection Agency, 2005b; United States Department of Health and Human Services, 2006). There is also evidence to suggest secondhand smoke increases the risk of all childhood cancers, studied collectively, as well as specific childhood cancers (California Environmental Protection

Agency, 2005b; United States Department of Health and Human Services, 2006). For several cancers with definitive evidence linking them to active smoking (including various digestive, kidney, and bladder cancers), there is not sufficient quantitative data to show a causal association with secondhand smoke exposure in humans (International Agency for Research on Cancer, 2009). The role of secondhand smoke in breast cancer remains more controversial with The California EPA (California Environmental Protection Agency, 2005b) being the first health agency to draw the conclusion of a causal association, while other agencies have not concluded that there is a strong link between active or passive cigarette smoke exposure and breast cancer (International Agency for Research on Cancer, 2009; United States Department of Health and Human Services, 2010).

Conclusive evidence of noncancer respiratory effects of passive smoking include lower respiratory tract illness in children and adults, prevalence of asthma in children, and severity of asthma in children and adults (United States Department of Health and Human Services, 2006). Secondhand smoke also causes recurrent otitis media and middle ear effusion in children (United States Department of Health and Human Services). Passive smoke exposure has also been found to cause adverse and lasting effects on lung function and lung development in children associated with prenatal passive smoking and secondhand exposure in childhood (United States Department of Health and Human Services). Secondhand smoke has been identified as a risk factor for sudden infant death syndrome, with sufficient evidence to suggest a causal association, and associated with a small reduction in birth weight when nonsmoking mothers are exposed while pregnant (United States Department of Health and Human Services).

In terms of cardiovascular diseases, secondhand smoke exposure is accepted as a cause of coronary heart disease morbidity and mortality in adult women and men as well as acute cardiac events (Institute of Medicine, 2010; United States Department of Health and Human Services, 2006). Even brief exposure to environmental cigarette smoke can lead to vascular function changes and arrhythmic effects associated with acute cardiovascular events in susceptible individuals (Institute of Medicine, 2010; United States Department of Health and Human Services, 2010).

The World Health Organization Framework Convention on Tobacco Control (FCTC) requires that all signatory nations adopt and enforce measures to protect their populations from exposure to tobacco smoke (World Health Organization, 2003, 2011). Protecting the population from secondhand smoke is identified as a key, evidence-based, measure to reduce death, disease, and disability caused by tobacco (World Health Organization, 2003). FCTC guidelines (and others International Agency for Research on Cancer (2009); United States Department of Health and Human Services, 2006, 2010) recommend that this be achieved through making all environments 100% smoke free as opposed to reliance on ventilation or creation of designated smoking spaces, which have proven ineffective. Legislation and other measures should apply equally to outdoor spaces wherever there is evidence of exposure (United States Department of Health and Human Services, 2006, 2010; World Health Organization, 2011).

A number of educational, legislative, occupational, and clinical interventions to eliminate exposure to tobacco smoke have been implemented and evaluated. Evidence from several countries has shown that legislated bans in a variety of settings including workplaces, bars, and restaurants have been effective in terms of: achievement of compliance, improved air quality, reduced human biomarker levels of exposure, and a corollary effect of reducing smoking prevalence among individuals exposed to the restrictions (Institute of Medicine, 2010; International Agency for Research on Cancer, 2009; United States Department of Health and Human Services, 2006). There is also growing evidence that event rates for acute cardiac events have been reduced successfully by legislative and other interventions to eliminate smoking in workplaces and other settings and reduce secondhand smoke exposure (Institute of Medicine, 2010; United States Department of Health and Human Services, 2010).

Sedentary Behaviors

Yori Gidron
Faculty of Medicine and Pharmacy,
Free University of Brussels (VUB),
Jette, Belgium

Definition

Sedentary behaviors are an increasingly common problem worldwide, with important health consequences. These behaviors include long durations of sitting in front of the TV or the computer, playing computer or TV games, and a general lack of peripheral limb movements. These behaviors have risen due to a multitude of reasons including technological advancements,

greater dependence on transportation, urbanization and hence smaller distances to work or schools spent walking, the omnipresence of TV and computers, and our dependence on such means for information, work, leisure, and communication. Various measures and scales exist to assess sedentary behaviors, and these depend on the type of behaviors assessed, the time frame the questions refer to (days, weeks, etc.), and the response format (e.g., a Likert scale or hours). This variability in assessment and use of different cutoffs could of course impact on the prevalence of sedentary behaviors identified in various samples. The prevalence of sedentary behaviors was found to be 58% in a nationally representative sample of Americans aged between 20 and 59 years. When looking just at sitting, one in four Americans spends 70% of their waking time sitting. Furthermore, people in developed countries may spend 4 h a day watching TV and 1 h a day in their vehicle. Importantly, the metabolic and health consequences of sedentary behaviors are distinct from the effects of lack of physical exercise (Owen, Healy, Matthews and Dunstan 2010). In a 21-year follow-up study, number of hours riding in a car, alone, or in combination with hours in front of a TV, significantly predicted cardiovascular disease mortality, independent of confounders (Warren et al. 2010). In contrast, taking daily breaks from sedentary behaviors is related to reduced waist circumference and to improved metabolic outcomes, independent of total amount of sedentary behaviors and of physical exercise (Healy et al. 2008). Mental health problems such as anxiety and depression are also associated with more sedentary behaviors, independent of general physical activity level (de Wit, van Straten, Lamers, Cuijpers and Penninx 2011). Thus, sedentary behaviors are an important topic for research and intervention in behavior medicine.

Selective Serotonin Reuptake Inhibitors (SSRIs)

Michael Kotlyar[1] and John P. Vuchetich[2]
[1]Department of Experimental and Clinical Pharmacology, College of Pharmacy, University of Minnesota, Minneapolis, MN, USA
[2]Department of Psychiatry, University of Minnesota School of Medicine, Minneapolis, MN, USA

Synonyms

Celexa®; Citalopram; Escitalopram; Fluoxetine; Fluvoxamine; Lexapro®; Luvox®; Paroxetine; Paxil®; Prozac®; Sertraline; Zoloft®

Definition

The SSRIs are a family of medications that act primarily (but not exclusively) by inhibiting serotonin reuptake pumps (Finley, 2009; Sussman, 2009). These medications are used to treat a variety of psychiatric disorders including depression, generalized anxiety disorder, obsessive-compulsive disorder (OCD), panic disorder, premenstrual dysphoric disorder, bulimia nervosa, social phobia, and posttraumatic stress disorder (Sussman). Clinicians should consult the product labeling for each individual medication to determine the indications that each drug is currently approved to treat, since not all of the SSRIs are indicated in the treatment of all of these disorders (although in some cases there is data in the literature suggesting efficacy for a given agent for the treatment of conditions for which it does not have an indication). In the treatment of most types of depression, the SSRIs have similar efficacy to older classes of medications such as the tricyclic antidepressants. However better tolerability at therapeutic doses and lower toxicity in overdose has led to an increased use of SSRIs and decreased use of these older agents over the past several decades (American Psychiatric Association [APA], 2010; Baldessarini, 2006; Finley, 2009). As with all antidepressants, full therapeutic effects are not observed for as long as 8 weeks in the treatment of depression or longer in the treatment of other disorders (such as OCD), however some symptoms may start to improve sooner (APA, 2010; Finley, 2009; Kirkwood, Makela, & Wells, 2008). In the treatment of depression, all of the SSRIs are thought to be approximately equally effective and therefore initial choice of therapy is often based on factors such as patient preference, prior response to the medication, cost, side effect profile of the individual agents, and the probability that a drug interaction will occur between the antidepressant being chosen and the other medications that the patient is on (APA, 2010; Finley, 2009). Although the mechanism of action of the SSRIs is similar, lack of efficacy following treatment with one of the drugs in this class does not necessarily predict lack of efficacy by another medication in this class (APA, 2010).

There are currently six medications classified as SSRIs that are approved for marketing in the United States (i.e., fluoxetine, paroxetine, sertraline, citalopram, escitalopram, and fluvoxamine) (APA, 2010). The SSRIs are similar in many respects; however, important differences between agents are present. Some of these differences are in the side effect profiles of the various drugs and in the likelihood of each drug contributing to a drug-drug interaction with other medications that a patient is taking.

All of the SSRIs have been commonly associated with side effects such as gastrointestinal complaints (e.g., nausea and diarrhea), disturbances in sleep and headache (APA, 2010; Finley, 2009). Although an individual patient could have any of the sides effects listed, fluoxetine is generally considered the most likely to cause insomnia while paroxetine is often considered to be the most sedating. In many patients, these side effects decrease after the first week of therapy. Additionally, all of the SSRIs have been associated with sexual dysfunction (in both men and women) with the most common symptom reported being delayed orgasm, although decreased interest in sex or erectile dysfunction can also occur (APA, 2010; Finley, 2009). Since many patients may not spontaneously report sexual side effects, clinicians should inform patients that these may occur and determine if these have been problematic. Serotonin syndrome which includes neurobehavioral (e.g., lethargy and mental status changes), autonomic (e.g., sweating, blood pressure, and heart rate changes), and neuromuscular (e.g., rigidity and tremor) signs and symptoms has been rarely reported with the use of an SSRI as mono-therapy (Chyka, 2008). However, the risk of serotonin syndrome increases when SSRIs are used in combination with other serotonergic agents, particularly with monoamine oxidase inhibitors (MAOIs) (APA, 2010; Chyka, 2008). SSRIs have also been associated with increased bleeding risk, likely due to the presence of serotonin transporters on blood platelets (Sussman, 2009). Other side effects such as increased sweating, osteoporosis, bruxism, akathisia, and hyponatremia have been reported occasionally as have a wide range of

other side effects (APA, 2010; Finley, 2009). As with all antidepressants, the SSRIs carry a warning regarding increased suicidality, particularly in children, adolescents, and young adults (under age 24) during the initial stages of therapy (Sussman, 2009).

Substantial differences between the SSRIs are present in the pharmacokinetic properties of the agents and in the likelihood that the drug can contribute to drug-drug interactions. For example, fluoxetine is notable for its long half-life (i.e., 4–6 days) and that of its active metabolite norfluoxetine (4–16 days) (Teter, Kando, Wells, & Hayes, 2008). A longer half-life means that any side effects will persist for a longer period of time after discontinuation of the medication. Discontinuation of SSRIs has been associated with withdrawal symptoms characterized by headache, anxiety, flu-like symptoms, and paresthesias (APA, 2010). Therefore, it is advisable to taper the medication when possible. The likelihood of a withdrawal syndrome is less likely in SSRIs with longer half-lives (such as fluoxetine) since the decline in the concentration of medications occurs more gradually.

Many of the SSRIs have been found to interact with other medications, some of which may be commonly co-administered with the SSRIs. The cytochrome P450 (CYP450) superfamily of enzymes is responsible for the metabolism of a large number of medications. There are numerous specific isoenzymes within the CYP450 superfamily of enzymes and the degree to which each is affected by an individual SSRI varies considerably. For example, paroxetine and fluoxetine are both strong inhibitors of CYP2D6 (with fluoxetine being a moderate inhibitor of several other CYP450 isoenzymes) (APA, 2010; Finley, 2009). Since antidepressants are frequently co-administered with other medications, care should be taken to identify and manage any potential drug-drug interactions. It is important to consider the impact of drug interactions both when initiating an enzyme inhibitor (since concentrations of affected medications can increase) and when discontinuing an enzyme inhibitor (since concentrations of affected medication can decrease).

Self-Blame

Stephanie Ann Hooker
Department of Psychology, University of Colorado, Denver, CO, USA

Synonyms

Responsibility

Definition

Self-blame is the attribution that the consequences one experiences are a direct result of one's actions or character. In the context of behavioral medicine, this may be either beneficial or harmful depending on if it leads to positive behavior change or increased negative affectivity and lack of behavior change.

Description

Self-blame is indirectly related to perceived control, where individuals who self-blame more often also are more likely to believe they have greater control over their lives. Because enhancements in perceived self-control are adaptive to psychological well-being, one may assume that self-blame may also be adaptive. However, this is not always the case.

Janoff-Bulman (1979) proposed two types of self-blame: (1) an adaptive, control-oriented response where the focus is on the individual's behavior and (2) a maladaptive, esteem-oriented response where the focus is on the individual's character. Self-blame is adaptive when individuals recognize that they had some control over the situation but failed to act appropriately. Thus, these individuals can modify their behavior for future events. On the other hand, self-blame is maladaptive when individuals blame their character flaws for the outcome; this is referred to as characterological self-blame. These flaws are generally seen as stable, so these individuals make no efforts to change. This can lead to recurrence of the same problems and feelings of helplessness and depression.

Although Janoff-Bulman's (1979) theory of self-blame seems plausible, there is little support for these notions in the literature. Two studies did not support the theory that behavioral self-blame is adaptive in breast cancer patients; rather, behavioral self-blame was positively associated with symptoms of anxiety and depression (Bennett, Compas, Beckjord, & Glinder, 2005; Glinder & Compas, 1999). Moreover, Bennett et al. found that both forms of self-blame were unrelated to perceptions of control, which directly contradicts the theory of self-blame.

However, one study of head and neck cancer patients supported Janoff-Bulman's (1979) theory. Low behavioral self-blame (smoking specific) was related to greater likelihood of continued smoking after the cancer diagnosis (Christensen et al. 1999). The relationship held for those patients with high and low perceived control over cancer recurrence, although those with low perceived control had almost a three times greater probability of continued smoking after a cancer diagnosis than those with higher perceived control over cancer recurrence. Furthermore, in this study, it appeared that specific behavior self-blame was more predictive of behavior than a general behavioral self-blame. The authors suggest this may be because of the patients' knowledge of how specific behaviors related to the likelihood of having cancer and that patients do not attribute their behavior in

general as the cause of cancer. This study illustrates the importance of understanding how patients' attributions of self-blame, perceived control, and knowledge of their condition may interact in predicting behavior change following a cancer diagnosis.

In the literature self-blame may be used interchangeably with responsibility. However, there are important differences between self-blame and responsibility that should be recognized. Self-blame differs from responsibility in that self-blame suggests that one intentionally brings about negative consequences, whereas responsibility is related more to perceived control over the event (Voth & Sirois, 2009). Indeed, Voth and Sirois demonstrated in their study of patients with inflammatory bowel disease that self-blame is related to poor psychological adjustment, whereas responsibility is related to better psychological adjustment. Self-blame was associated with increased use of avoidant coping strategies, whereas responsibility was associated with decreased use of avoidant coping strategies. Avoidant coping was related to poorer psychological adjustment.

Theories of self-blame in behavioral medicine suggest that self-blame has maladaptive and adaptive qualities. Self-blame can be adaptive when individuals recognize their past actions caused their negative consequences, and they also recognize that their behavior is modifiable. Thus, individuals can make positive behavior changes in these cases, which can improve health. However, self-blame is maladaptive when it is primarily characterological in nature. This may lead individuals to feel helpless and to have poorer psychological adjustment to disease. Thus, it is imperative for researchers to properly define the self-blame construct for their research in order to further understand self-blame's role in behavioral medicine.

Self-care

Linda C. Baumann and Alyssa Karel
School of Nursing, University of Wisconsin-Madison, Madison, WI, USA

Synonyms

Self-management

Definition

Self-care as described by Orem (1995) is "action of persons who have developed or developing capabilities to use appropriate, reliable and valid measures to regulate their own functioning and development in stable or changing environments" (p. 43). Self-care is both caring "for" oneself and "by" oneself. Self-care promotes well-being and is a perceived condition of personal existence characterized by experiences of contentment, pleasure, and happiness. It is associated with health and with sufficiency of resources. This definition is consistent with Diener's (2009) concept of subjective well-being as an individual's global judgment of values and standards that are significant to life satisfaction.

A paradigm that is emerging in health care delivery for people with chronic conditions is that they are their own principal caregivers; health care professionals act as consultants and advisors in

supporting them in self-care and self-management of their condition. This paradigm of collaborative care and self-management education involves shared decision making between providers and patients. Self-management education includes providing patients with information, problem-solving skills, and behavioral strategies to enhance their lives.

Diabetes is an excellent example of a health condition that requires self-management skills to maintain optimal control through healthy eating, being active, taking medications, monitoring, problem solving, reducing risks, and healthy coping. http://www.diabeteseducator.org/DiabetesEducation/Patient_Resources/AADE7_PatientHandouts.html Self-management education can occur in group settings where peers can provide emotional support and practical information for problem solving. In addition to knowledge and skills, self-care behaviors are determined by attitudes and beliefs, social and environmental influences, and self-efficacy expectations.

Definition

Self-concept can be defined as one's beliefs about oneself.

Description

Self-concept is a difficult yet important terms to define as self-concept attempts to explain human behavior (micro). Defining self-concept is difficult as a large number of terms use the term 'self' to define some sort of individualistic behavior (Burns, 1980). However, in its simplest form, self-concept can be defined as one's beliefs about oneself. Carl Rogers (1951) suggested that oneself, or the "self," plays a role in the development of personality and behavior.

Self-concept can be seen as what an individual understands him or herself to be, cultivated by the appraisal of oneself (Epstein, 1973). Self-concept is an organized system of learned beliefs, perceptions, and feelings that aid in the understanding of oneself. Simply, self-concept is the perception an individual has of one's personal characteristics, formed and shaped by society and attitudes. The understanding of oneself is established by one's character, personality, traits, and appearance. Self-concept is developed from an individual's "I," "me," and/or "mine" experience (Burns, 1980).

As individuals age, their self-concept is organized and reorganized by their social and nonsocial experiences (Burns, 1980). Characteristics in an individual's social environment structure understanding of who the individual is (Epstein, 1973). The self-concept or the "who am I" assessed by the individual can be defined and then redefined as the individual encounters many life experiences. In this sense, self-concept can be designated as a multifaceted phenomenon that is dynamic and can change due to experiences, environments, and social affiliations (Markus & Wurf, 1987). Thus, self-concept is not fixed and is based individual on the context or situation. Moreover, Burns (1980) suggests that individuals may have many overlapping self-concepts that have been shaped and developed by various beliefs, experiences, and events.

Therefore, self-concept can be seen as a multifaceted and individualized process.

An individual can develop a positive or negative self-concept based entirely on the evaluations of oneself. Bailey (2003) states that self-concept is associated with individualistic qualities that can be assessed rather than measured. "Non-measurable" aspects to one's self can be seen as physical attributes, religious preferences, and/or personality traits (Bailey, 2003). Thus, self-concept is a learned trait. Rogers (1951) suggests that the self, through self-concept, must be maintained in order to avoid anxiety and stress. This ability to maintain one's self-concept can be achieved through the maintenance of self-esteem (Rosenberg, 1979). It has been suggested that self-concept consists of one's self-image and one's self-esteem (Burns, 1980). Self-image can be defined as the perception individuals have of themselves physically, psychologically, philosophically, and politically, developed through the agency of their societal experiences and development (Fisher, 1986; Statt, 1990). Self-esteem is operationally defined as an individual's orientation toward oneself (Rosenberg, 1965); self-worth, motivations, and perceptions encompass the conceptualization of an individual's understanding of who they are (Rosenberg, 1965). Thus, the process in which individuals view themselves constructed by the perceptions they have of their self-worth aids in the development of self-concept.

Self-concept can be measured in children and adults by means of various psychometric scales such as the Tennessee Self Concept Scale (Fitts, 1991) and the Piers-Harris Children's Self-Concept Scale (Piers, 1984).

Self-determination Theory

Hannah G. Lawman and Dawn Wilson
Department of Psychology, University of South Carolina, Columbia, SC, USA

Synonyms

Cognitive evaluation theory

Definition

Self-determination theory is a theory of human motivation that describes two distinct types of motivation: autonomous (regulated through natural and internal processes such as inherent satisfaction) and controlled (regulated through externally held demands and expectations). Furthermore, autonomous motivation is more likely to contribute to long-term maintenance of a behavior compared to controlled motivation and can be facilitated through social contextual conditions (i.e., high autonomy, competence, and relatedness) that elicit and sustain intrinsic motivation versus conditions that undermine one's innate propensity for it.

Description

Self-determination theory (SDT) is a theory of human motivation that describes motivation in two distinct types: autonomous and controlled (Deci & Ryan, 2008). Autonomous motivation is regulated through natural and internal processes such as inherent satisfaction and can be thought of as an individual's innate desire to engage in healthy behaviors independent of external influences. For example, an individual may engage in autonomously motivated healthy eating because it is part of his/her self-concept and is enjoyable. On the other hand, controlled motivation is regulated through externally held demands and expectations that are contingent on rewards or punishments. An individual who engages in healthy eating because he/she has a high need for approval from others may not really enjoy eating healthy but is motivated by an external reinforcement. While both types of motivation represent an individual's intention to act, health behavior outcomes resulting from autonomous versus controlled motivation may be qualitatively different. For example, autonomous motivation is more likely to contribute to long-term maintenance of health behaviors compared to controlled motivation. Additionally, autonomous motivation can be facilitated through social contextual conditions that elicit and sustain intrinsic motivation in contrast to conditions that undermine one's innate propensity for it (Ryan & Deci, 2000).

Self-determination theory provides a motivational-theory-based framework for understanding influences on health behaviors, such as healthy diet, physical activity, safe sex practices, and substance use. The conceptualization of motivation on a continuum allows for distinctions to be made in the type and quality of motivation that may contribute to different outcomes. This can be compared to previous interpretations of motivation in which researchers' conceptualized motivation as unitary and, as such, universally concluded that more motivation would be better. SDT makes distinctions between autonomous and controlled motivation with autonomous motivation being more inherently enjoyable, long-lasting, and internally

regulated, while controlled motivation consists of motivation that is primarily driven by externally held demands, expectations and reinforcers (Deci & Ryan, 2008). For example, controlled motivation based on extrinsic values of fame and wealth has been shown to be related to higher risk for smoking (Williams, Cox, Hedberg, & Deci, 2000).

SDT originally conceptualized the motivation continuum as ranging from extrinsic to intrinsic motivation. On the left end, motivation was regulated extrinsically and controlled by rewards and punishments or other externally regulated processes. This was called extrinsic motivation. At the right end of the continuum was motivation that was regulated or controlled by an individual's inherent satisfaction, novelty, and drive called intrinsic motivation. Furthermore, extrinsic motivation was broken down into subcategories based on increasing levels of intrinsic regulation: extrinsic, introjected (i.e., somewhat external regulation or internal rewards and/or punishments), and identified (somewhat internal regulation and holds personal importance; Deci & Ryan, 1985; Ryan & Deci, 2000). Previous research has supported beneficial effects of intrinsic motivation compared to extrinsic motivation in sport (Vallerand & Losier, 1999). However, more recent research has combined extrinsic and introjected into controlled-type motivation and combined identified and intrinsic into autonomous-type motivation (Deci & Ryan, 2008). This has resulted in a shift of the primary motivation differentiation moving toward autonomous and controlled in conceptualizing intrinsic and extrinsic in a more dynamic fashion.

SDT emphasizes the role of social context in understanding health behavior motivation and suggests its influence on behavior is through affecting social contextual conditions that may help to elicit and sustain intrinsic motivation. These conditions are described as psychological needs that are inherent to being human and consist of the needs for competence, autonomy, and relatedness. Social relationships (e.g., social support), environmental characteristics (e.g., built environment, resources), and cultural practices and norms (e.g., gender roles) can influence these psychological needs and in turn facilitate or undermine one's sense of intrinsic motivation for engaging in healthy behaviors (Deci & Ryan, 1985, 2008; Ryan & Deci, 2000).For example, an intervention to increase physical activity may focus on increasing social support (relatedness), teaching behavioral skills (competence), and encouraging choice (autonomy) to provide conditions that facilitate the development of autonomous motivation to be physically active for a lifetime (Wilson et al., 2008). Indeed, researchers have begun to use SDT as a framework for large-scale health behavior interventions, such as the Active by Choice Today (ACT) trial to increase physical activity (Wilson et al.). Similarly, researchers and clinicians interested in reducing substance use may aim to teach strategies for resisting peer pressure (competence) to use substances while preserving those peer relationships (relatedness) and giving a variety of response options (autonomy) (Williams et al., 2000). In conclusion, SDT has been shown to be a promising theory for behavioral health change and emphasizes social context in understanding motivation as a dynamic construct.

Self-Efficacy

Jorie Butler
Department of Psychology, University of Utah, Salt Lake City, UT, USA

Definition

Self-efficacy: Self-efficacy is the belief in personal ability to successfully perform challenging life tasks. Self-efficacy plays an important role in a person's emotions, cognitions, motivational activities, and behaviors across a variety of activities.

Description

Self-efficacy is rooted within Social Cognitive Theory (Bandura, 1986) in which people are characterized as active agents of control within their own lives – dynamically influencing their personal environments by organizing responses to opportunities, reflecting on past performances, and self-regulating behavior. Self-efficacy influences response organization, develops in part from reflection, and contributes to self-regulation, particularly, by fostering approach-oriented behavior and persistence in the face of obstacles. Attribution Theory (Weiner, 1992), which includes the properties of locus, stability, controllability, also provides a framework for understanding self-efficacy. Locus reflects the cause of a situation as internal or external to a person. Stability reflects how changeable the situation is perceived to be. Controllability is an indicator of whether the person can willfully change a situation. A negative situation such as reaching an unhealthy weight could be interpreted as internal (*Being this heavy is my fault*), stable (*I've always been too heavy*), and uncontrollable (*It doesn't matter what I eat, I just get heavier*), resulting in poor self-efficacy for weight control in the future. In contrast, reaching an unhealthy weight could be interpreted as external (*Weight gain is common with age*), unstable (*This weight came on, it can come off!*), and controllable (*Now that I realize I'm eating too much and moving too little, I can change that behavior*), producing opportunities for improvements in future self-efficacy.

Social Learning Theory (Bandura, 1977b) explains development of self-efficacy via four principle pathways: mastery experiences, modeling, social persuasion, and physiology. Past experiences are most predictive of future experiences. People engage in tasks and actions, interpret the outcome, and develop perceptions of their competence within the task domain. Mastery experiences result from multiple successes and promote self-efficacy. Failures are detrimental to developing self-efficacy, although the negative impact of failures is diminished when failures occur attempting a task that has been successfully completed on multiple occasions. The primacy of mastery experiences in self-efficacy development speaks to the titration between efficacy development and actual performance. Self-efficacy develops in domains in which skills are acquired often through the combination of effortful practice and natural talent. Self-efficacy development can be fostered by modeling, particularly when successful completion of activities is modeled by someone viewed as admirable and possessing desired capabilities of the observer. Conversely, a model who fails to perform a desired activity can weaken an observer's sense of competence

for performing the activity. Social persuasions involve effective encouragement (not empty praise) that can be instrumental in fostering self-efficacy when the tasks are achievable or nearly achievable. Negative social persuasion deflates self-efficacy. Social persuasion is an important pathway by which parents, teachers, coaches, employment supervisors, and others can facilitate or damage developing self-efficacy. Physiological responses during task attempts influence self-efficacy development. Emotional states indicative of negative arousal such as stress and fear are indicators that the task is difficult and may indicate anticipated failure. In contrast, excitement, anticipation of fun, happiness, or a sense of work "flow" indicate positively developing efficacy. Individuals experiencing negative adjustment periods – such as depressive states or grief – will have difficulty developing self-efficacy. Self-efficacy can develop more freely when negative emotional states are resolved.

Self-efficacy influences behavior across many domains, including the choices of activities to become involved in effortful work to complete activities, persistence in the face of setbacks or failures, and resilience following adversity (Schunk & Pajares, 2005). Individuals tend to avoid activities for which they anticipate poor performance and approach tasks for which they anticipate success. Thus, individuals with low self-efficacy in a given domain may avoid it all together, thus contributing to narrowing of life skills. High self-efficacy contributes to task engagement. High self-efficacy is also associated with effortful engagement in tasks – particularly when intrinsic motivation to engage in the task is also present. Persistence in the face of setbacks is more likely when individuals have high self-efficacy for the task. With the expectation for eventual failure (a component of low self-efficacy), persistence is unlikely. In addition, when failures or enduring obstacles are encountered, low self-efficacy may contribute to a sense of failure and withdrawal from the situation whereas high self-efficacy may contribute to resilience.

Self-efficacy is an integral component of a number of models designed to explain health behavior – primarily because self-efficacy contributes to the willingness to try to change undesirable health behavior, successful implementation of health behavior change, and persistently maintaining health behavior change over time. The Theory of Reasoned Action was extended to form the Theory of Planned Behavior. The extension incorporated self-efficacy as a key factor in changing health behavior along with personal attitudes toward change and the attitudes of significant others toward the change (Ajzen, 1991). Self-efficacy was also incorporated into the Health Belief Model during the 1980s – reflecting understanding of the importance of the construct in promoting health (Rosenstock, Strecher & Becker, 1988). The Health Behavior Change Model (Prochaska & Velicer, 1997) incorporates self-efficacy as a contributor to stages of change. Self-efficacy can influence a person's thoughts about needing change (in the contemplation stage). A person high in self-efficacy will anticipate success and may progress more quickly to the active preparation stage – involving active planning for change behaviors. In addition, self-efficacy will influence effective active change (action stage) as persons high in self-efficacy may more effectively respond to setbacks with persistence and resilience. This quality of those high in self-efficacy also contributes to effective sustainment of the changed behavior (maintenance stage).

Self-efficacy is generally best understood in specific domains and the concept is well supported across multiple domains including school performance, athletic achievement, occupational arenas, and in health behaviors including health maintenance (such as diet and exercise), recovery from acute events such as surgery, and coping with chronic illness or dangerous diagnoses. There is some evidence for a generalized self-efficacy as individuals expect better competence for activities when they have demonstrated aptitude in other activities in the past (Smith, 1989). Self-efficacy contributes a theoretically grounded explanation for the myriad ways in which people shape their own environments by seeking out opportunities for success, persisting in the face of hard work and adversity, learning from past experiences, and responding with resilience to failure.

Definition

Self-esteem can be defined as a positive self-evaluation or a concept broader than confidence. It refers to an individual's cognitive appraisal that is constant over time. A positive self-appraisal indicates higher self-esteem, and a negative self-appraisal indicates lower self-esteem. Self-esteem is not perceived anytime, but it essentially influences one's actions, consciousness, or attitude. One who is perceived to have high self-esteem pursues goals aggressively and actively. Further, they are perceived to be amiable by themselves or by others. In this sense, self-esteem becomes indispensable to mental health or social adaptation.

In the previous study concerning self-esteem, an individual's self-esteem was considered in terms of not only his or her tendency and degrees of appraisal, which could be positive or negative, but also its relationship with the individual's cognitive faculty. James (1890) propounded that "self-esteem is successes divided by desire." This formula suggests that just thinking that one could succeed in the desired field increases self-satisfaction. This formula is similar to the theory on the gap between ideal self and real self (Rogers, Dorfman, Gordon, & Hobbs, 1951).

An individual's self-esteem strongly correlates with the affection, unconditional acceptance, and nurturing attitude that the parents display. Self-esteem can be measured in various ways, the most representative being Rosenberg's (1965)

questionnaire and Coopersmith's (1967) scales. Because each scale may be different in terms of its dimensionalities or factors, it is necessary to consider the characteristics of the scales used or interpreted on a case-by-case basis.

Self-assessment; Self-evaluation; Self-monitoring; Self-rating

Definition

Self-examination can be seen as a process of evaluation or appraisal of one's qualities, traits, and characteristics.

Description

Self-examination can be seen as a process of evaluation or appraisal of one's qualities, traits, and characteristics. The evaluation of one's qualities, traits, and characteristics helps develop one's self-image and aids in the development of one's self-awareness or self-concept. Self-examination may result in a positive or negative self-feeling, which may enhance or decrease individuals' ideas about themselves. The evaluation of oneself can be seen as the attempt to understand one's motivations and behaviors. In addition, the examination of oneself is likely to affect self-esteem, which may affect self-image. Individuals who deem themselves as worthy may have a greater self-esteem, which may maintain one's "self." Rogers (1951) suggests that the self must be maintained in order to avoid anxiety and stress. Further, theorists often define self-examination as the evaluation or rating of oneself. This evaluation or rating is often defined as the degree to which an individual is self-aware and may result in a negative or positive self-actualization. This formed self-awareness helps develop the basis of individual self-regulation or the ability of one to control one's behaviors and actions (Hull, 2002). Therefore, an individual defines one's self-concept from the degree to which the individual self-examines their personal traits, motivations, behaviors.

The act of self-examination may result in individuals self-monitoring themselves. Self-monitoring can be seen as the degree to which an individual manages or controls the image presented to others in social circumstances (Rawn, 2007). An individual who is a "high self-monitor" may be adept at self-monitoring and motivated to alter individual behavior in order to impact the responses of peers in social

situations (Rawn, 2007). An individual who is a "low self-monitor" remains constant in individual behavior and will not alter individual behavior in social situations (Rawn, 2007). Further, the act of self-examination may result in self-criticism, or the awareness that individual traits and/or characteristics do not compare to the ideal self-image one may have for oneself. This self-criticism may be a result of the self-examination of one's strengths and weaknesses and may increase the evaluation of one's image. One may examine and reexamine individual strengths and weaknesses in order to measure self-actualization, or the fulfillment of one's potential (Maslow, 1943, 1976). Therefore, the greater the self-actualization, the more defined one's self-concept may be, and possibly the greater the self-acceptance an individual may have for oneself. Self-acceptance is defined as the attitude toward one's self and ones individual qualities (English & English, 1958).

Research that explores how self-evaluation impacts everyday situations has become common. For example, Judge, Locke, and Durham (1997), in a study exploring workplace job satisfaction, found that individuals with greater self-evaluations were more likely to have a higher self-esteem, self-efficacy, personal control, and emotional stability and were motivated to perform well in the workplace. Judge et al. (1997) conceptually define self-esteem, self-efficacy, locus of control, and "neuroticism-stability" as core self-evaluations. Judge et al. suggest that core self-evaluations are the "fundamental, subconscious conclusions individuals reach about themselves, other people, and the world" (Judge, Locke, Durham, & Kluger, 1998).

Definition

Self-identity can be conceptualized as a dynamic, contextually based system (Baumeister, 1998). It is a complex structure centered in memory and cognition that helps define who we are, how we relate to others, and our place in the world (Swann & Bosson, 2008). It is also considered a key motivating force that influences personality and behavior. Self-identity is thought to drive our interactions with others (Andersen & Chen, 2002), goals and future roles (Markus & Wurf, 1987), and experience of emotions (Higgins, 1989). Self-identity is also believed to regulate and motivate behavior by providing key self-regulation through a feedback system (Carver & Scheier, 2002).

Description

A person's self-views are considered fundamental to how he or she interprets events, experiences emotion, and behaves. Individuals have distinct identities in different social roles, and differentiation into multiple role-related selves (e.g., self as a student, self as an athlete) is a process of normal development that begins in adolescence or earlier (Oosterwegel & Oppenheimer, 2002). Self-identity differs in content and structure across individuals, and likely varies as a function of culture or gender (Cross & Madson, 1997).

Research has examined the importance of the organization of positive and negative attributes within self-identity, namely, compartmentalization (i.e., negative attributes enclosed within a single role) and integration (i.e., negative attributes spread across multiple roles; see Showers & Zeigler-Hill, 2007). The structure of self-identity is considered contextual and fluctuates between situations as different aspects of the self-structure are activated, strongly relating to mood and self-esteem. A person with a compartmentalized self-structure would experience more positive moods when a role containing predominantly positive attributes is activated frequently, but experience negative moods when a role containing negative attributes is activated. In contrast, both positive and negative attributes are frequently activated in an integrated self-structure, moderating the adverse emotional consequences of activating negative beliefs.

Self-identity is also conceptualized as dynamic. Andersen and Chen (2002) take an interpersonal developmental approach to understanding self-identity in different situations. In their theory of the relational self, they suggest that self-identity develops through interactions with significant others, who set *exemplars*, or cognitive templates stored in long-term memory. These exemplars are set in motion by environmental cues, so that behavior with different individuals varies based upon the active exemplar. Therefore, *who we are now* may differ when with different people.

In addition to describing *who we are now*, views of self-identity also describe *who we may become*. Higgins (1987) suggests that a driving force in self-identity is comparison of the *actual* self to the *ideal* self and *ought* self. A discrepancy between the selves is thought to cause negative psychological states, which initiate behavior that is designed to reduce the discrepancy. Similarly, Carver and Scheier (1998) describe that all individuals strive toward goals, which organize and motivate behavior. Comparisons between future goals and current behavior create emotions that drive future behavior. Positive emotions are experienced and behavior is reinforced when an action is judged to move us closer to a goal; negative emotions are experienced and behavior may change when an action is inconsistent with attaining a goal. Therefore, self-identity is part of a regulatory system that not only reflects, but also drives, who we are and who we will become.

Markus and Nurius (1986) suggest that current self-identity is strongly influenced by *possible selves,* or who we either want to become, or fear becoming, in the future. In this view, self-identity is fluid, continuously developing as possible selves are achieved, modified, or relinquished. Possible selves are thought to directly influence current behavior by providing movement toward or away from possible selves (i.e., approaching hoped-for selves or avoiding feared selves).

Exposure to possible selves has been shown to influence exercise behavior (Ouellette, Hessling, Gibbons, Reis-Bergan, & Gerrard, 2005) and school involvement in adolescents (Oyserman, Terry, & Bybee, 2002) over time. Possible selves are thus considered to play key roles in self-regulatory processes of motivation and behavior (Hoyle & Sherrill, 2006). By comparing current self-identity with future selves, possible selves provide a framework in which to interpret and contextualize *who we are now*.

Self-identity is important for Behavioral Medicine because one's self-conceptions can influence how one responds to chronic illness, and can be altered by the experience of chronic illness. As views of the future are highly impacted by circumstances, major life events are likely to lead to changes in these views and, likewise, to changes in self-identity (Tesser, Crepaz, Collins, Cornell, & Beach, 2002). The diagnosis of a chronic illness is an example of this type of event. Adverse outcomes are likely if an illness contains attributes that reflect negatively onto an individual's self-identity. For example, individuals with lung cancer are more likely than individuals with prostate or breast cancer to associate stigma and self-blame with their illness, leading to negative psychological outcomes (Else-Quest, LoConte, Schiller, & Hyde, 2009). However, a growing body of literature suggests that positive outcomes such as perceptions of personal growth, improvements in life priorities and important relationships, and positive changes in personality (i.e., increased patience, tolerance, and empathy) can also occur as a result of dealing with adverse circumstances such as a chronic illness (Pakenham, 2005; Tedeschi, & Calhoun, 2004).

Self-identity is also relevant to health promotion and illness prevention behaviors. Self-identity plays key roles in self-regulatory processes of motivation and behavior (Hoyle & Sherrill, 2006), with the potential to influence health behavior in both positive and negative ways. For example, contemplating an image of a future possible self as an exerciser or non-exerciser influenced exercise behavior at four-week follow-up (Ouellette et al., 2005). Additionally, individuals' self-identity related to both smoking and quitting smoking independently predicted future attempts to quit. In contrast, sexually active teens who viewed STD's as more stigmatized were significantly less likely to have received STD screening over the last year (Cunningham, Kerrigan, Jennings, & Ellen, 2009). Goals that individuals wish to achieve, and views of who they are as they achieve these goals, are thought to be continuously present in the self-concept, providing a feedback loop that regulates these behaviors.

Self-image

Tara McMullen
Doctoral Program in Gerontology, University of Maryland Baltimore and Baltimore County, Baltimore, MD, USA

Synonyms

Self-attitude; Self-concept; Self-conception; Self-consciousness; Self-identity

Definition

Self-image is how an individual thinks they should be (English & English, 1958). An individual's self-image is comprised of many attitudes, opinions, and ideals.

Description

Like self-concept, self-image is conceptually a difficult term to define due to the large number of varied terms using "self" as a phrase to define some sort of behavior (Burns, 1980). However, self-image is important as it delineates how a self-aware individual views themselves or their image, which further establishes one's self-concept (Harriman, 1947). Self-image is how an individual thinks they should be (English & English, 1958). An individual's self-image is comprised of many attitudes, opinions, and ideals. Self-image develops at a young age and is a process which develops throughout the lifespan. Beginning at a young age, self-image can be seen as a physical process (Statt, 1990). However, self-image is developed not only from body image and physical aspects but also from concepts shaped by society and attitudes.

Self-image is a measurable assessment of one's characteristics. Measurable aspects belonging to an individual build and maintain an individual's self-image. Measurable aspects can be identified as achievements and appearance (Bailey, 2003). Self-image is how an individual perceives him/herself based on measurable traits developed at an early age (Bailey, 2003). Like self-concept, an individual's self-image may be a learned trait structured from an individual's attitude toward a group, idea, object, and so forth (Rosenberg, 1989). Thus, defined behavior may emerge from self-image; however, this behavior is not seen as fixed as it may deviate with the occurrence of different experiences and roles (Burns, 1980). In addition, self-image may be affected by an individual's self-esteem. Self-esteem is defined as an individual's orientation toward oneself (Rosenberg, 1965). Rosenberg (1989) suggested that the more uncertain an individual is in regard to who they perceive he/she is, the more likely the individual will have a lowered self-esteem. A lower

degree of self-esteem may render a negative self-image, diverging from the ideal self-image individuals may hold for themselves (Burns, 1980). The ideal self can be defined as who an individual aspires to be. The ideal self is one part of self-concept and helps individuals better evaluate who they are (Burns, 1980).

How individuals perceive who they are may depend on the individual's social environment and/or culture. Self-image can further be characterized as the perception an individual has of who he/she is physically, psychologically, philosophically, and politically, developed through the agency of individual societal experiences and development (Fisher, 1986; Statt, 1990). Individuals may develop a self-image that is associated with societal roles and norms (Markus & Kityama, 1991). Individuals in collectivist or individualistic cultures may establish who they are based on the culture in which they were raised. A collectivist culture accentuates individual's social roles and responsibilities within the context of social groups, while an individualistic culture accentuates individual identity and achievements (Nevid, 2009). Thus, experiences and culture aid in the development of one's self-image. In defining individual roles, culture imparts a strong effect on the individual self-image.

Self-image has been measured in many populations by means of various psychometric scales such as the Rosenberg Self-Esteem Scale (Rosenberg, 1989). Further, theory, such as the Social Identity Theory (Tajfel & Turner, 1979) and the Objective Self-Awareness Theory (Duval & Wicklund, 1972) have emerged from interpretations of self-image and self-consciousness.

Self-Inflicted Injurious Behavior

► Suicide

Self-management

Andrea Wallace
College of Nursing, University of Iowa, Iowa City, IA, USA

Synonyms

Self-care

Definition

The process of actively engaging in activities aimed at controlling the negative effects of an illness, particularly a chronic illness, on one's health.

Description

Self-management concerns the acquisition of knowledge, as well as application of skills, necessary to engage in a complex set of health-promoting behaviors in the context of daily living. This process of integrating a number of complex behaviors in an effort to maintain wellness often involves problem-solving, decision-making, resource utilization, and communicating with multiple health-care providers. The ability to adapt health behaviors based on physiological or psychological information is a key element of self-management. The importance of self-management is undergirded by its role in health outcomes: It has been demonstrated that those who successfully engage in self-management activities experience better health-related outcomes for a number of chronic conditions.

Based on early studies of those living with chronic conditions, it has been proposed that the tasks related to self-management generally fall within three primary categories addressing: (1) medical management, which includes activities such as taking medications or adhering to a special diet; (2) role management, which includes actions allowing one to adopt roles that accommodate for ones condition; and (3) emotional management, which includes actions aimed at coping with emotions associated with an illness, such as uncertainty, depression, and fear (Corbin & Strauss, 1988). It follows, then, that a wide array of psychosocial factors play a role in one's ability to successfully engage in self-management including, but not limited to, social support, motivation, confidence (self-efficacy), and depression. In addition, the ability to read and understand written information (literacy), understand and manipulate numerical information (numeracy), verbal memory, planning, and motor speed have all been associated with disease self-management behavior.

Although disease-specific self-management education is widely accepted as beneficial, its effect on health outcomes has been difficult to establish, primarily due to variability in the nature of the programs and populations tested. Because of the complexity associated with self-management, education and support aiming to train patients to manage their chronic disease attempt to address the many factors and tasks associated with self-management as well as tailor training to the individual needs of patients. However, some common elements among self-management education programs include general information about an illness (e.g., physiology), establishing and personalizing a treatment or self-care "plan" that addresses the behaviors necessary for improved disease outcomes and strategies to facilitate health-related behavior change and maintenance (Funnell et al., 2009; Lorig & Holman, 2003). Many programs are guided by a specific theoretical framework and plan training to target variables believed to be important facilitators and barriers to self-management such as means of promoting patients' perceived self-efficacy (confidence) in engaging in health-promoting activities (Bandura, 1997). A recent focus has been on the feasibility and broad dissemination of programs facilitating self-management and behavior change.

Driven by rising prevalence, costs, and poor outcomes associated with chronic illnesses, health-care settings have recently begun to focus on models of service delivery that best support patients' self-management needs. Although these efforts have been given a number of names, some common elements include easy access to health-care providers, providing disease-specific education, incorporating interdisciplinary teams of health-care providers (e.g., physicians, social workers, physical therapists), proactive reminders to both clinicians and patients about health maintenance needs (e.g., routine blood tests), and strategies for supporting the adoption and maintenance of health-promoting behaviors, such as behavioral goal setting between health-care providers and

patients (Bodenheimer, Wagner, & Grumbach, 2002a, 2002b; Patient-Centered Primary Care Collaborative, 2010; The MacColl Institute for Healthcare Innovation, 2010).

Self-medication

Nicole Brandt
School of Pharmacy, University of Maryland, Baltimore, MD, USA

Synonyms

Self-treatment

Definition

Self-medication is the use of medications, treatments, and/or substances by an individual without a medical prescription. Self-medication is the most popular form of self-care, which is defined as the personal preservation of health through prevention and self-treatment of ailments (Ryan, Wilson, Taylor, & Greenfield, 2009). In regards to self-care, substances used to self-medicate include but are not limited to over-the-counter (OTC) medications, nutritional supplements, and other nonprescription medications. The number of OTC medications has increased significantly, allowing more individuals to practice self-medication. These nonprescription medications can be purchased at various locations such as pharmacies, supermarkets, and retail superstores (Wazaify, Shields, Hughes, & McElnay, 2005).

This increase in self-medicating practices entails both advantages and disadvantages. The benefits of self-medication include increased access to treatment, increased patient involvement in their own health care, economical choices, and evidence of cost-effectiveness compared to prescription treatments in some situations. The drawbacks of self-treatment are the threat of misuse and abuse of medications, incorrect self-diagnosis, a delay in appropriate treatment, and an increased risk of drug-drug interactions (Hughes, McElnay, & Fleming, 2001). Due to the many risks listed above, safety is a major concern with self-medication. To ensure safety with self-treatment, patient education about the

medication is a necessity (Bradley & Blenkinsopp, 1996). Pharmacists are in a pivotal position to help ensure appropriate and safe use of various medications by patients that are obtained without a prescription.

Self-Monitor

- ▶ Self-Monitoring

Self-Monitoring

Thomas Webb
Department of Psychology, The University of Sheffield, Sheffield, UK

Synonyms

Seek feedback; Self-evaluate; Self-monitor

Definition

Self-monitoring can refer to:

1. Self-monitoring expressive behavior and self-presentation: the extent to which people observe and control their expressive behavior and self-presentation (Snyder, 1974).
2. Self-monitoring goal progress: periodically noting current state and comparing these perceptions with whichever goals are currently relevant (Carver & Scheier, 1990).

Description

Self-Monitoring Expressive Behavior and Self-Presentation

People differ in the extent to which they self-monitor (observe and control) their expressive behavior and self-presentation (Snyder, 1974, 1979). High self-monitors think about how they appear to others and take care to portray themselves in a socially appropriate manner. Thus, high self-monitors are likely to monitor their facial expression, content of speech, tone of voice, expressed emotionality, and so on. In contrast, low self-monitors do not monitor these things, either because they lack the ability to do so or because they are not motivated to do so (for a review, see Gangestad & Snyder, 2000).

The Self-Monitoring Scale (Snyder, 1974) was developed to measure these individual differences. There are 25 items including "I guess I put on a show to impress or entertain people", "in different situations and with different people, I often act like very different persons", and "even if I am not enjoying myself, I often pretend to be having a good time." The scale was revised by Lennox and Wolfe (1984) who proposed a shorter 13-item scale with 6 items measuring sensitivity to the expressive behavior of others (e.g., "I am often able to read people's true emotions correctly through their eyes") and 7 items measuring the ability to modify self-presentation (e.g., "once I know what the situation calls for, it's easy for me to regulate my actions accordingly"). Lennox and Wolfe also proposed a separate 20-item "Concern for Appropriateness" scale

measuring cross situational variability (e.g., "different people tend to have different impressions about the type of person I am") and attention to social comparison information (e.g., "I usually keep up with clothing style changes by watching what others wear"). Despite this revision (and others), there remains debate over exactly what the Self-Monitoring Scale measures (e.g., Gangestad & Snyder, 2000).

A number of studies have examined differences between high and low self-monitors. For example, low self-monitors tend to behave in ways that are more consistent with their attitudes (Ajzen, Timko, & White, 1982) and are better able to imagine how their own behavior relates to particular traits (e.g., the extent to which they are sociable; Snyder & Cantor, 1980). In contrast, individuals who score high on Self-Monitoring Scales are particularly sensitive to social cues (Snyder, 1974) and are better able to imagine the prototypic type of person that would be described as holding a particular trait (e.g., a sociable person; Snyder & Cantor) perhaps because they are keen to be able to tailor their own behavior so as to demonstrate certain traits (e.g., to appear sociable). High self-monitors are even more likely to choose friends who facilitate the construction of their own situationally appropriate appearances (Snyder, Gangestad, & Simpson, 1983) and romantic partners with an attractive physical appearance (Snyder, Berscheid, & Glick, 1985). The idea that people self-monitor their expressive behavior has been hugely influential, and these studies just only hint at the wealth of differences (for a more comprehensive review, see Gangestad & Snyder, 2000).

Self-Monitoring Goal Progress

A separate, but potentially overlapping, literature has examined whether and how people monitor their current standing in relation to their personal goals. For example, whether and how people assess if they are on track to reduce their energy bill. While monitoring goal progress can involve feedback from external sources (for a review of feedback interventions, see Kluger & DeNisi, 1996), people can, and do, self-monitor. Self-monitoring in this sense involves periodically noting current state and comparing these perceptions with whichever goals are currently relevant (Carver & Scheier, 1990). For example, a person with the goal to reduce their energy bills might monitor how long they are spending in the shower. Monitoring goal progress, therefore, involves a series of processes from deciding to seek information (e.g., I need to monitor how long I spend in the shower), becoming aware of and directing attention toward relevant information (e.g., looking at the bathroom clock), interpreting the information (e.g., 10 min is quite a long shower), and so on. Relevant goals provide both a comparative standard, but also a schema for making sense of the information available (Ashford & Cummings, 1983). The person can monitor behavior (e.g., number of showers taken per week) or the outcomes of behavior (e.g., weekly energy costs) (Abraham & Michie, 2008). Monitoring may also vary on a temporal dimension (e.g., hourly, daily, weekly, or monthly) and can occur with respect to goals represented at different levels of specificity. For example, monitoring progress toward relatively high-level values comprising principles (or "be" goals, e.g., to be eco-friendly), specific behavioral goals (or "do" goals, e.g., to take shorter showers), or even the performance of motor programs (e.g., turn off the tap).

Monitoring goal progress is central to a number of models of goal striving and self-regulation (e.g., Control Theory; Carver & Scheier, 1982), but only a few studies have examined the effect of manipulating the likelihood that people would or could self-monitor. Polivy, Herman, Hackett, and Kuleshnyk (1986, Study 1) investigated the effect of being able to monitor consumption on unhealthy eating. Participants were asked to taste some chocolates and to "eat as many as necessary to ensure accurate ratings." Unbeknown to participants, the researchers manipulated how easy it was for participants to monitor their consumption; some participants were asked to leave their chocolate wrappers on the table, others to place them in a wastebasket that was already half full of wrappers. The main finding was that participants asked to leave their wrappers on the table

(and so, presumably, found it easy to monitor how many chocolates they had eaten) ate less than those asked to put the wrappers in the waste-basket. Quinn, Pascoe, Wood, and Neal (2010) found that self-monitoring helped people to break bad habits. Across two studies, prompting participants to use vigilant monitoring (thinking "don't do it" and watching carefully for mistakes) proved more effective in helping participants to avoid habitual responses (e.g., staying up too late, eating too much) than prompting stimulus control (removing oneself from the situation or removing the opportunity to perform the behavior). Prompting or facilitating behavioral monitoring has also proved an influential technique for promoting behavior change (for reviews, see Kanfer, 1970; Michie, Abraham, Whittington, McAteer, & Gupta, 2009). In summary, people who self-monitor their current standing in relation to their goals tend to be better able to achieve their goals and make changes to their behavior than people who do not.

Model of self-regulation; Self-control; Self-Regulation

Definition

Self-regulation is a dynamic and systematic process that involves efforts to modify and modulate thoughts, emotions, and actions in order to attain goals.

Description

Self-regulation refers to the dynamic cognitive, affective, and behavioral processes that underlie goal attainment. It is important to note that not all types of situations involving goal attainment or problem solving constitute self-regulation. What makes self-regulation unique is that the target of problem solving is set by or focuses on the individual (i.e., self), its "machinery" (e.g., physical problems such as symptoms), and subjective feelings or affect.

Models of self-regulation are based on the idea of cybernetic control and propose that actions are regulated by a TOTE (Test, Operate, Test, Exit) feedback control loop. Central to the idea of feedback loop is the corrective actions that result from the detection and evaluation of discrepancies between input (internal or external) and a reference value. In the context of health, "feeling good" (i.e., not having any symptoms) can be considered a reference value or goal. Thus, when a person experiences a headache (i.e., discrepancy between current state and feeling good), he or she will engage in corrective actions to rid himself or herself of the headache such as taking a pain reliever or resting. If the headache subsides (i.e., test has determined that the discrepancy was eliminated), then the loop ends (i.e., exit). If not, then a new loop will begin.

These self-regulation principles have been widely applied to the study and explanation of multiple psychological phenomena. Psychological models of self-regulation diverge in terms of their foci of interest and emphases; however, they do share core features. Common features of psychological self-regulation models are: (1) goal setting, (2) developing and enacting strategies to achieve these goals, (3) developing criteria to determine proximity to the goal, and (4) determining, based on goal proximity, whether corrective actions are needed or whether the goal needs to be revised. Self-regulation is an iterative process that may require constant evaluation to ensure that the distance between the person's status and the goal is the desired one. One additional commonality shared by behavioral models is the importance they ascribe to affective experiences as integral to self-regulation. Affect, as a core component of the motivational system, can be the reference value that

triggers self-regulatory behaviors, be the product of progress toward a goal or lack thereof (i.e., negative affect resulting from not attaining a goal), and/or influence cognitions and behaviors involved in self-regulatory activities (e.g., symptom perception). Models that integrate affective experiences with self-regulation propose that problem-focused and emotion-focused goals and the behavioral processes used by individuals to attain such goals operate in a parallel yet interrelated fashion (see commonsense model of self-regulation, stress-behavior model advanced by Lazarus and Folkman, or work on self-regulation of affect conducted by Carver and Scheier).

Hierarchical Structure of Goals

Goals are usually differentiated and hierarchically organized in terms of their level of abstraction (Carver & Scheier, 1990a). At the highest level of abstraction, one can find goals related to self-concepts (e.g., ideal self and undesired self), self-assessments (e.g., self-rated health), and general affect (e.g., depressed or happy mood). Specific, concrete actions such as daily activities performed by an individual (e.g., buying low fat food) are at the lower level of the hierarchy. Attaining higher-order goals requires that lower-level goals are accomplished; that is, lower-level goals constitute routes to higher-order ones (e.g., buying and consuming low fat food in order to achieve better health). Abstract goals also provide internal consistency and coherence to lower-level goals and to the actions performed to achieve specific higher-order goals. The relationship between goals of different levels of abstraction is quite dynamic. Thus, while a single abstract goal can be attained by pursuing multiple lower-level, concrete goals, it is also possible to simultaneously attain multiple, distinct higher-order goals by setting and pursuing the same lower-level, concrete goals. For instance, a person can get closer to their ideal, healthy self and farther from their undesired, decrepit self by engaging in similar lower-level self-regulatory activities (e.g., engaging in regular exercises and eating a healthful diet).

Feedback Loops and Behavioral Strategies Involved in Goal Attainment

In self-regulation, goals provide the reference values for feedback loops and motivate and guide actions. Individuals may engage in two types of overall feedback loops depending on whether the reference value (i.e., goal) represents a desired state (i.e., approach) or whether it represents an undesired one (i.e., avoidance, Carver, 2006). Behavior directed toward desired goals is regulated by a negative feedback loop. In this case, a reduction of the discrepancy between the current state (i.e., input) and the goal (i.e., reference value) dominates the individual's actions. Behaviors involved in the avoidance of reference value, on the other hand, are controlled by a positive feedback loop. Thus, efforts are deployed to maintain or enlarge a discrepancy between the input and the reference value. Many times avoiding an undesired state may require that individuals set desired goals. For example, infirmity (undesired goal) can be avoided by establishing a regime of regular exercise and a healthy diet (desired goals). One can argue that positive feedback loops are part of larger negative feedback loops that motivate individuals to reduce discrepancy between their current status and the reference value. In the case discussed above, an individual for whom avoiding infirmity is critical will need to develop achievable, concrete goals in order to appraise progress. Thus, the reference value for "avoiding infirmity" can take the form of "being symptom-free," a goal that is regulated by a negative feedback loop.

The two strategies discussed above assume that goals set by an individual are attainable; however, there are situations in which, regardless of effort, goal attainment can become difficult or impossible. In such situations, abandoning activities directed at the pursuit of the goal will result in better adjustment than maintaining goal-directed efforts. Research has shown that goal disengagement can result in improved well-being if goal-directed efforts are focused on alternative goals when available. If alternative goals are unavailable, inability to disengage from goal pursuit can result in frustration, negative affect, and increased stress (Miller & Wrosch, 2007).

For older adults, goal disengagement and goal reengagement may be a key strategy for adjustment to physical changes and for successful aging.

Goal attainment and affect. As indicated above, affect can be an indicator of progress toward the attainment of a goal. Carver and Scheier (1990b) have proposed a second feedback process that monitors whether a person's efforts are being successful in attaining a goal. Success in closing the gap between one's status and a given goal results in positive affect. Slow progress or failure to attain a goal, on the other hand, results in negative affect. Individuals differ in terms of the reference values they use to determine what constitutes acceptable or unacceptable progress. Accordingly, similar rates of discrepancy reduction can result in two very different responses if the individuals use different criteria to appraise the effectiveness of their actions.

Research on self-discrepancies provides an interesting example of how proximity to a goal can elicit positive or negative moods (Mora, Musumeci-Szabo, Popan, Beamon, & Leventhal, in press). These data have shown that individuals who felt they were farther from being at their worst (i.e., undesired self) reported less anxiety and depression and more happiness than their counterparts who felt closer to their feared self. These affective experiences can, in turn, influence subsequent evaluations of progress and actions. Negative mood arisen from perceptions that progress toward a goal is slow can result in maladaptive behaviors especially if new actions are focused on reducing negative feelings. Depressive feelings may alter perceptions of control over their environment and future outcomes, and lead individuals to give up on their efforts to attain a goal. Despite its critical and multifaceted role in self-regulation, there is a dearth of research examining the multiple interactive ways in which cognitive/behavioral and affective self-regulation operates.

Organization of Goals and Actions: Goal Cognitions

Germane to the relationships among goals of different levels of abstraction are goal cognitions (Karoly, 1993) and action plans (Leventhal, 1970). Goal cognitions are mental models or schemas that organize domain-specific goals and actions or procedures to attain those goals (in health literature, goal cognitions are referred as illness representations). For instance, a schema for an abstract, higher-order goal of "being healthy" would involve several less abstract concrete goals such as engaging in exercise, eating healthful food, and improving coping skills. These goals, in turn, would be connected in the mental schema to more concrete, lower-level goals such as setting days to go the gym, eating more complex carbohydrates, and learning how to meditate to reduce stress. Action plans translate aspects of goal pursuit (e.g., beliefs, attitudes, evaluation criteria) into actual, concrete behaviors. These behaviors help link goals at different levels of abstraction and provide continuity to the pursuit of abstract goals. In the current example, being healthy requires the person to set and attain multiple concrete goals. Goal cognitions will specify the action plans required to attain the concrete goals in route to reach the higher-order, abstract goal. Thus, to attain the various goals on route to being healthy, the person will need to engage in actions such as joining a gym, building a routine of going to the gym, and choosing the specific workout routine (e.g., cardio and/or weightlifting).

Conscious and Nonconscious Aspects of Self-Regulation

Although the terms "goal setting" and "self-regulation" suggest conscious volition, processes involved in self-regulation are the result of both automatic and intentional behaviors. Awareness of every single process involved in self-regulation would unnecessarily tax the organism and result in maladaptation. Action plans required for the attainment of a goal can become automated behaviors if goal pursuit is an ongoing activity. For instance, the management of a chronic condition such as hypertension requires that people take medications every day. To ensure that doses are not missed, a person may decide to put pills in a case and place this case on top of the counter next to the coffee maker.

By doing this, taking the pill can become an automated behavior that imposes a minimal burden on the cognitive system of the individual. It is in consciousness, however, where automatic and intentional processes are integrated. Ensuring that doses have not been missed, the person needs to engage in a conscious decision-making process (e.g., pick up the pill case and count the remaining pills).

Recently, investigators interested in the volitional aspects of self-regulation have been devoting increased attention to the idea of self-control. Although sometimes self-control and self-regulation are used interchangeably, self-control refers to the capacity to consciously and effortfully regulate one's affect, cognitions, and behaviors (Hagger, Wood, Stiff, & Chatzisarantis, 2010). In attempting to explain the reasons individuals engage in maladaptive behaviors (e.g., smoking), researchers have argued that self-control is a limited resource (Ego Strength model: Baumeister, Vohs, & Tice, 2007). The Ego Strength model argues that self-control works as "a muscle" that can become tired after repeated use (i.e., ego depletion). In other words, a person's capacity to engage in self-control becomes reduced following previous acts of self-control. Although the idea of ego depletion has received support from experimental studies, a recent meta-analysis suggests that the strength model does not fully explain the mechanisms underlying self-control and additional theoretical perspectives need to be integrated into the strength model (Hagger et al., 2010). The results from the meta-analysis suggest that motivation, fatigue, self-efficacy, and affect are involved in self-control and ego-depletion processes. Further research in this area is needed to better understand how self-control and ego depletion operate in real world contexts in which long-term and unplanned attempts at self-control occur frequently.

Moderators of Self-Regulation

Self-regulation occurs within particular settings and is, thus, influenced by individual, social, and cultural factors. Personality, an individual factor, has been implicated in various processes of self-regulation such as appraisal, coping, and behaviors (Cervone, Shadel, Smith, & Fiori, 2006). For instance, research has shown that individuals high in neuroticism (one of the big five personality traits) consistently and reliably perceive and report more physical symptoms than their low neuroticism counterparts (Watson & Pennebaker, 1989). Because physical symptoms are a departure from normal functioning, increases in symptomatology may trigger prompt self-regulatory actions (e.g., care seeking) if symptoms are perceived to be indicators of imminent threat. Research on coping has revealed that individual differences such as optimism and pessimism influence goal pursuit. Specifically, individuals who have positive views about the future tend to engage in problem-focused coping, whereas individuals who perceive the future as uncertain tend to either engage in emotion-focused coping or else disengage from goal pursuit (Rasmussen, Wrosch, Scheier, & Carver, 2006). Personality can also have an impact on the selection of specific behaviors used by individuals to deal with threat. There is evidence that individuals high in optimism and conscientiousness who face stressful situations select coping procedures that improve well-being and adjustment (O'Connor, Conner, Jones, McMillan, & Ferguson, 2009).

Social factors and culture can also influence the various stages of self-regulation from goal setting to selection and performance of corrective actions through multiple pathways. Social comparisons can help individuals to determine the origin of their physical symptoms (e.g., food poisoning if everybody at dinner has the same symptoms or stomach flu if symptoms are unique to one person) and, thereby, select the necessary corrective actions to deal with such symptoms (Leventhal, Hudson, & Robitaille, 1997). Research has also demonstrated that social relations (i.e., social network size) can influence long-term self-regulatory activities such as participation in cardiac rehabilitation among patients with acute coronary syndrome (Molloy, Perkins-Porras, Strike, & Steptoe, 2008).

Culture has been shown to influence the type of stimuli that trigger self-regulation, the content

of goals, the specific corrective actions, and the appraisal criteria involved in goal attainment. Anthropological research has shown that the interpretation and attribution of bodily symptoms varies across culture. This body of evidence suggests that culturally determined illness models are powerful determinants of the ways people experience illness conditions. For example, work on depression has shown that among certain ethnic groups (e.g., Chinese), depression is usually experienced as a somatic disorder (Kleinman, 1977). This difference in experience can shape what actions are taken to remediate the problem (e.g., seeing a primary care physician instead of a mental health specialist) and the criteria to determine the success of the remedial actions (e.g., improvement in physical versus affective well-being). The impact of culture on the construction and development of the self has led some authors to question the idea that self-regulation is set by and focuses on the individual. In collectivistic cultures where the self is construed as closely interrelated to others, goal setting can be motivated by a need to please the person's social network (Trommsdorff, 2009). Future research needs to determine whether the mechanisms of self-regulation guided by interrelatedness are different from those underlying self-regulation of intraindividual processes.

Self-Regulation and Health

Although most models of self-regulation have originated outside the domain of behavioral medicine (see the Commonsense Model of Self-regulation for an exception), the use of self-regulatory principles and ideas to understand health-related behaviors has been relatively widespread. Models such as the Health Beliefs Model, Theory of Reasoned Action, and Social Cognitive Theory which focus on specific aspects of self-regulation such as social (e.g., norms) and psychological (e.g., self-efficacy) determinants have been utilized to understand self-regulation of health behaviors. In general, the use of these models has focused more on the description of predictors of goals rather than on the underlying mechanisms that explain self-regulatory behaviors. In addition, goal pursuit is usually examined by these models as a single-event rather than a continuous process (Maes & Karoly, 2005). Recent efforts, however, have been directed at the understanding and examination of self-regulation as a process by investigating how goal-directed behaviors in health domains are initiated and maintained. Evidence has provided convincing support that the various phases of self-regulation are controlled by different processes. Studies examining health behaviors such as smoking cessation and engagement in exercise activities have revealed that factors such as self-efficacy and attitudes toward the specific behavior are important determinants of initiation. Maintenance of health behaviors, on the other hand, is influenced by factors such as satisfaction with behavioral change. A recent study examining data from participants in a smoking cessation program provided further evidence of the complexity of self-regulation processes (Baldwin, Rothman, & Jeffery, 2009). In this study, the authors found that maintenance of health-related behaviors was a heterogeneous process and that the factors that influenced satisfaction with behavioral maintenance varied according to whether they had quit smoking recently or not.

Final Remarks

Literature and research on self-regulation has grown rapidly over the past 20 years. New research has expanded the understanding of self-regulation mechanisms but more research is needed. Some of the research questions that remained underexplored include changes in self-regulation over time, factors that contribute to long-term self-regulatory behaviors (e.g., adherence to medical treatment for chronic conditions), and the multiple and simultaneous pathways through which cognitive and affective self-regulation interact.

New opportunities provided by advances in technology, especially in brain imaging, are opening exciting areas of inquiry (e.g., cognitive neuroscience of self-regulation). Similarly, increased understanding of the psychophysiology of stress offers an invaluable opportunity to understand how self-regulatory processes get under the skin.

Self-Regulatory Ability

► Self-Regulatory Capacity

Self-Regulatory Capacity

David Cameron and Thomas Webb
Department of Psychology, The University of Sheffield, Sheffield, UK

Synonyms

Self-control capacity; Self-regulatory ability; Strength model of self-control

Definition

Self-regulatory capacity refers to people's ability to exert control over their thoughts, feelings, and actions. For example, the capacity to inhibit prejudice, make oneself feel better, or select healthy food. Self-regulatory capacity is, however, thought to be a limited resource that (1) is temporarily depleted by exertions of self-control (an effect termed "ego-depletion") and (2) differs in strength from person to person.

Description

Limited Self-Regulatory Capacity

Self-regulatory capacity refers to an individual's ability to exert control over their behavior, thoughts, and feelings. The capacity for self-regulation differs between individuals and can depend on situational factors such as the experience of self-regulatory fatigue. Self-regulation is closely related to goal-driven behavior and is characterized by the process of attempting to work toward a desired held goal. For example, in terms of health behavior, an individual may regulate their diet in order to reach their goal of being a healthy weight or resist a personal temptation such as cigarettes to reach their goal of overcoming a smoking addiction. Self-regulatory capacity would influence how successfully an individual pursues such goals, alongside other factors such as the prepotency of the action that needs to be overcome. Persistence with self-regulation can lead to a temporary state of fatigue in which self-regulatory capacity is reduced and a state of depleted self-regulatory capacity is associated with lapses of self-regulation. In terms of the prior examples, this could include short-term gratifications such as deviations from a planned diet or the resumption of smoking.

Self-regulatory capacity can be measured using a wide variety of cognitive or behavioral tests. Examples include persistence at impossible (e.g., completing unsolvable anagrams) or aversive (e.g., consuming unpleasant drinks, squeezing a handgrip, cold pressor) tasks; response time or errors made in inhibition tasks (Stroop task, stop signal); resisting temptation (limiting alcohol consumption); and suppression of emotions. The key criterion for a task that measures self-regulatory capacity is the requirement for the person to override an otherwise dominant response (e.g., the desire to give up, to read the words in the Stroop task). Tasks that are simply difficult (e.g., complex math puzzles) or stressful (e.g., watching an emotional video) are unlikely to reflect the same ability. As self-control is considered to draw from a universal pool, putting two of these tasks together, one after the other, can provide a measure of self-control capacity – the extent to which a person's ability to perform a self-control task is impaired by the initial exertion of self-control.

Self-regulatory capacity has an important relation to health behavior. Many behaviors which are considered to be beneficial in the long term such as eating a healthy diet or maintaining an exercise regimen are notably absent from people's routines, while behaviors that are demonstrably harmful in the long term such as smoking, unhealthy diets, unprotected sexual intercourse, or substance abuse are common in society. The contrast between these behaviors can be seen in the temporal distance between

the costs and benefits: behaviors associated with improved health will generally only show a beneficial change over a longer term while the costs (such as the effort required to change behavior through self-regulation) are high in the short term, whereas behaviors that show a high cost of being harmful to health in the long term offer immediate benefits (such as the satiation of an immediate desire or need). In the context of temporal self-regulation theory (Hall & Fong, 2007), self-regulatory capacity acts as a moderator of the link between an individual's intentions for health behavior, which are shaped by the temporal differences between perceived costs and benefits for an action, and the individual's actual observed behavior. A greater capacity for self-regulation is predicted to be associated with the ability to overcome prepotent responses, such as habitual smoking, and follow intentions for behavior, such as intention to quit smoking. Limited capacity for regulation is predicted to be associated with lapses in self-control and the resumption of prepotent responses. Thus, despite the intention to quit smoking, this would not translate into actionable behavior.

Nature of Self-Regulatory Capacity

Despite many studies showing effects consistent with the idea that people have a finite capacity for self-regulation, the precise nature of self-regulatory capacity remains more elusive. Gailliot, Baumeister, DeWall, Maner, Plant, Tice, Brewer, and Schmeichel (2007) found that (1) depletions in self-control capacity (as evidenced by performance on self-control tasks) were correlated with blood glucose levels and (2) self-control performance could be restored by blood glucose supplements (namely, lemonade). On the basis of this evidence, they argue that self-regulatory capacity reflects the available supply of glucose. However, it seems unlikely that the body would struggle to quickly provide sufficient glucose to the brain following single or repeated attempts at self-control, and further research is needed to interrogate the glucose hypothesis in more detail (Beedie & Lane, 2012).

Self-regulatory capacity's apparent dependence on a glucose supply suggests a similarity with other broader processes in executive function which are known to be affected by available glucose levels, for example, that of the attentional system. Self-regulation is considered to exist alongside this diverse array of higher cognitive processes and may work in concert with others, particularly that of planning and error detection. Self-regulation can be considered as a goal-driven process because it is a process used by an individual who seeks to override one state of behavior, thoughts, or feelings with another goal state. As such, an individual is required to recruit multiple executive processes to reach goal states, representations of one's current state and goal state much be held alongside a plan for how to achieve the goal state, detection of discrepancy (or error) between these two states must occur, and self-regulation to change the current experienced state toward the goal is required. Apparent failures in the wider system of self-regulation may not be restricted to a depleted self-regulatory capacity; related systems such as that of error detection may impair self-regulation, if there is an incorrect perception of error between the current state and desired state.

Like other aspects of executive function, self-regulatory capacity is associated with the frontal lobes. Both neuroimaging and lesion studies indicate that self-regulatory actions such as the control of behavioral and emotional output is closely associated with the ventromedial prefrontal cortex. Alongside this, the ventromedial-orbitofrontal cortex has been particularly associated with the self-regulatory process of suppressing responses that have previously been considered rewarding. Damage to this area often results in a diminished or absent ability to inhibit immediately rewarding actions, even though the semantic knowledge of an action's inappropriateness may still be intact. These regions associated with self-regulatory capacity show high connectivity with executive areas related to the processes involved in self-monitoring, which support the process of self-regulation. The anterior cingulate cortex is associated with the degree and nature of conflict between competing responses to situations such as the short-term desire to satiate an immediate need against

the longer-term goal for a healthier lifestyle. The dorsolateral prefrontal cortex has been associated with the resolution of detected response conflict alongside attentional and planning behavior. These regions working in cohort are considered to form the neural circuitry underpinning self-regulation.

Individual Differences in Self-Regulatory Capacity

In addition to situational demands on self-regulatory capacity, there is also a body of research suggesting that there may be stable individual differences in self-regulatory capacity. Some people simply seem better than others at, for example, selecting healthy food, cheering themselves up, and acting in an egalitarian manner. In support of this idea, Hofmann, Gschwendner, Friese, Wiers, and Schmitt (2008) found that individual differences in working memory capacity moderated participants' ability to self-regulate their sexual interest, consumption of tempting food, and anger expression. In a similar vein, a number of authors have proposed measures of self-regulatory capacity such as the Self-Control Behavior Inventory (Fagen, Long, & Stevens, 1975), the Self-Control Questionnaire (Brandon, Oescher, & Loftin, 1990), and the Brief Self-Control Scale (BSCS; Tangney, Baumeister, & Boone, 2004). In each case, differences have been found between people that reliably map onto various self-control outcomes such as task performance, impulse control, interpersonal relations, and so on.

Building Self-Regulatory Capacity

Finally, there is some evidence that people can build self-regulatory capacity through regular training. For example, Muraven (2010) found that participants who practiced self-control by cutting back on sweets or squeezing a handgrip over a 2-week period showed significant improvement in self-control capacity relative to those who practiced tasks that were comparably effortful, but did not require self-control. This improvement was demonstrated in a stop signal task, unrelated to that of the training. In support of these findings, the meta-analysis conducted by Hagger, Wood, Stiff, and Chatzisarantis (2010) reported large and significant effect sizes across seven further tests of the training hypothesis.

Self-Regulatory Fatigue

David Cameron and Thomas Webb
Department of Psychology, The University of Sheffield, Sheffield, UK

Synonyms

Ego-depletion; Limited resource; Self-control failure

Definition

Self-regulatory fatigue refers to the temporary depletion of individuals' capacity for self-control. In a state of self-regulatory fatigue, individuals find it harder to resist making impulsive purchases, inhibit prejudice, or regulate their own emotions (an effect often termed "ego-depletion"). Self-regulatory fatigue arises from the extended use of self-regulation, which is thought to be a limited resource.

Description

Limited Self-Regulatory Capacity

Self-regulatory fatigue describes the temporary impairment in self-control performance after prior exertions of self-control (an effect also referred to as "ego-depletion"). The strength model of self-regulation, first suggested by Baumeister, Heatherton, and Tice in 1994, draws the analogy between muscular fatigue and self-regulatory fatigue. Muscular fatigue occurs after repeated or prolonged acts of physical exertion, where longer or more effortful exertions lead to a greater experience of fatigue. Similarly, persistent acts of self-regulation, such as the overriding of impulses, result in a mental fatigue, limiting the effectiveness of further regulatory efforts. Again, longer or more effortful exertions of self-regulation lead to a greater experience of self-regulatory fatigue. Like muscular fatigue, rest and recuperation are hypothesized to restore the temporary depletion in self-regulatory strength.

It is important to distinguish between subjective and actual self-regulatory fatigue, although the two can coincide. Self-regulatory persistence and ego-depletion is associated with the physiological indications and subjective feelings of fatigue such as somnolence and decreased attention. Subjective fatigue is thought to mediate between exertions of self-regulation and subsequent decrements in self-regulatory ability. However, subjective fatigue – or the belief that one is fatigued – can have effects that are independent of actual fatigue. Despite experiencing prior effortful self-regulation, individuals perceiving themselves to be low in fatigue can engage in subsequent regulation more effectively than those perceiving themselves to be high in fatigue. A second contributing factor to the state of self-regulatory fatigue is motivation. Individuals may cease persistence at self-regulation if they believe that the effort exerted during self-regulation costs more than the outcome of self-regulation is worth. Self-regulatory fatigue is, therefore, not merely a state of exhaustion in which the individual is willing to engage a task and yet unable to persist but can also lead to acquiescence – the person willfully consents to relax self-control because they are not motivated to do otherwise.

Measuring Self-Regulatory Fatigue

The state of the resource required for self-regulation (assuming that one subscribes to a limited resource model of self-regulation) has proven difficult to objectively measure. At present, the primary means of measuring self-regulatory fatigue is a comparison of performance at a self-regulatory task between individuals in a depleted state (those having exerted prior self-regulation) against individuals in a nondepleted state (those having completed a similar task that does not require self-regulation). Because experimental studies of ego-depletion rely on a comparison of self-regulatory task performance pre- and postdepletion, they only indirectly measure the limited resource. As a result, the relationship between subjective fatigue, motivation, and self-regulatory fatigue is

still unclear. Blood glucose levels have been reported to show a correlation with self-regulatory fatigue, suggesting a positive link between available caloric energy to the brain and available mental resource (Gailliot, 2008). This development offers an alternative avenue to exploring self-regulatory fatigue and the dynamics of ego-depletion through physiological measures rather than behavioral outcomes. However, suggestions of a direct, causal link have been criticized because recorded changes in blood glucose are too small to account for differences between depleted and nondepleted states (Beedie & Lane, 2012). Alternative physiological measures, such as glycogen store levels and heart rate variability, have been suggested as means of measuring resource availability and self-regulatory fatigue.

Overcoming Self-Regulatory Fatigue

The effects of self-regulatory fatigue may be moderated or counteracted by a number of means. The induction of a positive mood by others including humor and laughter, observation of others undergoing successful self-regulation, salient social goals, primed ideas of success, a broadened mindset through self-affirmation, external attribution of the causes of depletion, perception of a low state of fatigue, simultaneous tensing or firming of muscles, and monetary incentives all serve to encourage individuals to persist at self-regulation. However, in many cases, this increased persistence is believed to be associated with a decreased motivation to conserve remaining resources, rather than a restoration of resource levels. Poor performance in an unannounced third self-regulatory task after the standard two-task design often indicates that depleted participants have persisted beyond their typical point of self-regulatory fatigue rather than restored resource. Further interventions, such as the prior practice of self-regulation tasks or the formulation of implementation intentions ("if... then..." plans), serve to encourage persistence at self-regulation through moderating the effort required to expend during successful self-regulation (Webb & Sheeran, 2003). Self-regulatory fatigue may only be overcome on a longer-term basis through the replenishment of available regulatory resource, which is thought to only occur with caloric intake, or rest and relaxation. Sufficient sleep is closely connected with the reduction of subjective fatigue and with performance on cognitive tasks; while it has been suggested to reduce self-regulatory fatigue, it is yet to be formally integrated into the strength model.

Wider Implications of Self-Regulatory Fatigue

Self-regulatory fatigue has been implicated in a number of problems for both the individual and society. While warnings about substance abuse, risky sexual practice, and unhealthy diets are extensively promoted, there equally exists a widespread failure of individuals to adhere to these guidelines or rules. Experimental studies such as those examining alcohol or unhealthy food consumption demonstrate that these behaviors are affected by both self-regulatory fatigue and individuals' chronic tendencies. A chronic tendency that is typically suppressed, such as a high temptation to drink alcohol, becomes more likely to shape behavior when an individual is depleted. In contrast, an individual with low trait temptation to drink alcohol might show no change in alcohol consumption when depleted because it is not necessary to engage in self-regulation. Further examples of behaviors affected by self-regulatory fatigue include impulsive or overspending, emotional regulation such as anger management, interpersonal interaction, self-presentation or impression formation, and stereotype suppression.

Self-report

Jane Upton
School of Sport and Exercise Sciences, University of Birmingham, Edgbaston, Birmingham, UK

Synonyms

Self-report inventory

Definition

Self-report includes an individual's reports about what they are feeling, what they are doing, and what they recall happening in the past (Stone et al., 2009).

These are captured by validated self-report questionnaires, of which there are many. Indeed, one of the challenges facing behavioral medicine is the bewildering variety of measurement instruments (Dekker, 2009). Although validated, the limitations of self-report questionnaires are that the researcher is dependent on the research participant to be completely truthful and unbiased and to be able to accurately remember details.

Seligman, Martin

Stephanie Ann Hooker
Department of Psychology, University of Colorado, Denver, CO, USA

Biographical Information

Dr. Martin Seligman

Martin E. P. Seligman was born August 12, 1942, in Albany, NY. He received his A.B. from Princeton University in 1964 and his Ph.D. in Psychology from the University of Pennsylvania in 1967 (Shah, n.d.). After receiving his doctorate, he began his career as an assistant professor at Cornell University in Ithaca, NY. He soon returned to the University of Pennsylvania where he was promoted to associate professor and to professor of Psychology and then to director of the Clinical Training Program. He is currently the Zellerbach Family Professor of Psychology in the Department of Psychology at the University of Pennsylvania and the director of the Positive Psychology Center (University of Pennsylvania, 2007). Early in his career, Seligman studied depression and defined the theory of learned helplessness and pessimism. His worked progressed from a focus on pessimism to optimism, and hence from depression to happiness. He believed that psychology focused too much on mental illness and not enough on health and flourishing; thus, he pioneered the field of positive psychology in 2000 (Seligman & Csikzentmihalyi, 2000).

Major Accomplishments

In 1996, Seligman was elected president of the American Psychological Association (APA) by the largest vote in history. As president, he chose the theme of positive psychology and called for an integration of human flourishing, strengths, and virtues into the science and practice of psychology. He noted that psychology and psychiatry had focused primarily on mental illness (e.g., depression, suffering, victimization, anger, anxiety), but had forgotten positive forms of mental health (e.g., positive emotion, engagement, positive relationships, purpose, accomplishment) (Seligman, 2008). His mission in the APA paralleled his personal mission to promote positive psychology.

In 2008, he began his next mission: to promote a new movement in psychology, positive health (Seligman, 2008). He argued that people desire more than just the absence of suffering and pain; they desire well-being and flourishing that in itself can be protective against mental illness and disease. Thus, he defined positive health as the subjective, biological, and functional realms that can predict positive aspects of mental health, e.g., longevity, positive emotion, prognosis, and suggested areas for which positive health could be incorporated into studies of well-being and illness.

Seligman has published 20 books and over 200 articles on motivation and personality, including best sellers such as *Learned Optimism*, *Authentic Happiness*, and *The Optimistic Child* (Shah, n.d.). He is one of the most often-cited psychologists and the thirteenth most likely name to appear in a general psychology textbook (TED Conferences LLC, 2008). Seligman also created the Masters of Applied Positive Psychology program at the University of Pennsylvania. Many institutions, including the National Institute on Aging, the National Science Foundation, and the

National Institute of Mental Health, have supported his research. He has received numerous awards, including two Distinguished Scientific Contribution awards from the APA, the William James Fellow Award, and the James McKeen Cattell Fellow Award from the Association for Psychological Science, the MERIT Award from the National Institute of Mental Health, the Laurel Award of the American Association for Applied Psychology and Prevention, and the Lifetime Achievement Award of the Society for Research in Psychopathology.

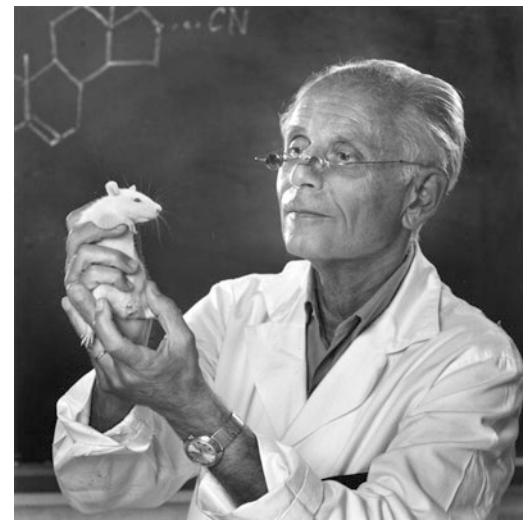
Selye, Hans

Adrienne Stauder
Institute of Behavioural Sciences, Semmelweis University Budapest, Budapest, Hungary

Biographical Information

Dr. Hans Selye 1973
Photo by Yousuf Karsh



Hans Selye was born on January 26, 1907, in Vienna, Austria. His mother Maria Felicitas Langbank was an Austrian, his father Hugo Selye was a Hungarian military surgeon, and his grandfather and great grandfather were family doctors. Selye completed his elementary and secondary school education in Komarno (Slovakia). Since 1924 he studied medicine in Prague, Rome, and Paris, and obtained his diploma at the German University of Prague in 1929. He started his research at the Institute of Experimental Pathology in Prague, and got his doctorate in biochemistry in 1931.

A Rockefeller Research Fellowship allowed Selye to continue his scientific career at the Department of Biochemical Hygiene of the Johns Hopkins University in Baltimore in 1931,

and then from 1932 at the Department of Biochemistry of the McGill University in Montreal. He became lecturer then associate professor in biochemistry, and also in histology. He received Canadian citizenship in 1939, and became Doctor of Sciences in 1942. From 1945 to 1976 he directed the Institute of Experimental Medicine and Surgery (IMCE) at the University of Montreal, which gained international reputation under his leadership. After his retirement he remained active as founding president of the International Institute of Stress in Montreal (1976), and as co-founder of the Hans Selye Foundation (1979) until his death on October 15, 1982.

Selye held honorary doctorates from 18 universities, was a member of the Academy of Science of the Royal Society of Canada and 43 scientific societies, was an honorary citizen of many cities and countries, and received numerous high-ranking awards and distinctions. He was nominated for the Nobel Prize in physiology or medicine for 10 consecutive years (first in 1949), but he never received it. In 2006 he was inducted as a member of the Canadian Medical Hall of Fame.

Major Accomplishments

Selye is one of the most well-known, most productive scientists of the twentieth century. He wrote his name in the history of science by introducing the concept of stress. As a result of his work the word "stress" previously used in other contexts gained a physiological meaning and has been adopted in all languages. His research work had great impact in the field of endocrinology, physiology, biochemistry, epidemiology of chronic diseases, and behavioral medicine, not only on scientific thinking but also among lay people all around the world. Selye authored or coauthored 39 books and over 1,600 scientific articles, and his work has been estimated to have been cited in more than 300,000 scientific papers, although Somorjai (2007) could compile a list of only 800 of all his publications.

Selye's most important finding, the discovery of the stress syndrome, was accidental during his attempts to isolate a special female hormone from the placenta (Selye, 1964, 1967b). The originality of his thinking was that he started to research the significance of the nonspecific reactions that he observed. His first short note describing "the nonspecific response to nocuous agents" was published in Nature in 1936, followed in the same year by a longer article in The British Journal of Experimental Pathology describing the General Adaptation Syndrome. In the following years, he systematically developed his comprehensive theory on stress (Selye, 1950) and envisaged the existence of diseases of adaptation (Selye, 1946).

His researches on steroids turned his interest to the inflammatory process (Selye, 1943, 1949, 1965), then to the phenomena of calciphylaxis (Selye, 1962) and of thrombohemorrhagy (Selye, 1967a). Through these experiments he confirmed his hypothesis that diseases such as heart disease, rheumatoid arthritis, anaphylaxis, depression, autoimmune diseases, and Alzheimer disease are in fact all diseases of adaptation. Although his experiments were always on animals, over the years Selye became more and more interested in how his research results could be applied to medicine and to society. While his original definition of stress – "nonspecific response of the living organism to any stimuli, for example, effort, focused attention, pain, illness, failure, joy, success, that cause changes," – implied that the stressor can be either pleasant or unpleasant, since similar physiological/biochemical changes are produced, he later made the distinction between good stress (eustress) and bad stress (distress) (Selye, 1974).

Selye expanded his model to include Perception, Conditioning Factors, and Coping Mechanisms. This so-called *Selye – Smith Conceptual Model of Stress Variables* served as theoretical basis to the comprehensive course "Stress Management for Optimal Health" offered by Selye's Institute first to health professionals and then to the lay public (Smith & Selye, 1979). Selye proposed that stress education and stress management should be important elements of preventive medicine.

Research was a passion for Selye. He was very much interested in great discoveries, the history

and psychology of science, and in personal characteristics of scientists. These topics appeared in his lectures, books, and also in his every day discussions. He emphasized that original ideas were the most important elements in research that must be tested and proved by well-designed experiments. He also gave special attention to research methodology. On one hand, he was reluctant to adapt complicated technological methods, and he emphasized in all forums that one always should try to view the entire organism in its complexity and not to get lost with tiny little details without considering how they relate to the whole organism (Selye, 1967b). On the other hand he introduced new methods in experimental surgery (Selye, Bajusz, Grasso, & Mendell, 1960). He also carefully selected his laboratory assistants based on their skillfulness.

Effective information processing was another key element of Selye's exceptional productivity. He systematically developed his library that became world famous. He worked out his own "Symbolic Shorthand System for Medicine and Physiology" (SSS) that was subsequently published and used until the start of the computer era (Selye & Mishra, 1957). He also followed a very structured daily schedule at his Institute as well as in his private life (Selye, 1964). Selye was also a charismatic teacher. He shared his knowledge and his devotion to science with his fellow workers and students, exerting a deep influence on their lives and careers. He invited talented young researchers from all over the world to work in his Institute. He also invited many world renowned professors (the so-called Claude Bernard Professors). Thus, young researchers had the opportunity to meet famous personalities. They not only delivered one or two lectures, but participated in daily routine of the Institute and at informal dinners and discussions at Selye's house. Selye also traveled over the world and very often he obtained the recognition of his audience not only by his research results and presentation style, but also by giving his lecture in the language of the respective country. He not only shared his experiences with the scientific community, but could transmit his knowledge about stress, the process of scientific research, and related subjects to the general lay population by writing several popular books such as The Stress of Life (1956), From Dream to Discovery (1964), In Vivo: The Case for Supramolecular Biology (1967b), and Stress without Distress (1974) that have been translated into many languages.

Selye's scientific heritage is formally maintained by the Hans Selye Foundation, Montreal, Canada, www.stresscanada.org.

Serostatus: Seronegative and Seropositive

Angela White
Department of Psychology, University of Connecticut, Storrs, CT, USA

Synonyms

HIV status

Definition

Serostatus refers to the extent to which HIV antibodies can be detected in an individual's serum. This detection is an indicator of HIV infection.

Description

An individual is considered to be seronegative when the amount of HIV antibodies are not sufficient enough to be detected using an antibody test, although indication of HIV infection can be determined through the use of more sensitive culture, antigen, and viral gene detection techniques (Fultz, 1989; Kaslow & Francis, 1989; O'Malley, 1988). Individuals who are seronegative may not produce HIV antibodies for months or year after HIV infection, or they may stop producing these antibodies after some unknown time interval. There is a long incubation period associated with being seronegative; individuals may not show physical symptoms associated with HIV/AIDS for several months or years after the initial HIV infection. As such, it is difficult to determine the ability of seronegative individuals to spread HIV (Kaslow & Francis, 1989).

An individual is considered to be seropositive when HIV antibodies are detected on a HIV antibody test (Fultz, 1989; O'Malley, 1988). Individuals who have detectable HIV antibodies are considered to be "HIV-positive." The period of time between HIV infection and seroconversion (the presence of detectable antibodies in the serum) may range from 2 weeks to 3 months; this period of time is referred to as the "window period" (Stine, 2003).

Some individuals who are seropositive, or "HIV-positive," exhibit symptoms associated with an acute mononucleosis-like syndrome immediately after being infected with HIV. This syndrome has been known as acute HIV syndrome or acute retroviral syndrome; its symptoms include sweats, lethargy, headaches, muscle aches, fever, and sore throat (Fultz, 1989; Stine, 2003). Not all seropositive individuals experience this syndrome. Other seropositive individuals remain asymptomatic for several weeks. All seropositive individuals, whether symptomatic or asymptomatic, are infected with HIV and can infect others through blood and genital secretions and by transmission from mother to fetus (Fultz, 1989; O'Malley, 1988). In 2001, the Center for Disease Control and Prevention proposed the Serostatus Approach to Fighting the HIV Epidemic (SAFE) program to encourage awareness that individuals may be HIV-positive even if they appear to be outwardly healthy. This program attempted to reduce the spread of HIV by extending prevention services and improving treatment adherence for individuals with a seropositive status and by providing training to individuals who give these services (Normand, Vlahov, & Moses, 1995; Stine, 2003).

Being notified of a seropositive status is associated with behavioral and psychological changes. For instance, individuals who receive a positive test result may reduce their high-risk sexual activity. However, they also may experience increased stress and depression. Also, these individuals may feel compelled to disclose their HIV status to family, friends, and potential sexual parents. Some barriers associated with the disclosing HIV status include the disclosure of a stigmatized identity (such as being gay or an intravenous drug user), the fear of losing health insurance or employment, and the concern of being stigmatized by family and friends (Stall, Coates, Mandel, Morales, & Sorensen, 1989).

Serotonin

Marc D. Gellman
Behavioral Medicine Research Center, Department of Psychology, University of Miami, Miami, FL, USA

Definition

Serotonin (5-hydroxytryptamine or 5-HT) is a neurotransmitter that is particularly important in central nervous system modulation. It is involved in the regulation of mood, appetite, and sleep, and in the cognitive functions of learning and memory.

Modulation of serotonin at synapses is thought to be a major action of several classes of pharmacological antidepressants, including selective serotonin reuptake inhibitors (SSRIs).

Serotonin Transporter Gene

Anett Mueller[1] and Turhan Canli[2]
[1]Department of Psychology, State University of New York at Stony Brook, Stony Brook, NY, USA
[2]Department of Psychology, Stony Brook University Psychology B-214, Stony Brook, NY, USA

Synonyms

SERT; SLC6A4 (solute carrier family 6, member 4)

Definition

In humans, the gene that encodes for the serotonin transporter is called the serotonin transporter gene which is modulated by the functional serotonin-transporter-linked polymorphism (5-HTTLPR), a variable number of tandem repeats in the 5' promoter region.

Description

The neurotransmitter *serotonin* (5-hydroxytryptamine, 5-HT) is probably best known for its modulation of neural activity and the modulation of various neuropsychological processes such as mood, perception, emotion, and cognition. Serotonin is also implicated in the pathogenesis of many psychiatric and neurological disorders and furthermore, it is involved in brain development and plasticity of brain areas related to cognitive and emotional processes (Berger, Gray, & Roth, 2009; Trevor, Katzung, & Masters, 2010). Additionally, the serotonin transporter is considered to be the initial site of action of broadly used antidepressant drugs, such as selective serotonin uptake inhibitors (SSRIs), and several potentially neurotoxic compounds.

Following neuronal stimulation, serotonin is transmitted into the synaptic cleft and then binds to receptors on the membrane of the postsynaptic

neuron. Serotonin is then removed from the synaptic cleft via special proteins, called *transporters*. Serotonin transporters are located in the serotonin neuron; they transport serotonin from the synaptic cleft back into the presynaptic neuron in both the brain and many peripheral tissues terminals. In humans, the gene that codes for the serotonin transporter contains a number of common variants (polymorphisms), including the serotonin-transporter-linked promoter region (*5-HTTLPR)* of the serotonin transporter gene (SLC6A4). This polymorphism is located upstream of the transcription start site on the long arm of the 17th chromosome (17q11.1-q12). The majority of alleles are composed of either fourteen ("short" or "*S*" allele) or sixteen repeated ("long" or "*L*" for allele) units, which differentially modulate on the expression and function of 5-HTT. The short form of *5-HTTLPR* has been associated with a reduced transcription of the 5-HTT gene, which leads to a decreased 5-HTT expression and availability and also a reduced 5-HT uptake (Lesch et al., 1996). In addition to the *S* and *L* alleles, there is an A > G single nucleotide polymorphism (SNP), a single nucleotide variation in a genetic sequence, upstream of the repetitive region that comprises the *5-HTTLPR*. The derived L_G allele has been associated with decreased 5-HTT transcription relative to the L_A allele. The frequency of *5-HTTLPR* alleles can vary substantially across ethnic groups, thus, showing population stratification.

The short allele variant of *5-HTTLPR* was first reported to be associated with personality traits such as neuroticism and harm avoidance (Lesch et al.,). Subsequent work has reported *5-HTTLPR* allelic variation to a wide range of phenotypes including aggression, anxiety, and affective disorders. Most studies have implied that *5-HTTLPR* has only a moderate impact on these behavioral predispositions of 3–4% or less of the total variance. The less active *S* allele has been associated, either by itself or in interaction with adverse life events, with abnormal levels of anxiety, fear, and depression. Despite the association between presence of the *S* allele and psychopathology, studies of patient responsiveness to SSRIs suggest no strong link between *5-HTTLPR* genotype and drug effectiveness.

However, if the *S* allele produced only deleterious consequences, evolutionary pressures should have led to its removal from the gene pool. Thus, more recent studies have begun to accrue evidence for favorable phenotypes associated with the *S* allele. For example, studies revealed an improved performance in (social) cognition in individuals with the *S* allele (Homberg & Lesch, 2010). On the other hand, the *L* allele, originally viewed as the protective allele, also has negative associations with at-risk phenotypes, such as cardiovascular health (e.g., increased cardiovascular reactivity and greater probability of myocardial infarction) (Fumeron et al., 2002; Williams et al., 2001) or certain psychiatric diseases (e.g., psychosis or posttraumatic stress disorder, PTSD) (Goldberg et al., 2009; Grabe et al., 2009). In addition to allelic association on observed phenotypes, there is growing evidence for gene-by-environment (G x E) interactions, suggesting that individuals possessing the *S* allele are predisposed to an increased risk for major depression or suicidal ideation as a function of early life stress. The first evidence for this G x E interaction in humans was presented by Caspi et al., (2003) who investigated more than 800 individuals over 23 years and found that life stress and depression was moderated by the *5-HTTLPR* genotype. Individuals with the *S* allele showed a higher probability of depressive symptoms, diagnosis of depression and suicidal attempts when exposed to stressful life events. However, replication studies have shown somewhat inconsistent results and thus, these findings are still a matter of debate. In addition to behavioral studies, noninvasive functional MRI (fMRI) studies have also shown that structural and functional characteristics of neural circuits involved in emotion and cognition can be moderated by the interaction of life stress and 5-HTTLPR genotype.

Most recently, investigators have come to recognize the potential gene regulatory role of epigenetic mechanisms in mediating environmental effects on brain function and on behavior

(Rutter, Moffitt, & Caspi, 2006). For example, it has been argued that environmental influences bear the potential to persistently modify neuronal units during early development by epigenetic programming of emotionality (Weaver et al., 2004; Weaver, 2007). This has first been shown with respect to the glucocorticoid receptor gene and individual differences in rodents' stress reactivity: variations in maternal care have been shown to modify the expression of genes that regulate behavioral and endocrine responses to stress and hippocampus synaptic development. Thus, alterations of particular genomic regions within the 5-HTT in response to varying environmental conditions might serve well as a major source of variation in biological and behavioral phenotypes. Indeed, there is now emerging evidence linking *5-HTTLPR* genotype to individual differences in epigenetic methylation (Philibert et al., 2007, 2008).

Studies that use biological endophenotypes, such as stress-induced HPA activation, might be more strongly associated with a specific polymorphism than a psychiatric disorder (Uher & McGuffin, 2010). However, given the fact that brain serotonin and more specifically *5-HTTLPR* shows pleiotropic behavioral effects, we need to learn and understand more about the biological function and how *5-HTTLPR* becomes associated with various different phenotypes. The modulation of these multiple behavioral processes might very likely be regulated by multiple serotonin receptors that are expressed in multiple brain regions. In summary, *5-HTTLPR* seems to play an important, though not yet fully understood, role in behavioral medicine. We will likely gain new serotonergic drugs and disease treatments as well as a more thorough understanding of complexity of human biology from this research.

Serum

Briain O. Hartaigh
School of Sport and Exercise Sciences,
The University of Birmingham,
Edgbaston, Birmingham, UK

Synonyms

Antiserum; Sera

Definition

Serum is blood plasma with the coagulatory proteins removed. It is a clear, pale-yellow, thin, and sticky fluid that moistens the surface of serous membranes or that is secreted by such membranes when they become inflamed. In blood, serum is obtained after coagulation, upon separating whole blood into its solid and liquid components. This is achieved whereby blood is drawn from the subject and is allowed to naturally form a blood clot. After blood is allowed to clot and stand, a centrifuge is used to extract the red blood cells and the blood clot, which contains platelets and fibrinogens. In practice, blood serum is used in numerous diagnostic tests as well as blood typing.

Sexual Behavior

Jennifer L. Brown
Department of Behavioral Sciences and Health Education, Emory University School of Public Health, Atlanta, GA, USA

Synonyms

Sex; Sexual activity

Definition

There is a diverse array of activities that can be classified as sexual behavior: masturbation, oral-genital stimulation (oral sex), penile-vaginal intercourse (vaginal sex), and anal stimulation or anal intercourse. Sexual behaviors may also include activities to arouse the sexual interest of others or attract partners. Individuals engage in sexual behaviors for a variety of reasons, differ in their acceptability based on societal norms, and change across the lifespan.

Description

What is Sexual Behavior: Types of Sexual Behaviors

Sexual behavior includes a wide variety of activities individuals engage in to express their sexuality (Crooks & Baur, 2008). Abstinence and celibacy are terms used for individuals who do not engage in certain or any sexual behaviors. Kissing and touching are sexual behaviors that stimulate the erogenous zones of one's partner. Masturbation is a sexual behavior referring to stimulation of one's genitals to create sexual pleasure. Individuals may also engage in oral stimulation of a partner's genitals; terms used to describe oral-genital stimulation include: oral sex (referring broadly to oral-genital stimulation), cunnilingus (oral stimulation of the vulva), and fellatio (oral stimulation of the penis). Anal stimulation includes either touching around the anus or penile insertion in the anus (often referred to as anal sex). Penile-vaginal intercourse involves insertion of the penis into a female's vagina; this behavior too has a variety of other synonymous terms (e.g., vaginal sex, coitus). The frequency that these and other sexual behaviors are engaged in has enormous individual variability and may differ based upon many factors (e.g., social acceptability, age).

Sexual Behavior: The Role of Societal Norms

Societal norms for acceptable sexual behaviors differ across cultures. Paraphilia refers to less common sexual behaviors within a given society or culture; an example of such behavior is a fetish. In some cultures, the nature of the relationship affects which behaviors are deemed acceptable. For instance, sexual behavior may be deemed appropriate only within the context of marriage. Similarly, societal perspectives on sexual orientation may influence whether sexual behaviors are viewed as socially acceptable.

Reasons for Sexual Behavior Engagement

Individuals engage in sexual behaviors for a multitude of reasons. Sexual behavior may be engaged in to experience sexual pleasure, sexual arousal, or orgasm. Procreation or a desire for children may motivate sexual behavior. Sexual behaviors may also be used to earn money or acquire other goods or services; prostitution refers to the exchange of a sexual behavior for monetary or other compensation. Additionally, pornography may motivate engagement in sexual behaviors. Unfortunately, sexual behaviors also occur in nonconsensual or coerced contexts (e.g., rape) and in the form of abuse (e.g., child sexual abuse) or sexual exploitation (e.g., pedophilia). Sexual behavior engagement

may also have unintended consequences (e.g., unplanned pregnancy) or pose health risks associated with the acquisition of sexually transmitted diseases, including human immunodeficiency virus (HIV).

Developmental Perspectives on Sexual Behavior Engagement

Engagement in sexual activity changes across one's lifespan, and there is considerable variation in sexual development (Crooks & Baur, 2008). During childhood, sexual behaviors may include self-stimulation of the genitals or engagement in play that may be viewed as sexual in nature (e.g., "playing doctor" with a peer). Puberty typically occurs during adolescence and results in dramatic physical changes including the development of secondary sex characteristics. Adolescence is typically linked to increases in sexual activity, both self-stimulation behaviors and sexual behavior with partners. During adulthood, and as people age, there is considerable individual variation of sexual behavior engagement.

Sexual Functioning

Robyn Fielder
Center for Health and Behavior, Syracuse University, Syracuse, NY, USA

Synonyms

Sexual dysfunction

Definition

Sexual functioning is characterized by absence of difficulty moving through the stages of sexual desire, arousal, and orgasm, as well as subjective satisfaction with the frequency and outcome of individual and partnered sexual behavior.

Description

Sexual functioning is an important aspect of quality of life. Our understanding of sexual functioning is influenced by not only the current state of medical knowledge but also the social values upheld in our culture. Healthy sexual functioning is characterized by a lack of pain or discomfort during sexual activity and a lack of physiological difficulty moving through the three-phase sexual response cycle of desire, arousal, and orgasm. In addition, sexual functioning is indicated by subjective feelings of satisfaction with the frequency of sexual desire and sexual behavior, as well as subjective pleasure during individual and partnered sexual activity.

Kaplan's three-phase model is the basis for current models of healthy sexual response. The desire phase consists of sexual fantasies and desire to engage in sexual behavior. The arousal phase involves subjective feelings of pleasure along with physiological changes conducive to sexual intercourse. Males experience penile tumescence and erection, and females experience pelvic vasocongestion and vaginal lubrication. The orgasm phase consists of peak feelings of

sexual pleasure and a release of sexual tension. Males ejaculate semen, whereas females experience contractions of the outer vaginal wall; additionally, in both males and females, the anal sphincter contracts. Individuals may experience physiological and/or psychological difficulties at any or all of the three phases of sexual response. A resolution period, characterized by relaxation and, for males, a refractory period, follows orgasm.

Etiology of Sexual Dysfunction

The etiology of sexual problems is often a complex combination of biological/medical, psychological, and social factors. For example, the sexual dysfunction may be secondary to a chronic health condition or psychotropic medication. In other cases, performance anxiety, low mood, or previous traumatic experiences may impair sexual functioning. Moreover, conflicts within a relationship as well as within the larger sociocultural context may affect an individual's sexual functioning. Due to the variety of potential predisposing, precipitating, and maintaining factors, clinicians are encouraged to take a biopsychosocial approach to assessment and treatment of problems in sexual functioning.

Sexual Dysfunction Disorders

Consistent with the medical model of disease, most research and scholarship focuses on sexual dysfunction rather than healthy sexual functioning. The American Psychiatric Association's Diagnostic and Statistical Manual of Mental Disorders (2000) describes nine main disorders of sexual dysfunction, which are grouped into four categories: desire, arousal, orgasm, and pain. All nine disorders share some common diagnostic criteria: the dysfunction is persistent and recurrent; the dysfunction is not substance-induced, due to a general medical condition, or part of another Axis I mental disorder; and the dysfunction causes clinically significant distress or interpersonal difficulty. Sexual dysfunctions are also classified according to their onset (lifelong or acquired), context (generalized or situational), and etiology (due to psychological factors or due to combined psychological and medical factors). Additional diagnostic options include sexual dysfunction due to a general medical condition, substance-induced sexual dysfunction, and sexual dysfunction not otherwise specified.

Desire disorders are characterized by lack of interest in sex, absence of sexual fantasies and sexual behavior, or fear of sexual contact. In hypoactive sexual desire disorder, there is a low level of sexual fantasy and desire for sex. In sexual aversion disorder, genital sexual contact is feared and actively avoided.

Arousal disorders are characterized by difficulty attaining or maintaining sexual arousal. Male erectile disorder is the most researched type of sexual dysfunction and receives the most media attention, particularly since the advent of Sildenafil (Viagra) in 1998. Erectile dysfunction is the inability to maintain an erection adequate for sexual penetration until completion of sexual activity. Female sexual arousal disorder is the inability to attain or maintain vaginal lubrication until completion of sexual activity.

Orgasm disorders are characterized by delay in or absence of orgasm on one extreme, or, on the other extreme, by occurrence of orgasm before the individual wants. In female orgasmic disorder and male orgasmic disorder, orgasm is delayed or absent despite normal sexual arousal and sufficient sexual stimulation. Premature ejaculation describes the occurrence of ejaculation with minimal stimulation before, upon, or soon after penetration and before the individual wants to orgasm.

Sexual pain disorders are characterized by genital pain that is not due to a general medical condition. In dyspareunia, which affects both males and females, genital pain occurs during sex. In vaginismus, involuntary muscle spasms of the vagina prevent penetration or may cause pain if it is attempted.

Prevalence of Sexual Dysfunction

Epidemiological surveys suggest problems with sexual functioning are common among the general population. For example, prevalence rates of premature ejaculation, erectile dysfunction, and female orgasmic disorder are 5%, 5%,

and 10%, respectively, among community samples (Wincze & Carey, 2001). Symptoms that do not meet full diagnostic criteria for a sexual dysfunction disorder are likely much more common. Patients struggling with sexual health problems may be reluctant to seek medical consultation due to embarrassment or privacy concerns. Many health care providers are also uncomfortable discussing sexuality, so patients' sex-related questions and concerns may be neglected in clinical settings.

Assessment of Sexual Functioning

Clinicians are advised to employ multimethod assessment of sexual functioning by including medical, psychosocial, and psychophysiological components. All three perspectives provide valuable information that aids in diagnosing sexual dysfunction, hypothesizing the etiology of the problem, and developing an appropriate treatment plan.

A medical evaluation is an essential piece of the sexual functioning assessment. A general physical examination allows for biological causes (e.g., general medical conditions, such as diabetes or cancer, as well as other vascular, neurologic, or hormonal conditions) to be ruled out. A gynecological or urological exam ensures no anatomical complications. Physical symptoms, such as bleeding or pain, can also be addressed. Medical providers should attend to any notable medical history (e.g., surgeries) as well as any prescription medications or substance use that may affect sexual functioning.

For the psychosocial evaluation, an interview is essential to learn about the onset, frequency, intensity, and duration of the presenting complaint(s). In addition, clinicians should assess pertinent areas including family history, adolescence, significant relationships in adulthood, sexual history, and sexual abuse or trauma. Although an individual patient may present with sexual complaints, difficulties with sexual functioning are often better understood in the context of the individual's sexual relationship. In many cases (e.g., when working with a patient who is married or in a committed relationship), involving the patient's sexual partner in the psychosocial evaluation (with the patient's permission) facilitates a better resolution. It is often advisable to interview the patient's sexual partner separately to find out more about the presenting complaint. A joint interview with the patient and his or her partner also provides additional insight into the couple's interaction style, relationship quality, and non-sex-related problems that may cause interpersonal tension. For some patients, self-administered questionnaires may be used to supplement the psychosocial interview. Questionnaires may provide an easier method whereby to disclose sensitive information compared to a face-to-face interview.

The third potential component of the evaluation is psychophysiological assessment. Depending on the presenting complaint, psychophysiological measures can be quite helpful in differential diagnosis. For example, nocturnal penile tumescence is the gold standard for differential diagnosis for male patients with erectile dysfunction. Inability to obtain erections during sleep indicates a medical cause, whereas ability to maintain erections during sleep suggests a psychosocial cause.

Treatment of Sexual Dysfunction

Often the first therapeutic intervention occurs during the comprehensive assessment. During the psychosocial and medical evaluations, clinicians normalize the patient's problem, provide information, and correct misunderstandings. Formal treatment plans will depend on the presumed cause of the sexual dysfunction. Medical treatments include options such as pharmacotherapy (e.g., Viagra for erectile dysfunction), gels and creams (e.g., lubricating gels to compensate for problems with female arousal), hormone replacement therapy (e.g., testosterone to increase sexual desire), and surgery (e.g., penile implants to treat organic erectile dysfunction). Psychological treatments include psychoeducation about healthy sexual functioning, behaviorally focused sex therapy with the patient or the patient and his or her partner (e.g., using the stop-start technique to treat premature ejaculation), interpersonally focused couples therapy with the patient and his or her partner (e.g., working on trust or

communication), or more traditional individual therapy with the patient (e.g., treating mood, anxiety, or trauma symptoms).

Sexual Hookup

Robyn Fielder
Center for Health and Behavior, Syracuse University, Syracuse, NY, USA

Synonyms

Casual sex; Hooking up

Definition

A sexual hookup is a sexual interaction between partners who are not dating or in a committed romantic relationship. There is no universal definition of sexual hookups, but qualitative research has begun to converge on the most common interpretation of hookup, which has three main components. First, hookups may involve a range of sexual behaviors, from kissing to sex. Kissing and sexual touching occur more frequently, but oral and vaginal sex occur during a significant minority of hookups. Anal sex during a hookup is rare. The variety of sexual behaviors that can occur during hookups causes ambiguity. From a research or public health perspective, behavioral specificity is needed to distinguish among different levels of sexual risk behavior. Condom use is rare during oral sex hookups, suggesting a potential risk for sexually transmitted diseases.

Second, hookup partners are not dating or in a committed romantic relationship. They may be friends, acquaintances, or strangers, or they may have been in a romantic relationship in the past. The most common connection between partners is friendship. Third, hookups do not signify an impending romantic commitment, so partners typically do not expect a relationship to result from the encounter. Instead, hookups are expected to serve a utilitarian function of sexual pleasure. However, individuals may desire a relationship with their hookup partner, and some engage in hookups with the hope that a relationship will eventually develop. Besides these three main criteria, hookups are also understood in terms of what they lack (emotional attachment and commitment). Emerging adults' descriptions of typical hookups are highly consistent, even between those who have and have not hooked up.

Several biomedical, sociocultural, and college environment changes occurring over the past 50 years have contributed to emergence of the hookup culture. Notably, emerging adults increasingly choose to postpone serious committed relationships to focus on self-development. Hookups offer a convenient way to obtain sexual intimacy without the commitment or time

investment required by a relationship. Accordingly, hooking up has become very common among adolescents and emerging adults. A minority of middle and high school students and the majority of college students report hookup experience. Hooking up has replaced traditional dating as the main way to explore relationships and sexual behavior on college campuses. Hookup behavior among similarly aged noncollege attending youth is rarely studied.

Research has investigated several characteristics of sexual hookups. Hookups frequently co-occur with alcohol use, and alcohol use is a strong predictor of hookup behavior. Hookups are often spontaneous, but some individuals plan to hook up (either with a particular partner or with anyone). A variety of sexual, emotional, and social motives may lead individuals to hook up, such as sexual desire, intoxication, excitement, and desire to feel attractive. Some hookup partners interact only once, but some hook up multiple times, which is sometimes known as "friends with benefits." Hookups are also related to casual sex, as both lack emotional attachment. The main differences are the greater variety of sexual behaviors and partner types involved in hookups compared to casual sex and the extent to which hooking up has become a normative experience for youth.

Sexual Orientation

Jason W. Mitchell
Center for AIDS Intervention Research, Medical College of Wisconsin, Milwaukee, WI, USA

Definition

Sexual orientation is the sexual attraction, emotional, and/or romantic state that a person endures toward women, men, or both sexes. Sexual orientation also pertains to a person's sense of identity that is tied to these attractions, behaviors, and membership into a community with similar individuals (American Psychological Association [APA], 2011). Therefore, sexual orientation is the compilation of a person's sexual behavior and sense of sexual identity.

These two core components of sexual orientation are developed across a person's life span, yet many believe it to be an innate and fixed state (APA, 2011). Nonetheless, an individual's sexual orientation is often characterized with a label, such as heterosexuality, homosexuality, or bisexuality. Sometimes asexuality is also considered as a separate entity of sexual orientation. Those labels normally, but not always, incorporate and include the individuals' sexual identity and sexual behavior of her or his sexual orientation. Because sexuality may be viewed as a fluid construct, an individual's sexual behavior may change over time while maintaining the same sexual identity. An example of this phenomenon would be when a heterosexual male experiments sexually with another male. Another exception to this generalization is when a self-identified lesbian woman has sex with a male. As such, these categories exist on a continuum of sexuality.

Scientists and psychologists have created measures of sexual orientation to better assess

an individuals' sexuality. Typically, these measures will include a range of "solely heterosexual" to "solely homosexual" with "bisexuality" falling somewhere in between these two categories and "asexuality" not being included. A variety of measurements exist to assess sexual orientation. However, an individual's sexual orientation may change over time, and as such, measuring this construct at a single point in time (i.e., cross-sectional study) does have its limitations. Nonetheless, more studies are including a variety of measures that assess the sexual behavior and identity dimensions of sexual orientation.

The most well-recognized measurement of sexual orientation for males and females is the Kinsey scale (Kinsey, Pomeroy, & Martin, 1948; Kinsey, Pomeroy, Martin, & Gebhard, 1953). The scale ranges from 0 for "exclusively heterosexual with no homosexual" to 6 for "exclusively homosexual." The original scale does not include an "asexual" rating or category nor does it take into account any changes of sexual orientation over a period of time. Since then, other measurements of sexual orientation have been created and reviewed. For more information and references, please refer to the further readings section.

Sexual Risk

▶ Sexual Risk Behavior

Sexual Risk Behavior

Theresa Senn
Center for Health and Behavior,
Syracuse University, Syracuse, NY, USA

Synonyms

Sexual risk; Unprotected sex

Definition

Sexual risk behavior is any sexual behavior (typically condom-unprotected oral, vaginal, or anal intercourse) that puts one at risk for an adverse health outcome. Adverse health outcomes may include an unwanted pregnancy or contracting a sexually transmitted disease (STD), including human immunodeficiency virus (HIV).

Vaginal intercourse is the only sexual behavior that puts an individual at risk for unwanted pregnancy. There are many methods for reducing the risk of unwanted pregnancy, including hormonal contraceptives, correct and consistent condom use, surgical methods such as a vasectomy or tubal ligation, and other methods such as an intrauterine device or a diaphragm.

Sexual behavior falls on a continuum from no risk to low risk to high risk for contracting an STD. The risk level of the sexual behavior depends on the STD under consideration. For example, with respect to HIV, masturbation incurs virtually no risk, oral sex is low risk, and vaginal and anal intercourse are high-risk behaviors. However, oral sex is a high-risk behavior for contracting some STDs such as gonorrhea.

The risk level of a particular sexual behavior also depends on with whom the behavior occurs.

Any sexual behavior that occurs when an individual is alone is generally no risk because the individual is not at risk of contracting an STD from him- or herself. In addition, any sexual behavior that occurs within the context of a mutually monogamous relationship, in which both individuals are not infected with any STDs (especially when confirmed by testing), confers no risk of contracting an STD for either individual. Sexual behavior puts an individual at risk for contracting an STD only when his or her sexual partner is infected with an STD.

The risk of a particular sexual behavior also depends on the individual's sexual network. Sexual risk increases with an increasing number of sexual partners, and/or an increasing number of a sex partner's partners, because there is an increasing likelihood that one of these individuals is infected with an STD. In other words, the larger the sexual network, the greater the sexual risk.

STDs can have serious consequences, including epididymitis in men, pelvic inflammatory disease and pregnancy complications in women, infertility, and cancer (Centers for Disease Control and Prevention, 2010d). In addition, the presence of another STD facilitates the transmission of HIV through sexual exposure (Centers for Disease Control and Prevention, 2007). HIV weakens the immune system, ultimately leading to death when the immune system is so weakened it is unable to fight off infections or cancers (Centers for Disease Control and Prevention, 2010a). STDs can also have negative relationship and social consequences due to the stigma surrounding some STDs.

The majority of STDs are either bacterial or viral (Holmes et al., 2008). In general, bacterial STDs can be cured with antibiotics, although some STDs are becoming resistant to antibiotics that had previously successfully treated the disease (Centers for Disease Control and Prevention, 2010b). Viral STDs have no cure, although there are medications that can help to manage outbreaks or viral load. STDs may sometimes be cleared from the body with no treatment (Centers for Disease Control and Prevention, 2010c).

Condoms are an effective way to reduce the risk of contracting an STD when they are used consistently and correctly. Although the value of condoms for the prevention of some STDs that can be transmitted through genital-to-genital contact, such as human papillomavirus and herpes simplex virus, has been debated, recent evidence suggests that condoms reduce the risk of STD infection from these pathogens as well (Holmes et al., 2008).

Numerous factors influence sexual risk behavior. These factors can be broadly categorized into individual-level factors, partner- or relationship-level factors, and social or structural factors. Researchers have typically focused on only one level of influence at a time, although the integration of individual-level, partner or relationship-level, and social or structural factors has recently been attempted in the Network-Individual-Resource Model for HIV prevention (Johnson et al., 2010).

The relation between individual-level factors and sexual risk behavior has been extensively researched. Numerous health behavior theories, including the health belief model, social-cognitive theory, the theory of planned behavior, and the information-motivation-behavioral skills model, have been used to explain why individuals engage in sexual risk behavior (Fisher & Fisher, 2000). Constructs from these models such as perceived risk, benefits of and barriers to risk reduction, self-efficacy, social norms, attitudes, intentions, and skills have been associated with sexual risk behavior (Fisher & Fisher, 2000).

Because sexual risk behavior usually occurs within a dyad, researchers have begun to consider partnership-level influences on sexual behavior. At the partnership level, variables such as intimate partner violence and the balance of power in a relationship may influence sexual risk behavior. There are few existing theories that incorporate partner influences on sexual risk behavior; one exception is a framework recently proposed by Karney et al. (2010), which posits that sexual risk behavior is influenced by the ability to communicate about and coordinate sexual behavior, which, in turn, is influenced by the individual beliefs and motivations of each partner as well as by the nature of the relationship.

Although it is commonly accepted that social and structural factors influence sexual risk behavior, because of the complexity and breadth of

these factors, it is difficult to develop a general model that predicts how these factors influence sexual risk behavior. Several broad frameworks have been suggested that specify different levels of structural influence (Gupta, Parkhurst, Ogden, Aggleton, & Mahal, 2008). Structural factors that influence sexual risk behavior vary depending on the social, cultural, and economic conditions faced by the population under study. Some structural factors associated with sexual risk behavior include gender inequality and poverty (Gupta et al., 2008). In the United States, one factor that has received considerable recent attention is the male-to-female ratio. Social and structural factors such as the high mortality rate among African American males due to disease and violence, high rate of incarceration among African American males, and high rates of poverty and unemployment among African American males (making them less desirable as potential husbands) have led to an unbalanced ratio of available African American men to women. This shortage of men relative to women may reduce women's power in relationships and their ability to insist on monogamy, ultimately leading to high rates of partner concurrency (Adimora & Schoenbach, 2002).

Behavioral medicine researchers and practitioners have played an important role in the design and evaluation of interventions to reduce sexual risk behavior. Numerous interventions have been developed to target the individual-level determinants of sexual risk behavior. These interventions, particularly those that include motivational and skills elements, are effective in reducing sexual risk behavior (Crepaz, Horn et al., 2007; Crepaz, Marshall et al., 2009; Johnson, Carey, Chaudoir, & Reid, 2006). Few interventions have been developed to target the partnership-level determinants of sexual risk behavior (Karney et al., 2010); this is an important area for future research. Although there are challenges to implementing and evaluating structural interventions, some programs, such as microcredit programs for women and policies requiring condoms be used for sex work, have successfully reduced sexual risk behavior in some settings (Gupta et al., 2008). Additional research on structural-level sexual risk reduction interventions is needed, as is research on interventions that target multiple levels of influence.

Syracuse University, Syracuse, NY, USA

Synonyms

Sexually transmitted infections; Venereal diseases

Definition

A sexually transmitted disease is a disease that is transmitted through sexual contact (World Health Organization).

Our knowledge of sexually transmitted diseases (STDs) is still evolving. Currently, at least 35 pathogens that can be transmitted sexually have been identified (Holmes et al., 2008). Although some sexually transmissible pathogens can be transmitted through other routes besides sexual contact, generally a disease is classified as an STD when the primary method of transmission in a population is sexual contact (Holmes et al.).

There are five different types of pathogens that can be transmitted sexually: (a) bacteria, such as gonorrhea or chlamydia; (b) viruses, such as human immunodeficiency virus (HIV), herpes simplex virus, or human papillomavirus (HPV); (c) protozoa, such as trichomoniasis; (d) fungi, such as *Candida albicans* (although the primary mode of transmission for this pathogen is not sexual); and (e) ectoparasites, such as pubic lice (Holmes et al., 2008). Depending on the pathogen, STDs can be transmitted through bodily fluids (e.g., blood, semen, cervicovaginal fluid), feces, or skin-to-skin contact. Thus, the transmission of an STD usually involves vaginal or anal intercourse, oral sex (including oral-genital contact and oral-anal contact), or genital-to-genital contact.

STD symptoms vary depending on the pathogen involved, as well as the sex of the infected person and the site of infection. Symptoms associated with some of the more common STDs include blisters or ulcers, pain or burning during urination, discharge, abdominal pain, and pain during intercourse. However, many individuals who are infected with an STD do not have any symptoms (Centers for Disease Control and Prevention, 2010d). Such "asymptomatic" individuals may unknowingly infect a sexual partner with the STD.

Testing for STDs is generally conducted in medical facilities (although community- and home-based testing protocols are now available). Depending on the STD, testing may involve urethral or cervical swabs, swabs taken from the site of an ulcer, urine testing, blood testing, and clinical examination (Centers for Disease Control and Prevention, 2010d). In the United States, some STDs must be reported (by health-care providers) to county, state, or federal health authorities; for example, positive test results for chlamydia, gonorrhea, and syphilis must be reported to the Centers for Disease Control and Prevention for disease surveillance and monitoring (Centers for Disease Control and Prevention, 2009).

STDs can have serious consequences, including epididymitis in men, pelvic inflammatory disease and pregnancy complications in women, infertility, and cancer (Centers for Disease Control and Prevention, 2010d). In addition, individuals who are co-infected with HIV and another STD are more likely to transmit HIV through sexual exposure, and individuals who are infected with an STD are more likely to acquire HIV through sexual exposure from an HIV-positive partner (Centers for Disease Control and Prevention, 2007). HIV weakens the immune system, ultimately leading to death when the immune system is so weakened it is unable to fight off infections and cancers (Centers for Disease Control and Prevention, 2010a). STDs can also have negative interpersonal and social consequences due to the stigma surrounding some STDs.

The majority of STDs are either bacterial or viral (Holmes et al., 2008). In general, bacterial STDs can be cured with antibiotics, although some STDs are becoming resistant to many classes of antibiotics that had previously successfully treated the disease (Centers for Disease Control and Prevention, 2010b). Viral STDs have no cure, although there are medications that can help to manage outbreaks or viral load. STDs such as HPV may sometimes be cleared from the body with no treatment (Centers for Disease Control and Prevention, 2010c).

An individual's likelihood of acquiring an STD is based on his or her sexual behavior and the risk of transmission per sexual act with an infected partner. Sexual behaviors that affect the likelihood of acquiring an STD include the number of sexual partners, the number of unprotected sexual acts, and the types of unprotected sexual acts. The risk of transmission per sexual act depends in part on the pathogen as well as the individual's biology. Different pathogens are associated with different risks of transmission per sexual act. Biological factors associated with transmission risk include the individual's immune response and the mucosal surface area exposed during the sexual act; women, for example, are more likely than men to be infected with an STD through vaginal intercourse because women have a larger mucosal surface area that is exposed during vaginal intercourse, and young women are more likely to acquire an STD because they have an immature cervix. STD risk is also affected by the STD prevalence in an individual's sexual network, which is influenced by the rate of sexual partner change, partner concurrency (i.e., multiple, overlapping sexual partnerships), and degree of disassortative mixing (i.e., sexual partners who are dissimilar in certain characteristics, such as age or sexual activity Garnett, 2008).

To date, some types of HPV and some types of hepatitis are the only STDs that can be prevented through vaccination. Other medical strategies are currently being developed for STD prevention, such as vaginal microbicides and preexposure prophylaxis. STDs can also be prevented through behavioral change. Abstaining from sexual contact is the only certain way to prevent most STDs. However, other behavioral strategies including correct and consistent condom use, engaging in sexual activity only with one partner who is not infected with any STD and who has no other sexual partners, and having fewer sexual partners will reduce the likelihood of acquiring an STD.

Behavioral medicine can play a large role in STD prevention. Behavioral interventions can promote sexual risk reduction behavior, by encouraging individuals to use condoms consistently and correctly for all sexual activity, be in a mutually monogamous sexual relationship with an uninfected partner, or adopt other strategies that will reduce the risk of contracting an STD. Behavioral interventions have been shown to be effective in reducing sexual risk behavior and STDs in a variety of populations (Crepaz, Horn et al., 2007; Crepaz, Marshall et al., 2009; Johnson, Carey, Chaudoir, & Reid, 2006). Behavioral medicine can also play a role in encouraging the adoption of biomedical strategies. For example, behavioral medicine strategies could be used to encourage STD and HIV testing, vaccine acceptance, the completion of medications for curable STDs and adherence to medications for viral STDs, and male circumcision, which may reduce the spread of STDs and HIV.

SF-36

Stephanie Ann Hooker
Department of Psychology, University of Colorado, Denver, CO, USA

Synonyms

Short form 36

Definition

The SF-36 is a 36-item self-report measure of health-related quality of life. It has eight subscales measuring different domains of health-related quality of life: physical functioning (PF), role-physical (RP), bodily pain (BP), general health (GH), vitality (VT), social functioning (SF), role-emotional (RE), and mental health (MH). Two component scores are derived from the eight subscales: a physical health component score and a mental health component score. The SF-36 also includes a single item that assesses perceived change in health status over the past year. Higher scores on all subscales represent better health and functioning. From its development to 2011, more than 16,000 articles were published using the SF-36. SF-36 is also known as the Short Form 36 Health Survey Questionnaire.

Description

Development

Ware and colleagues (Stewart & Ware, 1992; Ware, 1988, 1990) developed the SF-36 from the Medical Outcomes Study, a study of the health, well-being, and functioning of randomly selected patients seen by randomly selected physicians and other medical providers in three large metropolitan areas. Items were chosen for the SF-36 because they were items commonly used in other health surveys and the domains were ones that seemed to be commonly affected by differing health and disease states. After 10 years of use, the SF-36 was revised to address wording and response choice categories. The SF-36 version 2 (SF-36v2) is the current version (Ware et al., 2007).

Health Domain Scales

Physical Functioning (PF). The PF scale is a 10-item measure of physical limitation in a range of activities from vigorous exercise to performing self-care activities.

Role-Physical (RP). The RP scale contains four items and measures limitations in various roles, including work and daily activities.

Bodily Pain (BP). The BP scale has two items that measure body pain intensity and the extent to which pain interferes with daily activities.

General Health (GH). The five-item GH scale measures overall self-rated health.

Vitality (VT). The VT scale has four items that measure vitality, energy level, and fatigue and is meant to be a measure of subjective well-being.

Social Functioning (SF). The SF scale includes two items that measure the impact of physical and mental health on social functioning.

Role-Emotional (RE). The RE scale measures role limitations due to mental health difficulties with three items, including amount of time spent on work or other activities, amount of work accomplished, and the care with which work is performed.

Mental Health (MH). The MH scale has five items that measure anxiety, depression, loss of behavioral/emotional control, and psychological well-being.

Component Summary Scales

Component summaries were developed to reduce the number of scores derived from this measure from 8 to 2. They also have the advantages of having smaller confidence intervals than the health domain scales and limiting floor and ceiling effects. The Physical Component Summary (PCS) combines items from the PF, RP, BP, and GH scales, and the Mental Health Component Summary (MCS) combines items from the VT, SF, RE, and MH scales. Each provides one score to assess physical and mental health, respectively.

Reliability

Estimates for internal consistency reliability are very good for all subscales. The two component summary scores show evidence for very high internal consistency ($\alpha = .95$ and $\alpha = .93$ for the PCS and MCS, respectively). Internal consistency estimates for the health domain scales are also high, ranging from $\alpha = .83$ (GH) to $\alpha = .95$ (RP) (Ware et al., 2007). Evidence suggests that test-retest reliability for the SF-36 over a 3-week interval is very good, with estimates of .94 and .81 for the PCS and MCS scales, respectively (Ware, Kosinski, DeBrota, Andrejasich, & Bradt, 1995).

Validity

The SF-36 has been widely used in health research, and the user manual (Ware et al., 2007) provides a comprehensive list of studies offering evidence for the scales' construct validity. The content of the SF-36 survey was compared with other well-known health surveys to establish content validity (cf., Ware, Gandek, & the IQOLA Project Group, 1994, for a list of references).

Options

Along with the 36-item SF-36, the shorter 12-item (SF-12) and 8-item (SF-8) versions of the SF are also available. Both shorter versions offer scores on all eight health domains and the two component summary scores. Versions 1 and 2 of both the SF-36 and the SF-12 are available for use (there is only one version of the SF-8). All forms are available in the standard 4-week

recall and the acute 1-week recall versions. Additionally, the SF-8 is available in a 24-h recall version.

Administration

The survey is designed for adults 18 and over and can be given in a self-report paper/pencil format or in an interview format. The SF-36 and its other forms are available for licensure from QualityMetric Incorporated (www.qualitymetric.com).

Sickness Behavior

Aric A. Prather
Center for Health and Community, University of California, San Francisco, CA, USA

Synonyms

Cytokine-induced depression; Inflammation-associated depression

Definition

Sickness behavior is a coordinated set of adaptive behavioral changes that occur in physically ill animals and humans during the course of infection. These behaviors include lethargy, depressed mood, reduced social exploration, loss of appetite, sleepiness, hyperalgesia, and, at times, confusion. This set of behaviors often accompanies fever and is considered a motivational state responsible for reorganizing an ill individual's perceptions and actions to enable better coping with infection (Dantzer, O'Connor, Freund, Johnson, & Kelley, 2008).

Description

Sickness behavior is a normal response to infection and is characterized by endocrine, autonomic, and behavioral changes triggered by soluble proteins produced at the site of infection. Activated immune cells, such as macrophages and dendritic cells, release biochemical mediators called pro-inflammatory cytokines, such as interleukin (IL)-1, IL-6, and tumor necrosis factor (TNF)-alpha, which coordinate the local and systemic inflammatory response during active infection. These inflammatory mediators, in turn, act on the brain facilitating behavioral changes associated with sickness.

Much of the evidence supporting a link between pro-inflammatory cytokines and sickness behaviors comes from experimental studies in animals and humans. Peripheral and central administration of IL-1 and TNF-alpha in healthy laboratory animals induces fever and behavioral symptoms of sickness, including depressed activity, decreased food intake, and a curled posture. Sexual behavior is similarly reduced, particularly among females. IL-1 receptor antagonist (IL-1RA) blocks the biological effects of IL-1 when co-administered at 100- to 1,000-fold excess dose with IL-1. Treatment with IL-1RA abrogates the depressing effect on social behavior but not food-motivated behavior, suggesting that IL-1 is a key mechanism in social function (Bluthe, Dantzer, & Kelley, 1992). Similar effects are seen when IL-1RA is injected directly into the brain. Time course studies of the behavioral effects of IL-1 in animals show changes in social exploration gradually develop within 2 h of peripheral administration whereas changes in food-motivated behavior reach a maximum by 1 h following treatment. Interestingly, IL-6 administered systemically or centrally has no behavioral effects despite inducing a fever response. That said, IL-6 does have the capacity to potentiate the effects of subthreshold dose of IL-1 administration suggesting that IL-6 may be behaviorally active only in the context of other pro-inflammatory mediators.

In humans, administration of endotoxin, a component of the outer membrane of Gram-negative bacteria, leads to systemic elevations in pro-inflammatory cytokines. This stimulus has been shown to cause participants to experience flu-like symptoms (e.g., fever, chills) as well as fatigue and depressed affect (reviewed in DellaGioia & Hannestad, 2010). Moreover, a recent study demonstrated that subjects exposed experimentally to endotoxin led to increased self-reported levels of depressed mood and reduced activity in the ventral striatum in response to reward cues (Eisenberger et al., 2010), which is consistent with anhedonia.

There is substantial overlap between the behavioral components of sickness behavior and major depression in humans. As such, pro-inflammatory cytokines are proposed to participate in the pathophysiology of depression and potentially account for the high prevalence of depression among the medically ill (Smith, 1991; Raison, Capuron, & Miller, 2006; Dantzer et al., 2008). Patients treated with immune-activating medications, such as IFN-a therapy prescribed for patients suffering with Hepatitis C or certain cancers, show elevated rates of depression compared to patients undergoing alternative therapies (Raison et al., 2006). Indeed, patients undergoing IFN-a therapy tend to experience depressive symptoms coupled with anxiety and irritability over a background of neurovegetative sickness–like symptoms, including sleep disorders, fatigue, and decreased appetite. While the mood disturbances generally occur between 4 and 12 weeks of treatment, the neurovegetative symptoms occur more rapidly, within the first 2 weeks of treatment.

Significant research efforts have focused on the neurochemical effects of inflammation that underlie sickness behavior and related depressive symptoms. Experimental animal data demonstrates that pro-inflammatory cytokines enhance indoleamine 2,3 dioxygenase (IDO) that peaks 24-h after endotoxin administration. This increase in IDO leads to a decrease in tryptophan (TRP), an essential amino acid that is actively transported into the brain for the synthesis of serotonin. IDO also leads to a decrease in kynurenine (KYN) and other tryptophan-related metabolites. Animals pretreated with a potent anti-inflammatory agent that blocks

pro-inflammatory cytokines in the periphery and in the brain show significant reductions in both sickness and depressive behaviors. In contrast, animals treated with an inhibitor of IDO show a reduction in depressive behaviors but not neurovegetative symptoms, providing important evidence for the role of tryptophan metabolism in cytokine-induced depression (Dantzer et al., 2008). It is anticipated that this research will have important implications for effective treatment of inflammation-related depression in humans.

Siegrist, Johannes

Johannes Siegrist
Department of Medical Sociology, University of Duesseldorf, Düsseldorf, Germany

Biographical Information

Johannes Siegrist was born in Zofingen, Switzerland, on August 6, 1943. His nationality is Swiss, and he is married to Karin and has two daughters. Siegrist studied Sociology, Social Psychology, Philosophy, and History at the Universities of Basel (Switzerland) and Freiburg i.Br. (Germany). He received his M.A. (1967) and his Ph.D. (1969) in Sociology at the University of Freiburg. After postdoctoral training at the Universities of Ulm and Freiburg, he accomplished his habilitation in Sociology at the University of Freiburg (1973). In 1973, he was appointed as Professor of Medical Sociology at the Faculty of Medicine, University of Marburg (Germany), where he served until 1992, interrupted by Visiting Professorships at the Institute of Advanced Studies in Vienna (Austria) and at the Johns Hopkins University School of Public Health in Baltimore, USA. In 1992, Siegrist was appointed as Professor of Medical Sociology and Director of the Department of Medical Sociology at the Faculty of Medicine, Heinrich Heine-University of Duesseldorf, Germany, and as Director of the Postgraduate

Training Program of Public Health at the same university. While officially retired since 2011, he continues his research activities at Duesseldorf University and as a Visiting Professor at the University of Bern (Switzerland).

Siegrist has been President of the International Society of Behavioral Medicine (ISBM; 1996–1998), President of the European Society of Health and Medical Sociology (1990–1992), and Director of the European Science Foundation Program on Social Variations in Health Expectancy in Europe (1999–2003). He is Chair of the Section "Behavioral Sciences" of Academia Europaea (since 2004), member of the Expert Panel of the German Research Foundation (since 2006), and member of the Scientific Committee on Demographic Change of the German Academy of Sciences Leopoldina (since 2011).

He has been a Task Group Leader to the Marmot Review (Strategic Review of Health Inequalities in England post-2010) for the British Government, with a focus on work and health. In this same function, he has coordinated and edited a Report on Employment and Working Conditions in the context of the "Review of Social Determinants of Health and the Health Divide in the WHO European Region," commissioned by the WHO European Office in 2011.

Siegrist served and continues to serve as Associate Editor of several international journals, in particular International Journal of Behavioral Medicine, *Social Science & Medicine*, *Social Psychiatry and Psychiatric Epidemiology, Work & Stress, European Journal of Public Health*, and *Scandinavian Journal of Work, Environment and Health*. The awards he received include Honorary Member of the European Society of Health and Medical Sociology where he also received the Research Award, Member of Academia Europaea (London), and Corresponding Member of the Heidelberg Academy of Sciences. He received the Salomon Neumann Award of the German Society of Social Medicine and Prevention, the Hans Roemer Award of the German College of Psychosomatic Medicine, and the Belle van Zuylen Chair at the University of Utrecht, the Netherlands.

Major Accomplishments

Siegrist's major contribution to scientific research concerns the development and test of a theoretical model of an adverse psychosocial work environment with the aim of explaining stress-related disorders, termed "effort-reward imbalance" (ERI). The model posits that failed reciprocity of effort spent and rewards received at work ("high cost-low gain") elicits strong negative emotions and psychobiological stress responses with adverse long-term effects on health. Starting from cross-sectional and longitudinal epidemiological research in the late 1970s and early 1980s, together with collaborators Ingbert Weber, Karin Siegrist, Richard Peter, and others at Marburg University, he systematically elaborated and expanded research on the ERI-model in a network of national and international scientific collaboration. This model has been incorporated in many epidemiological studies, most importantly the British Whitehall II-Study and the French GAZEL Study. More recently, the model was successfully applied in other sociocultural contexts (e.g., Japan) and in rapidly developing societies (e.g., China, Brazil).

Evidence from prospective cohort studies indicates that continued experience of failed reciprocity in terms of the ERI model is associated with an almost twofold elevated risk of coronary heart disease as well as depressive disorder. Single studies additionally observed elevated risks of alcohol dependence, type 2 diabetes, reduced health functioning, sickness absence, and disability. This epidemiological evidence was supplemented by experiments and "naturalistic" studies (e.g., ambulatory blood pressure and heart rate monitoring), where reduced immune function, enhanced autonomic activity, and altered release patterns of stress hormones were linked to ERI, often in a dose-response relationship. Siegrist was also involved in some intervention studies where measures of reducing ERI at work were followed by improvements of well-being and mental health.

Siegrist applied the ERI model to other types of contractual social exchange, e.g., voluntary

work, marital, or parent-child relations. Available results support the notion that failed reciprocity in core social roles exerts negative effects on health and well-being, suggesting a basic link between perceived injustice of effortful exchange and the development of stress-related disorders in humans. Siegrist has expanded this research with a focus on retirement, volunteering, and healthy aging, together with Morten Wahrendorf and other colleagues, in the frame of the Survey of Health, Ageing and Retirement in Europe (SHARE) and additional longitudinal investigations on ageing populations. As a cross-cutting topic of his long-lasting research career, Siegrist has put special emphasis on explaining and reducing avoidable social inequalities in health, both as a scientist and as an advocate for different stakeholders where he has proposed evidence-based policy recommendations for improving quality of work and employment and for reducing the burden of disease.

Single Nucleotide Polymorphism (SNP)

J. Rick Turner
Cardiovascular Safety, Quintiles, Durham, NC, USA

Synonyms

SNP (pronounced "snip")

Definition

The term "single nucleotide polymorphism" contains two defining criteria. First, it refers to a single nucleotide, i.e., an individual base pair, that can differ between individuals. Second, the word polymorphism indicates that a particular nucleotide change of interest is shared by at least 1% of the population.

SNPs occur when one base pair replaces another base pair in a point mutation (see ▶ DNA entry for discussion of bases). For example, an A-T pairing may be replaced by a G-C pairing. Such a mutation does not typically harm the organism.

Skin Cancer Prevention: Sun Protection, Sun Safety, Sunscreen Use

Karen Glanz
Schools of Medicine and Nursing, University of Pennsylvania, Philadelphia, PA, USA

Definition

Skin cancer is the most commonly diagnosed cancer in the United States, with more than one million Americans diagnosed with skin cancer each year. The incidence of skin cancer has increased dramatically worldwide in the last decade. Both main types of skin cancer – malignant melanoma and non-melanoma skin cancer (NMSC) – are now significant public health concerns. While skin cancer rates are increasing, it is considered one of the most preventable types of cancer.

The greatest risk factor for skin cancer is exposure to ultraviolet radiation, or UV radiation, which comes mainly from the sun. Behavioral recommendations for primary prevention of skin cancer include: limit time spent in the sun, avoid the sun during peak hours (10 a.m. to 4 p.m.), use sunscreen with a sun protection factor (SPF) of 15 or higher when outside, wear protective clothing (hats, shirts, pants) and sunglasses, seek shade when outdoors, and avoid sunburn. These behaviors, if consistently practiced, can help prevent all forms of skin cancer. There is some concern that using sunscreen will lead people who are trying to get a suntan to stay in the sun for a longer time, so another recommendation for prevention is not to intentionally bake in the sun or seek a tan.

Additional, important recommendations for behaviors to prevent skin cancer and related morbidity and mortality include performing regular skin self-examination and seeking professional evaluation of suspicious skin changes. Further, avoidance of indoor tanning and the use of tanning salons and tanning beds (also called "solaria") are strongly recommended.

An understanding of patterns of behavior can help to guide efforts to prevent skin cancer. More people take precautions at the beach or on vacation than when taking outdoor recreation. Parents are more likely to protect their children than themselves. Children are more often protected from UV radiation if their parents also protect themselves. Adolescents seem especially resistant to advice about skin cancer prevention and minimizing sun exposure.

Most skin cancer prevention interventions reported in the literature are directed at the general population through school-based curricula, multicomponent community programs, or media campaigns, and some recent trials have targeted people with high sun exposure at work or during outdoor recreation. Children, adolescents, and adults at high risk are important audiences for skin cancer prevention.

This chapter provides an overview of skin cancer prevention for the general population and groups at increased risk due to genetic or environmental exposures. The reference sources include evidence reviews, key research articles reporting on well-designed studies, and works addressing issues in measurement and methodology for skin cancer prevention research and evaluation.

Description

Evidence Reviews

An extensive evidence review of strategies to prevent skin cancer was undertaken by the Task Force on Community Preventive Services, and the results and recommendations were published in Saraiya et al. (2004). This report presents the results of systematic reviews of the effectiveness of interventions to prevent skin cancer by reducing exposure to ultraviolet radiation (UVR). The Task Force on Community Preventive Services found that education and policy approaches were effective when implemented in primary schools and in recreational or tourism settings but found insufficient evidence to determine effectiveness in other settings. This evidence review is currently being updated to reflect the continuing growth of the scientific literature on behavioral interventions to prevent skin cancer during the past decade.

Comprehensive Community Programs Including Mass Media

There is a long history of comprehensive, multicomponent community skin cancer prevention programs, especially in Australia, where skin cancer is highly prevalent. These programs include mass media and communication campaigns as an integral part of these community programs.

Two related sun protection programs have been conducted in Australia for more than 20 years: Slip! Slop! Slap! from 1980 to 1988 and SunSmart from 1988 to the present (Montague, Borland, & Sinclair, 2001). These programs have played an important role in changing the whole society's approach to the sun and have resulted in marked reductions in sun exposure. An examination of trends in behavioral risk factors for skin cancer over 15 years was examined in an Australian population exposed to the SunSmart program including SunSmart television advertising. Higher exposure to SunSmart advertising in the weeks before the interview increased preferences for not tanning, hat and sunscreen use, and greater clothing protection. These results indicate that sustained multicomponent programs with media campaigns can both prompt and reinforce skin cancer preventive behaviors.

Interventions in Schools

The most often studied settings for skin cancer prevention programs are schools, and there is good evidence that educational and policy interventions can be effective in primary schools (Saraiya et al., 2004). Of the many reported studies, a few are particularly well designed, carefully described, have long follow-up periods, and/or use objective outcome measures. The Kidskin intervention trial in Western Australia is particularly noteworthy and had a 6-year follow-up period. The "Kidskin" study involved three groups: control, "moderate," and "high" intervention. Results showed that children in the intervention groups – especially the "high" group – reported less sun exposure and spent less time outdoors in the middle of the day. There was little difference between groups in the wearing of hats or sunscreen (Milne et al., 2001). Children in the intervention groups – especially the high group – were less tanned at the end of the summer; this effect was greater for the back than for the forearms. There was also a smaller increase in the number of nevi (or moles) on the backs of children in the intervention groups (English et al., 2005). Further, the program had a positive effect on hat wearing on the playground, especially in the "high" intervention groups, but did not change children's use of shade at lunchtime (Giles-Corti et al., 2004).

Outdoor Workers

Outdoor workers are at high risk for skin cancer because they receive regular and significant solar UVR exposure. In a well-designed study to reduce UVR exposure among ski instructors, greater program implementation was associated with less sunburn. In an intervention for US Postal Service workers, regular sunscreen and hat use were higher among the intervention group than among the control group after 3 months and at 3-year follow-up (Mayer et al., 2007, 2009).

Recreation Settings

Intense and prolonged sun exposure often occurs during outdoor recreation activities. High UVR exposure, often with minimal clothing, tends to occur at beach and swimming pool settings. Other outdoor recreation settings include camps,

zoos, and parks. Large and well-designed studies of skin cancer prevention in these locations have been reported. Effective skin cancer prevention programs for children have been evaluated in swimming pool settings (Glanz, Geller, Shigaki, Maddock, & Isnec, 2002; Glanz, Steffen, Elliott, & O'Riordan, 2005) and for beachgoers at Northeastern (Weinstock, Rossi, Redding, & Maddock, 2002) and Midwestern (Pagoto, McChargue, & Fuqua, 2003) beaches as well as at zoos (Mayer et al., 2001).

High-Risk Groups

Targeting skin cancer prevention to people at high risk may result in greater effects of preventive strategies and an efficient public health strategy. Risk factors for skin cancer include age, sun-sensitive phenotypes, excess sun exposure, family history, personal history of skin cancer or precancerous lesions, and some other medical conditions. There is a need to develop low-cost, effective interventions to improve skin cancer prevention and early detection behaviors among a broader population of persons at moderate and high risk. (Geller, Emmons, Brooks, Powers, Zhang, Koh, Heeren, Sober, Li, & Gilchrest, 2006) and Glanz, Schoenfeld, and Steffen (2010) describe studies of effective tailored interventions that specifically target individuals at high risk, either siblings of melanoma patients or adults determined to be at moderate or high risk for skin cancer. These studies focused on both prevention and skin examinations. A study of a group of people who have tested positive in genetic testing for skin cancer-related mutations and found that positive genetic test results led to greater intentions to obtain total body skin examinations and adhere to skin self-examination recommendations (Aspinwall, Leaf, Dola, Kohlmann, & Leachman, 2008).

Screening and Early Detection

Screening for skin cancer through health-care-provider skin exams and skin self-examination has the potential to help detect skin cancers at an earlier stage (i.e., when they are thinner) so that they are more curable and less serious. Although there has not been a large randomized trial of skin screening in the United States, an Australian trial reported by Aitken et al. (2006) provides promising evidence of the impact of skin screening and how it can be successfully implemented. A randomized trial was conducted to determine whether a multicomponent intervention can increase total skin self-examination (TSSE) performance. Participants received instructional materials, a video, and a brief counseling session and a brief follow-up phone call and tailored feedback letters. Results showed that the intervention group increased TSSE performance in the intervention group compared to the control group (Weinstock et al., 2007). A follow-up article aimed to identify the most important Check-It-Out intervention components for promoting TSSE. Results showed that watching the video, using the hand mirror, shower card, American Cancer Society brochure, sample photographs, and finding the health educator helpful were associated with performing TSSE at 2 months, 12 months, or both. The studies of high-risk groups reported by Geller et al. (2006) and Glanz et al. (2010) also targeted behavioral outcomes of skin self-examination and thorough examination of all moles.

Measurement and Methodology

Advances in skin cancer prevention depend on good quality research and ideally different intervention studies that can be compared to understand the impact of various strategies. Most skin cancer prevention studies uses verbal reports, or self-report, to measure habitual sun exposure and solar protection behaviors. Despite the well-known limitations of verbal reports of behavior, these measures are the most practical for use in both population surveillance and descriptive and intervention research (Glanz & Mayer, 2005). Therefore, the comparability of assessments across population-based surveys and outcome measures used in intervention research is important, and a core set of measures was recently published by a diverse group of investigators in the field (Glanz et al., 2008). In addition, because it is important to continue to build a research tool kit for measures other than surveys, including

objective biological measures and observational measures, recent research to validate self-reports of sunscreen use (Glanz et al., 2009) and other behaviors is of particular importance to the field.

Conclusion

Skin cancer prevention interventions have demonstrated modest success, with the majority of programs being conducted in school settings. It is believed that the ideal intervention strategies for reducing exposure to ultraviolet radiation (UVR) exposure are coordinated, sustained, community-wide approaches that combine education, mass media, and environmental and structural changes. Interventions within specific organizational settings such as schools, health care, recreation programs, and workplaces provide useful ways to reach important audiences like children and are suitable venues for structural supports such as environmental and policy change that complement educational efforts. It is generally agreed that environmental and structural changes also need to be part of successful skin cancer prevention efforts. Advances in measurement and methods in skin cancer prevention research will contribute to future efforts to address this important and widespread health and behavior problem.

► Serotonin Transporter Gene

Sleep

Martica H. Hall
Department of Psychiatry, University of Pittsburgh, Pittsburgh, PA, USA

Definition

Sleep is a complex reversible neurobiological state characterized by closed eyes, behavioral quiescence, and perceptual disengagement from one's surroundings.

Description

Healthy adults cycle between two types of sleep during the typical nocturnal sleep period: non-rapid eye movement (NREM) sleep and rapid eye movement (REM) sleep. When healthy adults fall asleep, they enter NREM sleep and usually move from lighter stages of sleep (e.g., Stages N1 and N2) to deeper sleep (e.g., Stage N3) before entering their first REM sleep period. The terms "light" and "deep" sleep refer to the ease with which one can be awakened from sleep and become fully oriented to one's surroundings. The descent from light into deep NREM sleep is characterized by decreasing inputs from external stimuli, a slowing of catabolic processes, and an increase in parasympathetic nervous system activity. In contrast, REM sleep is characterized by autonomic instability and active mental activity. In healthy adults, individual NREM-REM cycles generally last approximately 90 min, although the duration of sleep cycles varies across individuals. During the first third of the night, NREM sleep is more prevalent, whereas REM sleep becomes more prevalent during the last third of the night.

Sleep can be characterized along multiple dimensions. Here we focus on four dimensions of sleep that have been most widely evaluated in relation to health and functioning; these include sleep *duration*, *continuity*, *architecture*, and *quality*. It is important to recognize that each of these dimensions of sleep changes across the life span, from infancy through old age and may, additionally, be moderated by sex, race/ethnicity, and mental and physical health conditions (Carrier, Land, Buysse, Kupfer, & Monk, 2001; Carskadon & Dement, 2005; Hall et al., 2009; Ohayon, Carskadon, Guilleminault, & Vitiello, 2004).

Sleep Duration

The two most commonly assessed indices of sleep duration include "time in bed" and "total sleep time." Operationally, time in bed (TIB) may be defined as total hours elapsed between getting into bed to go to sleep at night ("good night time") and waking up in the morning ("good morning time"). Total sleep time (TST) may be operationalized as time in bed minus the amount of time needed to fall asleep ("sleep latency") and amount of time spent awake during the night ("wakefulness after sleep onset").

Sleep duration is one of the most widely studied dimensions of sleep in relation to health and

functioning (see entry on "▶ Sleep Duration, ▶ Sleep and Health"). For the most part, this literature has documented robust associations among sleep duration extremes (generally, <6 h or >8 h) and indices of morbidity and mortality. One meta-analysis of 23 studies reported pooled relative risk (RR) values of 1.10 (95% CI = 1.06–1.15) and 1.23 (95% CI = 1.17–1.30) for all-cause mortality and short and long sleep duration, respectively (Gallicchio & Kalesan, 2009).

It must be noted, however, that studies using objective measures (actigraphy, PSG) of sleep duration and health outcomes are lacking. This issue is especially important given discrepancies between self-reported and objective indices of sleep duration, which may be confounded by other risk factors for morbidity and mortality such as age, sex, race, BMI, and comorbidities. Nor do measures of sleep duration differentiate between individuals with or without primary sleep disorders such as sleep apnea and insomnia, which have been widely linked to health and functioning (Boivin, 2000; Somers, 2005).

Sleep Continuity

Measures of sleep continuity focus on one's ability to initiate and maintain sleep (see "▶ Sleep Continuity, ▶ Sleep Fragmentation" entries). *Sleep latency* refers to the amount of time it takes to fall asleep (e.g., minutes from "good night time" to onset of sleep), whereas *wakefulness after sleep onset* (WASO) refers to the total amount of wakefulness during the sleep period (e.g., minutes of wakefulness between sleep onset and "good morning time"). *Sleep efficiency* is a proportional sleep continuity measure which refers to the percentage of time in bed spent asleep. Although operational definitions may differ across laboratories, sleep efficiency is commonly calculated as follows: (time spent asleep/time in bed) × 100.

Compared to sleep duration, fewer population-based studies have evaluated relationships among sleep continuity and indices of health and functioning. Several studies have linked self-reported sleep continuity disturbances with incident Type 2 diabetes and cardiovascular disease (as reviewed by Mezick et al. under review). Although few in number, other studies have reported significant cross-sectional associations between objectively assessed sleep continuity disturbances and health outcomes including obesity, increased blood pressure, increased inflammation, decreased circulating natural killer cell numbers, and the metabolic syndrome (Hall et al., 1998; Knutson et al., 2009; Mills et al., 2007). In their longitudinal study of sleep and all-cause mortality in healthy older adults, Dew and colleagues reported that participants with PSG-assessed sleep latencies of greater than 30 min were at 2.14 times greater risk of death (95% CI = 1.25–3.6) compared to those who fell asleep in less than 30 min, after adjusting for age, medical burden, and other relevant covariates (Dew et al., 2003).

Emerging evidence based on experimental models of sleep fragmentation suggests that endocrine, immune, metabolic, and autonomic mechanisms may be important pathways through which sleep continuity disturbances influence health and functioning (Bonnet & Arand 2003; Janackova & Sforza, 2008; Redwine Dang, Hall, & Irwin, 2003; Tartar et al., 2009). In terms of its relevance to behavioral medicine and health, sleep continuity appears to be exquisitely sensitive to psychological and social factors such as stress, loneliness, relationship quality, and socioeconomic status Akerstedt et al., 2002; Cacioppo et al., 2002; Cartwright & Wood, 1991; Friedman et al., 2005; Hall, Buysse, Nofzinger, Reynolds, & Monk, 2008).

Sleep Architecture

Sleep architecture refers to the pattern or distribution of visually scored NREM and REM sleep stages as well as quantitative measures derived from power spectral analysis of the EEG (see "▶ Sleep Architecture" entry). Within NREM sleep, measures of sleep architecture include stages N1-N3. Lighter stages of sleep are characterized by low-amplitude, fast-frequency EEG activity whereas deeper stages of sleep are characterized by high-amplitude, low-frequency EEG activity generated by rhythmic oscillations of thalamic and cortical neurons (see Jones, 2005).

Patients with medical disorders including cardiovascular and kidney disease, diabetes, and cancer exhibit lighter sleep architecture profiles compared to healthy individuals (e.g., Jauch-Chara, Schmid, Hallschmid, Born, & Schultes 2008; Ranjbaran, Keefer, Stepanski, Farhadi, & Keshavarzian, 2007). Yet, these studies do not indicate whether sleep architecture profiles were a contributing cause or consequence of disease. Both possibilities are plausible given experimental evidence of bidirectional relationships among components of sleep architecture and physiological processes important to health and functioning including metabolic, endocrine, autonomic, and immune mechanisms (e.g., Hall et al., 2004; Opp, 2006; Rasch, Dodt, Moelle, & Born, 2007). The longitudinal study of sleep and mortality by Dew and colleagues (2003) is the only published study, to date, that has evaluated relationships among measures of sleep architecture and indices of morbidity or mortality. In this study, risk for mortality was significantly higher in individuals with extreme amounts of REM sleep (upper and lower 15th percentile of the sample distribution); the visually scored slow-wave sleep percentage was also modestly associated with survival time.

Experimental manipulation of sleep architecture, although technically complex, may be an especially promising approach to disentangling cause and effect and evaluating cellular and molecular mechanisms through which sleep architecture affects and is affected by health. Quantitative analysis of the EEG, which shows trait-like characteristics, may hold promise for identifying sleep phenotypes that confer vulnerability to or resilience against disease (e.g., Tucker, Dinges, & Van Dongen, 2007). This latter point may be especially relevant to behavioral medicine models of disease given that decreased slow-wave sleep and increased EEG spectral power in the fast-frequency beta band have been linked with symptoms of stress and a variety of chronic stressors including job strain, marital dissolution, and bereavement (Cartwright & Wood, 1991; Hall et al., 1997; Kecklund & Akerstedt, 2004).

Sleep Quality

Sleep quality generally refers to subjective perceptions about one's sleep. The Pittsburgh Sleep Quality Index (PSQI), which is the most widely used self-report sleep instrument and has been translated into over 30 languages, is an example of a "multiple-indicator" measure of sleep quality (Buysse, Reynolds, Monk, Berman, & Kupfer, 1989). The PSQI includes 18 retrospective questions about one's sleep over the past month. These questions are used to derive seven subscales (sleep duration, sleep latency, sleep efficiency, sleep disturbance, daytime dysfunction, use of medications for sleep, and overall sleep quality), each of which has a range of 0–3. These subscales may be summed to generate a global measure of subjective sleep quality with a range of 0–21; higher values reflect greater subjective sleep complaints.

In a community-based study of midlife adults without clinical cardiovascular disease, Jennings and colleagues reported that higher PSQI-assessed sleep quality complaints were associated with increased prevalence of the metabolic syndrome (Jennings, Muldoon, Hall, Buysse, & Manuck, 2007). Other cross-sectional studies have reported greater subjective sleep quality complaints in patients with hypertension, diabetes, kidney disease, polycystic ovary syndrome, and cancer compared to age- and sex-matched healthy controls (e.g., Liu et al., 2009; Sabbatini et al., 2008; Tasali, Van Cauter, & Ehrmann, 2006). Subjective sleep quality complaints may be a consequence of disease. It may also indirectly impact health via health behavior pathways. For instance, subjective perceptions that one's sleep is not sound or restorative may lead to increased daytime caffeine use and increased use of alcohol prior to sleep which, in turn, may negatively impact health and functioning.

Summary

Converging evidence suggests numerous links between specific dimensions of sleep and important indices of health and functioning. The two most prevalent sleep disorders, insomnia and sleep apnea, too have been prospectively linked to adverse health outcomes (see entries for

"► Insomnia, ► Sleep Apnea"). Yet, little is understood about *how* specific dimensions of sleep or sleep disorders may confer vulnerability or resilience to disease. Identification of the cellular and molecular pathways through which sleep affects and is affected by health is critical to advancing our understanding of the sleep-health relationship in the context of behavioral medicine.

Sleep deprivation

Definition

Sleep is defined as a reversible state of perceptual disengagement and unresponsiveness to the external environment. Sleep is a complex physiological and behavioral process that is part of every individual's life and a critical determinant of physical and mental health.

Description

It is generally accepted that 7–8 h is the optimal amount of sleep needed per night for adequate daytime functioning and to reduce the risk of developing serious medical conditions. However, many Americans sleep less than 7 h per night and many report sleep difficulties. The percentage of men and women reporting sleeping less than 6 h per night has increased significantly over the last 20 years. Broad societal changes, including longer work hours, shift work, later night life, increased dependence on technology, and a current mindset of "if you snooze, you lose" have contributed to the increases in sleep loss among adults. Sleep loss increases the risk and incidence of diseases that may ultimately result in death. Many of the studies examining sleep duration and adverse health outcomes have found a U-shaped relationship suggesting that too little sleep and too much sleep is detrimental to health. And, between 7 and 8 h of sleep appears to be associated with reduced health risk.

Sleep and Mortality

Growing evidence over the last few decades suggests that progressively shorter (<7 h per night) or longer (>8 h per night) sleep duration is associated with a greater risk of mortality (Cappuccio, D'Elia, Strazzullo, & Miller, 2010; Kripke, Garfinkel, Wingard, Klauber, & Marler, 2002). The mechanisms that underlie these associations are not fully understood. Potential adverse physiologic effects of short sleep duration may contribute to negative health outcomes like cardiovascular disease, diabetes, and obesity, all of which are associated with increased mortality risk. Sleep restriction has been shown to impair

glucose tolerance, increase evening cortisol levels, alter sympathetic nervous system activity, reduce leptin levels and increase levels of ghrelin, and increase inflammatory markers. The mechanisms linking long sleep duration with mortality is unknown and may be explained by underlying confounders such as depression, low socioeconomic status, undiagnosed medical disease, poor physical health, and less physical activity.

Sleep and Cardiovascular Disease

Sleeping less than 7 h per night has been found to increase the risk of developing high blood pressure (i.e., hypertension) and elevate blood pressure in those with existing hypertension (Calhoun & Harding, 2010). Long sleep duration (≥9 h per night) may also increase the risk of hypertension. The effect of insufficient sleep on blood pressure may help to explain the relationship between poor sleep and cardiovascular disease and stroke. Researchers have found both short (<7 h per night) and long (>8 h per night) sleep durations are associated with a greater risk of developing or dying from coronary heart disease and stroke (Cappuccio, Cooper, D'Elia, Strazzullo, & Miller, 2011).

There is also growing evidence of a connection between "► Sleep Apnea" and cardiovascular disease. People with sleep apnea have frequent awakenings at night as a result of repetitive pauses in breathing. This sleep fragmentation and reoccurring drops in oxygen levels in the blood called hypoxemia cause increases in blood pressure during the night that can persist during the daytime and over time can lead to hypertension. People with sleep apnea have an increased risk of developing coronary heart disease, stroke, and heart failure. In a 10-year study, severe sleep apnea was associated with an increased risk of fatal and nonfatal cardiovascular events.

Sleep and Obesity

Numerous studies have reported a link between sleep duration and obesity. For example, researchers have shown that people who sleep less than 6 h per night or more than 8 h per night are more likely to have a higher ► body mass index and that people who sleep 8 h have the lowest BMI (Cappuccio, Taggart, Kandala, & Currie, 2008). Several pathways have been identified that could mediate the relationship between short sleep and increased risk of obesity: alterations in glucose metabolism, appetite control, and energy expenditure. Sleep loss impacts hormones that regulate glucose processing and appetite (Taheri, Lin, Austin, Young, & Mignot, 2004). After sleep loss, the body's tissues are less responsive to insulin (i.e., insulin resistance), a hormone secreted by the pancreas that regulates the level of glucose in the body. As a result, glucose levels in the blood remain high, making it more difficult for the body to use stored fat for energy. Sleep loss also impacts hormones involved in appetite regulation causing people to eat even when they have had an adequate number of calories. Specifically, short sleep lowers levels of leptin, a "full signal" hormone, and increases levels of ghrelin, an appetite stimulant hormone. One night of sleep loss can decrease energy expenditure (i.e., calories burned) during rest.

Sleep and Diabetes

Numerous epidemiological studies have found that short (≤6 h per night) and long (≥9 h per night) sleep durations are associated with an increased risk of developing type 2 diabetes and impaired glucose tolerance, a precursor to diabetes (Knutson & Van Cauter, 2008). Insulin resistance associated with sleep loss can over time compromise the ability of β-cells in the pancreas to release insulin, causing higher than normal levels of glucose in the blood which can lead to type 2 diabetes. In a study of healthy adults, restricting sleep to 4 h per night for six nights led to impaired glucose tolerance.

In addition, sleep apnea is a risk factor for developing type 2 diabetes. Several potential mechanisms explaining how sleep apnea may alter glucose metabolism have been proposed. Sleep fragmentation and hypoxemia associated with sleep apnea can alter autonomic and neuroendocrine function, increase release of inflammatory cytokines, and induce adipokines and thus play a role in altering glucose metabolism.

Sleep and Cancer

Emerging evidence suggests that sleep duration may increase risks of several types of cancer. The first investigation of the association between sleep and breast cancer found women with longer sleep durations (≥9 h per night) had a decreased risk of breast cancer. Subsequent studies have found mixed results with some studies finding an inverse relationship between short sleep duration and risk of breast cancer and one study found no association. Short sleep duration was associated with an increased risk of colorectal cancer in patients undergoing colonoscopy screening and an increased risk of prostate cancer. Epidemiological studies have reported a significantly increased risk of developing a number of malignancies including breast, colon, prostate, and endometrial cancer in night-shift workers. Nocturnal melatonin suppression due to decreased sleep duration or light exposure at night in the case of shift workers may alter the oncostic action of melatonin (Blask, 2009).

Sleep and the Immune System

The relationship between sleep and immunity is reciprocal such that infections increase sleep duration and sleep deprivation negatively impacts immune function. Experimental studies have shown that sleep deprivation results in suppression in natural killer cell activity, reductions in interleukin-2 production, increased circulation of pro-inflammatory cytokines such as IL-6, tumor necrosis factor (TNF) α, and reduction of anti-inflammatory cytokines (Bryant, Trinder, & Curtis, 2004). Sleep is needed for optimal resistance to infection. Sleep restriction in healthy adults has been shown to reduce antibody production response to the influenza vaccination. One night of sleep deprivation reduced the formation of specific antibodies to hepatitis A antigens after vaccination. Short sleep duration in the weeks preceding exposure to rhinovirus increased the susceptibility to developing a cold.

Sleep and Neurocognitive Function

It has been established that sleep deprivation impairs cognitive and motor performance (Durmer & Dinges, 2005). However, some people are more vulnerable to the effects of sleep loss than others. Sleep deprivation studies have found a wide range of effects on cognitive function including decrements in attention especially vigilance, working and long-term memory, decision making, response inhibition, processing speed, and reasoning (Lim & Dinges, 2010). Sleep deprivation results in impairments in psychomotor performance that are comparable to those induced by alcohol consumption at or above the legal limit (Williamson & Feyer, 2000). Sleep loss increases the risk of traffic accidents as demonstrated by poor performance on driving simulators after sleep deprivation. In addition to an increased risk for motor vehicle crashes, sleep deprivation and related neurocognitive impairments are associated with work-related injuries and fatal accidents. Sleep apnea is also associated with deficits in cognitive function and accounts for a significant proportion of motor vehicle accidents.

Sleep and Mental Health

Numerous studies have shown a high rate of comorbidity between sleep complaints (e.g., insomnia) and psychiatric disorders, especially mood and anxiety disorders (Staner, 2010). This relationship goes beyond mere co-occurrence and is bidirectional since insomnia contributes to the development or exacerbation of depression and anxiety disorders, and affective disorders and their treatments contribute to insomnia (Neckelmann, Mykletun, & Dahl, 2007; Sateia, 2009). Nondepressed individuals with insomnia have a two times greater risk for developing depression than individuals without sleep difficulties. Sleep problems affect outcomes for patients with depression. Studies report that depressed patients who continue to experience insomnia are at greater risk of relapse and recurrence of depression and risk of suicide.

Conclusions

Sleep loss is a growing public health problem worldwide. The health consequences of a sleepy society are enormous and have a significant

economic impact with billions of dollars spent on direct medical costs associated with morbidities and sleep-related injuries and accidents. Sleep deprivation can alter biological processes underlying cardiovascular, metabolic, and immune function. Cumulative long-term effects of sleep loss have been associated with a number of serious health consequences, including cardiovascular disease, obesity, cancer, and type 2 diabetes. Sleep is not a luxury and is as important for health as other health-promoting behaviors like diet and exercise. Public awareness is needed to emphasize and reinforce the essentialness of sleep for health.

Sleep Apnea

Faith S. Luyster
School of Nursing, University of Pittsburgh, Pittsburgh, PA, USA

Synonyms

Obstructive sleep apnea; Sleep-disordered breathing

Definition

Sleep apnea is a common sleep disorder characterized by repetitive pauses in breathing or very shallow breaths during sleep (Strollo & Rogers, 1996; Young, Peppard, & Gottlieb, 2002). Pauses in breathing, known as apneas, and shallow breathing events, called hypopneas, can last

a few seconds to minutes and can occur multiple times during the night. The termination of apneas and hypopneas is associated with a transient arousal from sleep. Sleep disruption due to frequent arousals may lead to excessive daytime sleepiness or fatigue. Loud snoring, witnessed breathing interruptions, and excessive daytime sleepiness are the most common signs of sleep apnea. Obstructive sleep apnea (OSA) occurs when the airway collapses or is blocked during sleep. Central sleep apnea results from temporary loss of ventilatory effort lasting at least 10 seconds and can co-occur with OSA. An evaluation for sleep apnea entails an assessment for signs and symptoms and a detailed craniofacial examination followed by a full night of in-laboratory or portable polysomnography to confirm diagnosis (Epstein et al., 2009). Sleep apnea requires long-term management. Positive airway pressure therapy, oral appliances, and surgery are the most common treatments for sleep apnea, but other behavioral interventions such as weight loss, smoking cessation, body position, and alcohol and sedative cessation, can be useful adjuncts to conventional therapies (Epstein et al., 2009). Untreated sleep apnea can result in a number of negative consequences, including excessive daytime sleepiness and fatigue, psychological symptoms, cognitive and performance impairments, and increased risk for cardiovascular and cerebrovascular disease (Bradley & Floras, 2009; Sateia, 2003). Decreased vigilance or falling asleep at the wheel increases the risk of motor vehicle crashes in individuals with sleep apnea (Ellen et al., 2006).

Sleep Architecture

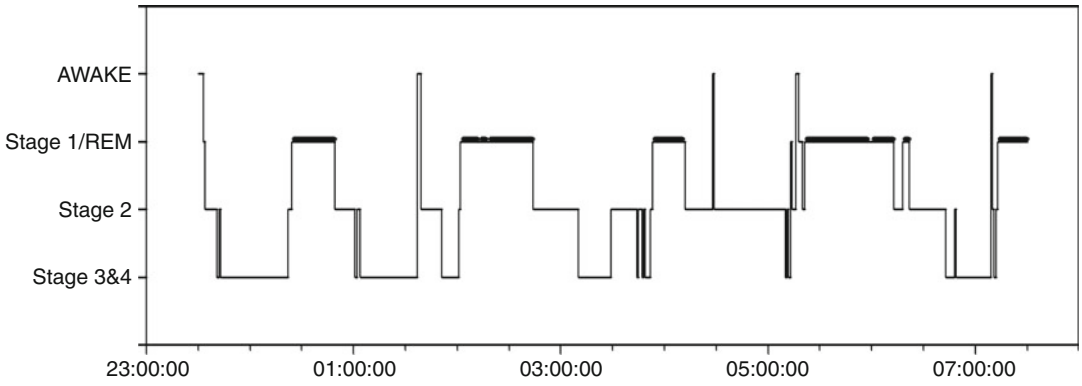
Salvatore Insana
Western Psychiatric Institute and Clinic, Pittsburgh, PA, USA

Definition

Sleep Architecture is the visual representation of the way sleep stages are organized throughout a polysomnographically recorded sleep interval. Sleep Architecture is displayed on a hypnogram plot.

Description

Sleep can be measured with polysomnography (PSG), which consists of multiple measures that include, but are not limited to, electroencephalography (EEG), electrooculography (EOG), and electromyography (EMG) (see for a review Keenan & Hirshkowitz, 2011). PSG literally translates to "many" (poly) "sleep" (somno) "writings" (graphy). When sleep is measured with PSG, the measured signals are typically sectioned into 30-s intervals consecutively throughout the entire PSG recording period. These 30-s intervals are termed "epochs." Within



Sleep Architecture, Fig. 1 Sleep hypnogram and sleep architecture during a 20-year-old female's overnight sleep monitoring period

each epoch, the PSG-measured signals (from EEG, EOG, and EMG) are cumulatively used to differentiate sleep from wake, and to further classify sleep into different categories that are known as sleep stages.

According to the 2007 American Academy of Sleep Medicine standard practice parameters, sleep can be classified into four stages that include N1, N2, N3, and Rapid Eye Movement (REM) sleep (Iber, Ancoli-Israel, Chesson, & Quan, 2007). The PSG signals are used to identify each individual epoch as a particular sleep stage. The act of using PSG signals to identify each epoch as a particular sleep stage is known as sleep stage scoring. Sleep stage scoring is completed by a trained technician who visually interprets the PSG signals in accordance with standard practice parameters.

Once the entire PSG sleep study is scored, the study is summarized into a clinical report. The clinical report describes the sleep parameters measured (e.g., EEG, EOG, EMG, airflow parameters), sleep scoring data (e.g., lights out clock time, lights on clock time, total sleep time), arousal events (e.g., number of arousals, arousal index), respiratory events (e.g., apnea index, hypopnea index), cardiac events (e.g., average heart rate during sleep), movement events (e.g., number of periodic limb movements during sleep), and summary statements (e.g., findings related to sleep diagnoses, behavioral observations, sleep hypnogram). Of particular relevance to sleep architecture is the sleep hypnogram.

The sleep hypnogram is a summary figure that visually displays the scored wake and sleep stages as they occurred throughout the entire PSG recording period. The sleep hypnogram is formatted with time throughout the entire PSG sleep study as a continuous variable on the X-axis, and the visually scored wake and sleep stages as categorical variables on the Y-axis. The categorical wake and sleep stages are positioned with REM closest to the intersection with the X-axis, followed by N3, N2, N1, and wake in an upward ascending order; however, the order and format of these stages can vary per laboratory (e.g., Fig. 1).

As time progresses throughout the sleep monitoring period, the person being monitored naturally enters and exits the wake and sleep stages that are indicated on the Y-axis. The time spent in a particular stage is represented by a horizontal line adjacent to the respective stage, and the length of that horizontal line reflects the time spent in that particular stage as it corresponds to the "real time" for which the stage occurred – indicated on the X-axis. During a stage transition, the horizontal line turns 90° (right angle) positive or negative to become vertical and adjacent to the newly entered stage – as indicated on the Y-axis; then the line turns 90° (right angle) once again to reach a horizontal position with a length that represents

the time spent in that particular stage – indicated on the X-axis. As the different wake and sleep stages fluctuate throughout the night, the hypnogram line appears at different horizontal levels (stage-dependent [Y-axis]), at different lengths on each level (time-dependent [X-axis]); and as the levels shift (stage shift), the horizontal line is connected to the previous and subsequent horizontal level by a vertical line (e.g., elbow connector).

Consequently, the wake and sleep stages represented on a sleep hypnogram resemble the back drop of a city skyline, with continuous geometric cubes and rectangles of different heights and widths that appear to continuously penetrate and retreat from the skyline. The figurative reference to a city skyline has been generally accepted, and has literally generated the term "sleep architecture." Thus, sleep architecture is the visual representation of wake and sleep stages that occurred throughout a polysomnographically recorded sleep interval, and is displayed on a hypnogram plot.

The visual structure of sleep architecture is dependent upon the sleep stage, and the time in the particular sleep stage. Typically, sleep is entered through N1, followed by N2, followed by N3, and then followed by REM – this progressive series is termed a "sleep cycle." The typical sleep cycle occurs throughout sleep at approximately 50-min intervals among infants (Grigg-Damberger et al., 2007) and approximately 90–110-min intervals among adults (Iber et al., 2007). The time spent in the different stages changes throughout the night. The first portion of the night primarily consists of non-REM sleep (i.e., N1, N2, and N3), and the second portion of the night primarily consists of REM sleep.

The sleep architecture displayed on the hypnogram from a normative adult PSG sleep study will display cumulatively longer horizontal lines adjacent to N1, N2, and N3 during the first portion of the night relative to the second portion, and will conversely display cumulatively longer horizontal lines adjacent to REM during the second portion of the night relative to the first portion. A sleep hypnogram will display the sleep stage cyclicity, as well as changes in time spent in particular stages as they occur throughout the recording period – this differs across nights. Since the time spent in different sleep stages generally changes throughout the lifespan (Ohayon, Carskadon, Guilleminault, & Vitiello, 2004), the percentage of time spent in each sleep stage, as reflected in the histogram, can differ by to the age of the person assessed.

Sleep Continuity

Elizabeth Mezick
Department of Psychology, University of Pittsburgh, Pittsburgh, PA, USA

Synonyms

Sleep efficiency; Sleep fragmentation; Sleep maintenance

Definition

Sleep continuity refers to the amount and distribution of sleep versus wakefulness in a given sleep period; it includes both sleep initiation and sleep maintenance (Hall, Greeson, & Mezick, in press). Specific indices of sleep continuity may include latency to sleep onset, number of awakenings after sleep onset, total time of wakefulness after sleep onset, and overall sleep efficiency. Sleep continuity is most often assessed using self-report questionnaires (i.e., retrospective reports, morning diaries or logs), wrist actigraphy, or polysomnography.

Sleep continuity declines as part of the normal aging process (Ohayon, Carskadon, Guilleminault, & Vitiello, 2004). Disruptions in sleep continuity are typical among individuals with insomnia and are also commonly reported by or observed in those with mood disorders, anxiety disorders, and substance disorders. Many medical conditions and treatments are also related to disrupted sleep continuity; some of the most common examples include sleep apnea, chronic pain, asthma and respiratory conditions, chronic renal disease, infectious diseases, and cancer. Decreased sleep continuity has been associated with increased inflammatory markers, susceptibility to infection, elevated blood pressure, obesity, presence of metabolic syndrome, diabetes, and cardiovascular disease. Several studies have reported a link between decreased sleep continuity and incident diabetes or incident cardiovascular disease.

Sleep Deprivation

Martica H. Hall
Department of Psychiatry, University of Pittsburgh, Pittsburgh, PA, USA

Synonyms

Sleep deprived

Definition

Sleep deprivation generally refers to the total loss of sleep due to experimental manipulations or circumstance.

Description

Sleep deprivation refers to the total loss of sleep. The term is generally used in the context of experimental manipulations which keep individuals (or experimental animals) awake throughout their usual sleep period. Sleep deprivation also occurs in naturalistic conditions such as when a student stays awake all night to study for an exam. Experimental and observational sleep deprivation studies have been used to evaluate the cognitive, behavioral, emotional, and physiological consequences of sleep loss.

Experimental sleep deprivation studies in humans generally deprive participants of

1–3 nights of sleep, resulting in 24–72 h of wakefulness. Experimental animal models can extend sleep deprivation for much longer periods of time (e.g., 2 weeks). In both kinds of studies, electroencephalographic (EEG) monitoring is used to ensure wakefulness, usually through interactions with study staff or procedural manipulations. For example, the classical "disk-over-water" method pioneered by Dr. Allan Rechtschaffen at the University of Chicago involved placing two animals on a rotating disk suspended above water (Rechtschaffen & Bergmann, 1995). A barrier divided the disk into half, with the experimental animal on one side of the disk and the yoked animal on the other. When the experimental animal showed EEG signs of sleep, the disk would rotate. If the animal did not wake up, they would fall into the water when they reached the barrier. Through conditioning, the experimental animal would learn to wake up as soon as the disk started to rotate. The yoked animal, on the other hand, would learn to sleep when the disk was *not* rotating. This elegant design allowed experimenters to tease apart the effects of movement and stress associated with older forms of sleep deprivation (e.g., placing the animal on a continuous running wheel with no option for escape) from the effects of sleep deprivation. In human studies, the constant routine protocol, which involves keeping participants in a recumbent position for the duration of the protocol, is used to control for the influence of extraneous factors such as increased movement on study outcomes.

Although individuals may feel that sleep deprivation has no adverse effects on them, experimental evidence suggests that perceptions of resiliency to sleep loss are unfounded. The "disconnect" between subjective perceptions of sleepiness and objective indices of health and functioning in humans has been systematically documented by Dr. David Dinges and his colleagues at the University of California (see Lim & Dinges, 2008). More recently, others have demonstrated that one night of total sleep deprivation in healthy young adults is associated with increased blood pressure and amydgala reactivity to negative emotional stimuli (Franzen et al., 2011; Yoo, Gujar, Hu, Jolesz, & Walker, 2007). As a complement to studies in humans, animal models, which allow exquisite control over sleep and wakefulness, have begun to elucidate the influence of sleep deprivation on gene expression, molecular signaling, and synaptic plasticity (e.g., Seugnet, Suzuki, Donlea, Gottschalk, & Shaw, 2011; Wang, Liu, Briesemann, Yan, 2010). Taken as a whole, these studies demonstrate that sleep is essential to health and functioning across species.

Sleep Duration

Christopher Kline
Department of Psychiatry, School of Medicine, University of Pittsburgh, Pittsburgh, PA, USA

Synonyms

Total sleep time

Definition

Sleep duration typically refers to the total amount of sleep obtained, either during the nocturnal sleep episode or across the 24-h period.

Description

Measurement

Sleep duration can be measured via questionnaire, diary, actigraphy, or polysomnography. In population-based epidemiologic studies, single-item questionnaire or self-report measures of sleep duration have often been utilized (e.g., *How many hours of sleep do you obtain on a typical night?*). In clinical and research settings, sleep diaries, actigraphy, and polysomnography provide assessments of sleep duration. Sleep diaries involve the subjective report of sleep duration, typically daily for a minimum of 1 week. Actigraphy provides an objective estimate of sleep/wake status from the detection of bodily movement, whereas polysomnography measures sleep duration through the assessment of multiple physiological signals, including brain, eye, and muscle activity. Although typically correlated, large discrepancies are often noted between subjective and objective measures of sleep duration; in most populations, self-reported sleep duration is overestimated compared to objective measurement (Silva et al., 2007).

Sleep Duration Across the Life span

Sleep is regulated by a complex interaction of homeostatic and circadian factors. The homeostatic process reflects the need for sleep, accumulating during sustained wakefulness and dissipating during sleep. The circadian process, driven by outputs of the circadian pacemaker, promotes wakefulness during the day and evening, and promotes sleep during the night, with the peak sleep-promoting signal during the early morning. Thus, circadian signals oppose the rise of homeostatic sleep pressure during the day, allowing for uninterrupted daytime wakefulness. Both circadian and homeostatic processes promote sleep onset, with circadian sleep-promoting signals facilitating a continuation of consolidated sleep despite the gradual dissipation of homeostatic sleep pressure over the course of the night. Aging results in changes in the homeostatic and circadian regulation of sleep, with a phase advance of the circadian wake-promoting signal (i.e., increased signal for wakefulness in the morning, but decreased in the evening) and reduced homeostatic drive for sleep with increasing age (Dijk, Duffy, Riel, Shanahan, & Czeisler, 1999). As a result, sleep duration in older adults is commonly phase-advanced, of shorter duration, and with greater fragmentation compared to younger adults.

In general, sleep duration decreases from infancy through old age. Sleep duration (per 24 h) averages 14 h during infancy, gradually declining to approximately 8 h during late adolescence (Iglowstein, Jenni, Molinari, & Largo, 2003). Normative sleep duration then declines throughout adulthood to approximately 6.5 h at age 60, at which point sleep duration tends to stabilize (Ohayon, Carskadon, Guilleminault, & Vitiello, 2004). It is important to note that these average values do not indicate whether actual sleep need is being met, particularly during development. For instance, although weekday sleep duration decreases throughout childhood and adolescence, weekend sleep duration remains similar from age 5 to 16. This pattern suggests a greater influence of environmental factors (e.g., school schedules) than biological or maturational influences on sleep duration during childhood and adolescence.

Whether sleep duration has changed dramatically over the latter half of the past century is

controversial. Whereas some studies have documented remarkable (i.e., >1 h) decreases in sleep duration and significantly increased prevalence of short sleep, others have presented evidence that longitudinal changes in sleep duration have been minimal (i.e., <20 min decrease over a >20-year span) (Rowshan Ravan, Bengtsson, Lissner, Lapidus, & Bjorkelund, 2010). Additional studies estimate that, although average sleep duration has changed from 8 to 7 h, the prevalence of extreme short and long sleep have not changed in the past 30 years (Kronholm et al., 2008). Moreover, longitudinal studies have documented that increased mortality risk is associated with an increase and decrease in sleep duration over time (Ferrie et al., 2007). The reduction in sleep duration in industrialized societies is likely due to both lifestyle (e.g., late bedtime due to television and/or computer diversions) and biological factors (e.g., reduced sleep need due to more sedentary lifestyles) (Horne, 2011).

Sleep Duration and Health

Sleep is an essential behavior for memory consolidation, development, and restoration of nervous, immune, skeletal, and muscular systems. Consequently, the amount of sleep obtained has a significant influence on one's health and functioning. Sleep duration is at least partly determined by genetic influences, so interindividual differences in sleep duration are to be expected. Nevertheless, a significant association between sleep duration and health has been consistently documented in epidemiologic research, highlighting the potential modulating influence of sleep on health (Bixler, 2009).

The association between sleep duration and health typically has a U-shaped distribution, with lowest risk associated with a sleep duration of 7–8 h (Cappuccio, D'Elia, Strazzullo, & Miller, 2010). Short and long sleep have been associated with increased risk of mortality and numerous morbidities, including cardiovascular disease (e.g., hypertension, atherosclerosis), metabolic dysfunction (e.g., type 2 diabetes, obesity), and cognitive impairment. However, the most marked morbidity and mortality risks have been associated with extreme short and long sleep (<5 and >9 h, respectively).

The possible mechanisms by which sleep duration affects health are likely different between short and long sleep duration (Krueger & Friedman, 2009). Most research has focused on how short sleep may adversely affect health, with studies finding alterations in the hormonal control of appetite, increased inflammatory levels, increases in hypothalamic-pituitary-adrenal axis and sympatho-adrenal activity, and blunted immunity to pathogens following short-term experimental sleep restriction (Grandner, Hale, Moore, & Patel, 2010). Plausible mechanisms linking long sleep duration to excess morbidity and mortality are less clear, though fatigue, impaired immunity, reduced photoperiod length, and underlying disease have been postulated (Youngstedt & Kripke, 2004). However, short and long sleep do share some common possible mechanisms. Both short and long sleep duration have been associated with low socioeconomic status, and sleep complaints are more prevalent in short and long sleepers compared to normal sleep duration. Moreover, poor health behaviors (e.g., smoking, alcohol, and physical inactivity) are more prevalent in short and long sleep in comparison to normal sleep duration.

Sleep Efficiency

► Sleep Continuity
► Sleep Fragmentation

Sleep Fragmentation

Elizabeth Mezick
Department of Psychology, University of Pittsburgh, Pittsburgh, PA, USA

Synonyms

Sleep continuity; Sleep efficiency; Sleep maintenance

Definition

Sleep fragmentation typically refers to brief arousals that occur during a sleep period. The American Sleep Disorders Association (1992) defines an arousal as an abrupt shift in electroencephalographic (EEG) frequency (suggestive of an awake state) which is 3 s or greater in duration and which occurs after at least 10 consecutive seconds of sleep. A number of other definitions of arousal have been published or suggested since that time, with some recommending that elements or physiological responses other than EEG frequency be taken into account (e.g., autonomic activation without cortical involvement) (Janackova and Sforza, 2008). When assessed with actigraphy, sleep fragmentation may refer to the amount of movement or restlessness in a sleep period. For example, actigraph software programs use algorithms to calculate a sleep fragmentation index, based on the number or proportion of total sleep epochs characterized by movement. When used in a more general sense, sleep fragmentation may also refer to the overall amount and distribution of wakefulness in a sleep period and can be considered the inverse of sleep continuity. For example, some authors have used the term "sleep fragmentation" to describe parameters such as wakefulness after sleep onset and sleep efficiency.

Elevated sleep fragmentation occurs in those with sleep apnea and may correlate with daytime sleepiness. Increased sleep fragmentation as assessed by actigraphy has been associated with

a number of physical and psychiatric health outcomes, as well as deficits in neurobehavioral performance. Experimental models of sleep fragmentation, which typically disrupt sleep briefly using auditory, mechanical, or other stimuli, have been used to examine the neurophysiologic, cognitive, and behavioral consequences of fragmented sleep.

Sleep Maintenance

▶ Sleep Continuity
▶ Sleep Fragmentation

Sleep Quality

Christopher Kline
Department of Psychiatry, School of Medicine, University of Pittsburgh, Pittsburgh, PA, USA

Synonyms

Sleep refreshment; Sleep satisfaction

Definition

Sleep quality is defined as one's satisfaction of the sleep experience, integrating aspects of sleep initiation, sleep maintenance, sleep quantity, and refreshment upon awakening.

Description

Sleep quality is a vital construct to clinicians and researchers due to the high prevalence of disturbed sleep and insomnia, and the clear relevance of sleep quality to optimal health and functioning. Yet, despite its common usage, "sleep quality" is a term without a clear definition (Krystal & Edinger, 2008). In fact, sleep quality is likely to have different meanings from one person to the next. For someone with problems initiating sleep, the sleep onset period may be the strongest determinant of sleep quality. In contrast, the relative difficulty of going to sleep may be of trivial importance to someone whose sleep is restless and rife with frequent awakenings.

Measurement

Measurement of sleep quality is difficult due to its imprecise definition. The construct of sleep quality likely incorporates aspects of sleep quantity, wakefulness (both prior to and following sleep onset), and feeling of refreshment upon awakening, as well as daytime sleepiness (Harvey, Stinson, Whitaker, Moskovitz, & Virk, 2008). Many of these aspects cannot be easily measured in an objective fashion. Nevertheless, assessment of sleep quality has been attempted through the use of diary-based measures, subjective and objective sleep parameters, and self-report questionnaires.

Sleep diaries employ perhaps the most appropriate measure of sleep quality. Either a Likert-type rating scale (e.g., 1: *very poor sleep quality*; 5: *very good sleep quality*) or a visual analogue scale (with anchors of *very poor* and *very good* sleep quality) are traditionally incorporated into sleep diaries, providing a distinction from subjective sleep parameters.

Sleep quality is sometimes defined by subjective or objective sleep parameters related to the magnitude of wakefulness during the night, such as sleep onset latency, total wakefulness, sleep efficiency, number of awakenings, or arousals. Moreover, measures of sleep "depth" derived from polysomnography, such as the amount of N1 sleep or N3 sleep (sometimes referred to as "light" and "deep" sleep, respectively) has sometimes been used to characterize sleep quality, with increased "light" sleep linked to poor sleep quality and increased "deep" sleep linked to good sleep quality. However, these parameters often fail to completely capture the essence of sleep quality. In particular, sleep quality should not be considered to be synonymous with the amount of sleep obtained. For example, in comparison to those who report a sleep duration of 7–8 h, poor sleep quality is more prevalent with short and long sleep.

Self-report questionnaires attempt to assess sleep quality through the measurement of different domains of the sleep experience. The most widely used questionnaire, the Pittsburgh Sleep Quality Index, is an 18-item instrument with seven components: sleep quality, sleep latency, sleep duration, habitual sleep efficiency, sleep disturbances, sleeping medication use, and daytime dysfunction (Buysse, Reynolds, Monk, Berman, & Kupfer, 1989). Another common measure, the Medical Outcomes Study Sleep Scale, assesses six different aspects of sleep: sleep disturbance, sleep adequacy, daytime sleepiness, snoring, awakening with shortness of breath or headache, and sleep quantity (Hays, Martin, Sesti, & Spritzer, 2005). Scores on both of these measures have been shown to identify individuals who characterize their sleep as being poor in quality.

Correlates with Sleep Parameters

Sleep quality is often only weakly associated with subjective or objective sleep parameters, with wakefulness after sleep onset, sleep onset latency, and total sleep time typically showing the strongest, yet still modest, correlations ($r < 0.50$). The lack of strong concordance between common sleep parameters and sleep quality is perhaps best exemplified by the sleep of insomniacs, who by definition report poor sleep quality. For instance, only about one-half of insomniacs show differences in objective sleep parameters compared to normal sleepers. However, among those insomniacs whose objective sleep parameters were comparable to normal sleepers, sleep quality was significantly associated with spectral electroencephalographic (EEG) content, specifically lower delta-frequency EEG and higher beta-frequency EEG (Krystal & Edinger, 2008).

Sleep Quality and Health

Poor sleep quality is believed to be widespread in modern society. Approximately one third of adults complain of poor sleep quality, though in most studies prevalence estimates are based upon insomnia-related symptoms. Poor sleep quality has been associated with increasing age, low socioeconomic status, poor general health, psychological distress, and poor lifestyle behaviors (e.g., high caffeine use, sedentary lifestyle, smoking, etc.).

How poor sleep quality may influence future morbidity or mortality risk is less clear. Epidemiologic studies have found that poor sleep quality is predictive of increased risk of metabolic dysfunction and mortality risk (Cappuccio, D'Elia, Strazzullo, & Miller, 2010; Kojima et al., 2000). However, most studies have focused on sleep duration rather than sleep quality, perhaps due to the difficulty in concisely defining sleep quality. Interestingly, in recent studies that have concurrently assessed sleep duration and sleep quality, stronger associations with health risk have been found for poor sleep quality than sleep duration (Chandola, Ferrie, Perski, Akbaraly, & Marmot, 2010).

Sleep Refreshment

► Sleep Quality

Sleep Restriction

Martica H. Hall
Department of Psychiatry, University of Pittsburgh, Pittsburgh, PA, USA

Synonyms

Partial sleep deprivation; Sleep curtailment; Sleep debt

Definition

Sleep restriction generally refers to situational or experimentally induced reductions in overall sleep duration.

Description

Sleep restriction refers to the partial loss of sleep. The term is generally used in the context of experimental manipulations which keep individuals (or experimental animals) awake for some portion of their usual sleep period. Sleep restriction also occurs in naturalistic conditions such as when new parents have to wake repeatedly to care for their newborn child or when an individual purposefully reduces their sleep time in order to meet the competing demands of work, family, or other obligations. Importantly, sleep restriction differs from insomnia in that sleep-restricted individuals do not have an adequate opportunity to sleep whereas individuals with insomnia have sleep difficulties despite adequate opportunity to sleep (see "► Insomnia" entry). Experimental and observational sleep restriction studies have been used to evaluate the cognitive, behavioral, emotional, and physiological consequences of sleep restriction, including the loss of specific components of sleep (e.g., slow-wave sleep).

Dr. Eve Van Cauter and her colleagues at the University of Chicago have been instrumental in highlighting the public health implications of partial sleep restriction, or sleep "curtailment" across the life span (Hanlon & Van Cauter, 2011). In a series of carefully controlled studies in healthy young adults, Van Cauter and colleagues demonstrated that sleep restriction is associated with metabolic and endocrine alterations that underlie glucose tolerance, insulin sensitivity, and weight gain. These results are mirrored in epidemiologic studies of obesity and diabetes risk in children and adults (Hanlon & Van Cauter, 2011). Other consequences of experimental sleep restriction include decrements in working memory, alterations in inflammatory markers, and decreased testosterone levels in males (Casement, Broussard, Mullington, & Press, 2006; Irwin, Wang, Campomayor, Collado-Hidalgo, & Cole, 2006; Leproult & Van Cauter, 2011; Prather et al., 2009). Experimental laboratory studies have also begun to selectively deprive experimental subjects of specific sleep stages to better understand their function. For instance, animal models have been

used to identify the neurophysiological mechanisms through which REM sleep regulates learning and memory (Poe, Walsh, & Bjorness, 2010). In the only study of its kind conducted to date, Tasali, Leproult, Ehrmann, & Van Cauter (2008) demonstrated that selective suppression of slow-wave sleep in healthy, lean adults resulted in marked decreases in insulin sensitivity. Importantly, these effects were independent of sleep duration.

Societal trends suggest that large numbers of adults are chronically sleep-restricted. During the work week, they may build up a sleep "debt" and perceive that this debt may be "paid" on non-work nights. Epidemiologic evidence that documents the buildup of sleep debt during the work week and its payment on non-work nights is lacking. Moreover, experimental evidence suggests that multiple, long recovery nights may be necessary to "repay" sleep debt induced by chronic partial sleep restriction (Banks, Van Dongen, Maislin, & Dinges, 2010). Although the systematic evaluation of the impact of sleep restriction on indices of health and functioning is in its infancy, the epidemiological and experimental data amassed thus far supports the belief that this is an important public health concern.

Slow-Wave Sleep

Salvatore Insana
Western Psychiatric Institute and Clinic, Pittsburgh, PA, USA

Synonyms

Deep sleep; Delta sleep; N3; Sleep stages 3 and 4

Definition

Sleep can be measured with polysomnography (PSG) (see review, Keenan & Hirshkowitz, 2011). Polysomnographically measured sleep behaviors can be classified into distinct categories. Slow-wave sleep (SWS) is a distinct sleep behavior classification. SWS is also known as stage N3 sleep as defined by the 2007 American Academy of Sleep Medicine sleep scoring manual (Iber, Ancoli-Israel, Chesson, & Quan, 2007). SWS is otherwise known as the combination of sleep stages 3 and 4 according to the Rechtschaffen and Kales "classic criteria" (Rechtschaffen & Kales, 1968). Other common terms used to describe SWS are "delta sleep" and "deep sleep."

A characteristic component of SWS is the organized pattern of neurological activity that is emitted from the brain as measured by electroencephalography. A component of the organized pattern of neurological activity is the presence of slow waves, otherwise known as delta waves. Slow waves have high amplitude (>75 V) and low frequency (0.5–2 Hz). When slow waves occur during sleep, and present within 20% or more of an epoch, that epoch is classified as SWS, or N3.

Although the true function of sleep and particularly SWS is unknown (e.g., Rector, Schie, Van Dongen, Belenky, & Krueger, 2009; Siegel, 2009), to date the primary explanation is that SWS reflects the homeostatic sleep drive, or one's escalating need for sleep with increasing time awake. This relation is exemplified when One's time spent in SWS increases relative to their time previously spent awake (Bersagliere & Achermann, 2010). Thus, SWS is described as the "restorative component" of sleep. Common parasomnias that can occur during SWS are sleep walking and night terrors.

Human Development: Due to developmental changes in infant sleep patterns, typically SWS can be scored by 4–4.5 months post-term (Grigg-Damberger et al., 2007). The percentage of SWS obtained is highest during early-life and decreases from early childhood through old age (Ohayon, Carskadon, Guilleminault, & Vitiello, 2004).

Definition

Health represents a physical, mental, and emotional state of well-being. Health is not simply the absence of disease or sickness but can be defined as a state of optimal wellness.

Cigarette smoking is the act of inhaling smoke from burning tobacco. Cigarette smoking is directly related to a decline in health and various associated health outcomes. There is no safe level of smoking; therefore, for optimal health, tobacco use should be avoided.

Description

The adverse health effects of smoking have been well documented. Each year, smoking causes more deaths than murders, suicides, HIV, drug and alcohol use, and auto accidents combined (Centers for Disease Control and Prevention [CDC] (2009)). In the United States, cigarette smoking is responsible for over 443,000 deaths, $96 billion in medical expenditures, and 5.1 million years of potential life lost annually (CDC, 2009). In fact, one out of five Americans will die prematurely from the effects of smoking. Tobacco use is responsible for five to six million deaths per year worldwide (Jha, 2009). This makes cigarette smoking the single largest preventable cause of disease and death.

Cigarette smoking causes much of its damage to the body through the inhaled smoke (U.S. Department of Health and Human Services et al. (2010)). Cigarettes contain over 7,000 chemical compounds, many of which are toxic and/or carcinogenic. It is the inhalation of these chemicals that leads to increased risks for heart disease, cancer, and stroke (USDHHS, 2004). Heart disease is the leading cause of death in the USA and particularly among smokers. Smoking cigarettes causes the heart to work harder by raising heart rate and blood pressure (Erhardt, 2009). Additionally, poisonous gases such as carbon monoxide limit the amount of oxygen carried in the blood. This results in a two- to four-fold increased risk of heart attack and stroke (USDHHS, 2004). Smoking also

causes lung disease such as chronic obstructive pulmonary disease (COPD), which includes emphysema and chronic bronchitis (U.S. Department of Health & Human Services et al., 2010). Indeed, smoking causes about 90% of all deaths from chronic airway obstruction (Forey, Thornton, & Lee, 2011). There is a well-established link between smoking and multiple cancers including the lung, mouth, throat, stomach, uterus, esophagus, cervix, bladder, and acute myeloid leukemia (USDHHS, 2004). Nearly one third of all cancer deaths can be linked directly to cigarette smoking (CDC, 2010). People who suffer from chronic diseases such as diabetes and HIV are especially vulnerable to the negative effects of tobacco use. Indeed, smokers with a chronic disease may experience increased complications, longer hospitalizations, interactions with medications, and increased risk of death (CDC, 2010).

Smoking also takes a toll on mental health and overall well-being. There is a robust relationship between cigarette smoking and perceived stress (Kassel, Stroud, & Parnois, 2003). Smokers tend to report greater stress levels compared to nonsmokers (Cohen & Williamson, 1988). And although smokers believe that cigarette smoking provides stress relief, research suggests that smoking might cause additional stress (Heishman, 1999). Smoking is also associated with increased risk of affective disorders, such as anxiety and depression. Smokers with mental health disorders report substantially greater symptom burden and functional disability compared to nonsmokers (Covey, 1998; McCloughen, 2003; Morissette, 2007). Smoking also reduces the effectiveness of a number of medications used to help manage the symptoms of depression and schizophrenia (Goff, 1992).

Smoking also affects health in other ways. Compared to nonsmokers, smokers have increased risks of blindness, periodontal disease, deafness, sexual dysfunction, sleeping difficulties, headaches, and premature aging, including wrinkles and damage to the skin (USDHHS, 2010). Among men, smoking causes an increased risk of erectile dysfunction (Tengs, 2001). Women who smoke have increased risk of hip fractures, infertility, and premature menopause (USDHHS, 2001).

Smoking not only affects the health of smokers but also impacts individuals around them (USDHHS, 2006). Nonsmokers who are exposed to tobacco smoke inhale many of the same toxins and cancer-causing substances as smokers. Secondhand smoke (or passive smoking) is responsible for numerous health problems among adults, including an increased risk of heart disease and cancer (USDHHS, 2006). Women who smoke during pregnancy risk passing on the toxins from cigarettes to their babies. Such exposure leads to increased risk for premature labor, low birth weight, and birth defects (USDHHS, 2006). Children and infants also suffer from secondhand smoke exposure including asthma attacks, ear infections, respiratory illness, and sudden infant death syndrome (USDHHS, 2006).

There are many immediate and long-term health benefits of smoking cessation (USDHHS, 2004). After the last cigarette, a person's heart rate and blood carbon monoxide level drop to normal within hours. Lung function and capacity improves within days. The excess risk of coronary heart disease, cancers of the lung and mouth, and stroke reduce to that of a nonsmoker 1–15 years after quitting smoking (USDHHS, 2004). Quitting smoking at any age and despite any existing medical conditions can help improve overall health.

Smoking Behavior

Elizabeth Baker and Monica Webb Hooper
Department of Psychology, University of Miami, Coral Gables, FL, USA

Synonyms

Cigarette smoking; Smoking habits; Smoking topography; Tobacco use

Definition

Smoking behaviors are actions taken by a person that are associated with the burning and inhalation of a substance. Smoking behavior is multifaceted and includes the actual act of smoking, puffing style, depth of inhalation, and rate and frequency of smoking.

Description

The act of smoking consists of several behaviors and is usually applied to tobacco/cigarettes. A smoker is defined as a person who has a lifetime history of smoking 100 cigarettes or more with current smoking on some days or every day.

Most people experiment with smoking during adolescence and do not intend to become regular, addicted, or dependent smokers. Environmental or social factors (e.g., peer pressure) often play a role in smoking initiation. Over time, smoking behavior can become a pattern (i.e., habit) and tolerance develops. The next step is the development of dependence, which is indicated by both tolerance and withdrawal symptoms during periods of abstinence from smoking. Finally, people maintain the compulsive (e.g., addictive) behavior largely because of nicotine dependence.

Smoking behavior is based on individual differences. Smoking topography is defined as the unique manner in which an individual smokes a cigarette. In particular, topography includes the quantity of puffs per cigarette, puff volume, velocity, and duration (Scherer, 1999). Each of these behaviors is a component of how a cigarette is smoked. On average, smokers ingest less than 1.5 mg of nicotine per cigarette (Jarvis, Boreham, Primatesta, Feyerabend, & Bryant, 2001; United States Federal Trade Committee, 2000). This amount varies depending on cigarette brand and how an individual smokes a cigarette (Djordjevic, 2000). Dependent smokers seek to regulate the amount of nicotine they receive to maintain the desired physical and emotional state and to avoid withdrawal. In general, a smoker takes about 10 puffs per cigarette (Scherer, 1999). A smoker can consciously or unconsciously control nicotine intake by the time taken in between puffs (referred to as puff frequency or puff interval). Smokers may also block the ventilation holes in filtered cigarettes to increase nicotine delivery. The depths of inhalation, duration of the puff, and the amount of smoke in a puff (volume) are all characteristics of smoking behavior that impact exposure to the chemicals and toxins in cigarettes and the subsequent damage to the body (Scherer, 1999).

The frequency of daily smoking is another aspect of smoking behavior. The Centers for Disease Control [CDC] (2005) reported that 83% of all smokers are daily users. Daily smokers average 20 cigarettes per day (CDC, 2005). Intermittent or light smokers do not smoke daily and are thought to be less nicotine dependent. The time to the first cigarette of the day and the frequency of daily smoking are indicators of nicotine dependence. Smoking immediately after waking is one of the best predictors of nicotine dependence. In addition, smoking most of one's cigarettes during the first 2 hour of the day is suggestive of dependence (Heatherton, 1989). A greater frequency of daily smoking may be related to difficulty quitting smoking.

Smoking behavior is variable and can change depending on the circumstance or day. For instance, puffs per cigarette may decrease while watching television or may increase while listening to another person talking. The number or duration of puffs may also change according to emotional state. Research has found that increased smoking often occurs during times of personal crisis and stressors (Shiffman, Paty, Gnys, Kassel, & Hickcox, 1996). Many smokers report increased smoking in social situations such as being in the company of other smokers or while attending parties. Smokers also vary in their handling of cigarettes; some may hold the cigarette in their mouth, while others allow them to burn in ashtrays or between their fingers.

Smoking behavior is complex. Learning models suggest that smoking behavior is maintained by operant conditioning, including positive and negative reinforcement, and classical conditioning, through the repeated pairing of smoking to various physical and emotional states (Wilker, 1973). Such learning makes smoking cessation a formidable challenge for most smokers (Patten & Martin, 1996).

Smoking Cessation

Denise de Ybarra Rodríguez and
Monica Webb Hooper
Department of Psychology, University of Miami, Coral Gables, FL, USA

Synonyms

Cigarette smoking cessation; Quit smoking; Stop smoking; Tobacco cessation; Tobacco smoking cessation

Definition

Tobacco smoking is defined as the practice of burning and inhaling tobacco. The combustion from the burning allows the nicotine, tar, and other chemicals and toxins to be absorbed through the lungs. Cigarette smoking is the most prevalent form of consuming tobacco. Most national surveys define a current smoker as having smoked at least 100 (5 packs) cigarettes in their lifetime and currently smokes on at least some days.

Cessation refers to a halting or stopping. Smoking cessation refers to the stopping of cigarette use. Smoking cessation may refer to choosing to stop smoking deliberately or become abstinent due to external and/or environmental factors leading to stopping or quitting smoking.

Description

Smoking cessation is the single most important health behavior change a person can make. Since the 1964 Surgeon General's Report concluded that smoking causes cancer, about 50 million people have successfully quit smoking. Approximately 69% of current smokers state that they want to stop, and 52% have made an attempt to quit smoking in the past year (Centers for Disease Control & Prevention [CDC], 2011).

Smoking cessation has major health benefits. The most common causes of death in the United States are cardiovascular disease, cancer, cerebrovascular accidents, and chronic lower respiratory diseases (Kochanek, Xu, Murphy, Miniño, & Kung, 2011); smoking cessation has been associated with a reduced risk of dying from these diseases (U.S. Department of Health & Human Services [USDHHS], 1990). The benefits of smoking cessation are greater the earlier one quits, though the benefits of quitting can be experienced even after an extended smoking history. For example, after 15 years of smoking cessation, the excess risk of heart disease for a former smoker is equivalent to a never-smoker. With the increasing duration of cessation, the overall rate of cancer mortality approaches that of nonsmokers (USDHHS).

There are several evidence-based smoking cessation methods. Behavioral interventions include brief physician advice to quit, self-help

materials, telephone-based interventions, internet-based counseling and support groups, and group and individual counseling (Fiore et al., 2008). Brief physician advice to quit smoking has been demonstrated to increase the likelihood of cessation by 30%. Self-help cessation interventions increase the likelihood of cessation by 20%. Telephone-based interventions increase the likelihood of cessation by 20%, though tobacco quitlines have increased the odds of cessation by up to 60%. Group and individual counseling increase the likelihood of cessation by 30% and 70%, respectively. The U.S. Food and Drug Administration (FDA) has approved seven smoking cessation pharmacotherapies. These include varenicline (marketed as Chantix in the United States and Champix in Canada and Europe), bupropion (marketed as Zyban), transdermal nicotine patches, nicotine gum, nicotine lozenges, nicotine nasal spray, and the nicotine inhaler. Nicotine patches, gum, and lozenges are available in the USA over the counter; varenicline, bupropion, nicotine nasal spray, and the nicotine inhaler require a physician's prescription. Use of nicotine replacement therapies or bupropion doubles the chances of smoking cessation, while recent evidence suggests that varenicline can triple the likelihood of cessation. Using more than one method when trying to quit (e.g., combination of nicotine replacement with counseling or a telephone quitline) further increases the likelihood of cessation, and the likelihood of cessation increases with the number of formats utilized.

There are also smoking cessation methods that are not based on empirical evidence. Indeed, the most common method of attempting to quit is unassisted quitting (going "cold turkey"). However, approximately 90% of unassisted quit attempts fail. Complementary and alternative methods such as acupuncture, acupressure, laser therapy, and hypnotherapy have been evaluated as smoking cessation methods. However, these methods are not more effective than a placebo (Barnes et al., 2010; White et al., 2011).

Public health policy and campaigns have been instrumental in decreasing the prevalence of smoking in the USA. These policies have restricted indoor smoking via clear indoor air acts (e.g., restaurants, airplanes, and workplaces) in most states and have increased taxes on cigarettes. Public health campaigns have utilized mostly media formats to increase knowledge about the dangers of smoking.

Smoking cessation can result in temporary discomfort, known as nicotine withdrawal. When a person quits smoking, they can enter into nicotine withdrawal within 30 min. The peak of withdrawal occurs within 48–72 h for dependent smokers and usually lasts 1–2 weeks if cessation is maintained. Symptoms of nicotine withdrawal include changes in mood (e.g., irritability, anger, depression, sadness, anxiety, and nervousness), desire or craving to smoke, difficulty concentrating, increased appetite, weight gain, insomnia, restlessness, impatience, constipation, dizziness, coughing, and dreaming or nightmares. The use of FDA-approved cessation aids can minimize withdrawal symptoms.

Smoking cessation is greatly encouraged because of the multiple health benefits that follow. Since the dangers of smoking have been identified, the prevalence has declined and leveled off at 20%. Cigarette smoking is the leading cause of preventable death, disease, and disability in the USA. Multiple methods to achieve smoking cessation exist, though some of these methods have a greater likelihood of success.

Tobacco control

Definition

Since up to 80% of smoking initiation has been shown to occur in adolescence, individual and group-level smoking prevention interventions have focused on youth to avert addiction and the long-term health consequences of smoking. A focus of policy efforts for youth prevention has been restricting youth access to tobacco products at the point of purchase. Effective interventions with broader reach to reduce tobacco product initiation among adolescents and adults include policies that increase the unit price of tobacco products and mass media campaigns when combined and coordinated with other interventions.

Description

From 2002 to 2010, the prevalence of past month tobacco use in the United States among those aged 12 and above declined from 30.4% to 27.4%, with stalled reductions in prevalence in the later years. Currently, 23.0% of the population aged 12 or older smokes cigarettes. Patterns in current tobacco and cigarette use and experimentation with smoking cigarettes were similar for middle school and high school students; while overall prevalence has reached a historic low, no overall declines were noted in youth tobacco use for the 2006–2009 period. Among youth, cigarette smoking is more prevalent among whites than blacks and slightly higher among males than females.

Young people are particularly vulnerable to tobacco addiction due to the effect of nicotine on the reward pathways in the developing brain (from in utero to young adulthood). Additionally, some people are at much greater risk of tobacco use due to genetics, poverty, abuse, neglect, trauma, and other comorbid psychological or cognitive factors such as mood disorders, behavioral, conduct, and attention problems. Beyond the individual, there are numerous variables that affect tobacco use, including adult, household and peer behavior, advertising and promotion, availability and

price of tobacco products, poverty, unemployment, neighborhood, community, and cultural norms.

Comprehensive national tobacco strategies use a combination of methods to achieve four main goals: (1) to prevent initiation among youth and young adults, (2) to promote quitting among adults and youth, (3) to eliminate exposure to secondhand smoke, and (4) to identify and eliminate tobacco-related disparities among population groups. Since up to 80% of smoking initiation has been shown to occur in adolescence, individual and group-level smoking prevention interventions have focused on youth to avert addiction and the long-term health consequences of smoking. A focus of policy efforts for youth prevention has been restricting youth access to tobacco products at the point of purchase. Recent data indicates increasing initiation in young adults in the USA, possibly due to targeted marketing efforts by the tobacco industry, and signals the need for extended prevention efforts beyond youth. Effective interventions with broader reach to reduce tobacco product initiation among adolescents and adults include policies that increase the unit price of tobacco products and mass media campaigns when combined and coordinated with other interventions.

Individual and School-Based Programs for Youth

For many years, smoking prevention efforts for adolescents were conducted primarily through school-based programs, which have been shown to have positive short-term effects, but little effect on long-term prevention. Early school-based tobacco curricula focused on social influences, training youth to resist social pressures to use tobacco; studies of these interventions have shown that social influences programming alone is not effective in reducing long-term initiation of smoking. More recent school-based programs have achieved greater success by addressing multiple determinants of tobacco use, including communication skills, coping, personal and social competence, and physical consequences of smoking.

Restricting Youth Access to Tobacco Products

Youth access laws prohibit retailers from selling tobacco products to youth under the age of 18. These laws require enforcement to ensure compliance by the many types of retailers selling tobacco products – from street vendors to convenience stores and online distributors. Adolescent access to cigarette vending machines, low enforcement of these laws, and difficulties in confirming age at purchase in online transactions are all barriers to the success of these laws. Studies indicate that youth access laws can slow increases in adolescent smoking and reduce both smoking prevalence and cigarette consumption, but a very high level of retailer compliance is necessary before these changes occur.

Interventions to Increase the Price of Tobacco Products

Tobacco taxation has been hailed as the most effective intervention to reduce demand for and consumption of tobacco products. Increases in tobacco taxes result in increased cigarette prices, and price has been shown to be a key factor in determining both smoking initiation and cigarette consumption among adults and adolescents.

Price elasticity of demand is defined as the percentage change in consumption of a product following a 1% increase in price. Among US adults, estimates of the price elasticity of cigarette demand typically fall between -0.3 and -0.5, relating to a 3% or 5% decrease in consumption, respectively, for a 10% increase in price. Adolescents have been shown to be almost three times more sensitive to cigarette price increases than adults for several reasons, including the following: First, adolescents have been posited to be less addicted to nicotine and more able to reduce or quit smoking following cigarette price increases. Second, adolescents typically have a lower income and spend a larger fraction of their disposable income on cigarettes than adults. Third, adolescents are also likely to be present-oriented and may not be willing to spend the additional money on cigarettes at the expense of other activities. Reductions in adolescent smoking following tobacco tax interventions may also result from fewer smoking peers.

Mass Media Campaigns to Prevent Tobacco Use

Tobacco marketing includes all efforts of the industry to promote tobacco products, and industry marketing has been linked to a variety of smoking behaviors among both adults and youth, notably youth tobacco initiation. Countermarketing is a strategy used by public health agencies to protect individuals who may be susceptible to the influence of tobacco industry marketing – particularly youth – by responding directly to that marketing. Prior to the end of 1999, major statewide comprehensive tobacco control programs in California, Massachusetts, Arizona, Oregon, and Florida included countermarketing media campaigns which were shown to reduce adult and youth smoking; results from evaluations of these interventions indicated that these campaigns had more influence on smoking behavior in younger compared to older adolescents. The 1998 Tobacco Master Settlement Agreement (MSA) in the United States included provisions for reducing youth access to tobacco products and restricted marketing in venues or media attended by youth. Funds were also dedicated from the MSA to create a foundation to develop and deliver national anti-tobacco messages. The truth® campaign, a national tobacco countermarketing effort launched in 2000 by the American Legacy Foundation, has repeatedly been shown to be effective in reducing smoking among adolescents, specifically younger adolescents. Around the same time, tobacco companies developed youth smoking prevention media campaigns which have been shown to be ineffective, and in the case of parent-targeted advertising, to reduce perceptions of smoking-related harm and to increase approval of smoking and intention to smoke among older adolescents.

Future Directions in Smoking Prevention

Passage of the Family Smoking Prevention and Tobacco Control Act in 2009 gave the Food and Drug Administration (FDA) authority to regulate tobacco products and their marketing to protect the public health. One of FDA's first actions was to ban candy flavorings in cigarettes shown to be appealing to youth in order to reduce youth smoking initiation. Other possible regulatory actions aimed at tobacco use prevention include banning menthol in cigarettes, reducing the amount of nicotine in cigarettes to a non-addictive level, and introducing large, graphic warning labels on health effects of tobacco use to cigarette and smokeless tobacco packaging. The national scale of regulatory action through the FDA has the potential to dramatically influence population-level tobacco use and must be complemented by tobacco control efforts at the community, local, and state levels to achieve the maximum impact on prevention.

Summary

Comprehensive tobacco control programs have taken a community-based approach to smoking prevention, using a combination of school-based, policy, educational, and mass media interventions to change the social environment and conditions related to smoking behavior with positive results. Reviews of community-based programs show that coordinated multicomponent interventions reduce smoking among young people more than single strategies alone and that the level of program funding and implementation is critical to the success of these interventions. A population-based health promotion approach that includes media, education, screening, interventions in community settings and policy can provide avenues to address tobacco use more comprehensively. Coordination of policy and program efforts from the local to the national level is needed to enhance the effectiveness of tobacco use prevention interventions.

Social Capital and Health

Martin Lindström
Department of Clinical Sciences in Malmö, Lund University, Malmö, Sweden

Social capital has no direct synonyms. Social cohesion is a broader concept which is *not* directly synonymous with social capital. Social cohesion is a combination of absence of latent social conflict, e.g., in the form of social and economic inequality, ethnic tensions or other forms of polarization, and the presence of strong social bonds measured by levels of trust and reciprocity (i.e., social capital), a strong "civil society" which bridge social divisions, and institutions of conflict management (e.g., a responsive democracy and an independent judiciary) (Kawachi & Berkman, 2000).

Definition

The definition of social capital varies by author and academic tradition. Robert Putnam (political science) defines social capital as "features of social organization, such as trust, norms, and networks that can improve the efficiency of society by facilitating coordinated actions" (Putnam, 1993). According to James Coleman (sociology), social capital is ". . .a variety of different entities (that) facilitate certain actions of individuals who are within a structure" (Coleman, 1990), while Pierre Bourdieu (sociology) defines it as ". . .the sum of the resources, actual or virtual, that accrue to an individual or a group by virtue of possessing a durable network" (Bourdieu & Wacquant, 1992). The definitions of Putnam, pertaining to the population level of social

capital, and Coleman, pertaining to social networks of individuals, have been more commonly used in behavioral medicine and public health than that of Bourdieu, which is closer to the individual level, is less distinct in relation to social support, and also concerns the power structure within social groups and structures. Health as a concept is defined elsewhere.

Description

The social capital concept was first used in 1916 but originates in its modern context in the fields of sociology and political science. Social capital concerns the characteristics of interaction between actors such as individuals, social groups, and organizations rather than the characteristics of actors per se. Social capital includes interpersonal trust, trust in institutions, reciprocity, civic participation, social participation, and social networks which increase cooperation and decrease transaction costs in society.

The first articles concerning social capital and health appeared in international medical and public health journals in the mid-1990s with a fast increase in the number of publications after 1996–1998. From approximately 40 international journal publications in 2001 (Macinko & Starfield, 2001), the number of journal publications has increased to 1,179 in 2011 in PubMed only (December 19, 2011). Already in 2001, Macinko and Starfield identified four levels of analysis of social capital and health: the macro (countries, regions), meso (neighborhoods, municipalities), micro (social networks), and psychological (trust) levels (Macinko & Starfield, 2001). Putnam's definition of social capital, which includes trust despite Putnam's macro and meso perspectives because the level of trust may be regarded as a trait of populations and countries just as well as a cognitive trait of the individual, has, together with Coleman's definition, had the strongest impact in the behavioral medicine and public health literature, although other authors such as Bourdieu and Portes are also referred to and their definitions also used in empirical studies.

Although Putnam had earlier stated that the area of health and public health was probably a research area not particularly strongly associated with and affected by social capital (Putnam, 1993), he 7 years later contended, based on the dramatic increase of results of empirical studies, that health and public health was probably one of the most important areas associated with and affected by social capital (Putnam, 2000). Kawachi, Kennedy, and Wilkinson (1999) suggested four main causal pathways by which social capital may affect health: direct psychological and psychosocial stress pathways, social norms and values which foster health-related behaviors, access to health care and amenities through social networks and contacts, and crime, particularly violent crime (Kawachi et al., 1999).

Kawachi, Kennedy, Lochner, and Prothrow-Stith (1997) found in an early ecological study that low levels of social capital were associated with a higher total mortality rate and higher rates of a wide range of major causes of death, including coronary heart disease (CHD), cerebrovascular disease, unintentional injury, and infant mortality (Kawachi et al., 1997). Later epidemiological, ecological, and individual level studies have, just to give some examples, revealed significant associations between low levels of social capital and higher age-adjusted mortality rates, shorter life expectancy, higher mortality and violent crime rates, higher coronary heart disease morbidity and mortality, low birth weight rates, higher incidence rates of a variety of sexually transmitted diseases, low life satisfaction, less happiness, poor self-rated health, poor mental health (measured with the GHQ12 index), poor physical and mental health measured by SF-12, depression, psychiatric morbidity, higher suicide rates, worse chronic conditions, functional limitations (Islam, Merlo, Kawachi, Lindström, & Gerdtham, 2006), and health-related behaviors such as lower levels of leisure time physical activity (Lindström, Hanson, & Östergren, 2001). Some studies have investigated associations between vertical social capital, i.e., trust and participation across a well-defined power gradient, and health (Sundquist, Johansson, Yang, & Sundquist, 2006). Multilevel studies, which mostly include the individual

level and one or more contextual levels of analysis, have e.g. shown that low social capital is associated with poor self-rated health and violent crime (Islam et al., 2006). Multilevel analyses have also demonstrated significant associations between social capital and access to health care (Lindström et al., 2006). Multilevel analyses have increasingly been conducted in order to disentangle the associations between contextual level social capital and individual level health in order to avoid the "ecological fallacy," which denotes the risk of drawing erroneous conclusions concerning individual health from observations of ecological data, and the "individualist fallacy," which denotes the risk of missing associations and effects of neighborhood or other forms of contextual social capital on individual health.

Since social capital is a characteristic of social relations, trust, and cooperation between individuals, groups, and organizations rather than of individuals, one important issue related to social capital and health is to define relevant social contexts for the analysis of the association and impact of contextual social capital on health and health-related phenomena such as health-related behaviors and access to health care and amenities. Most multilevel studies include neighborhoods or other geographic entities as second, third, and so forth levels of analysis. However, one question concerns whether geographic entities are the most relevant social contexts. This discussion is highly relevant because many multilevel studies have shown small or moderate associations between neighborhood and geographic social capital and health of individuals within single countries, while the statistical associations between social capital and health have been stronger and more consistent in individual level studies. Recently, some prospective cohort studies have investigated workplace social capital and found significant effects on, e.g., depression (Kouvanonen et al., 2008). In studies of social capital and school children and adolescents, the family and schools are relevant social contexts in addition to neighborhoods. Putnam suggested already in 2000 that the Internet would become a relevant area for studies of social capital and social networks (Putnam, 2000).

Most studies of social capital and health are cross-sectional, i.e., they measure all factors at the same point in time which makes causal inference formally impossible. In many instances, causality may go in both directions. Social capital may, e.g., cause poor mental health, but mental health may also affect social capital in the forms of social participation in social networks, civic participation, and feelings of trust and reciprocity. A few longitudinal studies with panel data including three waves of observations or more have been conducted in recent years (Giordano & Lindström, 2011).

Social capital is not always associated with better health. Szreter and Woolcock developed the concepts of bonding, bridging, and linking social capital. Bonding social capital denotes "trusting and cooperative relations between members of a network who see themselves as being similar in terms of their shared social identity," while bridging social capital refers to "relations of respect and mutuality between people who know they are not alike in some sociodemographic (or social identity) sense (differing by age, ethnic group, class, etc.)" (Szreter & Woolcock, 2004). While many social networks, associations, and organizations, e.g., youth organizations, sports clubs, and labor unions, manage to combine bonding and bridging social capital, some other, e.g., criminal networks, do not. This phenomenon of exclusion of outsiders and the rest of society is sometimes referred to as "the dark side of social capital," and its effects on health may be detrimental. Linking social capital refers to "norms of respect and networks of trusting relationships between people who are interacting across explicit, formal, or institutionalized power or authority gradients in society" (Szreter & Woolcock, 2004).

Critique against the research concerning social capital and health has been expressed by the so-called neo-materialists, who claim that it obscures underlying ideological, political, administrative, and economic determinants of health inequalities and other public health issues. The neo-materialists emphasize the importance of active governments, active welfare politics, and economic preconditions for the realization of public health programs (Navarro, 2004).

Social Class

G. David Batty
Department of Epidemiology and Public Health, University College London, London, UK

Synonyms

Socioeconomic position

Definition

Social class refers to particular social strata in society.

Social class can be measured at a personal or geographical level. For an individual, indicators include occupational social class, occupational prestige, educational attainment, household income, housing tenure, household amenities, and car ownership. For a geographical area, composite measures are often derived from the characteristics of residents in a defined location (Galobardes, Lynch, & Smith, 2007).

In the context of epidemiology, socioeconomic status has been most commonly related to

disease (particularly cardiovascular disease) and disease risk factors (particularly health behaviors such as smoking). Socioeconomic inequalities (variations) in health are essentially universal: with the exception of very few outcomes, poorer health is more common in poorer people. As such, reducing these differentials is a priority for many governments and health agencies.

Social Cohesion

Yori Gidron
Faculty of Medicine and Pharmacy, Free University of Brussels (VUB), Jette, Belgium

Definition

Social cohesion (SC) refers to the degree to which links between a society's members are strong and the degree to which people in a community share values and goals and are interdependent. Durkehiem conceptualized SC as a major protective variable against adversities including suicide. In his seminal work, Durkheim found that Catholics have lower suicide rates than Protestants, and he attributed this to greater social control and cohesion in the former than among the latter (Pickering & Walford, 2000). Kelleher and Daly (1990) found that reduced SC (indexed by reduced marriage rates and increased separations) was among the variables possibly contributing to increased suicide rates in Ireland, between 1970 and 1985. The Dutch sociologist Geert Hofstede conducted the first empirically based quantification of international cultural dimensions in the 1970s in IBM plants around the world. Among his four main cultural dimensions, individualism was conceptualized, which can be seen as the opposite of SC. Individualism does predict on a global level present suicide rates. Recent studies have also tested the relationship between SC and various health outcomes, pertinent to behavioral medicine. Chaix, Lindström, Rosvall, and Merlo (2008) found in Sweden that low SC predicted myocardial infarctions, independent of important demographic variables. More recently, Clark et al. (2011) found that each one point increase in SC predicted a reduction of 53% in deaths attributed to stroke, independent of confounders. SC was assessed individually by six items reflecting social interactions and contacts with neighbors. One mechanism could be that more cohesive societies (such as religious kibbutzim in Israel vs. secular ones) also promote a healthier psychosocial profile – higher sense of coherence and lower hostility levels (Kark, Carmel, Sinnreich, Goldberger, & Friedlander, 1996). The concept of SC is thus one domain where concepts important in behavioral medicine and sociology may influence health at the more macro level of societies. This could have important implications for preventative medicine.

Social Conflict

Orit Birnbaum-Weitzman
Department of Psychology, University of Miami, Miami, FL, USA

Synonyms

Interpersonal conflict; Negative social interaction; Relational distress; Relationship conflict; Social stress

Definition

Social conflict refers to the various types of negative social interactions that may occur within social relationships including, but not limited to, arguments, rejection, criticism, hostility, insensitivity, unwanted demands, and ridicule (Seeman, 2001). Social conflict can also escalate to include physical violence. Conflict refers to overt behavior rather than subjective states. It typically results from purposeful interaction among two parties in a competitive setting in which the parties are aware of the incompatibility of positions. Social conflict can extend to different social relationships including those with significant others such as spouses, family members, and friends, as well as less intimate relationships.

Description

Studies on social conflict and interpersonal stress suggest that negative aspects of social interactions including social conflict and social control are inversely related to emotional well-being and health (Miller, Chen, & Cole, 2009). There is substantial evidence that interactions marked by acute conflict and negative emotions have direct physiological consequences. Epidemiological studies have linked social isolation, low social support, and high levels of social conflict with morbidity and mortality (Miller et al., 2009). Changes in immune function and elevated inflammation have been suggested as key pathways underlying the association between social conflict and health (Kiecolt-Glaser, Gouin, & Hantsoo, 2010). Inflammation is a key pathogenic mechanism in many infections and cardiovascular and neoplastic diseases. Recent studies have also linked stressful interpersonal relationships to alterations in gene expression and intracellular signaling mechanisms (Miller et al., 2009).

Consistent evidence also points to the strong relationship between social conflict and psychological distress. Specifically, interpersonal stress and conflict with family and friends has been reliably associated with negative affect, depression, and emotional stress responses (Graham, Christian, & Kiecolt-Glaser, 2007). Depression has been proposed as a particularly important psychological mechanism by which social conflict in close relationships affect immune function (Miller et al., 2009). The literature indicates that social conflict is associated with a range of physiological and psychological mechanisms that are in turn associated with concomitant alterations in the cardiovascular, endocrine, and immune systems. Family conflict and discord and domestic violence have also been linked to suicidal behavior (Van Orden et al., 2010). In drug abusers, interpersonal conflict has been also associated with an increased probability of a history of suicide attempt and ideation (Van Orden et al., 2010).

Social conflict has been assessed using self-report questionnaires about relationship quality and quantity as well as in experimental studies of laboratory-induced marital conflict (Kiecolt-Glaser et al., 2010). To date, there is not one standard measure to assess social conflict. Different types of study designs have been used to assess the impact of social conflict on physical and emotional well-being including correlational studies, experimental studies of couples, and animal studies (see Kiecolt-Glaser et al., 2010). Correlational studies suggest that social isolation, lack of social support, and interpersonal conflict are associated with biological markers of inflammation (i.e., C-reactive protein and interleukin-6). More recent studies have also suggested

a plausible link between distressed pair-bond relationships and plasma levels of oxytocin in females and vasopressin in males. However, this research is still preliminary. In other correlation studies, men and women who had recently undergone a marital separation or divorce had poorer immune function than demographically matched married individuals (see Kiecolt-Glaser et al., 2010).

According to Kiecolt-Glaser, Glaser, Cacioppo, and Malarkey (1998), being married is not always protective, especially if there is frequent interpersonal conflict in the couple. In experimental studies with married couples, this group of researchers has shown that conflictive social interactions consistently result in heightened blood pressure and heart rate, especially for those with high trait hostility. Conflict discussion tasks are also widely used in marital research by this group and others. Discussion of marital problems has been associated with both immediate and longer term physiological changes related to the degree of negativity or hostility displayed during conflict (see Kiecolt-Glaser et al., 2010). Gender differences have been observed in these studies, with women evidencing greater sensitivity to negative marital interactions than men. Similarly, marital conflict shows a greater impact on health and physiological functioning in older adults compared to young couples. In general, this research suggests that relationships that are stable and long lasting but marked by social conflict have the potential to function as both an acute and chronic stressor that may impact health over an extensive period of time (Kiecolt-Glaser et al., 2010). Relationship conflict and termination can also provoke detrimental health behaviors including disturbed sleep, unhealthy diets, less physical activity, smoking, and greater use of alcohol and other drugs. Thus, relationships characterized by hostility and conflict could have negative health consequences.

The most common social conflict models involving laboratory animals are variations of the resident-intruder model wherein one animal is placed in the home cage of another. Animal studies have shown that social conflict and disruption of social relationships have important immunological and endocrine consequences (Huhman, 2006). In rodents, an aggressive social encounter is typically accompanied by elevated levels of stress hormones and changes in cellular and humoral immunity. Exposure to social conflict appears to have long-lasting behavioral and physiological effects not just in defeated/subordinate animals but also in dominant ones that appear to be moderated by developmental level (Huhman, 2006). Data from experimental primate models also show that stressful social relationships can exacerbate viral infections by altering gene expression responses to infection. Social conflict models in animals may be useful for studying the physiological concomitants of a number of psychiatric disorders including major depression (see Huhman, 2006).

Social Epidemiology

G. David Batty
Department of Epidemiology and Public Health, University College London, London, UK

Definition

While epidemiology is defined as the study of the distribution and determinants of disease and typically treats social determinants as background to biomedical phenomena, social epidemiology is a sphere of enquiry in its own right. It is distinguished by explicitly investigating social determinants of population distributions of health, disease, and well-being. Social epidemiology was perhaps first coined as a discipline in the 1950s; post-graduate programmes in social epidemiology are now offered.

Social Factors

Emily Kothe
School of Psychology, University of Sydney, Sydney, NSW, Australia

Synonyms

Social determinants of health; Socioeconomic status (SES)

Definition

The conditions under which people are born, live, work, and age are collectively known as the social determinants of health. These social factors include both economic and social conditions and are may be responsible for the health inequities both within and between countries.

Description

Research into the social factors underpinning health arose from the dual observations of health disparities both within and between countries. These disparities can be easily (although crudely) demonstrated by way of differences in life expectancy for different groups.

Between-country differences in adult mortality are growing rapidly. Whereas mortality rose in Africa, Central and Eastern Europe between 1970 and 2002, global mortality fell overall during the same period (World Health Organization, 2003). These differences in mortality rates are especially stark when comparing life expectancy by country. For example, while the average life

expectancy at birth is 89.78 years in Monaco, it is just 29.3 years in Haiti (CIA, 2011).

Large differences in morbidity and mortality are also apparent within the same country. For example, in Australia, the life expectancy for Aboriginal and Torres Strait Islanders is approximately 10 years below the national average (Australian Bureau of Statistics, 2010).

Study of the social factors that underlie health provides possible mechanisms by which this large health disparity can be understood. The major social factors which influence health include both structural determinants of health, and the conditions of an individual's daily life. Research linking social factors to health outcome has identified a number of key social determinants of health (e.g., Wilkinson & Marmot, 2003). These include:

- The social gradient
- Stress
- Early life
- Social exclusion
- Work and unemployment

These factors are thought to influence health both indirectly and directly. In many cases, social factors act in combination to have a cumulative impact on health. For example, while unemployment is known to have a direct influence on health, it is also likely to have an indirect influence on health through its influence on other social factors (e.g., stress).

The Social Gradient

It is widely recognized that poverty is related to high levels of illness and disease. Data consistently shows that the health status of individuals in the poorest countries leads to significantly lower life expectancy and significantly higher risk of disease than that of individuals in richer countries.

The influence of socioeconomic status is also apparent within countries and appears to have an influence on health across the socioeconomic spectrum. This effect, known as the social gradient, shows that even within industrialized countries, both mortality and morbidity are linearly distributed across different levels of socioeconomic advantage and disadvantage. This research suggests that even moderate differences in wealth, and associated social factors, can have an important impact on health status.

For more information, see ▶ Social Class.

Early Life

Maternal deprivation and ill-health during pregnancy have both been linked to poor fetal development. Factors such as malnutrition, maternal stress, and inadequate prenatal care all increase the risk of childhood mortality and have profound impacts on health throughout later life.

Research has also linked circumstances during infancy to both physical and mental health in adult life. Social functioning, physical health, and the performance of health-protective behaviors have all been linked to experiences in early life.

For more information, see ▶ Maternal Stress; ▶ Birth Weight; ▶ Child Neglect; ▶ Child Development; ▶ Stress, Early Life.

Stress

Social and psychological circumstance can have a profound impact on the number of stressors an individual is exposed to and the level of stress that they experience. Increased levels of stress have been linked to increased risk of both morbidity and mortality.

Research suggests that exposure to stressors can have both direct and indirect influences on health. Chronic stress can directly increase risk of disease through its influence on physiological processes such as immune function. However, both acute and chronic stress can also lead to high rates of health-damaging behaviors such as alcohol consumption and smoking.

For more information, see ▶ Stress; ▶ Stressor.

Social Exclusion

Social exclusion relates to the isolation of certain member within a society and is associated with high rates of disease and mortality. It is most often related to relative poverty, low educational attainment, unemployment, and experiences of stigma and discrimination.

Individuals who experience social exclusion are subject to a pattern of multiple deprivations

that prevent them from participating fully in society. This is often characterized by poor access to services, including health care, housing, education, and transport.

For more information, see ▶ Social Capital and Health; ▶ Stigma.

Work and Unemployment

Research suggests that work and unemployment have separate – but at times overlapping – influences on health.

In general, being unemployed places individuals at increased risk of a number of diseases (e.g., depression and heart disease). The effects of unemployment on health are linked to both material deprivation that may occur due to a lack of income, and to the psychological consequences of being unemployed. The influence of unemployment on health appears to manifest itself even before individuals become unemployed, such that experiencing high levels of job insecurity (in many cases, a precursor of unemployment) can be as harmful to health as being unemployed.

In addition to the role of perceived job security, it appears that there are a range of factors that determine the extent to which employment is health protective. These include:

- Level of job control
- Level of job demand
- Adequacy of rewards for job performance

In particular it appears that professions that are characterized by low control but high demand place workers at increased risk of ill-health. Importantly social support and recognition of job performance, either through higher wages or increased social status, both appear to be health protective.

For more information, see ▶ Work-Related Stress.

Social Causation and Social Drift: Explanation of Possible Causal Relationships Between Social Factors and Health

When attempting to understand the influence of social factors on health, it is important to consider the possible causal relationships between these social factors and health. Broadly speaking, there are two possible ways of understanding the causal relationship between these factors. These explanations are described below using the example of the social gradient (Morrison & Bennett, 2008).

The first explanation – called social causation – would suggest that low socioeconomic status is causally related to health problems (i.e., that there is something about low socioeconomic status that "causes" ill-health). For example, an individual who experiences being socioeconomically disadvantaged may be exposed to poor living conditions which cause later health problems.

The second explanation – called social drift – would suggest that ill-health is causally related to low socioeconomic status (i.e., that experiencing illness "causes" an individual to lose their socioeconomic position). For example, an individual who has to leave work due to illness may find that without a steady income, they are now socioeconomically disadvantaged.

Longitudinal studies provide evidence for both explanations. For example, studies have consistently shown that low socioeconomic status baseline is a predictor of heart disease at follow-up and that individuals who become unemployed are more likely to suffer from health complaints than individuals who stay employed. On the basis of this evidence, it would appear most likely that social factors and health have a bidirectional relationship (Morrison & Bennett, 2008).

Social Inhibition

Johan Denollet
CoRPS – Center of Research on Psychology in Somatic diseases, Tilburg University, Tilburg, The Netherlands

Synonyms

Behavioral inhibition

Definition

Social inhibition (SI) is a broad personality trait that refers to *the stable tendency to inhibit the expression of emotions and behaviors in social interaction* (Asendorpf, 1993). Individuals who are high in SI are more likely to feel inhibited, tense, and insecure when with others. In children, the label *behavioral inhibition* is often used to describe this tendency (Gest, 1997).

SI is more closely related to the *interpersonal dimension* of introversion/extraversion than to intrapsychic facets of extraversion such as positive affect or excitement seeking. Infants and children with an inhibited temperament tend to develop into adults who avoid people and situations that are novel or unfamiliar (Schwartz, Wright, Shin, Kagan, & Rauch, 2003). Hence, individuals who are high in SI try to avoid potential "dangers" involved in social interaction, such as disapproval or criticism by others, through the deliberate inhibition of self-expression (Asendorpf, 1993). They tend to experience discomfort in encounters with other people, may keep other people at a distance, and are less likely to actively seek social support.

Interestingly, recent imaging research demonstrates the effect of social inhibition on the *neural coding of threatening signals* in the human brain (Kret, Denollet, Grèzes, & de Gelder, 2011). Socially inhibited adults may show greater signal response in the brain to threatening stimuli than adults who are not socially inhibited (Schwartz et al., 2003). Other research also indicates that socially inhibited people tend to overactivate a broad cortical network in the brain when looking at fearful or angry facial and bodily expressions (Kret et al., 2011).

There are several reasons why it is important to account for individual differences in SI in clinical research and practice. First, SI has been related to *difficulties in coping with the challenges of everyday life*. For example, inhibited children may show a delay in establishing a first stable partnership and finding a first full-time job in early adulthood (Asendorpf, Denissen, & van Aken, 2008). Second, socially inhibited individuals may seem quiet on the surface, while they may actually *avoid interpersonal conflict* through excessive control over their emotional and behavioral responses. Third, SI has been associated with an increased long-term *risk of developing internalizing problems* (Asendorpf et al., 2008), including anxiety disorders (Rapee, 2002) and other forms of distress (Gest, 1997) in adulthood.

SI may also increase the risk of physical health problems. Individuals who are high in SI display physiologic hyperreactivity to stress

(Cole, Kemeny, Fahey, Zack, & Naliboff, 2003), and the active inhibition of emotions induces increased cardiovascular reactivity (Gross & Levenson, 1997). In clinical research, SI has been associated with the progression of HIV (Cole et al., 2003) and with an increased risk of adverse cardiac events in patients with heart disease (Denollet et al., 2006).

SI can be reliably *assessed with the 7-item SI measure of the DS14* (Denollet, 2005), a scale that was specifically designed to assess this broad and stable tendency to inhibit the expression of emotions and behaviors in social interaction.

Social Marketing

Sara Mijares St. George and Dawn Wilson
Department of Psychology, University of South Carolina, Columbia, SC, USA

Synonyms

Cause marketing; Noncommercial advertising; Public interest advertising; Public service advertising

Definition

Social marketing is the application of marketing principles to non-tangible "products," including ideas, attitudes, and lifestyle changes. Unlike traditional marketing, the primary goal of social marketing is to improve public health, not to increase the marketer's profitability (Lefebvre & Flora, 1988). Specifically, it is a planning and intervention model that targets audiences with marketing technologies to improve health and quality of life (Andreasen, 1995). There are five

principles addressed in the "marketing mix" of social marketing, known as the "5 Ps:" product, price, place, promotion, and positioning. "Product" is the target behavior (e.g., breastfeeding, healthy eating). "Price" refers to the social, economic, and psychological costs involved in adopting the target behavior. "Place" is the setting, community context, or distribution channels for the product. "Promotion" includes the steps taken to make the audience aware of the ideas, behaviors, and their benefits and may also involve interpersonal communication, media messages, grassroots approaches, special events, and incentives. Lastly, "positioning" describes how the product is framed, namely, to maximize perceived benefits and minimize perceived costs.

Social marketing campaigns using mass media strategies have been effective in promoting positive health behavior outcomes. For example, the Stanford Five-City Project for Heart Disease Prevention, (Farquhar et al., 1985, 1990) which targeted specific audiences, developed a product (i.e., a 6-week quitting contest), and involved local television stations, resulted in a 30% increase in smoking cessation. Similarly, the VERB Campaign (Huhman et al., 2005; Wong et al., 2004) utilized mass media techniques such as advertising on television, on billboards, through a website, and through school- and community-based promotions to increase physical activity in ethnically diverse youth and their parents. While both of the aforementioned social marketing campaigns involved mass media strategies to promote their "products," social marketing campaigns that use interpersonal channels and target the social context may maximize success in promoting health behavior change.

Indeed, effective and sustainable social marketing campaigns are driven largely by social factors (e.g., social norms, social support) and involve the target population in the social marketing processes to increase the integration of the program into established community structures (Bryant, Forthofer, Landis, & McDermott, 2000). For example, Wilson and colleagues (2010) used a collaborative community process to develop a social marketing campaign which motivated citizens in a low-income, high-crime community to use a walking path. With the assistance of a communications firm, a community steering committee guided the development of the overall social marketing objectives and approach. One of five key objectives, including increasing perceptions of safety and social connectedness, was targeted each month using corresponding print materials (e.g., a 12-month calendar, matching door hangers). Through grassroots social networking, the program engaged residents to participate in walks with peers, allowing them to feel safe and connected to their neighbors. This study is an example of how involving constituents in the process of social marketing ensures that the approach is tailored and truly fits the needs of the target audience. Furthermore, social marketing campaigns that strategically provide opportunities for interactions between neighbors, friends, and families may influence social norms and support around a particular health behavior and foster a social climate of behavior change.

Synonyms

Interpersonal relationships; Social networks; Social ties

Definition

Broadly defined, social relationships refer to the connections that exist between people who have recurring interactions that are perceived by the participants to have personal meaning. This definition includes relationships between family members, friends, neighbors, coworkers, and other associates but excludes social contacts and interactions that are fleeting, incidental, or perceived to have limited significance (e.g., time-limited interactions with service providers or retail employees). Scientists interested in behavioral medicine often emphasize the informal social relationships that are important in a person's life, or the person's social network, rather than formal relationships, such as those with physicians, lawyers, or clergy. Relationship phenomena of interest to scientists encompass both the specific interactions that individuals experience with members of their social networks and the global perceptions of those interactions, which are shaped by past and current interactions with important social network members. The interactions that occur with social network members are often positive, and include the provision

of emotional and material support, companionship, and encouragement of health-enhancing behaviors. Interactions with social network members also can be negative, however, and can include insensitive, unresponsive, hurtful, or intrusive actions by others.

Description

A large body of evidence suggests that social relationships are associated with health. Research has linked social relationships to mortality and morbidity (Berkman, Glass, Brissette, & Seeman, 2000; Cohen, 2004; House, Landis, & Umberson, 1988). People with fewer social network ties have been found to have an elevated risk for a number of diseases, including cardiovascular disease and stroke, some forms of cancer, infectious disease, and possibly dementia (Cohen, 2004; Uchino, 2006). Social relationships also have been linked to the onset and progression of chronic illness, as well as illness adjustment, postsurgical recovery, disability, and survival (e.g., Seeman & Crimmins, 2001). Increased confidence in the associations between social relationships and health stems from the fact that the associations emerge not only in large, well-controlled cross-sectional and longitudinal epidemiological studies, but also in experimental studies of humans and animals. Moreover, the strength of these associations is impressive, as evidenced by research suggesting that the effects of social relationships on health are comparable in size to the effects of conventional risk factors, such as smoking (House et al., 1988).

Structural Versus Functional Aspects of Social Relationships

Both structural and functional aspects of social relationships have been distinguished (Berkman et al., 2000). Structural aspects refer to the existence and objective characteristics of social relationships, whereas functional aspects refer to the functions performed by and subjective qualities of social relationships (House, Umberson, & Landis, 1988). Structural characteristics of interest to health researchers include the size of a person's social network, the frequency of contact with social network members, and the nature of the role relationships with network members (e.g., family member, friend, coworker). Research has demonstrated that some structural aspects of social relationships, such as social network size and frequency of contact, are related to health. For example, having more social ties and more frequent social interaction has been found to be associated with lower risks for mortality and poor mental and physical health outcomes. Similarly, the marital relationship has been found to be especially consequential for health, relative to other role relationships. Married individuals, compared to unmarried individuals, have a lower prevalence and incidence of both mental and physical health problems and a lower mortality risk (House et al., 1988). Furthermore, research suggests that men may derive more health benefits from marriage than do women. Poor quality marriages, however, and the disruption associated with divorce or widowhood appear to be particularly deleterious to mental and physical health (Burman & Margolin, 1992).

Although numerous robust associations between structural aspects of social relationships and health have been documented, functional aspects also need to be examined in order to understand how and why social relationships impact health. The most commonly studied social network function that contributes to health is social support. A great deal of evidence suggests that social support can help to buffer people from the adverse effects of life stress (Cohen, 2004; Uchino, Cacioppo, & Kiecolt-Glaser, 1996). Different types of social support have been distinguished (emotional, instrumental, informational), all of which are conceptualized as ways that social network members provide each other with care and aid in times of need. Different types of support are viewed as being important in the context of different stressors, although evidence suggests that emotional support is important across a very broad range of stressors (Cohen & Wills, 1985).

Beyond social support, social relationships also serve as sources of companionship, which

provides opportunities for enjoyable interaction and camaraderie. The positive affect and relief from stress afforded by companionship, in turn, help to sustain health and well-being (Rook, 1987). Social network members also monitor each other's health behavior and intervene to discourage health-compromising behavior, leading researchers to be interested in the health effects of social regulation (or social control; Umberson, 1987).

The beneficial functions of social relationships also have been posited to have negative counterparts (Rook, 1998). Specifically, social relationships not only can provide support, companionship, and social regulation, but also can fail to provide support or can provide misguided support, can reject or neglect others, and can foster bad, rather than good, health practices. Even though such negative interactions with others are relatively rare, they can take a considerable toll on health and well-being (Rook, 1998).

Pathways by Which Social Relationships Influence Health

Understanding the pathways by which social relationships influence health is a key goal for health researchers. Three main pathways have been identified (Berkman et al., 2000; Rook, August, & Sorkin, 2010): The first pathway involves psychological processes and conditions associated with social relationships, such as positive and negative emotions, feelings of self-worth and self-efficacy, coping strategies, and depression. The second pathway involves physiological processes, or activation of bodily systems (endocrine, cardiovascular, and immune) in response to various kinds of social interactions. The third pathway involves health behaviors that are fostered by interactions with social network members, including health-enhancing behaviors (e.g., exercise) as well as health-compromising behaviors (e.g., smoking). All three of these pathways have the potential to have independent and joint effects on morbidity and, ultimately, mortality.

Pathways having beneficial health effects. Social support, companionship, and social regulation are believed to affect health through unique mechanisms. Social support is thought to dampen the emotional, physiological (neuroendocrine, cardiovascular, immune), and behavioral effects of stress by improving one's perceived ability to cope with stress (Uchino, 2006; Uchino et al., 1996). Companionship, on the other hand, is thought to influence health and well-being by enhancing positive affect and providing a respite from stress (Rook, 1987). Positive affect, in turn, has been linked to lower rates of morbidity, fewer symptoms and less pain from health conditions, and greater longevity (Pressman & Cohen, 2005). Companionship also may activate physiological processes, such as the release of oxytocin, a neuropeptide that helps to counter harmful stress responses, including release of the stress hormone, cortisol. Social control is believed to affect health through two primary, but opposing, processes (Hughes & Gove, 1981). Specifically, social control may discourage health-compromising behaviors and encourage health-enhancing behaviors, thereby contributing to better health and ultimately, a lower risk of mortality. Yet, at the same time, to the extent that social control involves constraints on others' behavior, it may provoke psychological distress, erode feelings of self-efficacy, and kindle relationship tensions. The psychological and relationship costs of social control may thus reduce or cancel the health benefits of social control, although the net effects of social control on health are not yet fully understood (Rook et al., 2010).

Pathways having detrimental health effects. Persistent conflict in social relationships, as well as the absence or loss of social relationships, also impact health through a number of mechanisms. Specifically, recurring strains and conflicts in social relationships lead to repeated activation of physiological systems (e.g., hypothalamic-pituitary-adrenal axis or sympathetic nervous system activity) and impaired immune functioning. These chronically activated and dysregulated physiological systems, in turn, may accelerate disease onset and progression. Additionally, social isolation and loneliness have been linked to negative emotions, chronic stress, cardiovascular

activation, low physical activity, and impaired sleep (Cacioppo et al., 2002). Finally, it is important to recognize that social network members sometimes encourage undesirable, rather than desirable, health practices. For example, evidence suggests that adolescents sometimes recruit their peers to use illegal substances or to engage in other risky health behaviors. Thus, conflict and tensions in social relationships, social isolation and loneliness, and undesirable social influence all can increase the risk of disease onset and progression.

Conclusion

It is well established that social relationships are important for health and well-being, and research has identified key aspects of social relationships that warrant consideration in efforts to understand these links with health. The psychological, physiological, and behavioral pathways by which social relationships affect health also are beginning to be understood. As this literature evolves and expands to document patterns that exist across different sociodemographic and lifespan contexts, it may help to inform interventions designed to strengthen social relationships and, in turn, health.

Social Stress

Vanessa Juth and Sally Dickerson
Department of Psychology and Social Behavior, University of California, Irvine, Irvine, CA, USA

Synonyms

Interpersonal stress or conflict; Societal stress

Definition

Social stress can be broadly defined as a situation which threatens one's relationships, esteem, or sense of belonging within a dyad, group, or larger social context. Social stress can emerge in a number of situations. Social stress can stem from difficult social interactions, for example, a conflictual or tumultuous marital or family relationship (Kiecolt-Glaser, Gouin, & Hantsoo, 2010). Social stress can also emerge in the context of evaluated performance situations, where others could be judgmental or critical, or in contexts in which one feels rejected, ostracized, or ignored (Dickerson & Kemeny, 2004). Social stress can also be more broadly construed, representing perceptions of one's lower role or standing within a group or community.

Social stress can lead to a range of observable and measurable responses related to health outcomes (Miller, Chen, & Cole, 2009). In some cases, social stress can cause increases in negative affect and distress. It can also elicit specific negative emotions. For example, rejection or social-evaluative performance stressors can elicit increases in self-conscious emotions, such as shame and embarrassment. Severe interpersonal stressors (e.g., parental neglect) may lead to pathological forms of psychological distress, such as posttraumatic stress disorder.

By nature, social stress can range from being acute and relatively benign (e.g., delivering a speech) to chronic and severe (e.g., abusive relationship). Acute social stressors can lead to physiological responses. For example, social-evaluative performance stressors can elicit strong and significant increases in cortisol, as well as increases in cardiovascular activity (e.g., heart rate, blood pressure). Acute instances of rejection or conflict can also lead to changes in a variety of physiological parameters, including how the immune system functions. Chronic social stress can have implications for health. If social stressors are experienced repeatedly or consistently, stress-responsive physiological systems could be repeatedly activated, which could have negative health consequences; for example, high cortisol levels and immune dysregulation have predicted the onset and progression of different diseases. Additionally, those with chronic diseases (e.g., HIV, rheumatoid arthritis) who experience social stressors have shown faster disease progression than those without (Lepore & Revenson, 2007). Social stressors can also have long-lasting effects, such that social stress experienced early in life (e.g., childhood) can influence stress reactivity and the regulation of stress-responsive systems in adulthood. Furthermore, sociodemographic variables related to social status within a group, community, or

society at large (e.g., socioeconomic status, ethnicity) can increase the risk for negative health outcomes and/or behaviors.

Synonyms

Moderators/moderating factors; Social integration; Social network; Social resources

Definition

Social support refers to the belief that one is valued, cared for, and loved by others in a social network. Social support can generally be conceptualized as reflecting two broad factors (Cohen & Syme, 1985; Cohen & Wills, 1985). Structural support reflects properties of the social network and the degree to which a person participates in that network (i.e., social integration). Functional support refers to the ways by which network members aid the individual through tangible assistance or through psychological and emotional buffering. Social support is among the most widely studied and robust psychosocial moderators of health. This entry will expand upon this description, review evidence linking it to health, examine hypothesized mechanisms, and discuss future directions.

Description

Social support is a multicomponent construct reflecting the size, quality, and availability of one's social resources to moderate stress. Social support should be distinguished from conceptually related terms. *Social capital* is a sociological term referring to stock or stored social credit. *Social network* refers to the social collectives or groups to which a person may belong. *Social integration* refers to the degree to which a person is embedded in or a part of a social network. *Relationship* is a descriptor often used to characterize a specific type of social tie.

Social support is generally conceptualized as having structural (i.e., size of the social network, degree of social integration) and functional (i.e., support processes; support received versus support perceived) characteristics. In addition, the quality of support is increasingly recognized as an important moderator of the relationship between support and health. Importantly, relationships are not uniformly positive, with some acting as sources of stress (Uchino, 2004).

Measures

Social support is generally measured by self-report. Data sources may include demographic data from hospital, census, or other records; interviews; psychometrically validated instruments; and ad hoc items and measures.

Structural Measures of Support

The simplest of the social integration measures is marital status which is consistently identified as a protective factor in large, prospective studies of mortality. Marital status is a particularly attractive measure as it is a common demographic characteristic and, thus, available for analysis with many kinds of health data. Many researchers are also interested in measuring the size of one's social networks and the degree to which a person is embedded in the networks. One well-validated multicomponent measure of social integration is the Social Network Index (SNI: Berkman & Syme, 1979) which provides an aggregate score of social integration by sampling activity in multiple relationships. Lower SNI scores are predictive of a nearly two fold increase in mortality risk. Finally, the literature is replete with numerous ad hoc structural support measures including measures of number of networks, network size, as well as the number of specific kinds of relationships such as friendships, and others.

Functional Measures of Support

Functional measures can be classified into support received and support perceived. Interestingly, measures of received and perceived support tend not to be highly correlated. Measures of received supportive behavior allow assessment of the actual social resources available to an individual. For example, the Inventory of Socially Supportive Behaviors (ISSB: Barrera, Sandler, & Ramsay, 1981) is a 40-item structural support measure assessing the frequency with which one receives a variety of supportive actions. Measures of perceived social support assess an individual's beliefs about the social resources available to them. Perceived support measures generally consist of two factors: beliefs about support available, and satisfaction with level of perceived support. A widely used example of a perceived support measure is Cohen and Wills (1985) Interpersonal Support Evaluation List (ISEL) which assesses perceptions of belonging, tangible support, support appraisals, and confidence in support perceptions.

Quality of Support

Relationship quality has generally been assessed along a single dimension ranging from positive to negative. However, emerging models hypothesize that relationships can have both positive and negative characteristics. The Quality of Relationship Inventory (QRI: Pierce, Baldwin, & Lydon, 1997) is among the most popular multidimensional measures. The 25-item, self-report measure yields discrete support and conflict scales as well as a total quality rating. Several authors have suggested that the relationship quality dimensions of positivity and negativity are orthogonal, yielding four basic relationship types: (1) high positive, low negative (i.e., supportive relationship), (2) low positive, high negative (i.e., conflictual relationship), (3) high positive, high negative (i.e., ambivalent relationship), and (4) low positive, low negative (i.e., benign/irrelevant relationship). The Social Relationships Index (SRI: Uchino, 2004) is an example of this multidimensional relationship quality assessment approach. Although health outcome data is limited, this conceptualization appears to be gaining acceptance as a more theoretically sound approach.

Social Support and Health

Social support is among the most robust predictors of disease and all-cause mortality. For example, a recent meta-analysis of 148 studies estimated the effect of social relationships to improve survival rates by 50% (Holt-Lunstad, Smith, & Layton, 2010). This effect varied by measurement, with multidimensional measures of social integration associated with more than 90% increase in survival rates. As noted by the authors, the magnitude of the effect of social support on mortality is likely diluted in these studies by unmeasured negative aspects of social relationships (e.g., a conflictual marriage). The results of this meta-analysis extend the work of previous systematic reviews and meta-analyses in identifying that social support is a substantial health and disease moderator with effects equivalent to more traditionally acknowledged risk factors such as cigarette smoking and obesity.

Cardiovascular Disease

The strongest evidence for a protective role of social support on health comes from studies of cardiovascular diseases such as coronary heart disease (CHD) morbidity and mortality (Smith & Ruiz, 2002). Multiple prospective studies of initially healthy samples have demonstrated that lower social integration and social support are associated with greater CHD incidence, faster disease progression, risk of myocardial infarction (MI), and greater risk for all-cause mortality. Among persons with diagnosed CHD, lower social support is predictive of significantly greater risk of recurrent MI and death. For example, Welin, Lappas, and Wilhelmsen (2000) found an almost three-fold increased chance of cardiac mortality in post-MI patients with low perceived emotional support at 10-year follow-up. A similar effect size was found by Berkman, Leo-Summers, and Horwitz (1992). Some studies indicate that low social integration is only associated with survival in the most severely isolated of the population. In a review of the literature, Mookadam and Arthur (2004) estimated a two to three times increased risk of 1-year mortality in the socially isolated population, with little health benefits resulting from support systems above this threshold. Moreover, there is some evidence that the beneficial effects of social support on cardiac health are stronger among women and that functional measures of support are more strongly related to cardiac disease compared to structural measures.

Effect sizes for social integration in healthy samples for future development of CHD are comparable to those of more traditional risk factors such as cigarette smoking (Orth-Gomer, Rosengren, & Wilhelmsen, 1993). Similarly, social integration is as strong a predictor of mortality among clinical populations as traditional risk factors such as cholesterol level, tobacco use, and hypertension in the patient population (Mookadam & Arthur, 2004). An important conceptual issue is whether high social support connotes a cardiovascular benefit akin to physical activity or whether it is simply the absence of support that is relevant. In addition, the relative value of structural versus functional support remains an open question. Regardless, the cumulative evidence indicates social support is an important moderator of cardiovascular risk.

Cancer

The relationship between social support and cancer is quite mixed. A recent systematic review of the prospective longitudinal literature concluded that in the context of breast cancer, greater social support was associated with slower disease progression in five of seven well-designed studies. Structural indices were the more commonly used and significant measure of social support in these studies. In contrast, there were no associations between measures of social support and other types of cancer with the paradoxical exception of more social support related to faster cancer progression in a sample of colorectal patients (Villingshoj, Ross, Thomson, & Johansen 2006). A meta-analysis of 87 studies estimated the relative risk of perceived social support and measures of social network size on mortality among cancer patients to be .82 and .80, respectively, suggesting a beneficial effect (Pinquart & Duberstein, 2010). Inconsistencies between studies may be partially explained by differences in support types measured and patient needs. The type of support associated with improved prognosis appears to vary by cancer site, with perceived social support representing a stronger predictor for leukemia and lymphoma, whereas breast cancer patients benefit more from have a large number of social ties (Pinquart & Duberstein).

In contrast to the mixed findings regarding physical outcomes, a robust literature supports the beneficial effects of social support on emotional and psychological reactions to cancer and associated treatments. Moreover, cancer is often a shared interpersonal experience – affecting supports as well as patients. A meta-analysis of these *contagion effects* estimated the correlation between patient and caregiver distress is .35 (Hodges, Humphris and Macfarlane, 2005). Importantly, partner response to illness affects patient adjustment, particularly in terms of quality of life. The type of coping employed (e.g., positive versus negative), relationship maintenance

behaviors, and the amount of communication about the relationship may also be important moderators of couples adjustment.

With respect to interventions, efforts have largely focused on increasing the patient's social network size and opportunity for emotional support. Perhaps the most well known of these interventions was conducted by Spiegel, Bloom, Kraemer, and Gottheil (1989). Women with late-stage metastatic breast cancer were randomized to either supportive group therapy or wait-list control. Findings that women in the treatment condition survived approximately 18 months longer generated interest in the possible healing role of support. Several clinical and prospective trials have failed to replicate these results, fueling doubts about the potential physical benefits of the approach. Regardless, there is substantial effort to translate socially based interventions from bench to bedside where their emotional and quality of life benefits are well recognized.

HIV/AIDS

Conclusions regarding the benefits of social support on physical outcomes in the context of HIV/AIDS are limited by the small number of published studies. A prospective study of HIV-positive men with hemophilia demonstrated that lower levels of perceived support at baseline were predictive of faster decreases in CD4 T-lymphocyte levels, a key marker of AIDS status, over a 4-year follow-up (Theorell et al. 1995). Leserman and colleagues conducted a study of 82 asymptomatic gay men, in which greater satisfaction with social support was associated with slower progression to AIDS, regardless of network size (Leserman et al. 1999). In contrast, other studies have found perceived support to be unrelated to progression to AIDS. More research is needed to adequately evaluate these relationships.

The social environment of the HIV/AIDS population may be uniquely important because of the social stigma associated with the diagnosis (Herek & Glunt, 1988). Stigma is associated with both personal distress and hesitancy to self-disclose status to sexual partners, potentiating further transmission of the infection either by the individual or the individual's un-informed sexual partners. A meta-analysis of 21 studies showed that greater perceived social support was associated with increased likelihood of self-disclosing one's HIV-positive status (Smith, Rosetto, & Peterson, 2008). Disclosure of HIV status is associated with increased social support within those relationships, indicating that disclosure may be a positive method of eliciting support from others.

Mechanisms

Social support is hypothesized to affect health and well-being through two pathways. The *main effects* hypothesis suggests that having more social resources reduces the chances of exposure to stressful circumstances or the magnitude of threat associated with certain environments. For example, one is likely to be safer walking at night with a large group of friends than when walking alone. Numerous studies have shown that having more social resources (measured as the number of social ties, the degree of social integration, etc.) is predictive of lower disease incidence, better survival following illness, lower all-cause mortality, and greater longevity irrespective of the quality of those relationships. Interestingly, these social resources need not be human to have a beneficial effect. Several studies have demonstrated that having a loving pet is associated with less stress and better survival following disease incidents such as a heart attack.

Social support may also affect health by moderating or reducing the impact of stressful circumstances (i.e., *stress buffering hypothesis*). After a stressful romantic breakup, a friend may comfort you with a hug, by providing you with an opportunity to vent your emotions, or by introducing you to someone new. Substantial laboratory data demonstrates that provision of support reduces self-reported stress and acute physiological responses to lab stressors. For example, individuals who received a note communicating emotional support from a supportive friend experience less blood pressure increase during a subsequent speech task relative to those who receive a note from a less supportive person (Uno, Uchino, & Smith, 2002). Importantly, the perception of support appears to

be more important than the actual provision of support. For example, imagining a supportive tie prior to a stressor results in less cardiovascular reactivity and less self-reported stress (i.e., buffering) compared to imagining an acquaintance (Smith, Ruiz, & Uchino, 2004). These findings support the idea that social support, received or perceived, can reduce stressful experiences.

Future Directions

Future research will continue to expand upon conceptual distinctions regarding sources of support and related actions. Longitudinal research is also needed to understand the biobehavioral mechanisms by which social support translates into disease risk. Further, more research is needed to determine whether it is better to have substantial support or simply to not be alone. Finally, emerging social phenomenon such as texting and online social networking through Facebook, Twitter, and other forums presents new challenges for researchers to conceptualize, measure, and gauge as moderators of health.

Definition

The Society of Behavioral Medicine (SBM) is a nonprofit organization founded in 1978. The organization strives to be multidisciplinary in nature, creating a dialogue between nursing, public health, psychological, and medical professionals to promote the study of interactions between behavior, biology, and the environment and to apply that knowledge to improve the health and well-being of individuals and communities. This is further illustrated through SBM's vision statement, which is "Better Health Through Behavior Change." In 2011, over 2,000 behavioral and biomedical researchers and clinicians were members of SBM.

SBM hosts an annual meeting for its members and other behavioral medicine researchers and clinicians to share recent research findings and clinical strategies. SBM also sponsors two journals, *Annals of Behavioral Medicine* and *Translational Behavioral Medicine: Practice, Policy, and Research*.

Definition

"Sociocultural" refers to a wide array of societal and cultural influences that impact thoughts, feelings, behaviors, and ultimately health outcomes. Sociocultural determinants of health and illness encompass socioeconomic status (SES) factors (traditionally assessed by income, education, occupation) and cultural factors. There are several dimensions encompassed by the term, which can include race, ethnicity, ethnic identity, sex, acculturation, language, beliefs and value systems, attitudes, and religion.

Description

Sociocultural factors are salient determinants of health and have been found to be associated with a multitude of health outcomes including health behaviors (e.g., physical activity, diet, health screenings, and health-care utilization) and illness (e.g., cancer, diabetes, cardiovascular disease, and depression). Sociocultural factors are complex and may vary by sex, age, and racial/ethnic groups. In recent years, the term sociocultural has been extensively used in the literature in connection with physical and mental health outcomes.

Social and cultural factors play a central role in preventing illness, maintaining good health, and treating disease. Research has shown that an individual's social environment, family, neighborhood, school, and workplace have a significant impact on health. At the same time, cultural factors influence how physical and mental illness are viewed and diagnosed. A great advance in understanding the determinants of health and disease has been the identification of social and cultural factors influencing them. Social and cultural factors are pertinent not only to understanding individuals' health status but also recognizing the existing health disparities among different populations. In particular, a substantial body of research suggests that social factors stand at the root of health disparities (Marmot, 2005).

Some of the most salient sociocultural factors studied in relation to health disparities, including morbidity and mortality, are SES and race/ethnicity. Levels of health within the USA vary dramatically among different social, economic, and racial/ethnic groups. Moreover, considerable research suggests that determinants of health often reflect economic disparities (Braveman, Cubbin, Egerter, Williams, & Pamuk, 2010). Higher income levels are linked with overall better health, including self-rated health, lower cardiovascular risk factors, and lower mortality (Braveman, Egerter, & Mockenhaupt, 2011; Hajat, Kaufman, Rose, Siddiqi, & Thomas, 2011). The incidence and prevalence of many diseases (e.g., cardiovascular disease, arthritis, diabetes, and cervical cancer) increases as SES decreases. In addition, SES differences in mortality have been observed for many causes of death including some cancers, diabetes, and cardiovascular disease. Similarly, individuals with higher SES have greater life expectancy rates than individuals with lower income levels (Braveman et al., 2011). In terms of health status, adults with lower incomes are more likely to report their health status as poor or fair compared with adults with higher incomes (Braveman et al., 2011).

Several explanations have been proposed to account for the association between socioeconomic standing and health. First, economic stability enables individuals to live in safer neighborhoods, access healthier food alternatives, have more leisure time for physical activity, and endure less stress. Second, income impacts access to high-quality health care such that lower SES individuals are less likely to be covered by health insurance and to receive high-quality health care (Braveman et al., 2011). Hence, the uninsured may have less access to preventive services (e.g., health screenings) and early diagnosis. Greater education is also linked with longer life expectancy. Individuals who have completed college have a greater life expectancy (at least 5 years longer) than individuals who have not completed high school (Braveman et al., 2011). Higher education levels are associated with greater knowledge regarding health and feelings of control (Braveman et al., 2011) over different domains of one's life.

Therefore, education increases the likelihood that individuals will have the knowledge to prevent illness. As illustrated by these health patterns, SES disparities in health mirror a gradient pattern, with greater social and economic advantage being associated with better health.

Differences in health have also been observed based on race/ethnicity. For example, compared to non-Hispanic Whites, morbidity and mortality rates for cardiovascular disease (CVD) are higher among African-Americans (Payne et al., 2005). Compared to non-Hispanic Whites, African-Americans and Hispanics are more likely to have diabetes (Centers for Disease Control and Prevention, 2011). Moreover, ethnic-minority and low-income groups have a disproportionate burden of death and disability as a result of cardiovascular disease. In addition, although significant progress has been made in reducing cancer mortality rates in the USA, decreases in cancer mortality rates in ethnic minorities have been slower compared to non-Hispanic Whites (Cancer Facts & Figures, 2011).

Culture refers to the shared values, beliefs, and norms held in common by a defined group of people. Within each culture, there is a set of behaviors and values related to health and illness which may vary between different groups, causing differing viewpoints toward illness. Each culture has a set of norms for behavior with related beliefs, knowledge, and customs. Acculturation, a related cultural construct, is often used to explain ethnic disparities in health outcomes. Acculturation as a predictive variable is based on the premise that culturally based knowledge, attitudes, and beliefs influence people to behave in particular ways and to select specific health choices. For limited English proficiency (LEP) individuals, language barriers can contribute to health disparities. For example, LEP individuals may encounter difficulties communicating with medical professionals, understanding printed health information or accessing health-related services due to lack of information about available services (Racial and Ethnic Disparities in Health Care, 2010). Moreover, some individuals may fear jeopardizing their immigration status by using health services. Research also suggests that cultural norms within the USA or Western society contribute to lifestyles and behaviors associated with risk factors for diseases (e.g., cancer, diabetes, cardiovascular disease) (Thomas, Fine, & Ibrahim, 2004). Therefore, health behavior interventions must address the target group's belief systems as well as cultural values.

Although the US population is diverse, health policies and interventions are often based on Western cultural assumptions. Often, minimal attention is given to aspects of culture from the perspective of individuals from diverse ethnic or SES membership groups. It is key to acknowledge that social and cultural factors may explain related health behaviors and, in part, elucidate disparities between ethnic/racial and SES groups. More specifically, research findings examined from the perspective of sociocultural differences may provide more meaningful information and help develop innovative intervention strategies for ameliorating some of the disparities in health outcomes and access to health care.

Sociocultural Differences

Melissa Walls
Biobehavioral Health & Population Sciences, University of Minnesota Medical School – Duluth, Duluth, MN, USA

Definition

Sociocultural approaches to understanding differences in health call attention to the roles of and potential interdependence between social and cultural factors for health outcomes.

Cultural attitudes, beliefs, values, history, and systems of knowledge are interdependent with the social environment that includes economic status, community and family systems, and interpersonal relationships. Together, sociocultural factors may impact health in numerous ways, such as influencing access/barriers to health care and service utilization preferences/patterns as well as affecting health behaviors such as diet and exercise.

Sodium

▶ Salt, Intake

Sodium Chloride

▶ Salt, Intake

Sodium, Sodium Sensitivity

Jonathan Newman
Columbia University, New York, NY, USA

Definition

Sodium chloride (NaCl), commonly known as salt, is a molecule crucial for fluid balance and free-water homeostasis. However, overconsumption of sodium/salt plays an important role in the

development of essential hypertension. Essential hypertension is seen almost exclusively in societies where average daily sodium consumption is greater than 2.3 g. In contrast, hypertension is rare in populations with low-sodium consumption (typically less than 1.2 g/day). These effects of sodium consumption appear independent of other potential causes of essential hypertension, such as obesity.

The blood pressure (BP) responsiveness to variations in sodium intake is known as salt sensitivity.

The change in BP to salt intake varies significantly between individuals and in the same individual at different times.

Salt sensitivity also increases with age and is more prominent in those with diabetes, obesity, and metabolic syndrome.

It may also be more common in African-Americans and other populations, in which excess salt intake may play an important role in the development of hypertension.

There is evidence to suggest that salt-sensitive individuals with normal blood pressure are at a greater risk of developing hypertension and at further risk of hypertension progression and poor blood pressure control. The mechanisms of salt sensitivity are incompletely understood but likely involve a combination of altered salt/water homeostasis, abnormal vascular signaling pathways, and other metabolic abnormalities such as type 2 diabetes and electrolyte abnormalities, such as hypokalemia.

Somatic Symptoms

Kurt Kroenke
Department of Medicine, Indiana University, Regenstrief Institute, VA HSR&D Center for Implementing Evidence-Based Practice, Indianapolis, IN, USA

Definition

Mental health professionals commonly label bodily symptoms as "somatic" to distinguish them from cognitive, emotional, or other types of non-somatic symptoms (Kroenke, 2007a). In contrast, bodily symptoms are more often referred to as "physical" symptoms by those practicing in general medical, surgical and other non-mental health care professions. Somatic symptoms are exceedingly prevalent, accounting for over half of all outpatient encounters. About half of these are pain complaints (e.g., headache, chest pain, abdominal pain, back pain, joint pains), a quarter are upper respiratory (e.g., cough, sore throat, ear or nasal symptoms), and the remainder are nonpain, non-upper-respiratory symptoms (e.g., fatigue, insomnia, dizziness, palpitations).

Description

Epidemiology

About 80% of individuals in the general population experience one or more symptoms each month, of who less than 1 in 4 seek care (Kroenke & Rosmalen, 2006). This ubiquitous nature of somatic symptoms mandates that some thresholds be set to distinguish most "persons" who experience common symptoms from the smaller subset of individuals who qualify as "patients." Some thresholds might include severity of the symptom: its duration or persistence; the degree of occupational or social

impairment; the level of patient distress, concerns or worries; the decision to seek treatment or use health care; and the direct and indirect financial costs.

An exact medical diagnosis that accounts for the symptom is often not established, with at least one-third of somatic symptoms lacking an adequate physical explanation and referred to by a variety of labels, including functional, idiopathic, atypical, somatoform, or unexplained.

About three-fourths of outpatients presenting with somatic complaints experience improvement within 2 weeks, while 20–25% of symptoms become chronic or recurrent.

Functional Somatic Syndromes

These conditions consist of a cluster of somatic symptoms for which the etiology is poorly understood and include disorders such as irritable bowel syndrome, fibromyalgia, chronic fatigue syndrome, temporomandibular disorder, interstitial cystitis, and others. Experts have questioned whether these are all separate disorders or instead part of a group of poorly explained somatic conditions sharing common features. Supporting the latter, literature syntheses have revealed that these disorders frequently overlap, both at the level of specific syndromes (half to two-thirds of patients with one syndrome also suffer from one or more additional syndromes) as well as in terms of individual symptoms (Kroenke & Rosmalen, 2006). Second, they are similar in rates of psychiatric comorbidity, particularly depression and anxiety (Henningsen, Zimmermann, & Sattel, 2003). Third, functional somatic syndromes respond similarly to certain therapies traditionally considered "psychological" treatments, such as antidepressants and cognitive-behavioral therapy.

Psychological Comorbidity

In patients presenting with poorly explained physical symptoms, a depressive disorder can be diagnosed 50–60% of the time, and an anxiety disorder 40–50% of the time, regardless of the type of symptom. While the specific type of symptom is not particularly important in terms of predicting depression or anxiety, the number of symptoms is. In two primary care studies involving 1,500 patients, those who endorsed 0–1, 2–3, 4–5, 6–8, or ≥ 9 physical symptoms on a 15-symptom scale, the proportion with a depressive or anxiety disorder was 6%, 20%, 33%, 58%, and 80% respectively, suggesting a "dose-response" effect between the number of physical symptoms and the likelihood of psychiatric comorbidity.

Two-thirds of primary care patients with major depression present exclusively with somatic complaints, and half report multiple, unexplained somatic symptoms. Also, depression is present in a quarter to a third of patients referred to medical specialty clinics and, if depressed, referred patients are only about a quarter as likely to have a physical diagnosis established as an explanation for their symptoms triggering the referral. Even disease-specific somatic symptoms (e.g., chest pain in patients with coronary artery disease, dyspnea in patients with pulmonary disease, joint pain in patients with arthritis) are at least as strongly associated with depression and anxiety as they are with objective physiologic measures of the medical disorder (Katon, Lin, & Kroenke, 2007).

Overlap among somatic, anxiety and depressive symptoms (the *SAD triad)* is more common than the "pure" form of any of the three types of symptoms (Löwe et al., 2008). For example, very high levels of depressive, anxiety and somatic symptoms are present in 7%, 8%, and 10% of primary care patients, respectively. However, only 26% of depressed patients have depression alone (i.e., without high levels of anxiety and/or somatic symptoms), 43% of anxious patients have anxiety only, and 46% of patients with high somatic symptom levels have somatization alone. Predictors of psychological comorbidity in patients with somatic symptoms are summarized in Table 1.

Somatoform Disorders

Somatoform disorders currently defined in the American Psychiatric Association's Diagnostic and Statistical Manual, 4th Edition (DSM-IV) include somatization disorder (chronic history of multiple medically unexplained symptoms), conversion disorder (unexplained neurological symptoms), hypochondriasis (preoccupation with having a serious medical illness that persists despite medical evaluations and reassurance), body dysmorphic disorder (distorted perceptions

Somatic Symptoms, Table 1 Predictors of psychological comorbidity in patients with somatic symptoms

Symptom remains medically unexplained after clinical assessment
Multiple symptoms
Three or more unexplained symptoms
Pain symptoms in two or more regions of the body
Multiple functional somatic syndromes
Chronic or recurrent symptom (s)
Excessive health care use
Medication history
Polypharmacy (especially for symptoms)
Poor response of symptoms to multiple medications
Nocebo response (nonspecific adverse effects to multiple medications)
Difficult clinician-patient relationship
Number of S4 predictors [a]
Stress recently
Symptom count is high
Self-rated health is low
Severity of symptom is high

[a]The four S4 predictors are (1) stress in past week (yes/no); (2) Patient reports being "bothered a lot" by five or more symptoms on the PHQ-15 scale of 15 somatic symptoms; (3) self-rated overall health of poor or fair on a 5-point scale (excellent, very good, good, fair, poor); (4) self-rated severity of presenting somatic symptom of $^{3}6$ on 0 (none) to 10 (unbearable) scale. The likelihood of a depressive or anxiety disorder with 0, 1, 2, 3, or 4 of these S4 predictors is 8%, 16%, 43%, 69%, and 94%, respectively

of specific bodily features), and chronic pain disorder. However, these are likely to be substantially revised in DSM-V (Kroenke, Sharpe, & Sykes, 2007). In particular, criteria for the most common type of somatoform disorder (full and abridged versions of somatization disorder) are likely to rely less on symptom counts or the degree to which symptoms are "medically explained" and more on positive psychological criteria characteristic of somatizing patients (e.g., excessive illness worry and health anxiety, inordinate health care use, catastrophizing).

Measuring Somatic Symptoms

The PHQ-15 is a brief, freely-available scale (www.phqscreeners.com) that measures 15 symptoms that account for more than 90% of non-upper-respiratory symptoms seen in primary care (Kroenke, Spitzer, Williams, & Löwe, 2010). The PHQ-15 asks patients to rate how much they have been bothered by each symptom during the past month on a 0 ("not at all") to 2 ("bothered a lot") scale. Thus, the total score ranges from 0 to 30, with cutpoints of 5, 10, and 15 representing thresholds for mild, moderate, and severe somatic symptom severity, respectively.

Increasing scores on the PHQ-15 are strongly associated with functional impairment, disability, health care use, and somatoform disorder diagnoses. Also, items on the PHQ-15 overlap better with other validated somatization screeners than any other two screeners do with one another. There is emerging evidence that the PHQ-15 is responsive to treatment.

Treatment

Treatment of somatoform disorders as well as functional somatic syndromes has been recently reviewed (Abbass, Kisely, & Kroenke, 2009; Jackson, O'Malley, & Kroenke, 2006; Kroenke, 2007b). In addition to symptom-specific treatments (e.g., analgesics for pain, medications specific to the symptoms for irritable bowel syndrome, medications recently approved for fibromyalgia), the two most evidence-based treatments for both somatoform disorders and functional somatic syndromes are cognitive behavioral therapy and antidepressants, which have a beneficial effect on the somatic symptoms in these conditions independent of their effect on psychological symptoms such as depression and anxiety. Additionally, regular visits with a primary physician, avoidance of excessive testing, and evaluation of new symptoms (but not repeated evaluation of chronic symptoms) is beneficial. A clinical approach to the patient with unexplained somatic symptoms is outlined in Table 2.

Strategies for managing chronic somatization

- Schedule regular, brief appointments that are not related to symptom exacerbations
- Limit extensive diagnostic testing and multiple subspecialty referrals, especially for symptoms previously evaluated
- When new symptoms arise, conduct focused evaluations and testing rather than exhaustive work-ups

Somatic Symptoms, Table 2 Clinical approach to the patient with unexplained somatic symptoms

Initial visit	
Symptom-specific evaluation	Focus the interview and physical examination on the relevant symptom(s) Stratify symptoms into those that are at higher risk of a serious cause (e.g., angina-like chest pain; acute abdominal pain; syncope) and those that are seldom urgent (back pain, fatigue, insomnia). Identify "red flags" of a potentially serious cause (e.g., focal neurologic findings in patient with dizziness or headache; abnormal cardiac exam in patient with syncope)
Probe for symptom-specific concerns and expectations	"Is there anything else you were worried about?" (Serious cause? How long symptom might last?) "Is there anything else you wanted or thought might be helpful?" (Test? subspecialty referral? Specific treatment?)
Consider short-term use of symptom-specific medications (often available over-the-counter)	Simple analgesics for pain Gastrointestinal medications for dyspepsia or constipation Decongestants, antihistamines, cough suppressants for upper respiratory symptoms
Watchful waiting	Have patient follow-up in 2–6 weeks if symptom is not resolved
Follow-up visits	
Psychological screening	Especially for treatable depressive and anxiety disorders (see www.phqscreeners.com) Assess for somatization (PHQ-15 or other scale)
Diagnostic evaluation	Selective testing and/or specialty referral, especially if new unexplained symptom, if findings on interview or examination are worrisome for serious cause, or if patient insists
Chronic symptom therapies	Pharmacological – analgesics; gastrointestinal medications; antidepressants, other Nonpharmacological – cognitive-behavioral therapy (CBT); other psychological or behavioral therapies; exercise; pain self-management programs; reattribution

- Empathize with the complaint. Do not dispute the reality of the symptom or associated impairment.
- Focus on symptom management/reduction rather than elimination (coping rather than cure).
- Strive for gradual rehabilitation (maximizing function despite the symptom) rather than chronic disability
- Emphasize that referral is for consultation or co-management rather than dismissal (i.e., you are not "dumping" the patient)

Somatization

Winfried Rief
Department of Clinical Psychology and Psychotherapy, Philipps University of Marburg, Gutenbergstr, Marburg, Germany

Definition

The term "somatization" goes back to psychodynamic theory, and describes the transformation of unconscious conflicts and repressed emotions into somatic symptoms. Later on, Lipowski defined somatization as "a tendency to experience and communicate somatic distress in response to psychosocial stress and to seek medical help for it" (Lipowski, 1986). Therefore this definition postulates that psychosocial stress is the cause for somatization, and that seeking medical help is a necessary feature of this syndrome. However, current concepts of somatization use this term more descriptively. According to these modern concepts, somatization could be defined as "the tendency to experience a variety of somatic symptoms that are usually poorly described by biomedical disease processes." In this definition, the presence of multiple somatic complaints is the core feature of somatization.

Somatization itself is not a diagnosis, but is frequently related to the diagnostic group of "somatoform disorders," and especially to "somatization disorder." If multiple somatic symptoms are part of a depressive syndrome or anxiety disorder, the term could be also used. It is not recommended to use the term "somatization" for a postulated association between psychological conflicts and serious medical conditions (e.g., cancer). However, medical conditions like cancer or diabetes can also be associated with multiple medical symptoms that are not explained by the biomedical disease itself. For this subgroup of patients with serious medical conditions, the additional use of the term "somatization" could be appropriate.

Current behavioral-medical concepts prefer the process of "somatosensory amplification" to describe the development and maintenance of somatization. Somatosensory amplification summarizes the process of focusing attention to bodily perceptions; together with health worries and a catastrophizing style of interpreting bodily perceptions, selective attention leads to an amplified style of perceiving somatic symptoms. If symptoms are chronic, further sensitization processes might be involved. Further details on modern concepts of somatization can be found in Barsky (1992), Looper and Kirmayer (2002), and Rief and Broadbent (2007).

Somatoform Disorders

Winfried Rief
Department of Clinical Psychology and Psychotherapy, Philipps University of Marburg, Gutenbergstr, Marburg, Germany

Synonyms

Functional somatic symptoms; Medically unexplained physical symptoms

Definition

The common feature of somatoform disorders is the presence of physical symptoms that could indicate a general medical condition, but the physical symptoms are not fully explained by a well-known biomedical disease, by the direct effects of a substance, or by another mental disorder. The group of somatoform disorders includes diagnoses such as somatization disorder, undifferentiated somatoform disorder, conversion disorder, pain disorder, hypochondriasis, and body dysmorphic disorder.

Description

The term "somatoform disorder" has been introduced by DSM-III (*Diagnostic and Statistical Manual of Mental Disorders*, 3rd version) as a category for a group of diagnoses. The common feature of somatoform disorders is the presence of physical symptoms that could indicate a general medical condition, but the physical symptoms are not fully explained by a well-known biomedical disease, by the direct effects of a substance, or by another mental disorder (e.g., panic disorder, depression). Symptoms must cause clinically significant distress or impairment. Somatoform disorders have to be distinguished from factitious disorders and malingering; the physical symptoms in somatoform disorders are not intentional or imagined, but patients perceive these symptoms similar to other physical symptoms caused by medical conditions.

The group of somatoform disorders includes diagnoses such as somatization disorder, undifferentiated somatoform disorder, conversion disorder, pain disorder, hypochondriasis, and body dysmorphic disorder. Somatization disorder is the prototype for patients suffering from many physical complaints including pain symptoms, gastrointestinal symptoms, sexual symptoms, and pseudoneurological symptoms. In DSM-IV, the onset of symptoms was required before age 30 years, and the diagnosis was only justified if symptoms persisted over a period of several years. The criteria for this diagnosis have been criticized because somatization disorder does not include the majority of patients with multiple somatoform symptoms, as the diagnosis is over-exclusively defined. Therefore many patients fall under the diagnosis of "undifferentiated somatoform disorder," which only requests one or more physical complaints that are medically unexplained. Both diagnoses cannot only be used in the absence of medical conditions, but these diagnoses are also justified if general medical conditions do not fully account for all somatic symptoms presented by the patient. While most people suffer from somatic symptoms from time to time, a diagnosis of somatoform disorder should be only given if the symptoms cause clinically significant distress or impairment. A diagnosis of conversion disorder is justified if people suffer from motor or sensory symptoms or deficits that are not fully accounted by a medical condition. Hypochondriasis ("fears and worries about illnesses") and body

dysmorphic disorder ("preoccupation with an imagined defect in appearance") are disorders that are considered to indicate an overlap with anxiety disorders/OCD (obssessive-compulsive disorders). Pain disorder is also classified under somatoform disorders, although many pain conditions are associated with both psychological factors and a general medical condition. In fact, in "Western" cultures pain symptoms are the most frequent somatic symptoms. If pain duration is longer than 6 months, it should be considered to be chronic. In most cases, chronic pain conditions are not sufficiently understood with pure biomedical approaches, but psychological and social factors have to be also considered.

Somatoform disorders can develop as a result of the interaction of psychological factors (selective attention to bodily processes, overinterpretation of somatic sensations, illness fears, demoralization) with biomedical factors (e.g., traumatic injuries, car accidents, biological dysregulation of stress and immune responses) and with social factors (e.g., reinforcement of symptom expression by proxies, strong biomedical orientation of health care systems, fears of doctors to overlook biomedical causes). While somatization typically refers to the experience of multiple medically unexplained symptoms, the concept of somatosensory amplification refers to the self-reinforcing circle of attention to somatic processes, overinterpretation of somatic sensations, intensified physical sensations, and behavioral consequences (Barsky, 1992). Somatoform disorders (especially somatization disorder and undifferentiated somatoform disorder) are more prevalent in women than in men. While prevalence rates for diagnoses such as somatization disorder are significantly lower than 1%, general somatoform symptoms can be found in more than 10% of the population (Wittchen & Jacobi, 2005).

The category of somatoform disorders has been criticized (e.g., Mayou, Sharpe, Kirmayer, Simon, & Kroenke, 2005). In some countries, the term "somatoform" was interpreted as indicating "not real symptoms," although the term was originally introduced as a pure descriptive term. For patients with multiple somatic symptoms, the diagnosis "somatization disorder" is overrestrictive (see above). Finally, the classification of "medically explained" versus "medically unexplained" symptoms is unreliable and medical doctors highly disagree in their ratings about causality of somatic symptoms. Some experts criticized that the concept of somatoform disorders further continues a "mind-body separation" instead of favoring a biopsychosocial model. The revision of this category in DSM-V tries to overcome these shortcomings.

To date, no well-founded pharmacological treatment is available for patients with somatoform syndromes. There is some evidence for the use of SSRIs (selective serotonin reuptake inhibitors) in patients with hypochondriasis and body dysmorphic disorders. Psychological interventions (especially behavioral-medical interventions) have been shown to be effective in all groups of somatoform disorders. However, effect sizes vary substantially, with highest effect sizes for the psychological treatment of hypochondriasis, while effect sizes for the treatment of somatization disorder or chronic pain conditions are only in the low to medium range. The rate of overlooked medical conditions that can explain the somatic symptoms does not seem to be increased compared to other mental disorders: Long-term studies reveal that less than 10% of patients with somatoform disorders must be considered to be misdiagnosed (Rief & Broadbent, 2007).

Speech and Language Therapy

Steven Harulow
Royal College of Speech & Language Therapists, London, UK

Synonyms

Speech and language pathology; Speech therapy; Speech, language, and communication therapy

Definition

Speech and language therapy is an evidence-based discipline that anticipates and responds to the needs of individuals who experience speech, language, communication, or swallowing difficulties. Speech and language therapy works in partnership with individuals and their families and with other professions and agencies to reduce the impact of these often isolating difficulties on well-being and the ability to participate in daily life (Royal College of Speech and Language Therapists, 2005).

Speech and language therapists (SLTs) are the lead experts regarding communication and swallowing disorders. This does not mean that others do not work within these areas or that others do not have many skills that may overlap with or complement those of SLTs. Rather, SLTs, through their preregistration education, and later experience, have greater depth and breadth of knowledge and understanding of these clinical areas and associated difficulties. This enables SLTs to lead on the assessment, differential diagnosis, intervention with, and management of individuals with communication and swallowing disorders.

Speech and language therapy assistants and bilingual co-practitioners are integral members of the speech and language therapy team, employed to act in a supporting role under the direction of a professionally qualified SLT.

Description

A wide range of individuals can potentially benefit from speech and language therapy, including:

- Babies with feeding and swallowing difficulties
- Children (from neonates to school age), adolescents, and adults with special needs in communication, communication disability, and/or swallowing disorders associated with diagnosed impairments, genetic and medical conditions, trauma, developmental delays, mental health problems, and learning disability
- Children (from neonates to school age), adolescents, and adults with special needs in the following areas: speech, voice, fluency, language, psychologically based communication disorders, social skills, problem solving, literacy, swallowing functions, and alternative and augmentative communication (AAC)

- Parents and families, caregivers, communication partners, friends, and colleagues of people with communication and swallowing disorders

Speech and language therapists work in and across a variety of settings.

Within education, these settings include:

- Local education authority nurseries and schools (mainstream and special)
- Language and communication units and colleges of further education
- Independent nurseries and schools
- Play groups
- Government-funded initiatives

Within health and social care, settings include:

- Hospitals inpatient and outpatient centers and hospices
- Specialist centers: child development centers, rehabilitation centers, specialist joint consultative clinics
- Primary care: community clinics, community day centers
- Supported living homes
- Mental health services
- Initiatives in areas of social deprivation (such as Sure Start)

Speech and language therapists have an increasing role within the legal system, including within the penal system/prisons, in court tribunals, and as part of adult and child protection services.

They also work in independent practice, as part of social enterprises and for the voluntary/charitable sector.

All speech and language therapy intervention is delivered on the basis of ongoing assessment and review of progress with the individual (and/or carer as appropriate) as measured against targeted outcomes. Various approaches or models of working have been developed to meet the needs of individuals and context.

The following are key principles guiding the provision of services:

- The rights, wishes, and dignities of each individual and their carers are respected at all times.
- Effective intervention is based on a holistic understanding of the individual, including their social, cultural, economic, political, and linguistic context.
- The safety of the individual is paramount.
- Speech and language therapy intervention aims to be efficient and effective, i.e., best results against targeted outcomes within given resources.

Speech and language therapy services may operate at the level of the person (working with individuals); the level of their environment (working with people, processes, or settings); and the level of the wider community (influencing attitude, culture, or practice). The form of intervention will vary according to the changing needs of the individual and contexts.

Benefits

Speech and language therapy can contribute to the following health, educational, and psychosocial benefits:

- Improvement in general health and well-being
- Increased independence
- Improved participation in family, social, occupational, and educational activities
- Improved social and family relationships
- Reduction in the negative effects of communication disability and the harm or distress this may cause to the individual and others
- Reduced risk of surgical intervention and poor nutrition in the case of individuals with swallowing disorders
- Reduced health risks and length of hospital stay through the prevention of respiratory problems associated with swallowing difficulties
- Reduced risk of surgical intervention by maintaining healthy voice mechanisms
- Reduced risk of educational failure
- Reduced risk of social isolation
- Prevention of certain speech, language, and communication disorders

Outcomes

The outcomes of speech and language therapy include:

- Diagnosis of communication and/or swallowing disorders
- Maintenance of optimal communication and/or swallowing abilities

- Improvement in the speech, language, and communication abilities of individuals
- Improved use of existing function
- Reduction of communication anxiety and avoidance
- Provision and use of AAC where oral communication is limited or precluded by a physical condition
- Improvement in interaction and effective social communication
- Increased awareness of others about communication and/or swallowing disorders, intervention, and management
- Improved communication environment
- Greater opportunities for communication
- Improvement in the individual's understanding of the nature and implications of a communication and/or swallowing disorder

In 2010, the Royal College of Speech and Language Therapists (RCSLT) commissioned analysts Matrix Evidence to review the existing evidence and undertake an economic evaluation of the provision of speech and language therapy to four specific client groups. The aim of this was to pinpoint the benefits generated by speech and language therapy in relation to the costs of provision. The result was the UK-wide study "The economic case for speech and language therapy" (Marsh et al., 2010).

The Matrix research aimed to determine the costs and benefits for four common speech and language therapy client groups:

- Adults with dysphagia post stroke
- Adults with aphasia post stroke
- Children with speech and language impairment (SLI)
- Children with autism

Matrix Evidence undertook an evaluation of the costs and benefits of speech and language therapy intervention for each condition and compared either the effects of speech and language therapy with the effects of alternative forms of treatment, or the effects of intensive against less intensive therapy. Specifically, the analysis evaluated:

- Speech and language therapy for stroke survivors with dysphagia compared with "usual" care
- Enhanced NHS speech and language therapy for stroke survivors with aphasia compared with usual NHS therapy
- Enhanced speech and language therapy for children with SLI compared with existing therapy provision
- Enhanced speech and language therapy for children with autism compared with usual SLT treatment

The results of the Matrix report show that speech and language therapy for all four cohorts and conditions represents an efficient use of public resources. The net benefits of the interventions – including health and social care cost savings, quality of life, and productivity gains – are positive and exceed their costs. The report shows the total annual net benefit across aphasia, SLI, and autism is £765 million; it excludes dysphagia from the calculation since the two poststroke conditions are not mutually exclusive.

The RCSLT

Established as the College of Speech Therapists in 1945, the Royal College of Speech and Language Therapists (RCSLT) is the membership organization for UK SLTs, providing and promoting:

- Support and professional leadership for members, including the setting of standards
- Strategic direction for the profession
- Consistent, effective, and accurate professional representation to external bodies and the government
- Heightened public awareness of the medical, social, and emotional effects of communication, eating, drinking, and swallowing difficulties
- Heightened awareness of the contribution of speech and language therapy with the public, government, other professions, and the media

The RCSLT provides leadership so that issues concerning the profession are reflected in public policy and people with communication, eating, drinking, or swallowing difficulties receive optimum care.

Religious beliefs; Spirituality

Definition

The concept of spiritual beliefs is a critical component of the broader terms *spirituality* or *religiousness* and is to some degree inseparable from them. The meanings of these terms, however, remain elusive. In fact, the paramount importance, and difficulty, with defining spiritual concepts has proven a prominent obstacle to establishing a cohesive body of literature. The empirical research is littered with varying, and sometimes incompatible, ways of understanding spiritual constructs (Hill & Pargament, 2003; Kapuscinski & Masters, 2010). Researchers disagree, for example, regarding the relationship of religiousness and spirituality. This issue takes on special significance when *beliefs* in particular are the subject of consideration because Western notions of religion often differentiate believers from unbelievers based on their convictions (beliefs), rather than behaviors. Historically, spirituality and religiousness were considered to be,

if not the same entity, intimately tied to one other. One's personal ideas about and experiences of the sacred were both informed by and occurred in the context of institutional religious beliefs and practices. In recent years, however, a growing minority of Americans have begun to identify themselves as "spiritual but not religious." The distinction often involves the term spiritual being used to signify personal beliefs or experiences of the sacred, apart from traditional religious doctrine and organizations. Interestingly, although most people recognize religion and spirituality as somewhat different concepts, they also see the terms as sharing much in common, including traditional religious concepts of God, Christ, and the church (Zinnbauer, Pargament & Scott, 1999).

Some researchers have taken the connotation of spirituality as an individual's internal communion with the transcendent and sharply separated it from the idea of religiousness now defined narrowly as involvement with organized beliefs and practices (Hill & Pargament, 2003; Zinnbauer et al., 1999). In some cases, the supernatural or sacred is completely removed from the notion of spirituality or spiritual beliefs, leaving a search for meaning or perspective that is unrelated to the transcendent. Some researchers (Kapuscinski & Masters, 2010; Koenig, 2010) do not support this separation on several grounds, including that the removal of the sacred creates a somewhat artificial notion of spirituality, devoid of any substance that separates it from mental health variables like optimism and purpose in life. Therefore, the conceptual state of affairs on these topics does not allow spiritual beliefs to be cleanly separated from spirituality or religiousness. All of these concepts overlap significantly.

Nevertheless, despite the overlap, thematic elements in the literature suggest that spiritual beliefs per se may be defined as convictions about self, others, and the world, which emerge from a search for the transcendent or sacred, and include the values regarding lifestyle and moral conduct derived from these convictions. Spiritual beliefs may be roughly synonymous with the notion of spiritual worldview, the basis of which is a belief in the transcendent. Beliefs may or may not include doctrine associated with religious institutions (e.g., that an omnipotent God created the universe, as in the Judeo-Christian tradition).

Description

Most of the questionnaires designed to assess spirituality emphasize beliefs as a critical element of what is measured, and a few, like the Beliefs and Values Scale (King, Barnes, Low, Walker, Wilkinson, Mason, et al., 2006) and the Royal Free Interview for Spiritual and Religious Beliefs (King, Speck, & Thomas, 2001), focus on beliefs specifically. Thus, consistent with the discussion above, the spiritual beliefs component of religiousness and spirituality (R/S) is strongly embedded in research findings on R/S, even when studies do not claim to focus specifically on beliefs. A wealth of evidence demonstrates that both R/S in general, and sometimes beliefs in particular, influence physical and mental health.

Physical Health

Available research generally indicates a relationship between R/S variables and better physical health and implicates the value of incorporating this aspect of culture into health-promoting interventions. Masters and Hooker (2011) provide an overview of the R/S and health literature. Religious service attendance stands out as a variable that consistently predicts mortality. Frequent attendees are at reduced risk of mortality compared to those who never attended services, even when standard controls are included, and the relationship is especially strong for African Americans. Importantly, this relationship appears to transcend culture, with research demonstrating that R/S serves as a protective factor against mortality in a variety of countries, including non-Western societies such as China and Israel. In this light, it is very important to note that service attendance does not measure spiritual beliefs per se. Nevertheless, the literature also indicates that spiritual beliefs are related to improved outcomes for seriously ill individuals.

In cancer patients, for example, spiritual beliefs predict positive psychological adjustment and higher rates of perceived cancer-related growth. Studies also indicate spiritual beliefs and practices may be helpful for cardiac patients, putting them at reduced risk of morbidity, complications, and depression following surgery. However, the relationship between R/S and health is complex, with some studies indicating a detrimental relationship between certain R/S variables and health outcomes. For instance, cardiac patients who viewed God as responsible for their *illnesses* had more difficult recoveries, whereas individuals who attributed their recoveries to God enjoyed better outcomes. Psychologists have theorized several pathways to explain the relationship between R/S and health variables, including the idea that R/S is associated with increased social support, positive coping skills, and the adoption of a healthy lifestyle (e.g., abstinence from smoking and alcohol use, regular exercise, and utilization of preventative health care).

Mental Health

The vast majority of research also indicates a positive association between mental health and spiritual beliefs (Koenig, 2010). Individuals scoring higher on measures of spirituality are consistently less likely to have depressive symptoms or disorders, with an effect equivalent in size to that of gender and depression. Similarly, many studies indicate that anxiety is lower for individuals who are more spiritual and that spiritually based interventions result in reduced anxiety. However, the results are mixed – with some research indicating a positive correlation between certain spiritual variables (e.g., spiritual struggle) and anxiety. The relationship between spiritual beliefs and substance use is less ambiguous, with the preponderance of evidence indicating that more spiritual individuals are significantly less likely to engage in substance use, misuse, and abuse.

Despite marked disagreement regarding conceptualization of spiritual constructs, the interaction (whether beneficial or detrimental) of spiritual beliefs with both physical and mental health highlights the significance of recognizing this dimension of human experience in both the science and practice of psychology.

Definition

Spirituality is a very unclear concept that has no concrete definition. By its very nature, the concept of spirituality is deeply rooted in religion, yet in contemporary spirituality, there is an incremental divide emerging between religion and spirituality. Therefore, in present-day society, the formation of a dichotomy with spirituality representing the personal, subjective, inner-directed, unsystematic, liberating expression, and religion signifying a formal, authoritarian, institutionalized inhibiting expression is being witnessed. Spirituality has also been defined as a subjective and fluid approach to experiences which leads one to search for enlightenment whereby behaviors are practiced in accordance with these sacred beliefs. Similarly, one can also consider spirituality to be something personal, which is defined by individuals themselves and is mostly likely devoid of the rules and regulations associated with religion.

Description

Pathways Linking Spirituality to Health

Rendering a congruent spiritual outlook on life has been associated with an enhanced quality of life, better mental and physical health, and improved recovery from various illnesses. However, the precise mechanisms behind these relationships remain unclear. This can be partly attributed to several reasons: first, the lack of a clear conceptual definition of what spirituality is; second, researchers using both concepts of religion and spirituality interchangeably; third, measuring both concepts with similar assessments (e.g., denomination and frequency of religious observance) which clearly are not adequate to capture a measure of one's spiritual beliefs. Finally, there is a social acceptance that being spiritual entails performing soothing activities such as mediation, yoga or praying, etc., which may be tied to social interactions. Thus, it is necessary to distinguish social factors involved in these practices from spirituality itself. All of the above make it difficult to draw any firm conclusions; thus, caution must be warranted when interpreting the data from such studies. Nonetheless, a number of pathways linking spirituality and health have been proposed, from direct physiological mechanisms (e.g., immune functioning) to more indirect stress buffering (e.g., coping strategies) and lifestyle choices (e.g., dietary and exercise behaviors coupled to one's spiritual beliefs) (Miller & Thorensen, 2003). For example, a positive correlation between spirituality and T-cells percentages in HIV positive women has been reported, suggestive of a more direct physiological route, while other studies support a more indirect pathway; spiritual beliefs have been found to be linked to lower stress, better nutrition, and more exercise, all of which are associated with positive health indices (Koenig McCullough, & Larson, 2001). However, what is more interesting is the strong evidence coming from intervention research; a number of studies have been conducted along this line, but one study found that those taught spiritual meditation had greater decreases in anxiety, negative affect, and frequency of migraine headaches compared to those who practiced internally focused secular meditation, externally focused secular meditation, or muscle relaxation

(Wachholtz & Pargament, 2009). Taken together, these studies indicate that spirituality influences health and that interventions targeting this concept can bring health benefits.

However, despite these positive benefits, a word of caution is warranted when investigating these relationships as there is also negative health consequences associated with spirituality. For example, a spiritual struggle denotes the anxiety and pressure about spiritual concerns inside oneself, with others, and the godly. Indeed, this spiritual struggle is associated with poor mental and physical health among suffers in some traditional faith practices (Rosmarin, Pargament, Flannelly, & Koenig, 2009); hence, it is sometimes difficult to determine whether spirituality is a resource or a liability and adds to the complexity that already exists in this spirituality-health relationship, which in some instances may not be linear. Further, there have been attempts to adopt the concept of spirituality into an overall definition of health, and some now argue that spiritual health and growth are equally important for quality of life (Sawatzky, Ratner, & Chiu, 2005); thus, spirituality can now be viewed and measured as an endpoint itself.

Measuring Spirituality

Measuring spirituality is a very difficult task due to lack of agreed upon definition and its close knit ties with religion. However, there have been some admirable attempts to capture the concept using self-report methods, and some of the measures include the Daily Spiritual Experience Scale (Underwood & Teresi, 2002), the Spiritual Well-being Scale (Paloutzian & Ellison, 1991), the Theistic Spiritual Outcome Survey (Richards et al., 2005), and both the Spiritual Transcendence Scale (Piedmont, 1999), and the Beliefs and Values Scale (King et al., 2006) offers a conceptualization of spirituality which is nonreligious; these may be useful when one is dealing with individuals who are more inclined to adopt a contemporary view of spirituality.

Definition

Spirituality is an elusive term for which definitional consensus has yet to be reached. Many definitions include concepts concerning that which is beyond the material world and may include features of life that are not commonly perceptible by the physical senses. This is sometimes said to include a search for the sacred or belief in the transcendent. Common themes in definitions of spirituality include connectedness or relationship, subjectivity, personal experience, behaviors reflecting sacred or secular beliefs, and belief in something transcendent. This entry regards spirituality as related to health, an area of significantly increased research activity over the last 15–20 years.

Description

Over the last 15–20 years, scholars have become significantly more interested in determining if there is a relationship between spirituality and health, what the strength of this relationship might be, and if the relationship varies depending on the specific dimensions of both spirituality and health under consideration. Clearly both spirituality and health are multidimensional constructs, and thus, any general statement on their relationship will be an oversimplification.

The first major problem that investigators have in this area is, indeed, defining both terms. In this entry, the definitional focus is on spirituality. An important first question pertains to the similarities and differences between religion and spirituality. Most scholars currently agree that they are related, but not synonymous constructs. This understanding diverges from the historic conceptualization that viewed spirituality and religion as indivisible entities but coincides temporally with the increasing secularization of Western culture (Zinnbauer, Pargament, & Scott, 1999). Compared to spirituality, religion is often viewed as including more organized social or group practices with well-defined rituals, doctrinal creeds, and statements of faith. Spirituality, on the other hand, is thought to be more subjective and personal, lacking in the organizational elements that characterize religion. Shahabi et al. (2002) reported that 10% of individuals in a US national stratified sample classified themselves as spiritual, but not religious. Nevertheless, most highly religious individuals note that their spirituality is pursued within the context of their religion. Further, a common theme for definitions of both religion and spirituality is reference to a higher power, and 70% of spirituality definitions referred to traditional concepts of God, Christ, and the church as constituting what is sacred (Zinnbauer et al., 1997). Based on a review of the nursing literature, Emblen (1992) defined spirituality as "a personal life principle which animates a transcendent quality of relationship with God" (p. 45). More recently, Saucier and Skrzypinska (2006) demonstrated that subjective spirituality and tradition-oriented religiousness are empirically independent and correlate quite distinctly with personality dimensions. It has also been observed that neither spirituality nor religiousness can be simply reduced to a commonly measured personality variable (Piedmont, 1999; Saroglou & Muñoz-García, 2008; Saucier & Skrzypinska, 2006).

Given the definitional problems with spirituality, it is not surprising that there are measurement concerns as well. Recently, Kapuscinski and Masters (2010) reviewed work in this area. They not only observed the lack of

definitional consensus and related measurement confusion but also suggested that, given the dearth of lexical studies of spirituality, it is quite likely that the spiritual construct as defined by researchers differs from popular understanding and use of the term.

Clearly, these basic problems limit the extent that strong statements can be made regarding spirituality and health. At this point, most of the research has not focused on spirituality per se, as differentiated from religiousness, but rather has used measures such as religious service attendance as proxies for spirituality or has confounded religion and spirituality often using the R/S naming convention to represent both simultaneously and therefore demonstrate that no attempt at conceptual separation was made. There is significant research suggesting that some practices that are often associated with spirituality or considered behavioral indicators of spirituality can be effective. For example, meditation has a strong history of beneficial findings in the area of stress management and has been an important component in some major lifestyle interventions such as the Ornish Lifestyle Heart Trial (Ornish et al., 1983, 1990). Nevertheless, intervention studies that include a specifically spiritual intervention are almost nonexistent, and observational research, even if longitudinal, is severely limited in considering cause and effect relations. For example, it is clear that people tend to pray more when they are ill (negative relationship with health), but it is quite likely that it is the illness that is "causing" the increase in prayer rather than prayer having a negative impact on health. Investigations on frequency of prayer and health are, at this point, nonconclusive and largely characterized by cross-sectional research designs of self-report data. A few studies have investigated the content of prayer and found that, for example, self-esteem is higher among older adults when they pray, believing that only God knows when and how to best answer prayer (Krause, 2004). Krause (2003) also found that prayer for material things did not alleviate the burden of financial strain on physical health. But these are very preliminary findings, and much work in this area remains.

Finally, there are many behavioral and cognitive practices that could be considered either spiritual or not spiritual depending on how they are conceptualized and contextualized. These include concepts such as gratitude, forgiveness, relaxation, compassion, hope, optimism, faith, and connectedness among others. The extent that these may be considered aspects of spirituality depends on many factors notably the extent to which they are conceptualized as aspects of relating to the transcendent or sacred.

Spirituality, Measurement of

Afton N. Kapuscinski
Psychology Department, Syracuse University, Syracuse, NY, USA

Definition

Quantitative assessment of spirituality, typically in the form of self-report questionnaires.

Description

Measuring spirituality poses a serious challenge to research in the psychology of religion and spirituality. The principal source of difficulty is researchers' inability to reach a consensus on how to define spirituality, especially regarding its relationship to the concept of religiousness (Kapuscinski & Masters, 2010). As language in the United States has shifted over the past few decades, such that religion and spirituality are no longer considered to be synonymous, researchers have created instruments intended to measure spirituality as a concept distinct from religiousness. However, the definitions used to generate measures of spirituality are highly diverse, resulting in some instruments that appear to share little overlap in content (Kapuscinski & Masters, 2010). For instance, some measures define spirituality using language stemming from traditional religious institutions (e.g., "God"), whereas others include no reference to the transcendent or sacred in their conceptualizations. An additional concern is that some themes in the way researchers tend to understand spirituality stand in contrast to how the term is used in common language by the general public (Hill & Pargament, 2003; Zinnbauer, Pargament & Scott, 1999). Specifically, researchers tend to sharply divide spirituality from religion, such that religion is considered to be comprised of external behaviors (e.g., religious service attendance) and is associated with formal institutions, whereas spirituality is comprised of personal, inner experience that is separate from organized religion. Further, researchers are inclined to view spirituality as a health-promoting quality associated with positive psychological and societal benefits, and religiousness, in contrast, is perceived to be restrictive and unhealthy. The empirical literature, however, indicates that non-researchers regard the concepts as overlapping considerably and view both religiousness and spirituality as positive qualities. Moreover, researchers' connotations are not consistent with research linking both religion and spirituality to positive mental and physical health outcomes (Masters & Hooker, 2011).

Further, theoretical concerns arise regarding the feasibility of quantifying and operationally defining a concept that seems to be, by its nature, highly experiential and personalized. The literature indicates that like researchers, individuals differ in how they understand spirituality (Zinnbauer et al., 1999). Interestingly, the majority of researchers do not consult participants regarding conceptualization of spirituality when developing new measures (Kapuscinski & Masters, 2010). Miller and Thoresen (2003) comment that from the believer's perspective, scientists can at best explore mere reflections of

spirituality, which approximate but never fully capture its essence.

The disagreement regarding how to conceptualize spirituality is implied by the sheer number of available spirituality instruments. Reviews of measures (Hill & Hood, 1999; MacDonald, LeClair, Holland, Alter, & Friedman, 1995; MacDonald, Friedman, & Kuentzel, 1999) indicate that over 100 measures exist that are designed to measure a variety of spiritual constructs, including spirituality, intrinsic spirituality, spiritual experiences, spiritual meaning, spiritual development, spiritual transcendence, spiritual transformation, and spiritual well-being. Most measures appear to address interest in or search for the sacred and focus on assessing cognitive (e.g., meaning, beliefs, values) or emotional (e.g., peace, hope, connection) experiences associated with the sacred. Several high-quality measures should be considered as appropriate for use in health psychology research. The FACIT Spiritual Well-Being Scale (Peterman, Fitchett, Brady, Hernandez, & Cella, 2002) was designed specifically to assess aspects of spirituality relevant to quality of life for chronically ill individuals. The Daily Spiritual Experiences Scale (Underwood & Teresi, 2002) includes language that is relevant to individuals from various faith traditions and has demonstrated a relationship to important health variables such as alcohol consumption and depression. Additionally, the Spiritual Transcendence Scale (Piedmont, 1999), which does not include language associated with institutional religion, is noteworthy for its high-quality scale development and validation practices and includes an observer report form. When selecting a measure for use, researchers should carefully consider whether or not the content of scale items is consistent with the conceptualization of spirituality relevant to their study and population of interest.

Stages-of-Change Model

Jonathan A. Shaffer
Department of Medicine/Division of General Medicine, Columbia University Medical Center, New York, NY, USA

Definition

The Stages-of-Change Model was developed by James Prochaska and Carlo DiClemente as a framework to describe the five phases through which one progresses during health-related behavior change (Prochaska & DiClemente, 1983). It is part of their broader Transtheoretical Model, which not only assesses an individual's readiness to act to eliminate a problem behavior but also includes strategies and processes of change to guide the individual through the stages. The Stages-of-Change Model originated in research related to psychotherapy and the cessation of addictive behaviors, such as smoking, alcohol and substance abuse, and issues related to weight management (Buxton, Wyse, & Mercer, 1996). Although Prochaska and DiClemente initially hypothesized that individuals progress linearly through a series of discrete stages of change, researchers now believe that a cyclical or "spiral" pattern more accurately represents how most people change unhealthy behavior over time. Since its development, the Stages-of-Change Model has been related to a variety of problem behaviors, associated with treatment outcomes, and integrated in stage-based interventions. Although most scientists and clinicians agree that the model has heuristic value, it has been criticized by some researchers.

Description

History of the Model

Stage theories have been integral to the field of psychology since its inception and include Freud's and Erikson's psychosexual stages, Kohlberg's stages of moral development, Piaget's stages of cognitive development, and Maslow's hierarchy of needs (Dolan, 2005). DiClemente and Prochaska's Stages-of-Change Model uses language similar to Horn. Specifically, Horn hypothesized four stages of change associated with health-related behavior: (1) contemplating change, (2) deciding to change, (3) short-term change, and (4) long-term change (Horn, 1976). DiClemente and Prochaska initially identified four stages of changes associated with smoking cessation and maintenance: (1) thinking about change (contemplation), (2) becoming determined to change (decision making), (3) actively modifying behavior and/or environment (action), and (4) maintaining new behaviors (maintenance). Precontemplation was later identified as a separate stage preceding contemplation.

Description of Stages

Precontemplation. The individual in the precontemplation stage has no intention to change his or her behavior in the foreseeable future (Prochaska & Norcross, 2001). Although individuals are unaware of their problems, their families, friends, neighbors, and employees are often very aware of these problems. Individuals presenting for treatment in the precontemplation stage generally do so because of pressure from others.

Contemplation. During the contemplation stage, individuals are aware that a problem exists and seriously consider overcoming it. However, they have not yet made a commitment to do so. According to Prochaska and Norcross, individuals often remain stuck in this stage for long periods.

Preparation. The preparation stage combines intention and behavioral criteria. Individuals in the preparation stage intend to enact change in the next month and have unsuccessfully attempted to do so in the past year. These individuals report small behavioral changes, but they have not yet reached a criterion for effective action, such as abstinence from smoking or sufficient weight loss. These individuals do intend to take action in the very near future.

Action. Individuals in the action stage modify their behavior, experiences, and environment in order to overcome their problems. This stage involves the most overt behavioral changes and requires considerable commitment of time and energy. Modifications of the problem behaviors made in this stage are most visible to others and tend to elicit others' recognition. Individuals in this stage must have successfully altered their problem behavior for a period of 1 day to 6 months.

Maintenance. Individuals in the maintenance stage concentrate on preventing relapse and consolidating the gains attended during the previous stage. These individuals must have remained free of their problem behavior and consistently engaged in a new incompatible behavior for more than 6 months.

Termination. Individuals who reach this stage have completed the change process and no longer have to work to prevent relapse. This stage involves total confidence or self-efficacy across all high-risk situations and no temptation to relapse.

Assessing Stages of Change

Multiple ways for measuring stage of change have been proposed and devised, and researchers/clinicians usually assign people to stages on the basis of their responses to questions concerning their prior behavior and current behavioral intentions (Weinstein, Rothman, & Sutton, 1998). A Stages-of-Change Questionnaire has been developed as a brief and reliable instrument for measuring stages of change in psychotherapy and has been adopted to evaluate stages of change for specific problem behaviors (McConnaughy, Prochaska, & Velicer, 1983). This continuous measure includes questions such as "As far as I'm concerned, I don't have problems that need changing" (precontemplation), "I have a problem and I really think I should work on it" (contemplation), "I am working really hard to change" (action), and "I may need a boost right now to help me maintain the changes I've already made" (maintenance). Given that attributes that define the stages of change are mainly internal to the individual (e.g., beliefs, plans, attributions), measurement is often imperfect (Weinstein, Rothman, & Sutton, 1998).

Stages of Change and Specific Health Behaviors

The Stages-of-Change Model has been used to understand a variety of problem behaviors including smoking cessation, cessation of cocaine use, weight control, high-fat food consumption, adolescent delinquent behaviors, risky sexual behaviors, sunscreen use, radon gas exposure, exercise acquisition, mammography screening, and physicians' preventive practices with smokers (Prochaska et al., 1994).

Stage-Based Treatments

The Stages-of-Change Model has been use to aid in treatment planning and to develop stage-based treatments. Prochaska (1991) has argued that a person's stage of change provides proscriptive and prescriptive information about appropriate treatments (Prochaska, 1991). For example, those who are in the preparation or action stages presumably benefit from action-oriented therapies, whereas those in the precontemplation or contemplation stages likely may benefit more from insight-oriented, consciousness raising interventions.

Several interventions based on stage-based models of change have been developed to modify risk behaviors. These interventions are tailored to take into account the current stage an individual has reached in the change process in contrast to "one size fits all" interventions. A systematic review of these interventions identified 37 RCTs of such interventions aimed at smoking cessation, promotion of physical activity, dietary change, multiple lifestyle changes, mammography screening, and treatment adherence (Riemsma et al., 2002). The authors of this review concluded that there is little evidence to suggest that stage-based interventions are more effective compared to non-stage-based interventions, no intervention, or usual care. Nonetheless, they recommend additional studies of tailored interventions which involve frequent reassessment of patients' readiness to change. Reviews of

stage-based lifestyle interventions in primary care (Van Sluijs, Van Poppel, & Van Mechelen, 2004) and stage-based interventions for smoking cessation (Riemsma et al., 2003) have likewise resulted in limited scientific evidence in support of these interventions.

Revised Stages-of-Change Model

Freeman and Dolan (2001) offered a revised Stages-of-Change Model with five additional changes to more precisely determine a psychotherapy patient's position on the continuum of change (Freeman & Dolan). This revised model has been recommended as a more dynamic and flexible one that provides clinicians with a more experience-centered focus from which to make treatment decisions.

Non-contemplation is the stage during which an individual is not considering or even thinking about changing. These individuals do not actively avoid, resist, or oppose change; they are rather unaware of their need to change or of the effect their behavior has on others. Anti-contemplation involves the process of becoming reactive and violently opposed to the notion of needing change, a response often seen in individuals who are legally mandated to attend treatment or who come to treatment at the urging of their family, friends, or significant others. Freeman and Dolan's precontemplation and contemplation stages are identical to those of Prochaska and DiClemente. Their action planning stage occurs when the clinician and patient have collaboratively developed a treatment focus and treatment plan. Patients in this stage are actively willing to plan change, and next progress to the action stage of Prochaska and DiClemente's model. Prelapse, lapse, and relapse stages may then occur prior to the maintenance stage. During prelapse, an individual experiences overwhelming thoughts, desires, and cravings to engage in the problem behavior. During lapse, the skills needed to maintain the action stage decrease or are ignored. During relapse, the individual returns to the problem behavior. As in Prochaska and DiClemente's model, the maintenance stage occurs when the individual actively works toward maintaining the cessation of the problem behavior.

Evaluation of the Stages-of-Change Model

The Stages-of-Change Model is not without criticism. Those who have criticized the model argue that its inherent concept of discrete stages involves arbitrary distinctions; it falsely assumes that individuals make coherent and stable plans, and it neglects the role of reward, punishment, and associative learning that contribute to the maintenance of problem behaviors (West, 2005). Others have found that minimal supportive evidence for the Stages-of-Change Model exists (Whitelaw, Baldwin, Bunton, & Flynn, 2000) and questioned the model's internal validity (Ahijevych & Wewers, 1992; Bandura, 1997; Farkas et al., 1996), external validity (Clarke & Eves, 1997), and ethical difficulties associated with interventions derived from the Stages-of-Change Model (Piper & Brown, 1998).

Notwithstanding the criticisms and absence of evidence discussed above, the Stages-of-Change Model provides a pragmatic framework for practitioners and clinical researchers, and it is intuitively appealing to many in the fields of clinical psychology, behavioral medicine, public health, and other fields. Future research promises to offer improved measurement of stages, qualitative case studies of practitioner utilization, and process-based implementation evaluation of the model in various settings (Whitelaw, Baldwin, Bunton, & Flynn, 2000).

Standard Deviation

J. Rick Turner
Cardiovascular Safety, Quintiles, Durham, NC, USA

Definition

A simple measure of dispersion is the range, the arithmetic difference between the greatest (maximum) and the least (minimum) value in a data set. While this characteristic is easily calculated and useful in initial inspections of data sets, by definition it only uses two of the values in a data set. In a large data set most pieces of numerical information are therefore not used in the calculation of the range, and it is not known whether many data points lie close to the minimum, maximum, or mean, or in any other distribution pattern.

Two more sophisticated measures of dispersion are variance and the standard deviation. These measures are intimately related to each other and take account of all values in a data set. The calculation of variance involves calculating the deviation of each data point from the mean of the data set, squaring these values, and summing them. The process of squaring the deviation is mathematically necessary: If the raw deviations were to be summed they would always sum to zero. However, the squaring process creates the problem that the units of measurement of variance are not the same as the units of measurement of the original data. In the vast majority of cases, the data points in our studies are not simply numbers, but numerical representations of information measured in certain units. For example, a systolic blood pressure measurement of "125"

is actually a measurement of 125 millimeters of mercury (mmHg). Since the calculation of variance involves squaring certain values, the variance of a set of blood pressure data points would actually be measured in squared millimeters of mercury, a nonsensical unit.

Fortunately, this problem can be solved by simply calculating the square root of the variance. The resulting value is called the standard deviation (SD), and the unit of measurement of the SD is the same as the unit of measurement of the original data points. The SD is a very commonly presented descriptor in research studies. It is usually presented in conjunction with the mean in the form "mean ± SD."

Standard Normal (Z) Distribution

J. Rick Turner
Cardiovascular Safety, Quintiles, Durham, NC, USA

Synonyms

Z distribution

Definition

The Standard Normal distribution, also known as the Z distribution, is one particular form of the Normal distribution in which the mean is zero (i.e., 0) and the variance is unity (i.e., 1). This can be written as ($\mu = 0, \sigma = 1$).

Before presenting the Z distribution, it is necessary to discuss the Normal distribution in general. Imagine that the heights of a large number of adult males (or females) are measured and the results plotted as a histogram. Height is plotted in inches on the x-axis and the number of people within each height category is plotted on the y-axis. There would be many more people close to the middle of the histogram than close to either end, since more individuals are close to the mean height, and very few are very tall or very short. Given a large sample and decreasingly thin bars in the histogram (that is, the width of the measurement intervals along the *x*-axis becomes infinitely small such that the height data become continuous), a curve can be superimposed on this histogram. One particular version of a density curve is called the Normal distribution. This distribution is of considerable interest since height and many physiological variables conform very closely (but not perfectly) to this distribution. Since the word normal is used in everyday language, and since its meaning in Statistics is different and important, the word is written in this entry with an upper case N when it is used in its statistical sense.

The Normal distribution has several notable properties:

- The highest point of the Normal curve occurs for the mean of the population. The properties of the Normal distribution ensure that this point is also the median value and the mode.
- The shape of the Normal curve (relatively narrow or relatively broad) is influenced by the standard deviation (SD) of the data. The sides of the curve descend more gently as the standard deviation increases and more steeply as it decreases.
- At a distance of approximately ±2 SDs from the mean, the slopes of the downward curves change from a relatively smooth downward slope to a curve that extends out to infinity and thus never quite reaches the *x*-axis. For practical purposes, the curve is often regarded as intercepting the *x*-axis at a distance of ±3 SDs from the mean, but this is an approximation.

Area Under the Normal Curve

The area under the Normal curve is of considerable interest in the discipline of Statistics. That is, it is of considerable interest to define and quantify the area bounded by the Normal curve at the top and the *x*-axis at the bottom. This area will be defined as

1.00, or as 100%. Given this interest, the final bullet point in the previous list raised an issue that appears problematic. That is, it appears that, if the two lower slopes of the Normal curve never quite reach the *x*-axis, the area under the curve is never actually fully defined and can therefore never be calculated precisely. Fortunately, this apparent paradox can be solved mathematically.

The solution is related to the observation that the sum of an infinite series can converge to a finite solution. An example that effectively demonstrates the solution here is the geometric series "1/2 + 1/4 + 1/8 + . . . *ad infinitum*." That is, the series starts with 1/2, and every subsequent term is one half of the previous term. Given this, the terms of the series never vanish to zero. However, the sum of them is precisely 1.00. The proof of this is as follows, where the series is represented as *S*:

$$S = 1/2 + 1/4 + 1/8 + \ldots ad\ infinitum \quad (1)$$

Both sides of this equation are then multiplied by the same value, namely, 2 (multiplying both sides of an equation by a constant means that the sides are still of equal value):

$$2S = 1 + 1/2 + 1/4 + \ldots ad\ infinitum \quad (2)$$

The value *S* is then subtracted from both sides (subtracting a constant from both sides of an equation means that the sides are still of equal value). First, consider the left-hand side (LHS) of Eq. 2:

LHS of Eq. 2: $2S - S$, which equals S

Now consider the right-hand side (RHS) of Eq. 2. Subtracting *S* from this quantity can be represented as:

RHS of Eq. 2: (1 + 1/2 + 1/4 + . . . *ad infinitum*) − *S*, which equals what, exactly?

To determine the unknown value we can use Eq. 1, which shows that *S* is equal to (1/2 + 1/4 + 1/8 + . . . *ad infinitum*). Therefore, the right-hand side of Eq. 2 can be written as follows:

RHS of Eq. 2: (1 + *S*) − *S*, which equals 1

Equation 2 can therefore be rewritten as:

$$S = 1$$

Therefore, despite the initial paradoxical nature of the statement, it can indeed be shown that the sum of an infinite series can converge to a finite solution.

Returning to the topic of immediate interest, i.e., the area under the Normal curve, the statement that the terms of the geometric series never vanish to zero can be reinterpreted in this context as saying that the curves of the Normal curve never intercept the *x*-axis. Despite this statement, however, an adaptation of the proof just provided shows that the area under the Normal curve is indeed precisely equal to 1.00, or 100%. The visual equivalent of this is that there is indeed a defined area under the Normal curve, bounded by the curve and the *x*-axis, and the value of this area can be represented as 1.00, or 100%. This can be demonstrated formally using integral calculus. It can also be thought of as analogous to the statement that the probability of all mutually exclusive events must sum to 1.00.

It is of particular interest in Statistics that the means of many large samples taken from a particular population are approximately distributed in this Normal fashion, i.e., they are said to be Normally distributed. This is true even when the population data themselves are not Normally distributed. The mathematical properties of a true Normal distribution allow quantitative statements of the area under the curve between any two points on the *x*-axis. It was just demonstrated that the total area under the Normal curve is 1, or 100%. It is also of interest to know the proportion of the total area under the curve that lies between two points that are equidistant from the mean. These points are typically represented by multiples of the standard deviation (SD). From the properties of the mathematical equation that governs the shape of the Normal curve, it can be shown that:

- The central 90% of the area under the curve lies between the mean ±1.645 SDs
- The central 95% of the area under the curve lies between the mean ±1.960 SDs
- The central 99% of the area under the curve lies between the mean ±2.576 SDs

The area under the curve is representative of the number of data points falling within that

range. That is, the percentage of the area under the curve translates directly into the percentage of data points falling between the two identified points. Of particular relevance for many research studies is that 95% of the area under the curve lies between the mean ±1.960 SDs. The value of 1.960 is often rounded up to 2, leading to the statement in many practical examples in textbooks that 95% of the data points fall within the mean ±2 SDs.

The Z Distribution

The Z distribution is such that the mean and the standard deviation in the immediately preceding statements can be removed, leading to the following statements:

- The central 90% of the area under the curve lies between ±1.645.
- The central 95% of the area under the curve lies between ±1.960.
- The central 99% of the area under the curve lies between ±2.576.

This distribution is used extensively in Statistics, and underpins many more complex statistical procedures (Durham & Turner, 2008).

Statins

Ken Ohashi
Department of General Internal Medicine, National Cancer Center Hospital, Chuo-ku, Tokyo, Japan

Synonyms

HMG-CoA reductase inhibitors

Definition

Statins, also known as HMG-CoA reductase inhibitors, are a class of cholesterol lowering agents that are prescribed worldwide to hyperlipidemic patients who are at high risk for cardiovascular disease. Statins currently on the market include pravastatin, simvastatin, fluvastatin, atorvastatin, rosuvastatin, and pitavastatin. Statins exert their effect through inhibition of 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase, the rate-limiting enzyme of cholesterol biosynthesis in the liver. In many clinical trials, statins have been beneficial both in the primary and secondary prevention of coronary heart disease. Recent clinical and experimental data suggest that the benefit of statins may extend beyond their lipid lowering effects. Those cholesterol-independent or "pleiotropic" effects of statins involve improving endothelial dysfunction, enhancing the stability of atherosclerotic plaques, decreasing oxidative stress and inflammation, and inhibiting the thrombogenesis.

Statistical Inference

J. Rick Turner
Cardiovascular Safety, Quintiles, Durham, NC, USA

Synonyms

Inferential statistics

Definition

Statistical inference is a process of using the precise data and results from a specific group of subjects in a research study to infer the likely responses to the same treatment in the general population of patients who would receive the treatment or intervention if it entered general behavioral medicine practice.

The ultimate purpose of the results from a single behavioral medicine study, such as a randomized clinical trial, is not to tell us precisely what happened in that trial, but to gain insight into likely responses to the behavioral treatment or intervention in patients with the disease or condition of clinical concern who would receive the treatment. Inferential statistics allows us to do this.

The treatment effect calculated from the data in the single study is regarded as the treatment effect point estimate. Confidence intervals are then placed around this point estimate. The range of values between the lower limit and the upper limit of the confidence interval represents a range that covers the true but unknown population treatment effect with a specified degree of confidence.

Statistics

J. Rick Turner
Cardiovascular Safety, Quintiles, Durham, NC, USA

Definition

For present purposes, the discipline of Statistics (recognized here by the use of an upper case "S") can be usefully defined as an integrated discipline that is critically and fundamentally important in all of the following activities associated with clinical research in behavioral medicine:

- Identifying a research question that needs to be answered.
- Deciding upon the design of the study, the methodology that will be employed, and the numerical information (data) that will be collected.
- Presenting the design, methodology, and data to be collected in a study protocol. This study protocol specifies the manner of data collection and addresses all methodological considerations necessary to ensure the collection of optimum quality data for subsequent statistical analysis.
- Identifying the statistical techniques that will be used to describe and analyze the data in a section within the protocol or in an associated statistical analysis plan, which should be written in conjunction with the study protocol.
- Describing and analyzing the data. This includes analyzing the variation in the data to see if there is compelling evidence that the treatment is safe and effective. This process includes evaluation of the statistical significance of the results obtained and, very importantly, their clinical significance.

- Presenting the results of a clinical study to the research and clinical communities in conference talks and posters, and in journal publications.

Stem Cells

Keiki Kumano
Department of Cell Therapy and Transplantation Medicine, The University of Tokyo, Bunkyo-ku, Tokyo, Japan

Definition

Stem cells are found in all multicellular organisms. They are defined by the ability to renew themselves through mitotic cell division (self-renewal) and to generate all the differentiated cell types of the tissue (multipotency). For this definition, one stem cell divides into one father cell that is identical to the original stem cell and another daughter cell that is differentiated.

The mammalian stem cells are divided into two broad types: embryonic stem cells and adult somatic stem cells. Embryonic stem cells are isolated from the inner cell mass of blastocysts, and adult somatic stem cells that are found in adult tissues. In a developing embryo, stem cells can differentiate into all of the specialized embryonic tissues. The stem cells can become any tissue in the body, excluding a placenta. Only the morula's cells are totipotent, able to become all tissues and a placenta.

In adult organisms, stem cells and progenitor cells act as a repair system for the body, replenishing specialized cells, but also maintain the normal turnover of regenerative organs, such as blood, skin, or intestinal tissues. In addition to the definition described above, adult stem cells are thought to be quiescent within the niche, dividing infrequently to generate one stem cell copy and a rapidly cycling cell (transient amplifying cell). Transient amplifying cells undergo a limited number of cell divisions and differentiate into the functional cells of the tissues.

Recently, the third stem cells, artificially established, induced pluripotent stem cells (iPSCs) are generated. Previously, nuclear transfer of embryo into the adult somatic cells is known to be able to reprogram the somatic cells. These are not adult stem cells but rather reprogrammed cells (e.g., epithelial cells) given pluripotent capabilities. So reprogramming factors are thought to exist in the embryo or embryonic stem cells. Using genetic reprogramming with transcription factors, pluripotent stem cells equivalent to embryonic stem cells have been derived from human adult tissue. Shinya Yamanaka and his colleagues used the transcription factors Oct3/4, Sox2, c-Myc, and Klf4 in their experiments on cells from human faces. Another groups used a different set of factors, Oct4, Sox2, Nanog, and Lin28, and more limited combination of these factors (Oct3/4, Sox2, Klf4 (OSK), OS, only Oct3/4) can reprogram the adult tissue.

Stem cell therapy has the potential to dramatically change the treatment of human disease. A number of adult stem cell therapies already exist, particularly bone marrow transplantation that is used to treat hematological disease (leukemia, lymphoma, etc.). In the future, stem cell therapy will be broadened to treat a wider variety of diseases including cancer, neurological diseases, several inherited diseases, and so on.

Steptoe, Andrew (1951–)

Mika Kivimaki
Epidemiology & Public Health, University College London, London, WC1E 6BT, UK

Biographical Information

Andrew Steptoe was born in London on April 24, 1951. He is British Heart Foundation Professor of Psychology at University College London, UK, where he is also the Director of the Division of Population Health, a grouping of academic departments including Epidemiology and Public Health, Primary Care and Population Health, Infection and Population Health, and the Medical Research Council Clinical Trials Unit. Steptoe graduated in Natural Sciences from Cambridge in 1972, and completed his Doctorate at Oxford University in 1976. He was appointed lecturer in psychology at St. George's Hospital Medical School in 1977, becoming professor and chair of the Department in 1988. He moved to his present research chair at University College London in 2000, where he is the Director of the Psychobiology Group. Steptoe is also the Director of the English Longitudinal Study of Ageing, a population cohort of older men and women in England.

Major Accomplishments

Steptoe was one of the small group of behavioral medicine specialists, who developed the International Society of Behavioral Medicine (ISBM) in the 1980s. He served as the third President of the ISBM from 1994 to 1996. Additionally, he was the former President of the Society for Psychosomatic Research in the UK. He was the cofounding editor of the *British Journal of Health Psychology* along with Jane Wardle, and has served as an associate editor of *Psychophysiology*, the *Annals of Behavioral Medicine*, the *British Journal of Clinical Psychology*, and the *Journal of Psychosomatic Research*, and is on the editorial boards of six other journals.

Steptoe is the author of more than 550 journal articles and papers, and author or editor of 17 books, most recently the *Handbook of Behavioral Medicine* (Steptoe 2010) and *Stress and Cardiovascular Disease* (Hjemdahl, Rosengren, & Steptoe, 2012). His research has addressed many topics in behavioral medicine, including stress and health, socioeconomic status, the determinants of health behavior, health behavior change, cardiovascular disease, respiratory disorders, aging, and positive well-being. His collaborative research with Professor Marmot has focused on understanding the biological processes through which lower socioeconomic status and psychosocial risk factors influence cardiovascular disease risk. This work has involved laboratory studies of the influence of psychosocial factors on cardiovascular, neuroendocrine, and immune function, and naturalistic studies of blood pressure, cortisol, and other biological measures.

Steptoe has advanced our understanding of the psychobiology of health and diseases and the multiple associations between affect and biology in everyday life. He and his team found that people from lower socioeconomic groups tend to suffer the biological effects of stress for longer than more affluent people. This is a potential pathway linking low socioeconomic status with increased risk for coronary heart disease. Further studies by Steptoe's group showed that in some patients, intense episodes of anger and stress occurred in the hours immediately before the onset of chest pain. In experiment settings, episodes of mental stress, similar to those encountered in everyday life, were found to cause transient (up to 4 h) endothelial dysfunction in

healthy young individuals. These studies have been important in demonstrating the role of emotional factors in the triggering of coronary ischemia and acute coronary syndromes. Steptoe is also one of the leading scientists on the protective effects of positive affect in physical health.

Steptoe has received many honors for his work. He is a Fellow of the Society of Behavioral Medicine and the Academy of Behavioral Medicine Research in the USA, the Academy of Medical Sciences, the Academy of Learned Societies for the Social Sciences, and the British Psychological Society.

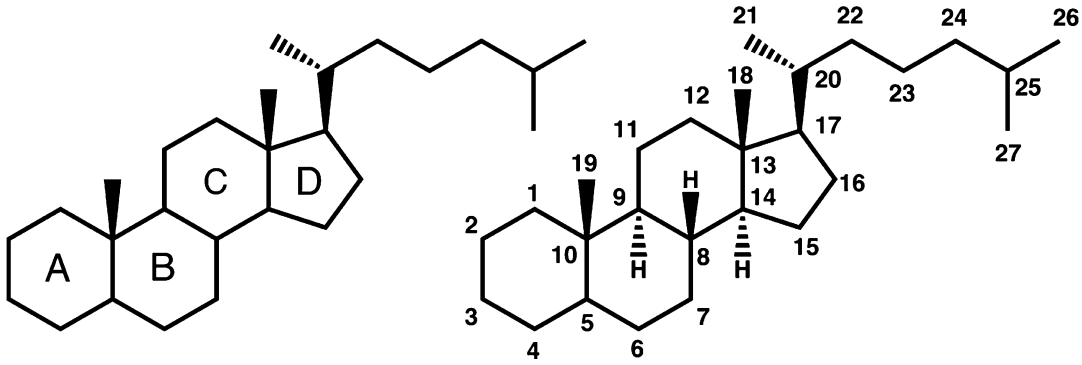
Synonyms

Steroid hormones

Definition

A steroid or steroid hormone is a biomolecule derived from cholesterol, with a characteristic structure containing four fused rings (see Fig. 1).

Cholesterol is the precursor for five major classes of steroid hormones: progestagens, glucocorticoids, mineralcorticoids, androgens, and estrogens. These hormones are powerful



Steroids, Fig. 1 Structure and carbon numbering scheme for cholesterol and other steroids

signaling molecules that are released in order to elicit a specific response.

Androgens, such as testosterone, are responsible for the development of male sex characteristics, whereas estrogens are responsible for the development of female sex characteristics. Dehydroepiandrosterone (DHEA) is the most abundant circulating steroid in humans, and is a precursor for the sex hormones, testerosterone and estradiol. In addition, DHEA is a cortisol antagonist.

Glucocorticoids, such as cortisol, promote the formation of glycogen and inhibit the inflammatory response. They enable humans (and animals) to respond to stress.

Steroids act by interaction with cellular receptors that serve as transcription factors to regulate gene expression. Steroids are incredibly potent and elicit very specific responses due to their interaction with steroid receptors.

Definition

A stigma is a personal attribute, mark, or characteristic that is socially devalued and discredited (Goffman, 1963). A wide variety of attributes are stigmas, including physical illnesses (e.g., HIV/AIDS, tuberculosis, epilepsy), mental illnesses (e.g., schizophrenia, mental disability), social norm violations (e.g., homosexuality, sex work, drug use, obesity), and certain demographic characteristics (e.g., racial/ethnic background, gender, socioeconomic status).

People who possess a stigma are perceived and treated negatively by others and ultimately suffer worse physical, psychological, and behavioral outcomes than people who do not possess a stigma.

The following sections describe how certain attributes become socially devalued, how stigma impacts individuals who possess a stigma (i.e., stigmatized people) and who do not possess a stigma (i.e., nonstigmatized people) via a series of stigma mechanisms, and other considerations relevant to stigma. Because HIV/AIDS is one of the strongest stigmas throughout the world and has received a great deal of empirical attention related to stigma (e.g., Aggleton & Parker, 2002), it used as the primary example of stigma throughout these sections.

The Social Construction of Stigma

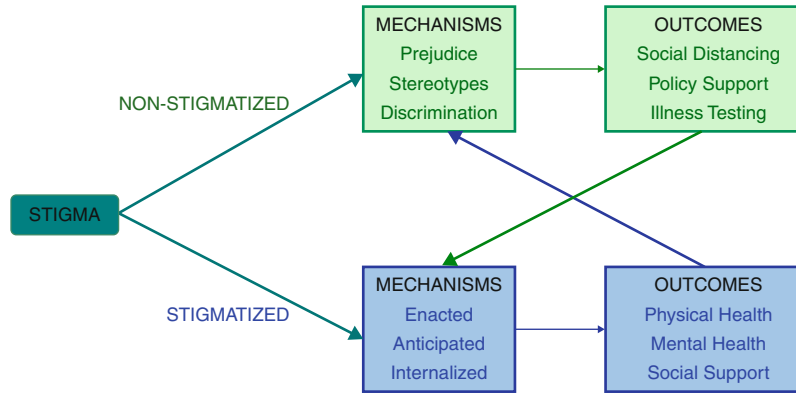
Stigmas are socially constructed (Crocker, Major, & Steele, 1998). In other words, certain attributes become devalued as the result of a social process (Link & Phelan, 2001) rather than as the result of innate differences between people who possess the attribute and people who do not possess the attribute. This social process involves stereotyping by associating the attribute with negative characteristics. For example, people living with HIV/AIDS (PLWHA) may be stereotyped to be promiscuous. The social process also involves separating the people who have the attribute into out-group categories. HIV-negative people may view other HIV-negative as part of their social group (i.e., part of "us") but PLWHA as part of a different social group (i.e., part of "them"). Finally, the social process involves experiences of status loss and discrimination by people who have the attribute. PLWHA may not be given medical care because of their HIV-status. Importantly, the social process that results in stigma relies on power. Nonstigmatized people have more power than stigmatized people and use this power to produce and reproduce social inequities and inequalities. This happens in both subtle ways (e.g., stigmatized people being paid systematically less than nonstigmatized people) and blatant ways (e.g., stigmatized people being enslaved by nonstigmatized people).

Because stigma results from a social process, the extent to which an attribute is devalued varies across different social contexts. Social contexts include both individual relationships and cultural contexts. For example, individual people (e.g., friends, family members, employers, and health-care providers) vary in the degree to which they view HIV/AIDS as a devalued attribute. Similarly, HIV/AIDS may be more devalued in some sociocultural contexts (e.g., Asian cities) than others (e.g., North American cities; Rao, Angell, Chow, & Corrigan, 2008). The extent to which an attribute is devalued also varies across time. For example, devaluation associated with HIV/AIDS decreased during the 1990s within the United States (Herek, Capitanio, & Widaman, 2002). Taken together, the degree of devaluation associated with a stigma is not universal or fixed; instead, it changes relative to specific social contexts and time periods.

Stigma Mechanisms and Outcomes

Individuals are impacted by stigma via a series of stigma mechanisms. Stigma mechanisms refer to the ways in which people react to either possessing or not possessing a particular stigma (Earnshaw & Chaudoir, 2009). Stigma mechanisms, in turn, result in physical, psychological, and behavioral outcomes for both stigmatized and nonstigmatized people. Figure 1 is adapted from the HIV Stigma Framework (Earnshaw & Chaudoir, 2009) and shows how stigma leads to stigma mechanisms, which in turn lead to outcomes. Because they represent the link between the social process of stigma and outcomes associated with stigma, stigma mechanisms are often measured by researchers.

Individuals who do not possess the stigma experience the stigma mechanisms of prejudice, stereotyping, and discrimination. Prejudice refers to negative emotions and feelings toward people who possess the stigma. For example, HIV-negative people may feel disgust toward PLWHA. Stereotypes refer to group-based beliefs about people who possess the stigma. HIV-negative people may believe that PLWHA are mostly gay men. Finally, discrimination refers to behavioral expressions of prejudice



Stigma, Fig. 1 Stigma framework

directed toward people who possess the stigma. HIV-negative people might refuse to hire, medically treat, or give housing to PLWHA. Although people who do not possess the stigma have more power than people who possess the stigma, people who do not possess the stigma may still suffer negative consequences due to stigma mechanisms. For example, an HIV-negative person who endorses the stereotype that PLWHA are mostly gay men may be less likely to engage in safe sex, be tested for HIV, or seek health care for HIV-related symptoms if they do not identify as a gay man. Consequently, belief in stereotypes can put HIV-negative people at risk for contracting HIV and not receiving treatment.

Individuals who possess the stigma experience the stigma mechanisms of anticipated stigma, enacted stigma, and internalized stigma. Enacted stigma, also called experienced stigma, refers to experiences of prejudice, stereotyping, and/or discrimination. For example, PLWHA may experience social rejection from friends and family members. Anticipated stigma refers to expectations of prejudice, stereotyping, and/or discrimination. PLWHA may expect that they will not be hired by a potential employer. Finally, internalized stigma refers to the endorsement of prejudice and stereotypes associated with one's stigma and applying them to the self. PLWHA may feel that they are dirty due to their HIV status. Further, stigma mechanisms experienced by individuals who do not possess the stigma may impact the outcomes of individuals who do possess the stigma. Discrimination perpetuated by HIV-negative people may be experienced as enacted stigma by PLWHA.

Stigma mechanisms profoundly impact the physical, psychological, and behavioral outcomes of stigmatized individuals. Meta-analytic evidence has shown that stigma mechanisms are associated with decreased physical health (e.g., increased physical illnesses and illness symptoms; Pascoe & Smart Richman, 2009) and mental health (e.g., increased depression and decreased self-esteem; Mak, Poon, Pun, & Cheung, 2007). Additionally, stigma mechanisms are associated with maladaptive behaviors which may further undermine the health of stigmatized individuals. For example, stigma mechanisms are related to behaviors such as delayed HIV treatment initiation and nonadherence to medication regimens (Chesney & Smith, 1999). Stigma mechanisms are further related to decreased likelihood of disclosure among individuals living with concealable stigmatized identities including HIV/AIDS (Smith, Rossetto, & Peterson, 2008).

Other Considerations

Intersectional stigma and layered stigma refer to the possession of multiple stigmas. For example, a gay man living with HIV possesses two stigmas: homosexuality and HIV. Possessing multiple stigmas may exacerbate the impact of stigma on individuals.

Associative stigma, courtesy stigma, and affiliate stigma refer to being connected to someone who possesses a stigma. For example, an HIV-negative man who has a daughter living

with HIV/AIDS may experience associative stigma due to his connection to his daughter. People who possess an associative stigma may experience negative outcomes via stigma mechanisms typically reserved for people who possess a stigma.

Concealable stigmas refer to devalued attributes that cannot be seen by others. Examples of concealable stigmas include many physical and mental illnesses and some social norm violations such as homosexuality and drug use. In contrast, visible stigmas refer to devalued attributes that can be seen by others. Examples of visible stigmas include many demographic characteristics such as racial/ethnic background and gender. Whereas people with concealable stigmas can hide their stigma from others in some social interactions, people with visible stigmas cannot.

Department of Psychology, University of South Florida College of Arts & Sciences, Tampa, FL, USA

Synonyms

Anxiety; Distress; Mental stress; Pressure; Psychological stress

Definition

Stress is a transactional process occurring when an event is perceived as relevant to an individual's well-being, has the potential for harm or loss, and requires psychological, physiological, and/or behavioral efforts to manage the event and its outcomes (Lazarus & Folkman, 1984). The stimuli or events that cause stress are referred to as stressors (Mason, 1975). Stress often results in psychological distress and efforts to cope with the event. Physiological stress responses are often in support of efforts to manage the stressful event and protect the organism from harm (McEwen & Seeman, 1999). Stress may not be a uniformly negative experience, as stressful events may also include the potential for benefit and growth (Lazarus & Folkman). Early views of stress focused on physical stress – events that perturb the resting homeostasis of the body, such as changes in temperature or physical injury (McEwen & Seeman, 1999). Current views of stress focus heavily on social and psychological sources, with appraisals of the event and the perceived coping resources as key features. Stress may be categorized by its severity, its time course (acute, repeated, or chronic), and degree of control over the stressor. Distinctions also have been made between active coping stressors and passive coping stressors (Obrist, 1981). Active coping stressors require overt behavioral action, such as giving a speech or performing a reaction time task, whereas passive coping stressors require that the individual endure without behavioral action, such as watching gruesome photos. Psychological and physiological stress responses have been shown to differ based upon these dimensions (Tomaka, Blascovich, Kelsey, & Leitten, 1993).

Coping with stress; Relaxation techniques; Stress reduction

Definition

Stress management techniques and interventions can be broadly categorized into skills that are provided via education, relaxation training, psychosocial interventions, and group formats, alone or in combination, that aim to reduce the stress response by targeting coping strategies and relaxation skills.

Description

The deleterious effects of stress on health and well-being are well documented and have led to the incorporation of stress management techniques into many psychosocial treatment protocols, alone or in combination with medical treatments. Chronic stress has been linked to physiologic changes such as neuroendocrine and immune dysregulation, and worsened disease profiles. One of the most prominent associations between stress and poor health has been in the area of cardiovascular risk. For example, evidence suggests that chronic stress is associated with increased sympathetic cardiovascular activity and damage to endothelial functioning, which increases the risk of several cardiovascular conditions, such as arterial hypertension, coronary artery disease, and arrhythmias. Therefore, incorporation of stress management into clinical and research protocols designed to improve health and well-being has become increasingly popular.

The field of stress management is comprised of a variety of methods and techniques. Relaxation skills training methods with the most empirical support include progressive relaxation or progressive muscle relaxation, autogenic training, biofeedback, mental imagery, and other Eastern or Westernized meditation methods. Various cognitive techniques and in some cases, pharmacotherapy, are also part of stress management programs. Other methods that have been incorporated into stress management include listening to relaxing music, massage, aerobic exercise, diaphragmatic breathing, and postural relaxation methods. Some evidence suggests that "active" stress management techniques (e.g., breathing-guided relaxation training) may be more effective in reducing stress symptoms and inducing improved autonomic cardiovascular regulation than "passive" techniques (e.g., massage). Several

standardized stress management interventions have been developed and shown to be efficacious in reducing symptoms of stress and improving various indicators of physical and mental health and quality of life. Empirical evidence supports the use of stress management techniques in the treatment of migraines, pain, and other somatic complaints, and have also been used to reduce stress symptoms, improve adjustment, well-being, and quality of life in a range of patient populations, including those diagnosed with type 2 diabetes, coronary heart disease, fibromyalgia, chronic fatigue syndrome (CFS), human immunodeficiency virus (HIV), and cancer.

Stress management intervention strategies range from single session psychosocial treatments to multifaceted treatments involving psychosocial and behavioral modification components. Likewise, intervention aims and target outcomes also range from behavior and lifestyle changes (e.g., diet, exercise, and utilization of stress management techniques) to changes in psychological and physical well-being (e.g., relief of depressive or anxious symptoms, cortisol regulation). It is hypothesized that if one can manage stress effectively, an individual's ability to adopt lifestyle changes that positively impact health outcomes will be maximized. Conversely, chronic stress has been associated with negative lifestyle factors including poor diet, sedentary lifestyle, alcohol and substance use, and poor adherence to medical regimens. Therefore, many stress management programs include medical endpoints such as disease risk factors, disease morbidity, and mortality. For example, stress management interventions in coronary heart disease may include known risk factors as relevant endpoints, such as being overweight or obese, smoking status, blood pressure, cholesterol, lipids, cardiac ischemia (e.g., angina), and number of cardiac events and/or procedures (e.g., myocardial infarction, angioplasty). Endpoints may be measured at proximal, intermediate, or distance time points, depending on the outcome of interest.

Cultural factors have also been shown to be associated with stress and stress management. Although all cultures experience stress and its sequelae, psychosocial sources of stress, the expression of stress symptoms, and the use and acceptability of stress management techniques varies across cultures. For example, evidence suggests that Hispanics are more likely to experience somatic symptoms in response to stress, compared to non-Hispanic Whites. Cultural differences in stress symptoms will likely lead to varying intervention and treatment approaches. Individuals who present with emotional symptoms of stress without a somatic component, for example, receive more treatment in the United States compared to South Korea, a collectivist culture in which individuals are less likely to express signs of emotional distress directly. However, there is no cross-cultural difference between the United States and South Korea in treatment of somatic symptoms of stress, suggesting that treatment methods may be culturally biased.

Stress Management Techniques and Interventions

Many different methods of stress management have been employed with empirical support across a range of populations. Progressive relaxation or progressive muscle relaxation consists of consecutively tensing and relaxing different sets of muscle groups throughout the body, generally starting with the feet and systematically progressing up to the head. Diaphragmatic breathing consists of taking deep breaths in which the diaphragm contracts and the abdomen, rather than the chest, is extended. This type of breathing involves a slow and deep inhalation through the nose, usually to a count of 10, followed by slow and complete exhalation for a similar count; the process is repeated for a preferred number of times to facilitate relaxation. Using mental imagery as a stress management tool involves imagining a scene, place, or event that is considered safe, peaceful, and restful; one that is associated with affective feelings of happiness, job, and contentment. Alternatively, images may involve mental pictures of stress flowing out of the body or being locked away in a padlocked chest. All of the senses are incorporated into the mental imagery exercise

and it is encouraged to develop details and complex images that invoke sensual perceptions. The imagined place is used as a retreat from environmental stressors, with the goal of having the body react to imagined scenes of peace and tranquility as if they were real, counteracting the adrenergic effects of stress. These methods have been shown to be beneficial through self-report measures of stress and well-being and physical measures of the body's stress response through biofeedback methods.

Biofeedback is a method that keeps track of the body's physiological responses in real time, generally through machines that measure heart rate, muscle tension, or brain waves. Most often, biofeedback is used as a tool to facilitate control over the stress response sequelae. Individuals are taught to recognize the stress response when it is underway and employ relaxation techniques (e.g., deep breathing, mental imagery, or adaptive cognitive replacement) to calm physiological arousal. Theory and empirical evidence suggest that the real-time feedback of physiological changes in response to stress and the utilization of stress management techniques facilitate learning and adoption of effective relaxation methods into daily life.

Stress Management Programs

Many stress management interventions for clinical populations consist of a combination of methods that frequently incorporate a variety of cognitive and behavioral techniques. For example, cognitive-behavioral stress management (CBSM) interventions have been employed and been shown to have beneficial effects in stressed nonclinical subjects and a range of patient populations. These interventions typically aim to improve adaptive coping and reduce psychological distress through the use of emotion regulation strategies and relaxation training. Didactic training typically addresses stress appraisal and cognitive coping strategies to improve stress management of general- and disease-specific stressors. Often, a psychoeducational component about the nature and consequences of stress and disease processes is also incorporated into intervention protocols. The CBSM protocol consists of a 10-week manualized group intervention in which groups meet for 2 h per week; sessions consist of 90 min of didactic discussion and exercises and 30 min of relaxation training. During the didactic portion of each session, participants are provided information regarding stress awareness, physical responses to stress, and the appraisal process and are taught a variety of cognitive-behavioral techniques designed to manage general- and disease-specific stress. Cognitive techniques include learning to identify cognitive distortions and cognitive restructuring processes (e.g., rational thought replacement), effective coping strategies (e.g., emotional-focused vs. problem-focused coping), and anger management and assertiveness training (e.g., effective communication). Information related to disease physiology, diagnosis, and treatment are also provided and health maintenance strategies are reviewed. During the relaxation portion, participants are taught a variety of techniques through group relaxation exercises, including progressive muscle relaxation, guided imagery, meditation, and diaphragmatic breathing. Participants are encouraged to practice the techniques at home on a daily basis. The CBSM intervention has been shown to be effective in increasing stress management skills, which has been related to improvements in a number of quality-of-life domains, in HIV, cancer, and CFS populations.

Similarly, some have demonstrated the efficacy of a group-based stress management program that included progressive muscle relaxation training, didactic training in the use of cognitive and behavioral skills to bring awareness to and reduce physiological symptoms of stress (e.g., guided imagery, deep breathing techniques, thought stopping, and recognition of life stressors), and education on the negative effects of stress on health in improving glycemic control in patients with type 2 diabetes. Participants learned stress management techniques in a group-based intervention format and were instructed to practice muscle relaxation at home twice daily with the aid of an audiotape. Specific instructions were given to encourage "mini-practices"

(i.e., brief, 30-s versions of a progressive relaxation session) to facilitate the use of stress management and relaxation techniques into daily life. Although similar interventions have been conducted and shown positive effects on blood glucose, findings have been mixed as several others have failed to show a therapeutic effect of stress management on diabetes control.

Mindfulness-based stress reduction (MBSR) is a clinically standardized meditation program, originally developed as a group-based intervention for chronic pain but has since demonstrated efficacy for patients with a range of mental and physical disorders, as well as healthy subjects. The MBSR protocol consists of three different stress management techniques: body scan, which involves focusing on different parts of the body, bringing attention and awareness to sensations and feelings, breath awareness, and relaxation; sitting meditation, which involves focusing on body sensations and breathe, as well as nonjudgmental awareness of the cognitions and the stream of thoughts and distractions that pass through the mind; and Hatha yoga practice, which consists of breathing exercises, stretching, and postural exercises designed to strengthen and relax the musculoskeletal system. The MBSR program is an 8- to 10-week group intervention in which sessions typically last 2.5 h, with an additional single all-day session per course. Homework of at least 45 min a day, 6 days a week, is also encouraged, which may consist of meditation practice, mindful yoga, and/or incorporating mindfulness into daily life. Groups may be either homogenous or heterogeneous with regard to illnesses or presenting problems of participants. Empirical evidence provides consistent and relatively strong effect sizes regarding the efficacy of MBSR on a number of psychological (e.g., depressive and anxiety symptoms, coping style) and physical (e.g., medical symptoms, sensory pain, physical impairment, and functional quality of life) well-being in clinical and nonclinical populations. Clinical populations have included patients diagnosed with anxiety disorders, depression, chronic pain, fibromyalgia, cancer, and stress related to environmental contexts (e.g., medical school, prison life), as well as relatively healthy individuals interested in improving their ability to cope with normal stressors of daily living.

Stress management interventions for healthy and patient populations are promising. However, findings have been mixed and the literature is limited by measurement and research design problems, insufficient information regarding intervention components and protocol fidelity, clinical relevance of statistically significant effects, and feasibility and dissemination concerns regarding the translation of research protocols into clinical practice. Nevertheless, given the detrimental effects of stress on psychological and physical well-being, further research is needed using large-scale, randomized clinical trials, with sound methodological procedures that include objective markers of health and disease status, in addition to self-report measures of psychosocial well-being and functional indicators of distress.

Stress responsivity

Definition

Stress reactivity is the capacity or tendency to respond to a stressor. It is a disposition that underlies individual differences in responses to stressors and is assumed to be a vulnerability factor for the development of diseases.

Description

People respond differently when exposed to the same stressor. Such differences can be observed in all four major stress response domains, namely, physiology, behavior, subjective experience, and cognitive function. Within the physiological domain, two response systems are of particular importance: cardiovascular responses (indicated by blood pressure and heart rate), driven by sympathetic nervous system (SNS) activity, and output of the glucocorticoid hormone cortisol from the adrenal cortex, driven by hypothalamic-pituitary-adrenal (HPA) axis activity. Stress reactivity is assumed to be stable over time, i.e., persons showing high responses at an initial assessment also show high responses when the assessment is repeated at a later time. Stress reactivity can be conceptualized as specific or general. Whereas specific stress reactivity reflects reactivity of a particular response system (e.g., cardiovascular stress reactivity; endocrine stress reactivity; affective stress reactivity), general stress reactivity is indicated by aggregation of responses across domains and/or stressors.

The relevance of stress reactivity for behavioral medicine rests primarily on the assumption that high stress reactivity is assumed to be a vulnerability factor for disease that predicts disease outcome variance independently of well-established risk factors. As early as in the first half of the twentieth century it was proposed that the size of blood pressure responses to placing the hand in cold water (cold pressor test) would indicate the risk of later development of hypertension. More recently, a growing body of evidence from longitudinal studies that used laboratory stress tests support the assumption that cardiovascular stress reactivity is indeed a risk factor for subclinical and clinical cardiovascular disease. This has been shown for both physiological stressors such as the cold pressor test and psychological stressors such as pressure to perform in a social situation (e.g., public speaking). On the basis of this evidence it has been concluded that cardiovascular stress reactivity is a risk factor for cardiovascular disease in addition

to the classic risk factors of family history, obesity, smoking, diabetes mellitus, and hypercholesterolemia. As for endocrine stress reactivity, a few longitudinal studies found evidence for associations between endocrine stress reactivity and increased risk for disease. However, this research area is much less developed than that for cardiovascular stress reactivity, and the evidence is less robust. Finally, it has been suggested that endocrine and affective stress reactivity might be a risk factor for the development of mental disorders such as psychosis, depression, and anxiety disorders. Again, research in this area is still relatively scarce and the evidence mostly relies on cross-sectional studies.

In contrast to specific stress reactivity, the concept of general stress reactivity emphasizes generalizability of responses across response systems and stressors. It is based on the notion that stress responses have a common origin in brain areas that mediate activation of the HPA axis and the SNS, as well as behavioral and subjective-emotional responses. In particular, hippocampus, amygdala, and prefrontal cortex are higher central mediators of subjective-emotional responses. These areas are functionally connected to the hypothalamic and brainstem nuclei which are critical in activating the HPA axis and the SNS. If a stressor is processed in higher brain areas, stress responses are expected to show relatively high covariance. This is to be expected for psychological stressors, but less so for physiological stressors. Thus, dissociations between responses systems might reflect individual differences at both levels. In addition, observed physiological stress responses are influenced by peripheral factors such as receptor sensitivity in the periphery or vascular resistance. Although high covariance between response systems would be expected, a number of factors such as different dynamics of the response systems, habituation effects, measurement error, and limited variance due to limited stressor intensity act at attenuating associations between responses.

Complementary to the notion of general stress reactivity, the concepts of individual response specificity (IRS) and stimulus response specificity (SRS) reflect observations of dissociation between response systems or stressors. The concept of IRS describes individual differences in patterns of responses, for example, one person might respond to stressors with a high blood pressure but low cortisol increase, whereas another person might also show a high cortisol increase. SRS describes such response patterns as related to stressors, for example, it has been proposed that the HPA axis in humans is activated by stressors that include social evaluative threat, but not by cognitive effort without that component. In research, it is often difficult to reliably detect general stress reactivity, IRS or SRS response patterns. Although there is now increasing evidence for the concept of general stress reactivity, associations between responses are usually moderate. Therefore, it is important to note that it is not possible to use the stress response in one domain or system as a general indicator of responses in other domains. Although it has been suggested that such dissociations might present useful information about psychobiological responses systems of an individual that could be valuable for behavioral medicine, to date little is known about the stability and implications of response dissociations.

Stress reactivity can be assessed both in the laboratory and in daily life. The major advantage of laboratory stress tests is the high degree of standardization over the conditions implemented. However, stress responses in the laboratory have limited ecological validity, i.e., do not necessarily reflect stress reactivity in daily life. For that reason, ambulatory assessment methods are increasingly used and present the opportunity to assess real-time stress reactivity in daily life for both research and clinical practice. A number of factors influence stress reactivity, with implications for clinical decisions. For example, it is known that stress reactivity is associated with sex, age, ethnicity, personality factors, preexisting disease, and the presence or absence of chronic stress. Due to such moderating factors there is a wide range of associations between stress reactivity and disease outcome. Therefore, the predictive value varies across individuals, making it difficult to use stress reactivity scores in clinical practice. Although the reliability of

stress reactivity assessments could be increased by assessing aggregated stress responses in a repeated measure/multiple stressors design, few studies have implemented this design due to the high demands on resources. It would be expected that stronger and more consistent association with disease could be observed with such a design. Finally, an important conclusion from the variety of findings on associations between stress response systems is that, as mentioned above, a single assessment of one response system cannot be used as an indicator for stress responses in other systems. The notion of a consistent "gold-standard" indicator of stress reactivity is not supported by the research literature.

As the assessment of physiological stress responses is relatively expensive and fraught with practical problems, clinicians often rely on retrospective self-reports of individual stress experience to assess stress reactivity. However, such subjective measures of stress experience confound individual stress reactivity with frequency of exposure to daily life stress. Recently, a self-report instrument for the assessment of perceived stress reactivity has been developed and evaluated. Although retrospective self-report methods cannot replace real-time measures, they present an opportunity to assess patients' perceptions of their own stress reactivity in daily life when resources to assess real-time responses are lacking or when such self-observations are of primary interest.

Stress reactivity is assumed to be a consequence of the individual genetic makeup and early environmental factors. Quantitative genetic studies using mainly twin designs have concluded that approximately 50% of the variance in stress responses is due to genetic factors. However, there is some variability of estimates between studies, and the amount of heritability seems to change with repeated exposure to the same stressor. Molecular genetic studies have revealed a number of single gene variants that might influence stress responses in different systems, although many of these effects of candidate genes need replication before valid conclusions can be drawn. In addition to genetic makeup, factors of the environment early in life have been shown to influence stress reactivity. A number of studies suggest that an adverse prenatal environment might exert long-term effects on stress reactivity in the offspring. Similarly, adverse early postnatal environmental factors such as maternal care or abuse have been shown to affect stress reactivity, with consequences for the risk of mental disorder later in life. Animal studies have suggested that such early environmental effects might be mediated by epigenetic changes in specific brain areas.

Despite good evidence for the prediction of cardiovascular disease by cardiovascular stress reactivity, potential pathways and causal chains of effects are unclear. In addition, not all individuals with high cardiovascular stress reactivity later develop cardiovascular disease. This points at another factor implicated in the pathway. It is likely that high stress reactivity leads to disease particularly if a highly stress reactive individual is exposed to chronic stress in daily life (diathesis-stress model). Other areas of discussion are the potential adaptive function of high stress reactivity in an evolutionary context, and the significance of low levels of stress reactivity for the development of diseases and disorders.

Definition

Stress responses are psychological, physiological, and behavioral responses to an event perceived as relevant to one's well being with some potential for harm or loss and requiring adaptation. Psychological stress responses often include negative emotions, such as anxiety, distress, or anger, although positive emotional states related to feeling challenged and driven may also occur. Cognitive efforts aimed at coping with the stressor, such as planning, distancing, and/or reinterpreting, also occur (Lazarus & Folkman, 1984). Physiological stress responses are often those that are in support of coping with or fleeing from the stressor, and protecting the organism from potential harm. These responses include, but are not limited to, changes in heart rate, blood pressure, cortisol, and immune function (Sapolsky, 1994). Behavioral stress responses involve actions also aimed at coping with or fleeing from the stressful event, such as actively performing a task or withdrawing effort from a situation perceived as impossible (Lazarus & Folkman, 1984).

Definition

Laboratory mental stress tasks are commonly used in behavioral medicine to assess the physiological responses to a standardized stressor in a controlled setting (Turner, 1994).

Description

Even though originally it was thought that particularly exaggerated physiological responses to mental stress can be predictive of cardiovascular disease (Obrist, 1981), there is now growing evidence that blunted physiological responses can also be associated with poor health (Carroll, Lovallo, & Phillips, 2009). Other evidence is available that not the responses to mental stress itself, but the physiological recovery upon completion of the stress task can be related with the poor health outcomes (Larsen & Cristenfeld, 2011). There is a large body of research that explores the associations between psychological traits (e.g., competitiveness and hostility) as well as mental disorders (e.g., depression and anxiety) with the individual differences in physiological responses to mental stress (Lovallo, 1997). Participants that have been included in these stress studies comprise of young healthy participants, elderly people, and a wide variety of clinical populations. This section will describe the general setup of a laboratory stress task and the most commonly used mental stress tasks in behavioral medicine. Even though the focus will be on mental stress tasks, it is worth noting that physical tests, such as exercise, tilt test, and cold pressor, are also readily used in laboratory settings.

In order to assess the physiological responses to a mental stress task, it is important to assess the resting physiological state of the participant. To quantify the stress response, a reactivity score is calculated, which is the difference between the physiological activity during the stress task and the activity during the rest period (Turner, 1994). A typical stress session starts with a resting period of 15–30 min, during which the participant is relaxed. Relaxation can be facilitated by listening to music, reading magazines, or watching a low-stimulating video. This is followed by an explanation of the stress task with, where appropriate, a brief practice session and the actual stress task. Upon completion of the stress task, a recovery period is started, during which the participant is asked again to relax, similar to the baseline rest period. The duration of the recovery period is depending on the variables that are under investigation. Whereas heart rate is known to return to baseline relatively soon after the end of the stress task, changes in other variables, in particular blood based measures such as cytokines, will not be seen until 30 min or longer

(Steptoe, Hamer, & Chida, 2007). In general, physiological data collection is conducted throughout each of these periods.

When exploring the effects of individual differences in physiological responses to mental stress, it is crucial that the testing procedures are identical between participants (Turner, 1994). The conditions in the laboratory, such as temperature and number of experimenters present, but also time of day, should be kept consistent. Care should also be taken to standardize the instructions of the task, which can be done by having the instructions prerecorded. Finally, adherence of the participants to the presession instructions is important. These involve most commonly avoiding strenuous exercise, food, caffeine, and smoking, as well as instructions about the medication which could influence the physiological measurements. The presession instructions are dependent on the physiological measures that are under investigation.

Mental Stress Tasks

Public Speaking – The participant is asked to give a speech in front of an audience and/or a video camera, following a brief preparation period. The topic of speech is psychologically stressful such as "pretend that you are falsely accused of shoplifting and that you have to defend yourself to the shop owner" or "describe your personal strengths and weaknesses" or "describe a recent event that caused anger." The participant will be told that the audience will be critically evaluating the content and delivery of the speech (Van Eck, Nicolson, Berkhof, & Sulon, 1996).

Mental Arithmetic – Different varieties are available for mental arithmetic tasks, which include serial subtraction or addition of double digit numbers or serial addition of single digit numbers with an element of retention. These tasks, even though not complicated in nature, have been developed to be provocative by adding components of increased time pressure, competition, harassment when a wrong answer is given, and social evaluation (Veldhuijzen van Zanten et al., 2004).

Trier Social Stress Test – This is a combination of mental arithmetic task followed by a public speech, all under conditions of social evaluation. In addition to the two varieties of mental stress, this task also has a postural component as the speech is conducted while upright (Kirschbaum & Hellhammer, 1993).

Computer Games – A variety of computer games have been used to induce stress in participants, which has been mainly conducted in younger participants. These tasks often have a strong component of competition; participants are either directly competing against the experimenter (often in a modified situation to standardize the success rate between participants) or competing against the other participants in the study.

Stroop Color Word Task – The participants are presented with words which describe colors, but the color of the letters is incongruent with the color that the word is written in. For example, the word red is written with yellow ink, and the word yellow is written with red ink. The participant is asked to call out the color of the ink (Stroop, 1935).

Mental stress tasks are subject to the effects task novelty and habituation (Turner, 1994). For example, even though all of these tasks provoke an increase of heart rate throughout the task, typically, the peak heart rate response is seen at the start of the test. Particularly when a participant is asked to complete the task on different occasions, it is important to maintain the engagement of the participant in each session. It has been shown that the addition of stressful elements such as social evaluation and competition will help to facilitate this. To ensure that the desired levels of stress are obtained, it is common practice to add a measure of self-reported perceptions of the task to each session. These can vary from a simple Likert scale related to perceived stressfulness and difficulty or measures of state stress and anxiety levels both before and after the stress task.

The stress tasks vary in terms of generalizability to real-life settings. Interestingly, an overview of various stress task revealed that public

speaking tasks were most consistently effective in inducing myocardial ischemia in patients with coronary heart disease (Strike & Steptoe, 2003). It is possible that this is due to the more naturalistic nature of the task than, for example, mental arithmetic or Stroop task. However, care should be taken when interpreting the effectiveness of a certain task to induce physiological changes between studies, as it is hard to compare the stressfulness of tasks between studies. Ambulatory recording techniques are available for the assessment of physiological measurements in real-life setting. Even though these field studies cannot be standardized between participants, it is worth noting that there is evidence that the laboratory cardiovascular responses to mental stress were predictive of ambulatory physiological assessments (Strike & Steptoe, 2003).

Stress Vulnerability Models

Conny W. E. M. Quaedflieg and Tom Smeets
Faculty of Psychology and Neuroscience, Maastricht University, Maastricht, MD, The Netherlands

Synonyms

Stress diathesis models

Definition

Vulnerability models are used to identify factors that are causally related to symptom development. Stress vulnerability models describe the relation between stress and the development of (psycho-)pathology. They propose an association

between (1) latent endogenous *vulnerability factors* that interact with stress to increase the adverse impact of stressful conditions, (2) *environmental factors* that influence the onset and course of (psycho-)pathology, and (3) *protective factors* that buffer against or mitigate the effects of stress on pathological responses.

Description

The prevalence of stress-related mental disorders encompassing mood and anxiety disorders in Europe is above 20%. This morbidity is associated with high health care costs, disability, and potential mortality. It is widely acknowledged that there are individual differences in how stressful people judge a particular event to be as well as in their ability to cope with adverse stressful life events. While historically stress was said to play an initiating role in the development of pathology, only a minority of people who experience adverse stressful life events go on to develop pathology. To distinguish people who develop pathology from people who do not (i.e., are resilient), vulnerability processes are suggested that predispose individuals to psychopathology when confronted with severe stressors. In the late 1970s, Zubin and Spring were the first to introduce this idea in the field of behavioral medicine by postulating a vulnerability model for schizophrenia. Specifically, they suggested that humans inherit a genetic predisposition to mental illness. However, an interaction between the genetic vulnerability and biological or psychosocial stressors is necessary to develop the disorder. The relationship between predispositional factors (or diathesis) and development of pathology has been described in four basic stress vulnerability models.

Stress Vulnerability Models

The first and most simple stress vulnerability model, the *dichotomous interactive* model, suggests that when predispositional factors are absent, even severe stress will not result in pathology. Instead, it is only when predispositional factors are present that stress may, depending on the severity of the stress, lead to the expression of pathology. Alternatively, the *quasi-continuous* model suggests varying degrees of predisposition with a continuous effect of predispositional factors on pathology once a threshold has been exceeded. The third, more extensive *threshold* model incorporates an individually specific threshold that is determined by the degree of vulnerability and the level of experienced stress. Finally, perhaps the most comprehensive model is the *risk-resilience continuum* model in which vulnerability is viewed as a continuum ranging from vulnerability to resilience, integrating different levels of severity of pathology into the model. Here, resilient characteristics that can make people more resistant to the impact of stress are also emphasized. Note that according to this latter model, even highly resilient individuals might still be at risk for developing pathology when experiencing extreme stress, but their individual threshold will be higher and the symptomatology likely less severe. Collectively, these four models are used to describe the relation between predispositional factors and the development of various pathologies.

Vulnerability Factors

In general, stress vulnerability models postulate that a genetic vulnerability interacts with adverse life events or stressors to produce pathology. This gene-environment interaction with regard to stress and the development of pathology has been most extensively investigated in mood disorders such as depression. Gene-environment interaction studies use monozygotic twin, adoption, and family studies as tools to identify predispositional factors in shared and non-shared environments in order to differentiate genetic from environmental influences. In twin studies, a higher prevalence of pathology in monozygotic twins reared in different environments is used to confirm a genetic predisposition, whereas in adoption studies the effect of the environment

(adoptive parents) can be offset against the effect of genes (biological parents). Using these methods the heritability of major depression, has been estimated at around 40%.

At the neurochemical level, the serotonin (5-HT) system has been implicated in depression. 5-HT regulates among others mood, activity, sleep, and appetite. Accumulating evidence indicates that individuals with a serotonergic vulnerability, manifested in a more sensitive brain serotonergic system, have an increased likelihood of developing mood-related disorders. Specifically, polymorphisms in the 5HT transporter system (5-HTT) have been associated with stressful life events, a heightened risk for depression, and reactivity to negative emotional stimuli. Individuals carrying two copies of the short variant of the 5-HTT allele (i.e., 5-HTTLPR), a less active gene resulting in fewer 5-HTT transporters, display an increased sensitivity to the impact of mild stressful life events, an excessive amygdala activity to fearful faces and produce elevated and prolonged levels of cortisol in response to a laboratory stressor compared to individuals with the long variant of the 5-HTT allele. The heritability of the stress hormone response has also been investigated with family studies in relatives of patients with depression using neuroendocrine functioning tests. For example, studies with the dexamethasone suppression test, a drug test used to measure the effectiveness of the negative feedback mechanism of the hypothalamic-pituitary-adrenal (HPA) axis at the level of the pituitary, have found an amplified set point of the HPA axis in relatives of depressed patients compared to healthy controls.

Moreover, 5-HT is also involved in the modulation of the HPA axis and its associated regulatory actions in the secretion of cortisol, the major human glucocorticoid stress hormone. Cortisol binds to two corticosteroid receptors in the brain, namely, the mineralocorticoid receptor (MR) and the glucocorticoid receptor (GR). Two mechanisms of cortisol binding are known. First, cortisol can bind to the hormone response element on DNA to influence gene expression (intracellular MR and GR binding properties). Secondly, cortisol can bind to membrane versions of the corticosteroid receptors to influence glutamate transmission and gene expression in the brain. The MR controls the basal HPA activity through inhibition of the HPA axis, facilitating the selection of adaptive behavioral responses and preventing minor adverse stressful life events to disturb homeostasis. In contrast, the GR promotes recovery after stress as well as the storage of information for future events. The balance between the MR and GR receptors determines the threshold and termination of the HPA axis response to stress. Studies have demonstrated that individuals with polymorphisms in the GR gene display higher cortisol responses and inefficient recovery of the HPA axis following standardized laboratory stress tests, thus revealing predisposition factors for stress-related pathology.

Genes can have a direct effect on the development of various brain systems. To illustrate this point, altered gene expression can reduce plasticity in brain circuits regulating mood, anxiety, and aggression and thereby decrease one's ability to cope with stressful life events. Moreover, genes can bias brain circuits to inefficient information processing which can result in the expression of pathology (e.g., intrusive memories in patients suffering from posttraumatic stress disorder). Genetic polymorphisms are then viewed as vulnerability factors given that they produce an increased sensitivity to the impact of stressful life events. However, it should be kept in mind that replication studies of candidate gene associations in pathology are relatively sparse and that most disorders are polygenetic. Additionally, the net outcome of a stressor is at least in part determined by the individual's personality traits that may be formed by genes, potentially indirectly influencing the selection of environments and thus the risk of exposure to adverse effects.

Lifespan models have examined the relation between early life stressful events, later stressful life events and pathology development. Undifferentiated neuronal systems are dependent on early experience during development. It is suggested that early life stress results in inefficient information processing and sensitization of brain circuits involved in regulating stress reactivity, which

may ultimately render people more vulnerable. Different brain structures have specific developmental trajectories resulting in a variety of pathological response after stress across the lifespan. For example, prenatal stress originating from maternal stress or postnatal environmental stress such as the quality of parental care influences the regulation of the HPA axis. However, exposure to a manageable stressor during childhood can also desensitize the stress circuits, producing experience-based resilience in which brain systems tend to become less reactive to future stress. Early life stress can hence be protective in that it can negate or diminish the negative outcomes or alternatively promote adaptive functioning in the context of adverse stressful life events. Additionally, other psychosocial factors during development like social support, parental care, and affective style have been identified as potentially protective factors that can enhance adaptive coping during or after stress. In a similar vein, brain frontal alpha asymmetry has been suggested to bias individuals' affective style and emotion regulation capacities. Specifically, left frontal activation has been linked to approach behavior and suggested to be an indicator of decreased vulnerability to depression whereas right frontal activation is viewed as a predispositional factor, lowering the threshold for adverse impact of stressful conditions.

In sum, stress vulnerability models underscore that the nature and intensity of the stressor in combination with genetic vulnerability factors, phenotypic vulnerability factors (personality, neuroendocrine reactivity), and both genetic and phenotypic protective (resilience) factors determine the impact and sequela of adverse stressful life events.

Stress, Caregiver

Youngmee Kim
Department of Psychology, University of Miami, Coral Gables, Miami, FL, USA

Synonyms

Caregiver burden; Caregiver hassle; Caregiver strain

Definition

The stress of caregivers is defined as a feeling experienced when a person thinks that the demands of caregiving exceed the personal and social resources the individual is able to mobilize (Lazarus & Folkman, 1984).

Description

An illness affects not only the quality of life of individuals with the disease but also that of their family members and close friends who care for the patients. The stress of caregivers is defined as a feeling experienced when a person thinks that the demands of caregiving exceed the personal and social resources the individual is able to mobilize (Lazarus & Folkman, 1984). The caregiver role of family members incorporates diverse aspects involved in dealing with an illness of the relative. This role includes providing the patient with cognitive/informational, emotional, financial/legal, daily activity, medical, and spiritual support, as well as facilitating communication with medical professionals and other family members and assisting in the maintenance of social relationships (Kim & Given, 2008). All of these aspects can contribute to caregivers' stress when they perceive it difficult to mobilize their personal and social resources to carry out each of the caregiving-related tasks. Therefore, identifying the gaps between resources available for caregiving and the caregiving demands, unmet needs in caregiving, should be the initial step in the development of programs designed to reduce caregivers' stress and enhance their quality of life.

In addition to assessing the diverse aspects of caregivers' stress and unmet needs, understanding how caregivers' stress varies across the illness trajectory is an importance concern (Kim, Kashy, Spillers, & Evans, 2010). For example, in the early phase of caregivership, caregivers' stress is often associated with providing informational and medical support to the patients. During the remission phase, dealing with uncertainty about the future, fear that the disease may come back, the financial burden of extended treatment needs of the patients, and changes in social relationships are major sources of caregivers' stress. After the death of the patients, spiritual concerns and psychological and physical recovery efforts from caregiving strain are the challenges caregivers face.

Another important aspect of caregivers' stress is their own unmet needs—things that are not directly related to caring for the patient but represent important personal needs to the caregivers. That is, in addition to caring for the individual with an illness, family caregivers likely have responsibilities for self-care and care for other family members that may have to be set aside or ignored in order to carry out the caregiver role.

This complex construct of caregiver stress has been associated with caregivers' demographic characteristics (Kim et al., 2010; Pinquart & Sörensen, 2003, 2005). For example, younger caregivers have reported greater stress in providing psychosocial, medical, financial, and daily activity support during the early phase of the illness trajectory. During the remission years after the illness onset, however, younger caregivers have reported greater stress only in daily activity. Gender has been also an important factor. Female caregivers have reported greater stress from dealing with psychosocial concerns of the patients, other family members, and themselves. Ethnic minorities tend to report lower levels of psychological stress but greater levels

of physical stress from caregiving. Studies have found mixed associations of caregiver stress to other demographic characteristics, such as education, income, employment status.

Perceived level of stress from providing care has been significantly related to the caregivers' quality of life, after taking into consideration the variations in caregiving stress related to the demographic characteristics mentioned above (Kim et al., 2010; Pinquart & Sörensen, 2003). Caregivers who reported higher levels of psychosocial stress from caregiving have shown poorer mental health consistently and strongly across different phases of the illness trajectory. Caregivers' poorer mental health has also been related to higher levels of stress from meeting the medical needs of the patients during the early phase of illness, whereas during remission, poorer mental health has been related to financial stress from caregiving.

With regard to the self-reported physical health of the caregivers, caregivers' perceived stress has been a fairly weak contributor beyond contributions of demographic factors (Kim et al., 2010; Pinquart & Sörensen, 2003). However, the physical burden of caregiving, documented in objective measures, is considerable. For example, compared with matched non-caregivers, caregivers for a spouse with dementia report more infectious illness episodes, have poorer immune responses to influenza virus and pneumococcal pneumonia vaccines (Glaser, Sheridan, Malarkey, MacCaullum, & Kiecolt-Glaser, 2000), show slower healing for small standardized wounds, have greater depressive symptoms, and are at greater risk for coronary heart disease (2000; Vitaliano, Zhang, & Scanlan, 2003). A recent meta-analysis (2003) concluded that compared with demographically similar non-caregivers, caregivers of dementia patients had a 9% greater risk of health problems, a 23% higher level of stress hormones, and a 15% poorer antibody production. Moreover, caregivers' relative risk for all-cause mortality was 63% higher than non-caregiver controls.

Immune dysregulation has been identified as a key mechanism linking caregiving stress to physical health. Chronically stressed dementia caregivers have numerous immune deficits compared to demographically matched non-caregivers, including lower T-cell proliferation, higher production of immune regulatory cytokines (interleukin-2 [IL-2], C-reactive protein [CRP], tumor necrosis factor-alpha [TNF- α], IL-10, IL-6, D-dimer), decreased antibody and virus-specific T-cell responses to influenza virus vaccination, and a shift from a Th1 to Th2 cytokine response (i.e., an increase in the percentage and total number of IL10+/CD4+ and IL10+/CD8+ cells) (Segerstrom & Miller, 2004; Vitaliano et al., 2003). A 6-year longitudinal community study (Kiecolt-Glaser et al., 2003) documented that caregivers' average rate of increase in IL-6 was about four times as large as that of non-caregivers. The mean annual change in IL-6 among former caregivers did not differ from that of current caregivers, even several years after the death of the spouse. There were no systematic group differences in chronic health problems, medications, or health-relevant behaviors that might otherwise account for changes in caregivers' IL-6 levels during the 6 years of the study period (2003).

Another mechanism linking caregiving stress to poor physical health is lifestyle behaviors. Family members with chronic strain from caring for dementia patients increase health-risk behaviors, such as smoking and alcohol consumption (Carter, 2002). They also get inadequate rest, inadequate exercise, and forget to take prescription drugs to manage their own health conditions, resulting in poorer physical health (Beach, Schulz, Yee, & Jackson, 2000; Burton, Newsom, Schulz, Hirsch, & German, 1997).

In summary, caregiver stress is a multidimensional construct that varies in nature across the illness trajectory. Certain caregivers by their demographic characteristics can be identified as a vulnerable sub-group to greater caregiving stress. Overall, however, caregiving stress takes a considerable toll on the caregivers' mental and physical health. Such effects deserve further systematic study to understand

their psychological, biological, and behavioral pathways.

Stress, Early Life

Christine Heim
Institute of Medical Psychology, Charité University Medicine Berlin, Berlin, Germany

Synonyms

Adversity, early life; Trauma, early life

Definition

In order to define early life stress in humans, two main criteria must be considered: (a) the developmental age range that is subsumed under "early life" and (b) the characteristics of the events that would be considered as "stressful" during early life. There is no such generally agreed upon definition (Heim, Meinlschmidt, & Nemeroff 2003).

Many investigators use an upper age limit to define the early life criterion, usually between 12 and 18 years. An alternative approach is to define the early life period by developmental stage, using, for example, sexual maturation (such as menarche in girls) as a cutoff criterion.

As for the stress criterion, prevailing models suggest that stress is generally experienced when an individual is confronted with a situation, which is appraised as personally threatening and for which adequate coping resources are

unavailable. In addition, threats to physiological homeostasis, such as injury or illness, elicit stress responses. Any such situation occurring within the defined developmental period may be classified as early life stress. The most salient forms of early life stress in humans are abuse (sexual, physical, emotional), neglect (emotional, physical), and parental loss (death, separation). Other forms of early life stress include accidents, physical illness, surgeries, natural disasters, and war or terrorism-related events. Less obvious experiences, which pose significant distress on a child, include unstable families, inadequate parental care, dysfunctional relationships between parent and child, and poverty.

Early life stress is often complex, inasmuch as various forms coexist or are associated among each other. While early life stress may be a single event, it more typically occurs as chronic or ongoing adversity in most cases. Taken together, there remains substantial ambiguity in the definition of early life stress in humans (Heim, Meinlschmidt, & Nemeroff 2003).

Description

It is well established that early life stress, such as childhood abuse, neglect, or loss, dramatically increases the risk for developing a wide range of psychiatric disorders as well as certain medical diseases later in life. Among the major psychiatric disorders, depression and anxiety disorders have been most prominently linked to early life stress. Medical disorders, for which early-life stress induces risk, include ischemic heart disease, lung disease, cancer, gastrointestinal disorders, and chronic fatigue and pain syndromes among others. Early life stress has further been linked to a variety of risk behaviors, including smoking, alcohol, or drug abuse, impulsive behavior, promiscuity, teen pregnancy, and suicide (for further reading, see Anda et al., 2006). Many of the above disorders and risk behaviors are elicited or aggravated by acute stress, and individuals with early life stress experiences have decreased thresholds to exhibit symptoms and risk behaviors even upon mild challenge (Hammen, Henry, & Daley, 2000).

The precise mechanisms that mediate the detrimental and persistent impact of early adversity on long-term adaptation and health have been the subject of intense inquiry over decades. Advances from neuroscience research have provided compelling insights into the enormous plasticity of the developing brain as a function of experience. For example, visual sensory input early in life is required for normal development of the visual cortex and perception, and disruptive experiences during such critical periods of plasticity can lead to lifelong and sometimes irreversible damage. The same principle may be applied to stress experiences during critical periods early in life that may permanently impact on the development of brain regions implicated in the regulation of emotion and stress responses (for further reading, see Weiss & Wagner, 1998). Enduring effects of early life stress on the brain and its regulatory outflow systems, including the autonomic, endocrine, and immune systems, may then lead to the development of a vulnerable phenotype with increased sensitivity to stress and risk for a range of behavioral and somatic disorders (for further reading, see Heim, Plotsky, & Nemeroff, 2004).

Compelling support for this hypothesis comes from a burgeoning literature of studies in animal models that provide the direct and causal evidence that early adverse experience, such as prolonged maternal separation or naturally occurring low maternal care, leads to structural, functional, and epigenetic changes in a connected network of brain regions that is implicated in neuroendocrine control, autonomic regulation and vigilance, and emotional regulation or fear conditioning. These neural changes converge into lifelong increased physiological and behavioral responses to subsequent stress in animal models (see Heim et al., 2004; Lupien, McEwen, Gunnar, & Heim, 2009; Meaney, 2001). These effects appear to be present across species and in different models of adversity, while the unifying element across studies is timing of the stressor in early life. Particularly intriguing are results

from animal studies suggesting that epigenetic changes, stress sensitization, and maternal care behavior are transmitted into the next generation (Francis, Diorio, Liu, & Meaney, 1999; Franklin et al., 2010).

Accumulating evidence suggests that these preclinical findings can be translated to humans. For example, adult women with histories of childhood sexual or physical abuse exhibit markedly increased neuroendocrine and autonomic responses to psychosocial laboratory stress, particularly those with depression (Heim et al., 2000). Other alterations in humans with early life stress experiences include glucocorticoid resistance, increased levels of inflammation, increased central corticotropin-releasing hormone activity and decreased activity of the prosocial neuropeptide, oxytocin (Carpenter et al. 2004; Danese, Pariante, Caspi, Taylor, & Poulton, 2007; Heim, Newport, Mletzko, Miller, & Nemeroff, 2008; Heim et al., 2009). A small hippocampus has also been linked to early life stress in humans (Vythilingam et al., 2002). Early adversity has also been found to be associated with epigenetic changes of the glucocorticoid receptor gene in hippocampal tissue obtained by postmortem from suicide victims, leading to reduced glucocorticoid receptor expression and enhanced stress responses (McGowan et al., 2008).

Taken together, these neurobiological and epigenetic changes secondary to early life stress likely reflect risk to develop depression and a host of other disorders in response to additional challenge. In several studies, these changes were not present in depressed persons without early life stress, suggesting the existence of biologically distinguishable subtypes of depression as a function of early life stress (Heim et al., 2008, 2004). These subtypes of depression were also found to be responsive to differential treatments (Nemeroff et al., 2003). Therefore, consideration of early life stress might be critical to guide treatment decisions.

Several genes moderate the link between childhood trauma and adult risk for depression and other disorders, including the serotonin transporter, corticotropin-releasing hormone receptor 1, FK506 binding protein 5, and oxytocin receptor genes. A more recent idea is that such genetic factors might reflect general sensitivity to the environment, inasmuch as persons who are susceptible to the detrimental effects of trauma might also be particularly amenable to the beneficial effects of a positive social environment or early psychological intervention (Binder et al., 2008; Bradley et al., 2008; Bradley, Westen, Binder, Jovanovic, & Heim, 2011; for further reading, see Caspi, Hariri, Holmes, Uher, & Moffitt, 2010).

Stress, Emotional

Tamar Mendelson
Mental Health, Johns Hopkins Bloomberg School of Public Health Johns Hopkins University, Baltimore, MD, USA

Synonyms

Emotional distress; Mental stress; Psychological stress; Stress

Definition

Emotional stress involves the experience of negative affect, such as anxiety, in the context of a physiological stress response that includes cardiovascular and hormonal changes. Emotional stress commonly occurs when an individual perceives that he or she does not have adequate personal resources to meet situational demands effectively (Lazarus, 1966).

Description

Early conceptions of stress characterized its physical properties, with a focus on the disruption of homeostasis in an organism (Selye, 1956). The stress concept subsequently evolved to include a greater emphasis on the influence of psychological factors on the stress process. The term "emotional stress" reflects the fact that the stress process in humans involves a substantial affective component.

Emotional stress includes both negative affect, such as anxiety and distress, as well as a cascade of physiological responses associated with the

stress-response system. Physiological responses promote "fight or flight" and include activation of the hypothalamic pituitary adrenal (HPA) axis, which stimulates secretion of cortisol, and activation of the sympathetic nervous system, which increases heart rate (Sapolsky, 1994). Behavioral responses may include attempts to flee or avoid the stressor or to actively address it.

Emotional stress can be triggered by various stress exposures, including major life events, chronic stressful situations, and daily hassles. Certain objective features of a stressor influence the likelihood that it will produce emotional stress. For instance, emotional stress is more likely to result from stressors that are not within an individual's control (e.g., a death) and affect central aspects of an individual's life (Dohrenwend, 2000).

Individual differences are also critical components in predicting levels of emotional stress, particularly when the stressor is not extremely traumatic. Thus, the same stressor may produce emotional stress in one individual but not in another. Richard Lazarus and Susan Folkman's work has established the importance of appraisal processes in generating or buffering against stress (Lazarus & Folkman, 1984). Emotional stress results from an appraisal that the situation is threatening and that efforts to address it effectively are not likely to be successful. In contrast, a sense of positive challenge may arise if the situation is not perceived as overly threatening or if the perceiver feels capable of an effective response. Similarly, a number of other factors can increase risk for, or protect against, emotional stress. These factors include the ability to employ effective coping strategies and the presence of positive social supports (Kessler, Price, & Wortman, 1985).

A life course perspective is important for understanding the etiology of vulnerability to emotional stress. Both vulnerability to stress and resilience are likely shaped over the life course by complex interactions of genetic factors, biological mechanisms, and environmental exposures. Emerging research suggests that exposure to stress and adversity during sensitive periods early in the life course (prenatal, early postnatal, childhood) may be especially critical in influencing genetic expression and impacting the developing stress-response system, with long-term effects on vulnerability to emotional stress (Anderson & Teicher, 2009; Dudley, Li, Kobor, Kippin, & Bredy, 2011; Shonkoff, Boyce, & McEwen, 2009).

A key reason for continued interest in the study of emotional stress is its well-documented link with development of both mental and physical disorders. Major depressive disorder and posttraumatic stress disorder are two commonly studied psychiatric sequelae of emotional stress. Emotional stress has also been found to predict cardiovascular disease and other physical health problems (Brotman, Golden, & Wittstein, 2007; Rozanski, Blumenthal, & Kaplan, 1999). Putative mechanisms linking emotional stress with psychiatric and physical disorders include stress-related neurobiological changes (e.g., dysregulation of the HPA axis) and increased cardiovascular reactivity to stress with slow recovery (Chida & Steptoe, 2010; Hammen, 2005); detailed understanding of these pathways requires more study.

A variety of psychosocial stress management interventions have been developed to reduce emotional stress and prevent its negative effects on health. Such interventions generally aim to enhance positive coping methods, including the use of relaxation techniques, exercise, and cognitive strategies for managing stress. Some stress management interventions have been shown to have positive effects on emotional and physical outcomes (e.g., Blumenthal et al., 2005).

Stress, Exercise

Rick LaCaille[1] and Marc Taylor[2]
[1]Psychology Department, University of Minnesota Duluth, Duluth, MN, USA
[2]Department 163, Behavioral Sciences & Epidemiology, Naval Health Research Center, San Diego, CA, USA

Definition

Exercise is a form of physical activity that involves repeated body movements that are both structured and planned with the intention of maintaining or enhancing one's health or physical fitness. Typically, exercise is characterized as either aerobic or anaerobic with the former emphasizing the use of oxygen for sustained movements such as jogging or swimming, whereas the latter emphasizes the use of muscle glycogen supply and metabolism as sources of energy for higher-intensity activities such as strength and resistance training. Moreover, exercise has been defined in terms of being chronic/regular/habitual or as acute/single bout.

Stress represents a response among biopsychosocial systems in an effort to adapt to a challenge. The nature of the challenge has been delineated along several dimensions, including but not limited to its intensity, duration, frequency, quality, and familiarity. The stress response has been measured in naturally occurring situations as well as in laboratory settings and ranged from self-reported questionnaires to physiological indices of neuroendocrine, heart rate, and blood pressure reactivity.

Description

The health benefits of exercise and physical fitness have been well documented in the literature. In particular, the effects of exercise on reduced morbidity and mortality from cardiovascular disease have received a great deal of attention, in part, due to the association between stress and

cardiovascular disease and the potential attenuation of physiological reactivity to stressors. Notably, an acute bout of exercise may also act as a stressor and elicit the same cardiovascular and neuroendocrine responses as psychosocial stressors without the detrimental effects health. As exercise becomes chronic and habitual, the physiological adaptations (e.g., reduced heart rate and blood pressure and increased parasympathetic activity) that occur are thought to yield similar responses and adaptations in the presence of psychosocial stressors. This beneficial adaptation and reduced sensitivity to stress is characterized in the literature as the cross-stressor-adaptation hypothesis. Thus, the effect of exercise on stress response is somewhat paradoxical as it is considered to be both a stressor and a potential modifier of stress. Most investigations of exercise-stress adaptations have relied upon laboratory stressors (e.g., mental arithmetic, public speaking and evaluative scenarios, cold pressor tests, reaction time, Stroop color-word test), cardiorespiratory responses, and cross-sectional designs. Although a number of studies have examined the association between exercise/fitness and psychophysiological stress responses, the findings have been rather mixed even among the reviews and quantitative analyses of the literature.

In an initial meta-analysis of the relationship between aerobic fitness and resistance to stress reactivity by Crews and Landers (1987), the overall effect size across multiple indices was d = 0.48 with effects ranging from 0.15 to 0.87. The findings from this review suggested that fitness/exercise training was beneficial in reducing reactivity to stressors with regards to heart rate d = (0.39), diastolic blood pressure d = (0.40), systolic blood pressure d = (0.42), self-reported stress d = (0.57), skin response d = (0.67), and muscle tension d = (0.87). The review has since been criticized for a number of methodological limitations including confounding reactivity with recovery. Later qualitative reviews reported no beneficial effect for fitness on stress reactivity in terms of heart rate, blood pressure, or catecholamine responses, with the effect on stress recovery determined to be inconclusive (Claytor, 1991; De Geus & Van Doornen, 1993). More recently, Jackson and Dishman (2006) revealed in a meta-analytic review that fitness was associated with a slight increase in stress reactivity to laboratory psychosocial stressors. Notably, a small effect size was present between cardiorespiratory fitness and stress response recovery, indicating that physically fitter individuals appeared to have an enhanced and quicker recovery following their peak stress response. In contrast to these findings, Forcier and colleague's (2006) meta-analytic review examining the effects of aerobic fitness on stress reactivity and recovery revealed that, despite considerable heterogeneity present in the analyses and no significant moderation effects (e.g., gender, stressor intensity), significant effects for exercise/fitness were found for decreased heart rate and systolic blood pressure reactivity. Additionally, a significant effect was found for fitness and heart rate recovery, though no such effect was present for systolic blood pressure. Thus, the findings from this meta-analysis suggest a beneficial attenuated physiological reactivity and improved recovery from psychosocial stressors as a consequence of fitness/chronic exercise. Although the effects between fitness and reactivity/recovery appeared small in magnitude (e.g., 1.8 bpm heart rate reactivity, 3.7 mmHg systolic blood pressure reactivity), the differences are equivalent to 15–25% reductions in reactivity which may still be of clinical importance.

Evidence from a recent meta-analysis (Hamer, Taylor, & Steptoe, 2006) examining blood pressure response to a psychosocial stressor suggested that an acute bout of aerobic exercise may result in a significant reduction in reactivity. That is, medium effect sizes revealed that exercise resulted in beneficial attenuated stress reactivity for both diastolic and systolic blood pressure with reductions of a 3.0 mmHg and 3.7 mmHg in diastolic and systolic responses, respectively. The observed effects appeared most robust with psychosocial stressors administered up to 30 min postexercise with moderate to vigorous exercise intensity and durations lasting from 20 min to 2 h. The findings from this review offer the possibility that the effects of acute exercise may account for some

of the mixed results from studies examining chronic exercise and blood pressure reactivity because habitually exercising may place an individual in the postexercise "window" more frequently when encountering daily stressors and thereby result in attenuated stress responses.

Although evidence from meta-analytic reviews is lacking, some studies have reported relationships between physical fitness and reduced hypothalamic-pituitary-adrenal (HPA) axis psychosocial stress reactivity, such as cortisol and inflammatory cytokine production. However, the ability to draw solid conclusions in this area is currently limited. With regard to sympathetic-adrenal-medullary responses, the findings appear conflicting as a result of sampling methodology and exercise intensity and durations employed. Some studies have found no effect of fitness on norepinephrine and epinephrine levels, whereas other studies have reported higher norepinephrine levels in the early phases of a stress response or, conversely, an association between lower levels of fitness and an increased norepinephrine response. In animal analogue studies, levels of norepinephrine have been shown to increase in the frontal cortex following an acute bout of exercise, suggesting increased vigilance to threat and reactivity; however, reduced levels have been found in the hypothalamus and hippocampus which suggests diminished stress reactivity.

In summary, although it appears that acute and chronic exercise and fitness may favorably influence an individual's response to psychosocial stress, further research is needed to clarify this relationship. Reviews of the literature suggest that there is a need for greater methodological rigor and reporting as well as examination of potential moderators of exercise-reactivity and exercise-recovery associations.

Stress, Posttraumatic

Viana Turcios-Cotto
Department of Psychology, University of Connecticut, Storrs, CT, USA

Synonyms

PTS

Definition

Posttraumatic stress is a stress reaction characterized by a multitude of symptoms following a traumatic event. Symptoms can be affective, behavioral, cognitive, and/or physiological in nature. These symptoms appear only after exposure to an event that involved a threat to one's physical integrity such as actual or threatened death or serious injury to oneself, witnessing such a threat on another person, or learning of such a threat experienced by a family member or other close person. A traumatic event can come in many forms including but not limited to a natural disaster (e.g., earthquake, tornado), violent personal attack, (e.g., rape, robbery), military combat, terrorist attack, severe automobile accident, or diagnosis of life-threatening illness (American Psychiatric Association [APA], 1994). Although posttraumatic stress is similar to posttraumatic stress disorder (PTSD), a diagnosable psychological condition, it is distinctly different in that the symptoms of posttraumatic stress may not be as severe or as numerous as those of PTSD. Thus, not all of the criteria necessary for diagnosis of PTSD are met, and the symptoms typically do not cause clinically significant distress or impairment in important areas of functioning.

Description

Rates of trauma exposure are unclear, but it is estimated that a majority of people, over 60%, living within the United States have experienced at least one traumatic event (Resick, Monson, & Rizvi, 2008). Some of those affected will develop no signs of distress, whereas some will develop clinically significant, diagnosable signs of distress, and yet others, people experiencing posttraumatic stress, can be categorized as developing subclinical levels of distress. Like many other psychological difficulties, whether or not someone develops significant signs of distress after a traumatic event depends on many variables such as the individual's coping abilities, trauma history, support system, type of traumatic event, intensity of the event, proximity to the event, and so on. Individuals with diminished coping abilities, extensive trauma histories, weak support systems, and who experience more intense and physical traumas closer to their bodies will be at greater risk for suffering from more severe posttraumatic distress (APA, 1994; Resick et al., 2008). Since the subclinical population does not warrant a diagnosis and most likely does not seek treatment due to the lack of or low level of impairment, it is difficult to estimate how many are afflicted by posttraumatic stress. However, individuals living with posttraumatic stress experience various difficulties, which can be categorized into groups of affective, behavioral, cognitive, and physiological symptoms.

Affective Symptoms

After a traumatic event, one can feel a variety of stressful emotions as a consequence for days, weeks, or even months after the experience. Intense fear and helplessness are characteristic markers of posttraumatic stress (APA, 1994; Beidel & Stipelman, 2007; Resick et al., 2008). A person can feel scared that the event might reoccur at any moment and horror that he or she will be unable to stop it from happening again. One might fear for their life and worry that death or severe injury is imminent, creating constant anxiety, and perhaps a sense of a foreshortened future (APA, 1994; Beidel & Stipelman, 2007). Some people may react to a traumatic incident with guilt and/or shame, unwilling to talk to others about the incident believing that they are at fault for the event. Sadness and even depression can also arise as a result from experiencing a trauma. This can lead to no longer finding pleasure in activities that the person once enjoyed or in diminished social involvement (Beidel & Stipelman, 2007). Lastly, an individual may experience a feeling of anger, manifested through irritability or outbursts (APA, 1994). This anger may be focused on the event itself; it may also be geared toward others, perhaps blaming others for the occurrence of the event or fueled by mistrust of others. Overall, the affective symptoms that result from posttraumatic stress are typically negative and can become harmful if they linger for too long.

Behavioral Symptoms

Certain behaviors that were not present before a traumatic event can also surface as a result. Hypervigilance, a constant watchful eye on one's surroundings, is a hallmark behavior used to protect oneself from unexpected threats. This hypervigilance includes heightened sensory sensitivity with an intense, somewhat irrational reaction or an exaggerated startle response (APA, 1994; Beidel & Stipelman, 2007). For example, an individual who has personally experienced an earthquake may become more aware of slight tremors, flickering lights, rattling windows, or rumbling sounds that others do not notice. These stimuli might arouse fear or anxiety in the individual who might feel as if they are reexperiencing the traumatic event. A person may also purposely work toward not reexperiencing or remembering the event. He or she might avoid certain places, people, smells, sounds, topics of conversation, or anything else that might trigger memories of the incident and may even be unable to recall certain aspects of the event altogether (Beidel & Stipelman, 2007; Resick et al., 2008). One might also learn to numb their feelings so that they no longer experience fear, anxiety, or anger as a protective measure from the various affective symptoms that may have developed after the trauma. However, this typically also leads to numbing positive affect such as joy and excitement as well, restricting one's range of affect (APA, 1994; Beidel & Stipelman, 2007). Avoidance and numbing can further cause a person to become somewhat reclusive and decrease involvement in social situations, resulting in a feeling of detachment or estrangement from friends and family. In general, the behavioral symptoms that appear after a traumatic event are used as coping mechanisms to either protect oneself to keep such an event from reoccurring or to distance oneself from the event that has occurred.

Cognitive Symptoms

There are key cognitions that are representative of those individuals who have experienced a trauma. Most often, there is an overgeneralization of the event and the harm that it caused (Resick et al., 2008). In other words, an individual might believe that harmful or deadly events happen more often and in more places than previously thought. He or she might feel that he or she is always at risk and lacks safety, misappraising minor events or stimuli as much more dangerous than they really are. A victim might lose trust in others and think that others are out to harm him or her, particularly if another human being caused the trauma. Other distorted cognitions about power and control may surface as well (Resick et al.). Such beliefs might be that one has no control or power over events in their daily life, perhaps lowering self-esteem. Another distortion might be self-blame where the victim believes he or she had complete control and power in the situation, bringing the traumatic event upon him or herself. This can result in a feeling of shame or guilt.

Although cognitive symptoms usually only include cognitions or beliefs that a person holds, in the case of posttraumatic stress, they also include ideas, images, and impulses that might materialize in one's mind after a traumatic event. Individuals might have sudden, intrusive memories of images, smells, sounds, etc., of the event flash in his or her mind (APA, 1994). The victim might also have distressing dreams about the incident or feel and act as if he or she is reliving the terrible moment (Resick et al., 2008). Due to the many stressors experienced after a traumatic event, concentration may be difficult for individuals with posttraumatic stress.

Physiological Symptoms

Posttraumatic stress causes physiological changes as well. Most notably, there is an increase in heart rate and sweat gland activity. Levels of cortisol may also rise. These symptoms may lead to exhaustion or various serious illnesses such as heart disease (Resick et al., 2008; Sarafino, 2008).

Summary

Posttraumatic stress is a psychological stress reaction following a traumatic event. It is characterized by a multitude of affective, behavioral, cognitive, and physiological symptoms that

negatively impact an individual. However, the symptoms are not severe enough to cause impairment in social, occupational, or other areas of functioning and therefore do not warrant a diagnosis. Nevertheless, if symptoms become more severe and do not diminish within a month's time, they may be a sign of a diagnosable psychological condition, posttraumatic stress disorder. In such a case, the individual should seek treatment from a professional psychologist or counselor.

Stress: Appraisal and Coping

Susan Folkman
Department of Medicine, School of Medicine, University of California San Francisco, San Mateo, CA, USA

Definition

Stress has been defined traditionally either as a *stimulus*, often referred to as a *stressor*, that happens to the person such as a laboratory shock or loss of a job, or as a *response* characterized by physiological arousal and negative affect, especially anxiety. In his 1966 book, *Psychological Stress and the Coping Process* (Lazarus, 1966), Richard Lazarus defined stress as a relationship between the person and the environment that is appraised as personally significant and as taxing or exceeding resources for coping. This definition is the foundation of stress and coping theory (Lazarus & Folkman, 1984).

Description

Stress and coping theory provides a framework that is useful for formulating and testing hypotheses about the stress process and its relation to physical and mental health. The framework emphasizes the importance of two processes, appraisal and coping, as mediators of the ongoing relationship between the person and the environment. Stress and coping theory is relevant to the stress process as it is experienced in the ordinary events of daily life, major life events, and chronic stressful conditions that stretch out over years.

Appraisal refers to the individual's continuous evaluation of how things are going in relation to his or her personal goals, values, and beliefs. Primary appraisal asks "Am I okay?" Secondary appraisal asks "What can I do?" Situations that signal harm or potential harm that is personally significant and in which there are few options for controlling what happens are appraised as stressful. Stress appraisals include harm or loss, which refer to damage already done; appraisals of threat, which refer to the judgment that something bad might happen; and appraisals of challenge, which refer to something that may happen that offers the opportunity for mastery or gain as well as some risk of an unwelcome outcome. Situations that are appraised as high in personal significance and low in controllability, for example, are usually appraised as threats, and situations that are high in personal significance and high in controllability are more likely to be appraised as challenges.

The concept of appraisal addresses the issue of variability of responses among people experiencing a similar stressor and why a given situation may be more stressful for one person than another. The situation may involve goals, values, or beliefs that are more personally significant for one person than for another, or one person may be better equipped than another to control the situation's outcome. Appraisal-based approaches now dominate the field (Pearlin, Lieberman, Menaghan, & Mullan, 1981).

Appraisals generate emotions that vary in quality and intensity according to the person's evaluation of personal significance (primary appraisal) and options for coping (secondary appraisal). Threat appraisals, for example, are often accompanied by fear, anxiety, and worry; harm/loss appraisals are often accompanied by anger, sadness, or guilt; and challenge appraisals are often accompanied by eagerness and excitement as well as a touch of threat.

People experience a complex array of emotions during real-life stressful events, including positive as well as negative emotions (Folkman, 1997, 2008). Emotions indicate that something is happening that matters to the individual. Emotions also often signal what the person intends to do. Negative emotions have long been associated with the individual's preparation to approach or avoid, fight or flee (Lazarus, 1991). Positive emotions have more recently been examined for their roles in the stress process. Positive emotions, for example, are associated with widened focus of attention, motivating meaning-focused coping, and eliciting social support (Folkman, 2008; Fredrickson, 1998).

Coping refers to the thoughts and actions people use to manage distress (emotion-focused coping), manage the problem causing the distress (problem-focused coping), and sustain positive well-being (meaning-focused coping). Emotion-focused coping includes strategies such as distancing, humor, and seeking social support that are generally considered adaptive, and strategies such as escape-avoidance, day dreaming, and blaming others that are generally considered maladaptive. Problem-focused coping includes strategies such as information gathering, seeking advice, drawing on previous experience, negotiating, and problem solving. Meaning-focused coping includes strategies such as focusing on deeply held values, beliefs, and goals; reframing or reappraising situations in positive ways; and amplifying positive moments over the course of a day (Folkman & Moskowitz, 2000).

Coping is influenced by the person's coping resources including psychological, spiritual, social, environmental, and material resources, and by the nature of the situation, especially whether its outcome is controllable or has to be accepted. Problem-focused coping is used more in situations that are controllable, and emotion-focused coping is used more in situations that have to be accepted. Meaning-focused coping appears to be used more in situations that are chronic and not resolvable, such as in caregiving or serious illness. It is hypothesized that meaning-focused coping becomes more active when initial coping efforts fail to make the situation better (Folkman, 2011). Meaning-focused coping sustains other coping efforts and restores coping resources.

People use an array of coping strategies in real-life situations. Most situations involve more than one coping task or goal, each of which requires a coping strategy tailored to that task or goal. And people switch coping strategies when the ones they are using do not have the desired effect. Coping also changes as an encounter unfolds in response to changes in the environment, the situation, or to changes within the person.

Coping effectiveness is determined contextually because effective coping in one situation may be ineffective in another. For instance, distancing may be ineffective when a person should be problem solving or preparing for an upcoming challenge, whereas it may be effective when there is nothing to be done, as when waiting for a test result. Researchers often identify on an a priori basis the outcome that is desired, such as improved mood. In such cases, effective coping is the coping that is associated with the desired outcome.

Another approach to evaluating coping is to examine the goodness of the fit between the

appraised options for coping and the choice of coping strategy. Problem-focused coping that is used when the situation is appraised as controllable, for example, would be a good fit, whereas the same form of coping in situation where nothing can be done would be a poor fit. Conversely, distancing that is used when there is nothing that can be done would be a good fit, whereas the same form of coping in a controllable situation that called for attention would be a poor fit.

Like appraisal, coping is key to understanding why the outcomes of given stressful situations can vary from person to person. Two people may cope quite differently with the same stressful situation because of differences in their resources, experiences, motivation, preferences, and skills for coping.

The dynamic quality of the stress process is evident in changes in the appraisal and reappraisal process, the fluidity of emotions, and changes in coping thoughts and actions as an encounter unfolds. The processes are also in reciprocal relationships. An outcome of appraisal and coping at Time 1, such as mood, for example, can become a predictor of appraisal and coping at Time 2.

Stroke Burden

Jonathan Newman
Columbia University, New York, NY, USA

Definition

Description

Strokes are one of the leading causes of death and disability: each year, nearly 800,000 Americans experience a new or recurrent stroke. Approximately 600,000 of these are first events and roughly 180,000 are recurrent attacks. In the United States, strokes accounted for 1 out of every 16 deaths in 2004, and more than 50% of the deaths attributable to strokes occurred outside of the hospital. When separated from other cardiovascular diseases, stroke is the third leading cause of death, behind heart disease and cancer. Importantly, strides have been made in reduction

of stroke mortality: the stroke death rate has fallen more than 20% from 1994 to 2004. However, important disparities remain. While Hispanic, Latino, American Indian, and Pacific Islander populations have somewhat lower stroke death rates than whites, black men and women continue to have significantly higher stroke death rates than all other populations, and the prevalence of stroke remains higher in minority populations than among whites. Lastly, because women live longer than men, in 2004, women accounted for greater than 60% of stroke deaths in the United States.

In addition to the significant mortality, the morbidity associated with stroke is considerable: more than 25% of stroke survivors older than age 65 are disabled 6 months later. The length of time to recover from a stroke depends on its initial severity. From 50% to 70% of stroke survivors regain functional independence, but 15–30% are permanently disabled, and 20% require institutional care at 3 months after onset. Although 70% of strokes are a first cardiovascular event, 15% of survivors will have a recurrent event within 1 year, and 30% will have a recurrent event within 5 years. The period soon after an acute stroke is associated with the highest rate of stroke recurrence, and the risk of stroke following a transient ischemic attack (TIA) is over 10% for the following 90 days.

The medical costs of stroke are high: the estimated direct and indirect costs of stroke for 2008 are $65.5 billion USD. In comparison, the 2008 costs for coronary heart disease were estimated at $156.4 billion USD, making stroke one of the leading US health-care expenditures. The mean lifetime cost of ischemic stroke is over $140,000 USD, and 70% of the first-year costs following an acute stroke are due to inpatient hospital costs.

Finally, the burden associated with stroke contains an important association with other cardiovascular disease processes and risk. Many risk factors for stroke overlap with those of cardiac and peripheral vascular disease. This overlap has led to the concept of "global risk" for cardiovascular disease in general, of which stroke is one component. High blood pressure is the greatest risk factor for stroke, but factors like smoking, diabetes, and low high-density lipoprotein levels are important risk factors. Depression has been suggested to be an independent risk factor for stroke. The occurrence of a stroke is therefore likely to be the initial manifestation of a global cardiovascular disease process, with high morbidity, mortality, and cost, and risk factors that overlap with traditional cardiovascular risk factor categories.

Definition

The Stroop test is commonly used in psychophysiological studies as a problem-solving task to elicit mental stress. The test is an incongruent task that requires participants to identify the

name of a color (e.g., "blue," "green," or "red") that is printed in a conflicting color not denoted by the name (e.g., the word "red" printed in blue ink instead of red ink). The task primarily evokes beta-adrenergically driven responses, resulting in increased heart rate and cardiac output. Functional neuroimaging studies of the Stroop effect have consistently revealed activation in the frontal lobe and more specifically in the anterior cingulate cortex and dorsolateral prefrontal cortex, two structures hypothesized to be responsible for conflict monitoring and resolution.

Structural Equation Modeling (SEM)

Maria Magdalena Llabre and William Arguelles
Department of Psychology, University of Miami, Coral Gables, FL, USA

Synonyms

SEM

Definition

Structural equation modeling (SEM) is a multivariate statistical methodology for the estimation of a system of simultaneous linear equations that may include both observed and latent variables. With origins in the path analysis work of the biometrician Sewell Wright and the factor analysis tradition of Charles Spearman, over the past 40 years, SEM has transitioned from a novel methodology for linear models to a mainstream statistical framework for the analysis of latent variable models. SEM-related techniques may be used to examine a wide variety of structures, including causal models, measurement models, growth models, latent classes or mixtures, and combinations of these. The generality and flexibility of SEM, the development of efficient estimation methods, and the availability of computer programs contribute to the utility of this methodology for addressing important research questions in behavioral medicine.

Description

The first step in an SEM analysis is the specification of the model. SEM models are specified via either a system of structural equations or, more commonly, a path diagram. Included in the path diagram are the observed variables to be analyzed, the constructs or latent variables to be inferred, the unobserved but ever-present errors or disturbances, and the ways in which these observed and unobserved variables are related to one another. The path diagram is a valuable tool in itself, helping investigators better understand their research questions and their data. A path diagram forces the investigator to think critically about every variable relevant to the phenomenon under study.

Observed variables (also called indicators) are the variables we measure directly. These could be exogenous (variables whose causes are not included in the model) or endogenous (variables whose causes are posited in the model). *Path analysis* is a special case of SEM in which all variables specified in a model are observed (except for the errors) and assumed to be perfectly reliable. However, when reliability is not perfect and indicators contain measurement error, as is often the case, parameter estimates may be biased. One of the key features of SEM is the possibility of combining multiple observed variables into *latent variables* (the constructs of interest). A latent variable, like a construct, is not observed directly, but is rather inferred from the covariances shared among its corresponding indicators. For example, we could combine multiple measures of depression into a latent variable to improve reliability. Thus, a general SEM model may be viewed as having two components: a structural model (which allows for the specification and testing of relationships among

variables) and a measurement model (which offers the advantage of using latent variables to represent constructs of interest, modeling sources of measurement error and bias associated with directly observed variables).

Generally speaking, the purpose of analyzing SEM models is twofold. First, we wish to test whether the specified model fits the data. Second and simultaneously, we want to estimate the parameters of interest and test them for significance. The most common *method of estimation* used by available computer programs is maximum likelihood (ML), performed iteratively to arrive at an admissible solution. ML parameter estimates are unbiased, consistent, efficient, and normally distributed in large samples. Given a particular model specification, this method is used to generate and compare a model-implied variance-covariance matrix to the data-based variance-covariance matrix. ML estimates are those that minimize the discrepancy between those two matrices, and as such, yield parameter values that have the greatest likelihood of having given rise to the sample values obtained, assuming a multivariate normal distribution. The typical output from a computer analysis will have indices of model fit, as well as the parameter estimates, their standard errors, and *z*-values used to test them for significance.

The primary index used to test model fit is a χ^2 statistic. However, given this statistic's direct dependence on sample size, with large sample sizes, even small differences between the two matrices may yield a significant χ^2 indicative of poor model fit. Several other indices have been developed and proposed as either alternatives or companions to the χ^2 in such cases, including the comparative fit index (CFI), the root mean squared error of approximation (RMSEA), and the standardized root mean residual (SRMR). Beyond overall measures of fit, it is important to make sure that parameter estimates make sense in relation to the problem being investigated.

In terms of the structural aspect of SEM, the *parameters of primary interest* are the path coefficients (or the direct effects among the variables). In SEM, the variances and covariances among the exogenous variables are also estimated, as well as the variances and covariances of the disturbances. In terms of the measurement aspect of SEM, the parameters of primary interest are the factor (or latent variable) loadings, the measurement error variances, and the variances and covariances of the latent variables.

When working within the SEM framework using ML estimation, it is possible to take advantage of its full information capabilities to include all of the available data. Often referred to as full information maximum likelihood (FIML), this approach to *missing data* has been shown to yield unbiased parameter estimates when missingness is related to variables that are accessible for analysis (Little & Rubin, 2002; Schafer & Graham, 2002). Comparable to multiple imputation, this method is superior to other missing data techniques such as listwise or pairwise deletion, or mean, regression, or hotdeck imputation, particularly when data are not missing completely at random (Enders, 2006).

SEM is a large sample methodology and the appropriate sample size must be considered keeping in mind several issues including model complexity, estimation method, and statistical power. With samples less than 100 participants, models must be simple and the variables normally distributed, otherwise problems with model convergence are likely to arise. As a general rule, more complex models or non-normal data will require more participants.

Of note, testing of *alternative models* is necessary to strengthen the causal inferences often associated with SEM. Sometimes researchers improperly assume that models that fit the data represent reality, without recognizing there are always multiple alternative models that fit just as well. Models can be rejected but not proven. It is important to consider design features such as randomization, experimentation, longitudinal designs, instrumental variables, or inclusion of other variables to strengthen model interpretation.

In addition to testing relationships among variables, means and mean structures may be analyzed. For example, multiple groups may be compared with respect to means of latent

variables, or mean changes over time may be modeled using *latent growth modeling*. Many other extensions are possible but their description is beyond the scope of this entry. However, this is an active area of research and readers are encouraged to learn more by consulting available textbooks, Web sites, and papers. A very readable conceptual introduction to SEM is provided by Kline (2010). A more detailed presentation of its use in behavioral medicine may be found in Llabre (2010). The Web site for Mplus (Muthen & Muthen, 2011) – one of the more popular computer programs – contains a lot of useful information on the basics of SEM, as well as extensions to more complex models.

Structured Clinical Interview for DSM-IV (SCID)

Ulrike Kübler
Department of Psychology, University of Zurich, Binzmuehlestrasse, Zurich, Switzerland

Definition

The Structured Clinical Interview for DSM-IV (SCID) is a semistructured interview created to make reliable psychiatric diagnoses in adults according to the Diagnostic and Statistical Manual, fourth edition (DSM-IV). The SCID has two parts: one for DSM-IV Axis I Disorders (SCID-I) and another for DSM-IV Axis II Personality Disorders (SCID-II).

In order to meet different needs, the SCID-I is available in two versions: the Research Version (SCID-I-RV; First, Spitzer, Gibbon, & Williams, 2002) and the Clinician Version (SCID-CV; First, Spitzer, Gibbon, & Williams, 1996). In contrast to the SCID-CV, the SCID-I-RV comprises more disorders, subtypes, severity, and course specifiers, and is easier to modify. The SCID-I-RV itself is also available in different versions. The broadest SCID-I-RV version comprises 10 self-contained diagnostic modules: Mood Episodes, Psychotic and Associated Symptoms, Psychotic Disorders, Mood Disorders, Substance Use Disorders, Anxiety Disorders, Somatoform Disorders, Eating Disorders, Adjustment Disorders, and an optional module which allows psychiatric diagnoses that may be of the interviewer's interest, such as the module on Acute Stress Disorder and on Minor Depressive Disorder.

The SCID-I starts with an open-ended overview that includes questions about demographic information, work history, chief complaint, past and present periods of psychopathology, treatment history, and current functioning. This is followed by the diagnostic modules, which are presented in a three-column format: the left-hand column contains the interview questions, the

middle column contains the corresponding DSM-IV criteria and in the right-hand column ratings for the criteria are indicated. Besides rating the presence of the DSM-IV criteria for Axis I Disorders, the SCID-I also enables rating of Axis III, IV, and IV of the DSM (see DSM-IV for more details).

The SCID-II (First, Gibbon, Spitzer, Williams, & Benjamin, 1997) is only offered in a single version. It covers the ten standard DSM-IV Axis II Personality Disorders (Avoidant, Dependent, Obsessive-Compulsive, Paranoid, Schizotypal, Schizoid, Histrionic, Narcissistic, Borderline, Antisocial Personality Disorder), as well as Personality Disorder Not Otherwise Specified, and the appendix categories Depressive Personality Disorder and Passive-Aggressive Personality Disorder. The item format and the conventions of the SCID-II are very similar to those of the SCID-I. The SCID-II consists of several questions organized in sections in accordance with the DSM-IV diagnoses for personality disorders. In most cases, the questions correspond accurately with the criteria. To shorten overall administration time, the SCID-II is also provided with a self-report screening questionnaire that is intended to be administered at first. After this questionnaire has been filled out, only those items indicating personality abnormalities need to be inquired in more detail during the interview.

The SCID-II is often used in conjunction with the SCID-I. While administration of SCID-I typically takes between 45 and 90 min, the complete administration time of the SCID-II usually lasts about 1 h. Ideally, the SCID is administered by a trained interviewer familiar with the diagnostic criteria used in the DSM-IV. The SCID can be used in both healthy individuals and psychiatric patients. In individuals with either severe psychotic symptoms or severe cognitive impairments, the administration of the SCID is not recommended.

Overall, the SCID is a widely used assessment tool in both research and clinical settings in many countries. Various versions of the SCID have been translated into multiple languages, including Mandarin, Spanish, French, and German. The psychometric properties of the SCID-I and the SCID-II have been evaluated in several adult populations in numerous investigations, with encouraging results for most Axis I and Axis II disorders (e.g., Lobbestael, Leurgans, & Arntz, 2010). Computer-assisted versions of the SCID are also available. For more information on the SCID, the reader is referred to the SCID website.

Study Protocol

J. Rick Turner
Cardiovascular Safety, Quintiles, Durham, NC, USA

Definition

The study protocol is "the most important document in clinical trials, since it ensures the quality and integrity of the clinical investigation in terms of its planning, execution, conduct, and the analysis of the data" (Chow & Chang, 2007). The study protocol is a comprehensive plan of action that contains information concerning the goals of the study, details of subject recruitment, details of safety monitoring, and all aspects of design, methodology, and analysis. (In some cases, a Statistical Analysis Plan, associated with and written at the same time as the study protocol, will contain the detailed description of the analyses to be conducted.)

Description

The creation of study protocol requires input from many individuals. Consider a study protocol for a pharmaceutical clinical trial, since this is likely to be more extensive (and complex) than some smaller trials for behavioral medicine interventions and treatments. By considering this more extensive version, one will be able to judge which parts are and are not needed on a case by case basis.

In the case of a pharmaceutical trial, input will be needed from clinical scientists, medical safety officers, study managers, data managers, and statisticians. Consequently, while one clinical scientist or medical writer may take primary responsibility for the protocol's preparation, many members of the study team make important contributions.

The requirements of a study protocol include:

- Objectives (usually primary and secondary objectives). These goals of the study are stated as precisely as possible.
- Measurements related to the drug's safety, and procedures to ensure the safety of all subjects while participating in the trial.
- Inclusion and exclusion criteria. These provide detailed criteria for subject eligibility for participation in the trial.
- Details of the procedures for physical examinations.
- Laboratory procedures. Full details of the nature and timing of all procedures and tests are provided.
- Electrocardiogram (ECG) measurement and any other measurements such as imaging.
- Drug treatment schedule. Route of administration, dosage, and dosing regimen are detailed. This information is also provided for the control treatment.
- In the case of later-phase trials, measurements of efficacy. The criteria to be used to determine efficacy are provided.
- In the case of later-phase trials, details of the method of diagnosis of the disease or condition of clinical concern for which the drug is intended.
- Statistical analysis. The precise analytical strategy needs to be detailed, here and/or in an associated statistical analysis plan.

Inclusion and exclusion criteria are central components of clinical trials. A study's inclusion and exclusion criteria govern which individuals interested in participating in the trial are admitted to the study as subjects. Criteria for inclusion in the study include items such as the following:

- Reliable evidence of a diagnosis of the disease or condition of clinical concern.
- Being within a specified age range.
- Willingness to take measures to prevent pregnancy during the course of treatment. This includes a female in the trial not becoming pregnant (she may be receiving the drug being tested), and a male participating in the

trial not causing a female to become pregnant (he may be receiving the drug being tested).

Criteria for exclusion from the study may include:

- Taking certain medications for other medical conditions and which therefore cannot safely be stopped during the trial.
- Participation in another clinical trial within so many months prior to the commencement of this study.
- Liver or kidney disease.

While inclusion and exclusion criteria are typically provided in two separate lists in regulatory documentation, exclusion criteria can be regarded as further refinements of the inclusion criteria. Meeting all the inclusion criteria allows a person to be considered as a study participant, while not meeting any exclusion criteria is also necessary to allow the person to become a participant.

Substance Abuse: Treatment

John Grabowski
Department of Psychiatry, Medical School, University of Minnesota, Minneapolis, MN, USA

Synonyms

Addiction rehabilitation; Chemical dependency treatment; Drug abuse: treatment; Drug and alcohol treatment; Drug dependence treatment; Drug rehabilitation; Inpatient treatment; Outpatient treatment; Residential treatment

Definition

Treatment refers to a defined, empirically evaluated, data-based intervention intended to manage, remediate, or cure a diagnosed condition, here,

impairing or problematic drug use. Historically, there have been two frameworks underpinning substance use treatment, the "disease" and "learning/conditioning" models (Higgins, 1997). While some assumptions are divergent and perhaps irreconcilable, a broad integrative view dictates that genetic and other biological factors interact with behavior and environmental factors as composite determinants of substance use disorders. The diagnostic criteria applied to determining need for treatment are found in the International Statistical Classification of Diseases and Related Health Problems (ICD) 10 (*"Mental and behavioral disorders due to psychoactive substance use"–"a wide variety of disorders that differ in severity and clinical form but that are all attributable to the use of one or more psychoactive substances, which may or may not have been medically prescribed"*) and The American Psychiatric Association Diagnostic and Statistical Manual (DSM) IV, (*"Substance Related Disorders"–"The Substance-Related Disorders include disorders related to the taking of a drug of abuse (including alcohol), to the side effects of a medication, and to toxin exposure"*). The intervention may include behavioral, psychological, social, and pharmacological components delivered by skilled practitioners. There is a wide range of self-help and other efforts with little or no documented efficacy that are beyond the purview of this entry as are a number of criminal justice–based interventions.

Description

Underlying Disciplines, Principles, Goals, and Focus

In the public and lay domain, putative treatments for substance use disorders (i.e., "drug abuse" or "addiction") are legend and varied in their underpinnings. However, the core principles for systematic treatment of substance use disorders reside in empirically based interventions of psychology, psychiatry, pharmacology, behavioral science, and neuroscience. Despite diverse theoretical, conceptual, and terminological differences, there are many commonalities in both practice and behaviors and thoughts that are the focus of treatment. Emphasis is typically placed on avoiding drug use–related circumstances (physical or social) and replacing drug-seeking, drug use, and drug-related thoughts with other behaviors (e.g., coping skills, problem-solving skills). The interventions focus on altering biology, behavior, and social interaction through behavioral/psychological and pharmacological techniques. Longer term pharmacotherapy focuses on substituting a therapeutic medication (e.g., methadone) at controlled doses for the drug used (opiate) or a medication blocking (e.g., naltrexone) the effects of the drug used (opiate) with untoward consequences. Each strategy produces blunting or elimination subjective drug effects. Short-term alleviation of withdrawal symptoms or disturbed behavior is achieved with specific symptomatic treatment (e.g., anxiolytics, sedatives, antidepressants, antipsychotics).

Two important considerations in discussion of treatment are the determinants and correlates of the disorders and the not uncommon existence of co-occurring psychiatric/behavioral or medical problems. These may predate or be a consequence of the substance use disorder(s). The most common comorbid condition for treatment is multiple drug use (e.g., cocaine, heroin, alcohol). Next, the psychological/psychiatric diagnoses of problematic drug use or dependence are not uncommon among individuals also diagnosed for schizophrenia, depression, posttraumatic stress disorder, etc. Indeed, observation of common symptoms associated with extreme drug use, for example, disorganization, paranoid ideation, hallucinations, may reveal existence of the other psychiatric condition. Increasing awareness of co-occurrence of other psychiatric conditions with substance use disorders has resulted in extensive research, discussion, and review of conceptualization of treatment. For example, should specialized single interventions be applied to each presenting condition or should integrated treatments be devised? Questions arise as to correlation, association, and causation. Did the substance use cause psychiatric illness or precipitate its onset and reveal its existence or a predisposition? Did the psychiatric illness predispose to drug use, perhaps

as a means to self-medicate the underlying condition? Finally, in instances of severe drug use, medical consequences (e.g., respiratory depression, cardiovascular event, accident-induced trauma) rather than psychiatric symptoms may lead to identification of problematic drug use and need for treatment.

Critical in establishing treatment strategies and regimens is understanding that the substance use disorder is the consequence of multiple determinants, some amenable to manipulation or intervention, others not. As with forms of some other common conditions, for example, hypertension, diabetes, obesity, a complex interplay of genetic, biological, behavioral, social, and other environmental factors contributes to the observed disease. However, limits must exist on diagnosis and treatment. Thus, while some patients present with reasonably stable life styles, educational backgrounds, and work histories, others using the same drugs may have limited education and skills. In both cases, systematic focus on diagnosed conditions is essential. However, the myriad collateral circumstances are the purview of other domains (e.g., social service networks, job counselors, educational systems), which can be addressed more effectively, for example, by adept case managers and other experts, rather than health care providers. The two historical models continue to influence the perspective and goals of treatment. Underpinning an integrative behavioral learning perspective is the concept that just as one learns other behaviors (reading, using the internet, sports), one learns to use drugs. The behavior is maintained by biological, behavioral, and social rewards or reinforcers. The treatment strategy is establishment or learning of other behaviors sustained by non-drug reinforcers, while drug seeking and taking are diminished or eliminated. The disease model assumes a "chronic relapsing disease" evidenced when a predisposed individual is exposed to and begins using psychoactive drugs; complete and perpetual abstinence is the goal and relapse is always imminent (Higgins, 1997). To the extent that biology underlies behavior, the integrated learning model accounts for genetic and biological differences but focuses on new behaviors and reinforcers rather than the chronicity of disease.

Treatment Settings, Dose, and Costs

Distinct from the intervention is the setting or environment in which treatment is provided. Settings include outpatient (e.g., office, clinics, emergency rooms), inpatient (e.g., hospital facilities), and residential (e.g., community-like living arrangements). The opportunity for access to patients is increased in controlled residential settings and some supplement the professionally driven therapy with a variety of "self-help" activities such as group discussions. Still others may have options for attending work or school. However, many of the same fundamental interventions can be applied in any of these settings. For example, a course of cognitive behavior therapy could be applied weekly in a mental health care practitioner's office, an inpatient facility, a residential care setting, or for that matter a prison. Another dimension of "setting" is whether care is provided to a single patient by a therapist, or with a group of patients, having the therapist interacting with individual members and also facilitating discussion among members. Attempts to match individuals to particular settings for treatment have been flawed and generally ineffective. For example, no data point to advantages of inpatient compared to outpatient care, regardless of severity for treatment of the behavior of substance use itself.

Similarly distinct is the actual amount or "dose" of intervention. Inpatient settings in which the patient resides continuously for days or weeks do not necessarily deliver more, or more efficacious therapeutic care than treatment delivered to a patient residing at home and functioning in her or his natural environment while receiving office-based care a few hours a week. For example, while inpatient or residential care may shield a patient from access to drugs, including alcohol and nicotine, it also prevents them from having exposure to the very environments in which it will be necessary to engage in life without problematic drug use; this exposure is both essential and therapeutic. As an aside, inpatient and residential care are extremely costly strategies that

are well beyond the resources of most individuals and, with increasing health cost burdens for society, will be of diminishing importance except in unusual circumstances.

Evaluation and Monitoring

Drug use severity, as determined by substance used, frequency and amount of use, may be critical to determining treatment required. Thorough diagnostics and history determination permit tailoring treatment. An interview method termed Timeline Follow Back (Sobel, Sobel, Klajner, Pavan, & Basian, 1986) permits careful structuring of a history of use. The accepted diagnostic interviews conforming to elements of the DSM or ICD criteria are necessary to determine severity, existence of comorbid conditions, and plausible treatment plans. A collateral finding in many studies of therapeutic interventions for substance use disorders is that individuals presenting with less severe conditions are more successful in treatment. For example, individuals who on entry for evaluation have negative biological screening tests for the drug used (see below) are more likely to continue successfully for a full course of treatment. Comorbid conditions and individual differences in a range of social and environmental circumstances must always be considered.

Both at intake and during treatment, objective measures of determining current use are essential. For alcohol use, this may be a breath test or urine screen. Tobacco smoking can be readily determined using CO monitoring while other tobacco use can be monitored with saliva or urine screens for cotinine, primary metabolite of nicotine. Virtually all other drug use can be monitored with simple and widely available urine screen procedures and this is essential, much as regular blood pressure evaluation is critical in treatment of hypertension or glucose level monitoring is critical to diabetes treatment.

Interventions: Behavioral, Pharmacological, and Combined

Behavioral therapy/psychotherapy and pharmacotherapy are the two broad classes of intervention applied to psychiatric disorders including substance use disorders. Current science points to remarkably effective interventions for specific types of substance use disorders, limited efficacy for some forms of substance use disorders, and for others, little efficacy or even exacerbation of drug use (e.g., olanzapine and cocaine use).

Some therapies are designed primarily to promote understanding of an existing problem or motivate entry into more extended or intensive treatment (e.g., motivational enhancement therapy). Other treatments are intended to provide a systematic course of intervention addressing the gamut of problems linked to substance use disorder and cessation of use (e.g., cognitive behavior therapy, contingency management). Still other interventions are composites with elements incorporated from a number of conceptual and pragmatic frameworks (e.g., community reinforcement approach, matrix model).

There is a clear need to distinguish between treatment of acute drug-related symptoms, notably withdrawal syndromes, and the complex behaviors of drug seeking and drug taking. A patient can achieve a "drug free" state within days by enforced abstinence. Sleep patterns and other biological functions and a variety of disrupted behaviors may stabilize within days or weeks. This normalization does not directly address the problems of drug seeking and drug use; however, for a small minority of individuals, a period of abstinence/cessation, however achieved, may be sufficient. Even this observation may be confounded since these individuals often undergo repeated cessation attempts before achieving behavioral change. For most, some supplemental intervention, ranging from brief, structured therapies to multiple structured sessions, will be required at some point in the drug use career to attain meaningful beneficial outcomes. Indeed, some scientists conceptualize substance use disorders as chronic for many individuals, requiring ongoing treatment and support, similar to obesity (McLellan, 2002).

There are several behavioral, or psychotherapy, interventions for which strong supporting data of efficacy exist. One is cognitive behavior therapy; another is contingency management sometimes applied within the broader

community-based reinforcement approach; and a third encompassing a range of theoretical frameworks entails variants of "talk therapy." Components or variants exist with labels such as "the matrix model" (Shoptaw, Rawson, McCann, & Obert, 1994), "relapse prevention," and "dialectical behavior therapy." Diverse techniques (e.g., hypnotism, acupuncture) have been incorporated into treatment models with little evidence of added efficacy compared to well-constructed behavioral therapies. All effective nonpharmacological therapies ultimately focus on behavior and thought directed at minimizing or eliminating drug use while increasing the frequency of a range of socially appropriate constructive behaviors. Among adults, these goals are more readily achieved when the individual arrives at therapy with an age and ability appropriate set of social skills, training, job history, and experience. Still, there are times when additional focused therapeutic elements may be included, for example, parenting or marital counseling.

In the realm of pharmacotherapy, opiate replacement therapy (methadone, buprenorphine) provides a clear example of robust and effective treatment applicable to use and dependence ranging from iv heroin use to oral oxycodone use. Some promising data suggest potential efficacy of a similar replacement, or agonist-like strategy for stimulant dependence though there are currently no FDA-approved medications. Possible substitute medications for stimulant dependence include amphetamine analogs. Similarly, while there are currently no approved medications for treatment of marijuana use and dependence, a promising agent that represents substitution or replacement, tetrahydrocannabinol/cannabidiol, is currently being evaluated. A variety of strategies addressing different behaviors and pharmacological mechanisms have been applied to alcohol use (disulfiram, benzodiazepines, naltrexone, acamprosate) with greater or lesser efficacy. Similarly, several medications (nicotine preparations, bupropion, varenicline) have been shown to have varying degrees, but nevertheless modest effectiveness in treatment of tobacco use and nicotine dependence. There are several nicotine preparations (gum or polacrilex, lozenges, nasal spray, patches, inhalers) that alone produce relatively modest rates of cessation across broad populations but have meaningful public health consequences due to the prevalence of tobacco use and the costs of associated diseases. Disulfiram for alcohol dependence has a unique profile: through metabolic interference, it results in high levels of acetaldehyde and induced severe discomfort; integrated into a well-controlled regimen, it can be very effective but is not widely used. Naltrexone and acamprosate appear to have modest effects in reducing alcohol intake or sustaining abstinence. For individuals whose alcohol use is found to be highly correlated with diagnoses of comorbid depression or anxiety, effective treatment may stem from administration of anxiolytics or antidepressants. In some instances, use of two or more medications may be a useful therapeutic approach. A dilemma across most medical and psychiatric is nonadherence or noncompliance with medication regimens. This is particularly true for antagonist medications such as disulfiram and naltrexone.

Ultimately, for many instances of substance use disorders, benefit of joint action of concurrently applied behavioral and pharmacological interventions may be important in all but the least severe cases. This is analogous to treatment of other disorders with clear biological and behavioral determinants. For example, hypertension may be treated with combined behavioral (e.g., exercise, diet) and pharmacological (e.g., ACE inhibitors) interventions. Similarly, depression, while amenable to both behavioral and pharmacological treatments, may be most effectively treated with a combination (e.g., CBT and SSRIs). The need for continuing intervention in treatment of substance use disorders may vary. For example, pharmacotherapy with an effective course of behavior therapy establishing (or reestablishing) alternative behaviors and eliminating drug use may still entail long-term maintenance pharmacotherapy. The latter may be necessitated by biological perturbations that predated or were a consequence of drug use. Here continued medication sustains biological and behavioral stability that would otherwise not be achieved or would only continue with

unnecessary behavioral, emotional, or biological burden on the patient. Exemplifying this is treatment of heroin dependence. On completing initial behavioral treatment combined with methadone or buprenorphine maintenance, some patients may successfully undergo gradual reduction in medication dose. In other instances, perhaps more severe and involving many years of heroin use, maintenance pharmacotherapy for years or decades is desirable and warranted. The need for maintenance may reside in engrained perturbations in biology and behavior, resulting from prolonged heroin use. Generally, the costs and inconvenience of maintenance replacement are outweighed by nearly inevitable return to drug dependence and associated dire psychosocial and medical consequences when abstinence without further treatment is undertaken.

Often discussed is the concept of "relapse," "return to drug use," or in some instances, "development of new drug use." Early in treatment (often within days but up to 3–6 months), there may be graded but rapid return to previous baseline levels of use. Some individuals may use a drug a few times, for example, smoke a cigarette, or consume alcohol. They may even engage in periodic use, heavy use, or a binge, but through sustained therapy eventually refrain from further use. The likelihood of return to use greatly decreases after a year. Confounding these general observations are individuals who enter treatment and never use the drug again as well as those who are abstinent for years and then resume use. In some cases, individuals treated for heavy use, for example, heavy alcohol drinking, may resume nominal social use without return to heavy drinking. Here the legal status of a drug is germane. Treatment with a goal of abstinence from cocaine or heroin use has positive implications beyond those related to reducing impairment from drug effects, for example, no risk of incarceration. For those engaged in heavy alcohol use, reduced use may be a realistic, achievable, beneficial goal. However, as with cigarette smoking, the entrenched habitual behavior combined with reinforcing effects of the drug may preclude a goal of moderation. Finally, a small subset of individuals who have well-established behaviors of problematic use may be successfully treated for use of one drug, but at some later date develop similarly problematic use of a different drug. This would reflect reestablishment of drug seeking and taking, but not "relapse" as the word is commonly used. As with any complex disorder with multiple determinants, the core constellation of symptoms, here drug seeking and drug taking, can be addressed directly with supplemental specialty intervention when appropriate.

Successful Aging

Barbara Resnick
School of Nursing, University of Maryland, Baltimore, MD, USA

Synonyms

Optimal aging

Definition

Successful aging has been addressed and discussed repeatedly with at least 29 different definitions articulated from both cross-sectional and longitudinal research studies. Common themes across all of this work describe successful aging as the absence of physical and mental disability. Generally, successful aging is noted to occur when the individual has perceived "good health."

Description

Successful Aging

The concept of successful aging emerged in the late 1980s and early 1990s as a departure from the loss-focused geriatric and gerontological research that preceded the concept. In their groundbreaking 1987 article, Human Aging: Usual and Successful, Rowe and Kahn argued that the cognitive and physiological losses documented in the literature as age-related changes were mischaracterizations of the natural aging process. "We believe that the role of aging per se in these losses has often been overstated and that a major component of many age-associated declines can be explained in terms of lifestyle, habits, diet, and an array of psychosocial factors extrinsic to the aging process."

Definition

Successful aging has been addressed and there are at least 29 different definitions articulated from both cross-sectional and longitudinal research studies. Common themes across all of this work consider successful aging as the absence of physical and mental disability and perceived "good health." In addition, successful aging has increasingly been associated with resilience and maintenance of an active lifestyle and having good supportive relationships. Everyone has the opportunity to age successfully. From the outside, objectively, this may look very different across people. For some, aging successfully is still working at age 98. For others, it is sitting quietly in a room in assisted living and reliving past memories reviewing very rich, fulfilling lives.

More important than the absolute state of health of the individual is the notion of one's conceptualization and acceptance of his or her health status. Acceptance of changes and optimization of physical and mental health are the most critical aspects of aging successfully. Changes that occur as part of normal aging must be accepted, addressed, and adjusted to. Vision changes that occur starting around age 40 provide the first experience adults have to cope with and age successfully. Successful adaptation includes buying reading glasses over the counter as needed or getting eye examinations and vision testing done and getting new glasses! Increasingly baby boomers carry small lights with magnification to read restaurant menus, telephone books, and other pertinent information. Other changes, such as painful degenerative joint disease, are not so easily or commonly recognized, accepted, and adjusted to. It is being able to accept and adjust to changes that are at the core of successful aging.

As noted, resilience is central to successful aging. The word "resilience" comes from the Latin world "salire," which means to spring up and the word "resilire" means to spring back. Resilience, therefore, refers to the capacity to spring back from a physical, emotional, financial, or social challenge. Being resilient indicates that

the individual has the human ability to adapt in the face of tragedy, trauma, adversity, hardship, and ongoing significant life stressors. Resilient individuals are able to adapt to all types of situations, especially with regard to social functioning, morale, and somatic health, and are less likely to succumb to illness. That is, a resilient individual may still get ill but will respond in a way in which he or she optimizes recovery, maintenance, or even death in a way that defines resilience. Resilience, as a component of the individual's personality, develops and changes over time through ongoing experiences with the physical and social environment. Resilience can, therefore, be perceived as a dynamic process that is influenced by life events and challenges. Increasingly, there is evidence that resilience is related to motivation, specifically the motivation to age successfully and to recover from physical or psychological traumatic events.

Resilience research has helped to uncover the many factors or qualities within individuals that are associated with resilience. These include such things as positive interpersonal relationships, incorporating social connectedness with a willingness to extend oneself to others, strong internal resources, having an optimistic or positive affect, keeping things in perspective, setting goals and taking steps to achieve those goals, high self-esteem, high self-efficacy, determination, and spirituality which includes purpose of life, religiousness or a belief in a higher power, creativity, humor, and a sense of curiosity. Strengthening any of these factors will help individuals to become more resilient when faced with a challenge.

Older women who have successfully recovered from orthopedic or other stressful events describe themselves as resilient and determined and tend to have better function, mood, and quality of life than those who are less resilient. These are the women who at 97 engage in rehabilitation services post–hip fracture to their fullest ability and then following discharge home are insistent on getting back on their exercise equipment at the gym. Resilience has also been associated with adjustments following the diagnosis of dementia, widowhood, management of chronic pain, and overall adjustment to the stressors associated with aging. Thus, it is through resilience he or she adjusts, adapts, and addresses the physical, emotional, and mental challenges that are to be anticipated as one ages.

Older adults accrue a lifetime of experiences through which resilience develops. Resilient individuals generally age successfully. A resilient older adult is exemplified by such things as accepting the loss of a spouse; symptoms associated with an acute medical event; or a fracture and responding with determination to recover and grow through the experience. He or she does not waste energy on complaining about what has happened but rather on pooling the resources needed to overcome the challenging event.

Resilience alone is not sufficient to assure successful aging. It is believed that all individuals have the innate ability to be resilient and return to homeostasis successfully and to transform, change, and grow, regardless of age. He or she must, however, summon motivation in the face of adversity to be resilient. Thus, motivation may be present independent of resilience, but resilience depends on being motivated to successfully reintegrate. Resilient reintegration requires increased energy, or motivation, for resilience to successfully occur.

Motivation comes from within and is based on an inner urge that moves or prompts a person to action. This is in contrast to resilience which is stimulated in response to adversity or challenge. Motivation refers to the need, drive, or desire to act in a certain way to achieve a certain end. We do not need to be challenged to be motivated. We do have to be motivated to respond, with resilience, to a challenging event. There are some factors that are associated with both resilience and motivation such as determination, self-efficacy, being open and willing to experience new things, and social supports. The capacity to be resilient and/or motivated is present in everyone and choices are made in the face of routine and challenging situations to be motivated and/or resilient. Motivation related to engaging in physical activities may be high for some individuals while others are motivated to sit

in a chair or lie in a bed. Conversely, some older adults are motivated to take classes in a senior center while others refuse to even consider this and are motivated to sit daily and watch television alone. Some individuals are resilient with regard to physical challenges but cannot cope with challenges associated with finances or cognitive changes. Thus, there are traits and characteristics of individuals associated with resilience and motivation as well as external factors that can impact resilience and motivation as individuals respond to challenges or activities within their lives.

Resilience, unlike motivation, relies on the individual experiencing a life challenge or some type of adversity. These challenges may be developmental challenges such as those associated with normal aging (e.g., vision changes), or they maybe social and/or economic challenges such as those experienced by the loss of employment, the loss of a spouse, or a move into an assisted living facility. Conversely, motivation is not dependent on an adverse event or challenge; rather motivation is a necessary component for all activity. Routine personal care activities such as bathing and dressing require motivation, as do making plans to have dinner with a friend or play cards. Resilience would be required, however, when he or she is faced with bathing and dressing challenges following a wrist fracture.

Keys to Aging Well

An individual has the ability to be resilient as long as he or she is motivated to do so. The first step in the process is to engage in appropriate health promotion activities, particularly exercise. Due to the changes that can occur with aging, underlying physical capability will vary among older individuals. For some individuals, maintaining a regular exercise program will involve running for 40 min on the treadmill. For others, it may be walking within their apartment building or long-term care facility, doing a sitting exercise program, or swimming or walking in the water. There is, however, an exercise program that matches each individual's needs. This is critically important to appreciate and recognize. The benefit of physical activity for older adults should not focus on preventing cardiovascular disease and managing blood pressure to prevent a stroke. Rather, it should be geared toward the mental health benefits associated with physical activity as well as the sense of achievement and physical benefit of maintaining function and improving balance and strength.

Successful Aging Guidelines

Meta-analytic reviews provide strong evidence to support the many benefits of exercise including decreased risk of coronary heart disease and stroke; decreased progression of degenerative joint disease; prevention of osteoporosis of the lumbar spine; decreased incidences of falls; increased gait speed if the activity is of sufficient intensity and dosage; improved cognitive function in sedentary older adults and in those with dementia; a modest benefit in quality of life for frail older adults; and a positive association with successful aging. Current guidelines from the American College of Sports Medicine and the American Heart Association recommend that all older adults engage in moderately intense aerobic exercise for 30 min daily at least 5 days a week or vigorous exercise 20 min a day, 3 days a week. In addition, each should do eight to ten strength training exercises, 10–15 repetitions of each exercise two to three times per week. These exercises are well described in a book published by the National Institute of Aging, *Exercise: A Guide from the National Institute of Aging*. For older adults at risk for falling, balance exercise is also recommended. It is not known, however, what dose of exercise is needed for each individual to age successfully. For some, a walk to get the mail is sufficient psychologically to constitute an exercise program. For others, one activity a day (e.g., playing bridge, going to dinner) makes them feel successful and engaged. The focus should be on helping the individual understand what successful aging means to them and helping them develop a plan to achieve that.

Unfortunately, all too many older adults assume that they cannot exercise or engage actively in routine life activities and social activities because of underlying disease, pain, shortness of breath, or other limiting symptoms.

Health outcomes can be achieved at even relatively low levels of exercise intensity, particularly for those who have previously been sedentary. Thus, initiation of physical activity even at 1-min intervals is an important step to successful aging. Adjustments can be made to engage them in social activities via chair positioning that will help them maintain independence in public or remain comfortable to sit for a game of bridge or an evening eating with friends. Solving these challenges is part of the necessary resilience needed to age successfully. Health-care providers can serve as sources to help with overcoming such challenges and barriers.

In addition to physical activity, mental stimulation may also be important for successful aging. In a recent meta-analysis, there was not statistical support to indicate that cognitive stimulation through structured programs prevents or slows the progression of Alzheimer's disease. The current research, however, is limited by a lack of consensus on what constitutes the most effective type of cognitive training, insufficient follow-up times, a lack of matched active controls, and few outcome measures showing changes in daily functioning, global cognitive skills, or a decrease in disease progression. Keeping actively engaged mentally through volunteer work or activities within one's own living space certainly will build resilience and likewise assure successful aging. Opportunities abound for such activities, however, as with physical activity the older individual must be motivated to initiate and engage in these activities.

Older adults should be encouraged to move beyond their level of comfort and engage in new and different activities to stimulate their minds and their bodies. If playing bridge or doing a crossword puzzle is lifelong acquired skill, newer activities such as learning a new language or playing an instrument will provide important mind stimulation and encourage plasticity and growth.

The Health-Care Provider's Role in Successful Aging

Informing young and older adults about the ways in which to age successfully is the first step toward facilitating successful aging for any individual. There are ways in which to measure resilience and motivation, although at a clinical level they will not necessarily direct interventions. Thus, the best approach is to motivate individuals toward resilient behaviors.

Synonyms

Suicidal impulses; Suicidal thoughts

Definition

Suicidal ideation refers to thoughts or impulses of engaging in behavior intended to end one's life (Nock, Borges, Bromet, Cha, Kessler, and Lee 2008). Suicidal ideation should be distinguished from suicidal plan, which refers to the formulation of a specific method through which one intends to die, and from suicide attempt, which refers to an actual engagement in potentially self-injurious behavior in which there is at least some intent to die (Nock et al., 2008).

Description

Ongoing suicidal ideation is a chronic risk factor and has been considered predictive of suicidal behavior especially if accompanied with severe hopelessness, prior suicide attempts, not having a child under 18 years old living at home, and a history of alcohol and drug abuse (Tishler and Reiss, 2009). Suicidal ideation represents an important phase in the suicidal process and often precedes suicide attempts or completed suicide. However, not all patients experiencing suicidal ideation attempt suicide (Weissman et al., 1999). While approximately 10–20% of the population across diverse countries report suicidal ideation and 3–5% have made a suicide attempt at some time in their life, only 0.01% will complete suicide (Kessler, Berglund, Borger, Nock, and Wang, 2005). Acute risk factors including severe anxiety, agitation, and severe anhedonia are most predictive of whether someone will commit suicide in inpatients (Tishler and Reiss, 2009, Bostwick and Rackley, 2007).

Physical as well as mental health problems have been associated with suicidal ideation. Patients with chronic medical illnesses, such as HIV and cancer, and especially those experiencing physical pain are more likely to report suicidal thoughts (Tang and Crane, 2006). Certain medical illnesses, such as neurological disorders and some cancers, appear to have higher rates of suicidal ideation and suicide compared to other medical disorders (Hugues and Kleespies, 2001). A higher prevalence of suicidal ideation has been

observed in patients experiencing pain associated with a variety of medical conditions including migraines, musculoskeletal pain, fibromyalgia, and arthritis (Tang and Crane, 2006). Research suggests that the location and type of pain as well as the intensity and duration of the pain may have implications for the risk of suicidal ideation (Tang and Crane, 2006). In addition, sleep-onset insomnia associated with pain is also a significant discriminator of the presence or absence of suicidal ideation (Tang and Crane, 2006).

Research in the elderly suggests that physical illness plays an important role in suicidal ideation and behavior (Szanto, Gildengers, Mulsant, Brown, Alexopoulos, and Reynolds, 2002). In the elderly with physical illness, untreated or undertreated physical pain, anticipatory anxiety regarding the progression of the physical illness, fear of dependence, and fear of burdening the family have been reported as the major contributing factors for suicidal ideation (Szanto et al., 2002). For all age groups, social isolation is considered another important risk factor that has been shown to be associated with suicidal ideation.

Sociodemographic factors including age and income level have also been associated with suicidal ideation (Kessler et al., 2005). In general, younger age, lack of education, and unemployment have been associated with higher rates of suicidal ideation and may represent an increased risk associated with social disadvantage (Nock et al., 2008). For all age groups, social isolation is considered another important risk factor that has been shown to be associated with suicidal ideation (Van Orden, Witte, Cukrowicz, Braithwaite, Selby, and Joiner, 2010).

Prior suicide attempts and the presence of a psychiatric disorder are the most consistently reported risk factors associated with suicidal ideation and behavior (Nock et al., 2008). Mood disorders such as anxiety and particularly depression significantly increase the risk of suicidal ideation in the general population and in medical patients in particular. Suicidal ideation has also been associated with other mental illnesses including severe anxiety, psychotic and personality disorders, and alcohol and substance abuse (Van Orden et al., 2010). A number of psychological processes have been found to exacerbate suicidal ideation. Specifically, findings from cross-sectional as well as longitudinal studies have attested to the role of hopelessness and helplessness, feelings of defeat and entrapment, deficits in problem solving abilities, and avoidant coping in the development of suicidal ideation (Van Orden et al., 2010, Nock et al., 2008, Szanto et al., 2002).

The presence of suicidal ideation in a clinical or medical setting typically requires a thorough risk assessment including chronic and acute risk factors as well as the frequency, intensity, and duration of suicidal thoughts (see Tishler and Reiss, 2009 for prevention in medical settings).

Definition

Suicide is the act of intentionally ending one's own life. The definition of suicide reflects three important components (Rudd, Joiner & Rejab 2001): (a) that the person died, (b) that the person's behavior caused death, and (c) that the person intended to cause his or her own death. While intentionality is the most precise characteristic that distinguishes those who have died by suicide and those who had died by other causes, its assessment remains controversial.

Description

Suicide is a major public health problem, and reports from the World Health Organization (WHO) indicate that suicide is projected to become an increasingly important contributor to the global burden of disease over the coming decades. Suicide is the 11th leading cause of death among all ages in the United States and the 13th leading cause of death worldwide. Suicide rates vary significantly cross-nationally (Center for Disease Control and Prevention, 2007). In general, rates are highest in Eastern Europe and lowest in Central and South America, with the United States, Western Europe, and Asia falling in the middle. Epidemiological surveys showed that 2.7% of the US population has made a suicide attempt (Nock et al., 2008). Most individuals that attempt suicide die during their first suicide attempt (Nock et al., 2008). Within medical settings, according to Joint Commission on Accreditation of Healthcare Organizations (JCAHO 2010), suicide ranks among the five top most frequent sentinel events in hospitals. Seeking help from mental health professionals can assist in the reduction of distressing psychological symptoms. However, according to a recent review, while 45% of people who successfully committed suicide contacted a primary care provider within 1 month of their death, only 20% contacted mental health services within the same time period (Lauma, Martin & Pearson 2002).

Rudd, Joiner, and Rejab (2001) provide in their book a good description on a number of psychiatric, psychological, demographic, and biological variables have been recognized as suicide risk factors. The presence of one or more psychiatric problem is a central variable explaining suicide acts. At least 90% of individuals who have died from suicide have had at least one psychiatric disturbance. In addition, past suicide attempts, history of childhood abuse, and family history of suicide are associated with increased risk of suicide. Other variables that contribute to suicide risk are psychological variables, such as hopelessness, impulsivity, problem-solving deficits, and perfectionism. In terms of demographic variables, men are more likely to die by suicide than are women. Death by suicide is more common in older, lower socioeconomic status, and veterans. Similarly, non-Hispanic White individuals have a higher rate of suicide than individuals from other ethnical background. In addition, individuals who are unemployed, single, divorced, or widowed are also at a higher risk. Biological variables have also been found to be associated with suicide behaviors. Family, twin, and adoption studies have found evidence

for heritable risk of suicidality. Biological factors related to lower levels of serotonin metabolites in the cerebrospinal fluid, higher serotonin receptor binding in platelets, and fewer presynaptic serotonin transporter sites were found in individuals who died by suicide. In addition, biological factors that inhibit impulsive behaviors, such as greater postsynaptic serotonin receptors in specific brain areas, such as the prefrontal cortex, have been associated with suicide behaviors.

The high rate of medical illness among individuals who committed suicide shows that both mental disorders and physical illness are important risk factors. Research shows variability in the risk of suicide according to the type of medical diagnosis. According to Hughes and Kleespies (2001), medical illnesses such as AIDS, cancer, chronic pain, end-stage renal diseases, severe neurological disorders, and chronic obstructive pulmonary disease have been correlated with increased risk of suicide. In contrast, they reported that other medical conditions including sclerosis, heart transplant, hypertension, rheumatoid arthritis, neoplasms, and cervix and prostate cancer have not been associated with increased risk. Studies have shown that at least one quarter of inpatients that have committed suicide in medical/surgical units did not report any previous psychiatric history (JCAHO 2010). Furthermore, suicide among these patients tends to happen within the first 2 weeks of their initial diagnosis (JCAHO 2010). This highlights the need of assessing suicidality in individuals who have chronic medical problems or who have been recently diagnosed with a life-threatening illness. Additionally, significant differences have been found between individuals who have completed suicide in inpatient psychiatric facilities and inpatient medical units. According to these studies, individuals who committed suicide in medical units tend to be older, their death did not include careful planning, and their means of committing suicide were significantly more violent (Nock et al., 2008).

In contrast to the vast literature on variables associated with suicide, there are some studies that have identified protective factors. Protective factors are those that decrease the probability of suicide in the presence of elevated risk. Rudd and colleagues (2001) summarized some of the most consistent findings in the literature are supportive social network or family, reasons for living, and religious beliefs. Being pregnant and having young children in the home are also protective against suicide.

Clinical providers face the difficulty of recognizing individuals at risk of committing suicide as no single factor is sufficient to trigger or protect an individual from a suicidal act. Suicide warning signs are the earliest detectable signs or symptoms that indicate high risk for suicide in the near term (i.e., within minutes, hours, or days before the suicidal act; Rudd et al., 2001). They provide immediate cues to loved ones or clinical providers of the imminent risk of attempting to end one's life. Some suicide warning signs include hopelessness, anger, dramatic changes in mood, acting recklessly or engaging in risky activities, reports of feeling trapped, increased alcohol or drug use, withdrawal from loved ones, agitation or anxiety, and drastic sleep changes (Rudd et al., 2001).

Due to the difficulty of preventing and recognizing suicide, the assessment of suicide risk should be completed in a standardized and systematic way. In addition to assessing risk and protective factors, as well as warning signs to understand the risk level of an individual, suicide ideation, suicide plan, intent to act, previous suicide attempts, and the medical lethality of means need to be considered. When assessing suicide risk, it is important to differentiate between chronic risk and acute risk (Rudd et al., 2001). Chronic risk involves the presence of risk factors. Acute risk is determined by suicide ideation, intention, and a suicide plan in combination with warning signs. Acute risk can be further classified into low, moderate, and high. Low acute risk involves the presence of suicide thoughts with no specific plan, intent, or behavior. Moderate acute risk involves the presence of suicide ideation and a plan without intent or behavior. High acute risk refers to the presence of persistent suicide ideation and a specific plan with the intent to die.

Definition

Death from suicide in 1998 was ranked by the World Health Organization (WHO) as the 12th leading cause of mortality worldwide. Suicide is the cause of death of one million people a year worldwide (Lineberry, 2009). Suicide has been committed via several methods, which vary across geographic regions (Ajdacic-Gross et al., 2008). It is a main cause of death in later adolescence (ages 15–24 years; Shields, Hunsaker & Hunsaker, 2006).

The main difficulty in suicide prevention is the prediction of rare events and the multiple risk factors of suicide. These include situational factors such as social stressors and life events (e.g., unemployment, poverty), psychological factors such as hopelessness and hostility, biological factors (e.g., reduced brain-derived neurotrophic factor, protein-kinase A; Dwivedi & Pandey, 2011), and mere access to means of suicide (e.g., arms). One main difficulty in predicting suicidal behavior is the reliance on self-reported instruments, where people either conceal their real replies or are unaware of them.

Conversely, some recent studies have shown that assessing implicit associations between the "self" and "life" versus "death," with the Implicit Association Test, predicted suicidal behavior beyond what was detected by traditional risk factors (e.g., depression, past attempts, clinicians' ratings; Nock et al., 2010). Similarly, attention biases to suicide-related words relative to neutral words, using the "emotional stroop," predicted suicidal behavior better than traditional risk factors (Cha, Najmi, Park, Finn, & Nock, 2010). More research needs to utilize such instruments to identify additional suicide risk factors assessed in such indirect manners. Often, an accumulation of risk factors occurs, culminating in the tragic event. To conclude, explicit and implicit psychosocial factors and biological and situational factors serve as risk factors for suicide and need to be considered in the important attempt to prevent this severe health outcome.

Sun Exposure

Yori Gidron
Faculty of Medicine and Pharmacy, Free University of Brussels (VUB), Jette, Belgium

Definition

Sun exposure refers to the amount and manner in which people expose themselves to sunlight. This is a highly complex parameter for quantification, as it relies on self-report and its effects depend on multiple environmental and personal factors, as well as frequency and location of exposure on the body. Most skin cancers are related to sun exposure, and a great majority of exposure to sun takes place before adulthood, making children and adolescents central target groups for assessment and prevention of sun exposure. Multiple studies have linked sun exposure to various cancers, particularly to skin cancer. In a review of 57 studies, intermittent sun exposure and history of burns were related to risk of melanoma. In contrast, high occupational sun exposure was inversely related to melanoma. Furthermore, factors such as country of study seem to moderate effects of sun exposure on melanoma, suggesting that effects of sun exposure depend on geographical factors as well. Indeed, latitude synergistically interacts with history of sunburn in relation to melanoma (Gandini et al., 2005). A major cause of melanoma due to sun exposure is ultraviolet light (Armstrong & Kricker, 1993). Various scales exist for assessing sun exposure, which consider the manner and duration of sun exposure, context (working vs nonworking days), and cumulating measures in relation to various time frames (years or one's life time; Kricker, Vajdic, & Armstrong, 2005). Importantly, to achieve greater test-retest reliability, it may be beneficial to assess sun exposure in relation to activities (e.g., with family, at work) rather than in relation to specific time periods (Yu et al., 2009). In children, important social factors related to usage of sun protective agents include parental reminders (Donavan & Singh, 1999). In children, sun protective behavior decreases with age though sun exposure increases with age, possibly reflecting greater peer pressure and reduced parental control in older children (Pichora & Marrett, 2010). Thus, sun exposure reflects a major and complex cause of various skin cancers and must be properly assessed and better controlled in attempt to prevent skin cancers.

Definition

Surrogate Decision Making

If an individual is unable to make decisions about personal health care, some other individual can be authorized to provide direction. Such a person is called the surrogate decision maker, a proxy, or some other term specific to the type of authorization. For example, under an advance directive, the decision maker is typically an "agent"; under a durable power of attorney for health care, the decision maker is the "attorney in fact" (although in slang, some health-care providers refers to such persons as "the POA"); an individual may be judicially appointed as a "guardian," or state law may identify certain next of kin or other close persons as eligible to serve as a surrogate. State law will determine the role of domestic partners in the absence of an advance directive appointing someone as an agent.

Each type of surrogate or proxy has a scope of authority to make health-care decisions for an individual depending on the source of the surrogate or proxy's authority and state law. For example, the surrogate may have broad authority to consent to health care and to refuse or direct the withdrawal of health care but with limitations if the care is life-sustaining. An agent under an advance directive from an individual may have immediate, broader authority to direct the withholding or withdrawal of life-sustaining treatment than a surrogate acting only under state law. Guardians may nor may not need court approval for certain actions involving life-sustaining treatment.

Surrogates or proxies appointed by the individual patient have decision making priority. Where there is no such person, state law determines the process for consulting with next of kin or others, which can include close friends, potentially in an order of hierarchy as to who priority, and how to resolve disagreements among those with the same level of relationship. Where there are no such persons or there is an irreconcilable disagreement, a judicial guardianship may be needed. Ethics committees or Patient Care Advisory Committees are examples of bodies within a health-care facility that can be very helpful in gathering an evaluating information about an individual's clinical condition, treatment options and prognosis, previously expressed wishes, interpretations of available documents, varying points of view, and related considerations.

In a recent study, it was noted that surrogate decision making is often required for older Americans at the end of life. Among a sample of 4,246 deaths of respondents in the Health and Retirement Study, proxies reported that 42.5% of these individuals needed decision making about medical treatment before death; 70.3% of subjects lacked the capacity to make those decisions themselves and, overall, 29.8% required decision making at the end of life but lacked decision-making capacity. These findings suggest that more than a quarter of elderly adults may need surrogate decision making before death.

Surveys

Seppo Laaksonen
University of Helsinki, Helsinki, Finland

Synonyms

Micro data collection and analysis system; Opinion poll; Statistical inquiry

Definition

Survey is a methodology and a practical tool used to collect, handle, and analyze in a systematic way information from individuals. These individuals or micro units can be of various types, such as people, households, hospitals, schools, businesses, or other corporations. The units can be simultaneously available from two or more levels such from households and their members. Information in surveys may be concerned various topics such as people's personal characteristics, their behavior, health, salary, attitudes and opinions, incomes, poverty and housing environments, or characteristics and performance of businesses. Survey research is unavoidably interdisciplinary, although the role of statistics is most influential since the data for surveys is constructed in a quantitative form. Correspondingly, many survey methods are special statistical applications. However, surveys exploit substantially many other sciences such as informatics, mathematics, cognitive psychology, and theory of submatter sciences of each survey topic.

Basic Survey Concepts

A key concept in surveys is *target population* the universe of which should be exactly determined and realistic. It is possible that there are more than one target population (e.g., hospitals of certain types and their clients during a specific period). Before determining a strict target population, a researcher can have in mind *population of interest*, but this is often too difficult to reach, and hence, a realistic population is chosen. For example, more or less heavy alcohol drinkers may be interest for a researcher, but such people cannot be found from any data source. Respectively, such a target population is not realistic, but fortunately, one can try with a larger target population where there are also nondrinkers or light drinkers. The study itself can, among others, concentrate on those heavy drinkers, and results are correct if there are in data enough such people in order to get appropriate results. This requires also that we have a good frame and *frame population* from which reasonable data are downloaded. A drawback is that although the frame seems to be ideal, it includes such people who do not belong to our realistic target population, nevertheless, and secondly, we cannot get responses from all selected people due to *nonresponse*. Thus, when designing data collection, it is necessary to predict nonresponse and other gaps as well as possible in order to get enough respondents for the study.

Sampling

Survey data can cover the whole target population, but if it is large, it is rational to use sampling. This leads to plan an optimal sampling design. The design may be more or less complex. The simplest one is to use completely random selection in which case every frame unit has an equal *inclusion probability* to be selected in the sample. Such a design is rarely rational since the data collection may be too expensive or such a frame is not available. For these reasons, the most common strategy in people surveys is in the first stage, to select so-called *clusters* (small areas, service houses, households), and in the second stage, the desired sample units (target people, clients, household members) are to be interviewed and studied. This strategy is called *two-stage sampling*, but *three-stage sampling* is also applied. These both strategies lead to *probability sampling* that is definitely a valid method. Naturally, next steps must have been done successfully too.

Two- and three-stage samplings are generally called multistage sampling, but if the study units are selected directly from the frame, it is one-stage sampling, but this term is not much used. In contrast, the term *element sampling* is common. Multistage sampling is *hierarchical* in its nature, that is, we approach to study units by stage by stage. This strategy is different from *multiphase sampling* in which case after one sample selection, a new sample from the first sample has been selected. This is much used in *panels* in which case the second or the

consecutive samples have been selected even with 100% from those who have responded in the first phase. This panel approach gives opportunity to follow respondents over time. It is common in health, poverty, and living condition research, for instance. Panel designs can be very complex too. *Rotating design* is much used when needed to analyze data both *cross-sectionally* (for a specific time point or time period) and *longitudinally* (for following individuals over time). Long panels might be hard to do well, and there can be met too much nonresponse that leads a worsening data quality.

Two-phase sampling is also useful when analyzing how respondents differ from nonrespondents. This information is necessary for survey quality documentation, but it can be used also for improving the quality. The second phase could in this case lead to draw a subsample of the nonrespondents, and then attempts to get some information from them. Naturally, this is not easy since they are reluctant, but most nonrespondents still are willing to answer to some simple but key questions of the survey.

Moreover, it is often advantageous to exploit *stratification* in surveys. This leads to create a number of strata that are like subpopulations. Sampling designs for each stratum may be similar or different. The main varying point is maybe that the sample size has been allocated for each stratum so that the research targets are satisfied ideally. Typically, the relative sample size is larger for a smaller stratum population and smaller for a larger population, respectively. This is due to an ordinary target to get about as accurate estimates (results) for each stratum.

Data Collection Tools and Methods

Data collection is not ready after selection a sample (or the full data). Three other major tasks are needed: (1) design the questionnaire, (2) decide the data collection mode (mail or phone or face-to-face interviewing or web or mixed mode such as web plus phone), (3) collect supported data (auxiliary) both for sampling and further data handling. Such data are required both from respondents and nonrespondents. *Auxiliary data* are very advantageous for adjusting *sampling weights* from the initial ones. Consequently, the bias in estimates will be reduced.

Data Cleaning and Analysis

Survey data should be cleaned before starting the analysis. In addition to computing the sampling weights, the following tasks are needed: data editing, imputation of missing data, data documentation (called metadata), data collection process documentation (called paradata), and selection of a good IT format (e.g., SPSS or SAS). The sampling design strategy is necessary to correctly take into account in the analysis.

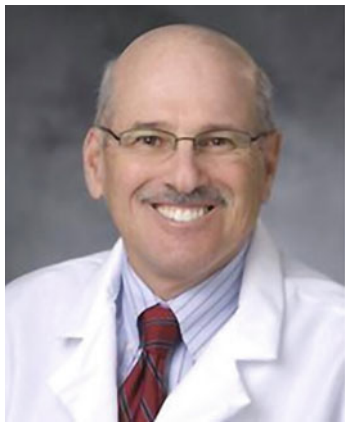
Surwit, Richard S.

James A. Blumenthal
Department of Psychiatry & Behavioral Sciences, Duke University Medical Center, Durham, NC, USA

Biographical Information



Richard S. Surwit received his B.A. from Earlham College and Ph.D. in clinical psychology from McGill University. He completed a postdoctoral fellowship in psychophysiology at Harvard University and joined the Duke faculty in 1977. He is currently professor of medical psychology and vice chair for research in the Department of Psychiatry and Behavioral Science at Duke University Medical Center, Durham, NC.

Major Accomplishments

Surwit's early work focused on the utility of biofeedback in the treatment of medical disorders, including Raynaud's disease and hypertension, and he was instrumental in establishing one of the first clinical biofeedback facilities in the country. Over the course of a long and productive career, his scientific contributions range from basic research on the use of mouse models to examine genetic and behavioral interactions in the development of obesity to clinical investigations of the effects of stress and hostility on glucose metabolism and diabetes. He also pioneered the use of computers in the medical management of such chronic diseases as diabetes and congestive heart failure. He has received multiple grants from the National Institutes of Health, private foundations, and industry to support his research program. He has played a key administrative role in the Department of Psychiatry and Behavioral Sciences at Duke University as vice chair for research and is a former president of the Society of Behavioral Medicine. He also has served on the editorial boards of such journals as *Health Psychology*, the *Journal of Consulting and Clinical Psychology*, *Obesity*, and *Metabolism*. He is the recipient of numerous awards and honors including the Research Career Award in Health Psychology from the American Psychological Association.

Sympathetic Nervous System (SNS)

Michael Richter[1] and Rex A. Wright[2]
[1]Department of Psychology, University of Geneva, Geneva, Switzerland
[2]College of Arts and Sciences, Department of Psychology, University of North Texas, Denton, TX, USA

Definition

The sympathetic nervous system (SNS) is one of two main branches or subsystems of the autonomic nervous system (ANS). It originates in the thoracic and upper lumbar segments of the spinal cord and commonly – but not always – yields peripheral adjustments that are complementary to those produced by its counterpart, the parasympathetic nervous system (PNS).

Description

The sympathetic nervous system is one of two main branches or subsystems of the autonomic nervous system, the physical system responsible for unconsciously maintaining bodily homeostasis and coordinating bodily responses. Working with the second main branch, the parasympathetic nervous system, the sympathetic nervous system regulates a wide range of functions such as blood circulation, body temperature, respiration, and digestion. Sympathetic activation commonly leads to adjustments on organs and glands that are complementary to those produced by parasympathetic activation and suitable for high activity ("fight and flight" as opposed to "rest and digest"). Examples of high-activity adjustments are constriction of blood vessels in the skin, dilation of blood vessels in the skeletal muscles and lungs, and increased heart rate and contraction force. Although sympathetic adjustments tend to complement parasympathetic adjustments, they do not always. For example, both sympathetic nervous system arousal and parasympathetic nervous system arousal increase salivary flow, although to different degrees and yielding different compositions of saliva.

Basic functional units of the sympathetic nervous system are preganglionic and postganglionic neurons. Preganglionic neurons have cell bodies in the thoracic and upper lumbar segments of the spinal cord and axons that extend to cell bodies of postganglionic neurons. Postganglionic neurons have cell bodies that are clustered in the so-called ganglia and relatively long axons that innervate target organs and glands. The major neurotransmitters of the sympathetic nervous system are acetylcholine and norepinephrine. Acetylcholine is the neurotransmitter of all preganglionic neurons. Stimulation of cholinergic receptors of the nicotinergic subtype located on the cell bodies of the postganglionic neurons by acetylcholine leads to an opening of nonspecific ion channels. This opening permits transfer of potassium and sodium ions, which depolarizes the postganglionic cell and initiates an action potential. Norepinephrine is the neurotransmitter of most sympathetic postganglionic neurons and stimulates adrenergic receptors lying on targeted visceral structures. All adrenergic receptors are coupled with G-proteins, but transmission pathways depend on the receptor subtype. Activation of alpha-1 receptors changes the calcium concentration in the cell, which in turn triggers the specific effect on the targeted visceral structure. Alpha-2 and beta receptors trigger visceral responses by affecting cAMP production in the cell. Specific effects depend on the receptor subtype and on the innervated visceral structure. For instance, stimulation of alpha-1 receptors on blood vessels of skeletal muscles leads to vasoconstriction and reduced blood flow, whereas stimulation of alpha-1 receptors on the radial pupil muscle leads to muscle contraction and increased pupil size. Stimulation of beta-2 receptors on the heart leads to increased heart rate and contraction force, whereas stimulation of beta-2 receptors on skeletal muscle blood vessels leads to vasodilation and increased blood flow.

In working jointly with the parasympathetic nervous system, the sympathetic nervous system

does not function in an all-or-none fashion, but rather activates to different degrees. Depending on the affected visceral structure and situation, it may be more or less active than the parasympathetic nervous system. Shifts in the magnitude of sympathetic and parasympathetic influence can occur locally within a single visceral structure (e.g., the eye) or across visceral structures, with local shifts occurring to meet highly specialized demands (e.g., a change in ambient light) and global shifts adapting the body to large-scale environmental changes (e.g., the appearance of a substantial physical threat). Autonomic control is maintained by structures in the central nervous system that receives visceral information from an afferent (incoming) nervous system. A key central nervous system structure is the hypothalamus, which integrates autonomic, somatic, and endocrine responses that accompany different organism states.

Sympathetic Nervous System (SNS) Activation

▶ Sympatho-Adrenergic Stimulation

Sympatho-Adrenergic Stimulation

Sabrina Segal
Department of Neurobiology and Behavior, University of California, Irvine, CA, USA

Synonyms

Adrenergic activation; Sympathetic nervous system (SNS) activation

Definition

Activation of one of the three branches (the sympathetic nervous system) of the autonomic nervous system via disruption of physiological homeostasis which results in the release of epinephrine/adrenaline and norepinephrine/noradrenaline from the adrenal medulla.

Description

The sympatho-adrenomedullary (SAM) system is one of two major components of the stress system. Stress activates the sympathetic nervous system and the goal of this response is to return the individual to physiological homeostasis. Epinephrine release from the adrenal medulla causes physiological alterations in cardiovascular tone, respiration rate, and blood flow to the muscles. Epinephrine does not cross the blood–brain barrier, but acts indirectly on the brain via the vagus nerve, which projects to the nucleus of the solitary tract (NTS), resulting in noradrenergic projections to the amygdala, as well as other brain regions. The release of epinephrine and norepinephrine from the adrenal medulla increases

blood glucose levels and enhances alertness, learning, and memory.

Symptom Magnification Syndrome

Karen Jacobs
Occupational Therapy, College of Health and Rehabilitation Science, Sargent College, Boston University, Boston, MA, USA

Synonyms

Learned symptom behavior; Maladaptation of symptom behaviors to chronic illness; Malingering; Martyr behavior; Secondary gain

Definition

Symptom magnification is a self-destructive, socially reinforced behavioral response pattern consisting of reports or displays of symptoms which function to control the life of circumstances of the sufferer.

Description

Symptom magnification syndrome (SMS) may be described as a conscious or unconscious self-destructive learned pattern of behavior which is maintained through social reinforcement and typically controls the individual's life activities. SMS may be labeled "malingering" or exaggerated psychological complaints which can be associated with individuals who are seeking financial compensation or a secondary gain, e.g., increased attention from a family member, from symptom reporting. The validity scales of the Minnesota Multiphasic Personality Inventory-2 (MMPI-2) are widely used for the detection of exaggerated psychological complaints.

Symptoms

Tana M. Luger
Department of Psychology, University of Iowa, Iowa City, IA, USA

Synonyms

Indicators

Definition

Symptoms are physical sensations or changes in internal state that a person recognizes, interprets, and reports (Pennebaker, 1982). Although symptoms are a key indicator of disease, it has been shown that perceived symptoms do not always correspond with objective, physiological pathology. Thus, researchers have sought to examine the various factors that can influence the perceptual processing and attributing of physical symptoms.

Because perception involves attention to certain cues while ignoring others, a person is more likely to recognize symptoms if their external world is not supplying them with information or distractions (Pennebaker, 1982). For example, a person with a boring job is more likely to report symptoms than one with a fast-paced job. The assumption is that the person with the boring job can focus more attention on his internal, physical state rather than managing the external.

There is much evidence that people selectively search for information when interpreting their symptoms. People tend to focus on information which either confirms their expectations or shows the potential symptoms to be benign (Leventhal, Leventhal, & Contrada, 1998; Pennebaker, 1982). Situational cues may also influence a person's search for information. For example, a recent outbreak of influenza in one's town may make a person more sensitive to his physiological changes and more likely to interpret his symptoms as signs of the flu. Previous experience with similar symptoms may also prime a person to attribute symptoms as being indicators of a particular disease (Jemmott, Croyle, & Ditto, 1988).

Finally, researchers have found that individual differences like gender, age, and personality can affect the amount that people report symptoms (Pennebaker, 1982). For example, women tend to report more physical symptoms than men, older adults report more than young adults, and those high in the personality trait of negative affectivity report more than those high in positive affectivity. One reason suggested for these differences are differing tendencies to focus on one's internal state, resulting in more attention and recognition of symptoms.

Symptoms Scale

Yori Gidron
Faculty of Medicine and Pharmacy, Free University of Brussels (VUB), Jette, Belgium

Definition

Symptoms scales are psychometric instruments aimed at assessing the frequency or severity of any type of symptom associated with a mental or physical health condition. Development of symptom scales requires the same type of rigor as any other self-report instrument requires, including tests of internal reliability and test-retest reliability and face, concurrent, construct and predictive validity.Questions on such scales can be asked in relation to a specific time frame (e.g., the present moment, the past week) and in relation to certain severity levels. For example, in the assessment of pain symptoms, patients may be asked to rate their level of average and worse pain in a given time frame. Finally, some scales also ask the extent to which certain symptoms interfere with one's daily functioning, as is often done in the domain of quality of life or pain. One of the earliest developed psychological symptoms scale is the symptom check list 90 (SCL-90) which was designed to assess psychological symptoms for evaluating the outcomes of mental health interventions and for research purposes. The symptoms are assessed in relation to the past 7 days and are categorized into nine dimensions (e.g., psychoticism, depression). Its internal reliability is adequate (e.g., Cronbach's alpha of .77 to .90 on its dimensions). Its concurrent, construct, and predictive validities have been shown as well. A physical symptoms scale is the Patient Health Questionnaire 15 (PHQ-15; Kroenke, Spitzer, & Williams, 2002). This scale assesses 15 common physical symptoms including stomach, back, head and chest pains, dizziness, shortness of breath, etc. Scores on the PHQ-15 correlate with functional status and with healthcare utilization. Numerous other instruments exist for assessment of various psychiatric symptoms including depression, anxiety, post-traumatic stress disorder, and for disease-specific symptoms. The latter include symptoms scales of upper respiratory infections (Orts et al., 1995), the Rose chest pain questionnaire (Rose, McCartney, & Reid, 1977), and others. Symptom scales are a basic element in diagnosis and monitoring of treatment effects and in research in many health disciplines including medicine and behavior medicine. However, it is noteworthy to consider the limitations of symptom scales, as in most self-report scales. These include reporting biases, memory, and lack of self-awareness. One important factor known to underlie reporting biases includes neuroticism or negative affectivity, which, when elevated, often leads to inflated symptom reporting and needs to be considered when patients complete symptoms scales (Watson & Pennebaker, 1989).

Graded exposure counterconditioning

Definition

Systematic desensitization or graded exposure is a behavioral intervention commonly used in the treatment of phobias and other anxiety-related disorders. Individuals with phobias tend to possess irrational fears of stimuli such as heights, close spaces, dogs, and snakes. In order to cope, the individual avoids such stimuli. Since escaping from the phobic object reduces anxiety temporarily, the individual's behavior to reduce the perceived fear is negatively reinforced. The aim of systematic desensitization is to overcome this avoidance by gradually exposing individuals to the phobic stimulus until their anxiety to the fear is extinguished (Sturmey, 2008).

Description

Joseph Wolpe (1915–1997)

Joseph Wolpe was a South African–born American doctor. During his work as a medical officer, Wolpe's task was to treat soldiers who were diagnosed with "war neurosis" which is now referred to as post-traumatic stress disorder. It was argued at the time that by talking about their war experiences would lead to a resolution of their symptoms. However, this was not found to be the case, and Wolpe became increasingly disillusioned by Freud's psychoanalytic therapy. It was this which served as a catalyst for Wolpe to discover other more effective treatment strategies (Wolpe, 1973).

Wolpe began to investigate behavioral strategies through laboratory experiments. One of his concepts was reciprocal inhibition by which anxiety is inhibited by a feeling which is incompatible such as relaxation (Wolpe, 1961). He pioneered the intervention assertiveness training and deciphered that this approach was useful for people who were anxious about social situations. As they learned assertiveness skills, this assisted to minimize the anxiety associated with such situations and in turn relaxed. As this proved to be highly fruitful, it further led to the development of systematic desensitization (Wolpe, 1973).

Systematic Desensitization

It was discovered that fears could be learned through the behavioral model of classical conditioning (see ► Classical Conditioning). Therefore, Wolpe (1973) sought to eliminate the fear response generated by the stimulus and replace it with a competing response of relaxation. The notion of systematic desensitization was based upon two principles of conditioning. The first was that an individual could not produce two different responses to stimuli such as fear and relaxation. Secondly, classical conditioning often involves stimulus generalization which refers to stimuli which are similar and lead to the learned response of fear (Sturmey, 2008).

During the process of systematic desensitization, the therapist works in conjunction with the

person who has a phobia to ascertain the exact stimulus which triggers the phobia. Next, the individual is taught relaxation-inducing techniques often related to a cue for relaxing. After this stage, the therapist and individual develop a list of fear-evoking stimuli, ranging from very mild to very intense anxiety. This list is referred to as a hierarchy of fears as the stimulus items are listed in order of the intensity of fear they evoke. Then, working gradually the therapist attempts to recondition the person so that the stimuli in the hierarchy become associated with a relaxed response rather than fear. Once the individual can eventually confront the stimulus which originally evoked the greatest anxiety and remains relaxed, then the phobia has been effectively extinguished (Sturmey, 2008).

Systematic desensitization has been found to be highly effective in the treatment of phobias (Clark, 1963), sexual disorders (Obler, 1973), and traumatic nightmares (Schindler, 1980).

Systematic Review

J. Rick Turner
Cardiovascular Safety, Quintiles, Durham, NC, USA

Definition

Systematic reviews present a descriptive assessment of a collection of original research articles related to a specific research question. These reviews "collate, compare, discuss, and summarize the current results in that field" (Matthews, 2006). Campbell, Machin, and Walters (2007) noted that "It has now been recognised that to obtain the best current evidence with respect to a particular therapy all pertinent clinical trial information needs to be obtained." This "overview process" (Campbell et al., 2007) has led to many changes in the way clinical trial programs are developed. They have become an integral part of evidence-based medicine, impacting decisions that affect patient care.

A considerable problem in writing such reviews is the retrieval of all relevant publications in the behavioral medicine literature, although the advent of computerized searchable databases has made this task much less arduous.

While such a narrative review can be very useful in its own right, it can also be the first step in a two-step process that also includes conducting a meta-analysis. This provides a statistical (quantitative) answer, whereas the authors' conclusions in a systematic review will largely be qualitative.

Systems Theory

Afton N. Kapuscinski
Psychology Department, Syracuse University, Syracuse, NY, USA

Definition

An approach to science that emphasizes unity and wholeness (Bertalanffy, 1968) and views factors that influence phenomena as mutually affecting each other at various levels of complexity.

Description

Systems theory, which became popular in the mid-twentieth century, developed in opposition to some of the philosophical assumptions that permeated the sciences across a variety of disciplines (Bertalanffy, 1968). Specifically, systems theory opposed the idea that knowledge about the universe is best obtained through a perspective rooted in notions of reductionism, mechanism, and objectivism (Midgley, 2000). Mechanism assumes that the universe and all phenomena contained within it can be likened to machines, composed of parts that operate in predictable, logical ways. Therefore, traditional scientific theory and methodology seeks to reduce complex phenomena to the functions of the smallest possible parts (reductionism), assuming that such analysis will yield complete understanding and ultimately control, in the area under study (Midgley, 2000). For example, a reductionistic approach to psychology may pose that all behavior can ultimately be traced to genetic endowment or chemical reactions occurring at the level of individual brain cells.

Systems theorists, however, argue that the search for simple, linear, cause and effect relationships between variables may lead to the neglect of developing more holistic, comprehensive conceptual models (Midgley, 2000), leaving the field of psychology impoverished in a couple of ways. First, mechanistic and reductionist approaches may struggle to explain emergent properties of systems, that is, those qualities of a system that cannot be explained merely as the sum of its individual parts (Bertalanffy, 1968), such as the human capacity for agency, creativity, or love. Even the concept of life itself cannot be explained by the activity of individual cells (Bertalanffy), but emerges from a complex system of interacting cells. Second, reductionistic scientific disciplines tend to exist in relative isolation from each other, without attempts at integration that may benefit the individual field, as well as facilitate broader societal improvement. Since system thinking views the boundaries between disciplines as somewhat unnecessary and artificial, a behavioral medicine investigator working from a systems perspective may draw from many sciences to obtain a more holistic understanding of a given topic. Therefore, in contrast to the "zooming in" approach of reductionism, systems thinking values panning outward to examine different levels of contextual factors that may be influencing and be influenced by a particular aspect of a system – including concepts across disciplines.

Ecological models of health behavior (see Sallis, Owen, & Fisher, 2008) are a good example of research grounded in systems thinking. These models assume multiple influences on health behaviors at various levels, with influences interacting across the levels (Sallis et al., 2008). For example, consider the problem of cardiovascular disease. A systemic approach to reducing the incidence of cardiovascular disease would aim to target a variety of factors that are interacting to determine one's degree of risk for developing the condition, including biological (e.g., hypertension, high cholesterol), psychological (e.g., hostility), social (interpersonal

relationships and support), and behavioral (e.g., diet, exercise, medication compliance) contributors. Such conceptualization in behavioral medicine is often referred to as taking a biopsychosocial approach, a form of systems thinking. A systemic model would also examine contextual factors that affect the individual, such as health care utilization or level of education, which may influence the individual's exposure to preventative medicine and information about healthy eating habits. Further, the approach would likely be mindful of broader social and economic concerns (e.g., unemployment rate, racial inequality) that may, in turn, influence one's access to these resources and thus would also be considered relevant to intervention efforts. These types of ecological models have been developed to further understanding of various health behaviors such as physical activity, tobacco control, and diabetes management (Sallis et al.).

Just as systems theory questions the validity of boundaries between disciplines, it also disputes the boundary between scientists and their objects of study (Midgley, 2000). Systems theorists reject the position that one can passively observe reality, standing separate from the object of study, but holds that scientists interact with these objects to actively create reality and interpret observations based on the lens through which they view them (Bertalanffy, 1968). If objectivism is not possible and scientists can never capture "reality," then theories and methodologies become "ways of seeing" that are full of value (Midgley, 2000). A critical implication of this shift in thinking is the possibility for theoretical pluralism, wherein investigators value contributions from various perspectives and types of research.

Influence on Psychotherapy

The principles inherent in the systems approach have influenced important shifts in the way psychotherapists understand the process of facilitating client change. First, there has been a shift away from the traditional psychoanalytic approach, which viewed the therapist as a relatively objective figure who could successfully remove his or her self from the process, providing the patient with a "blank screen" on which to project unconscious material for interpretation by the therapist. Modern psychoanalytic approaches, such as the object relations or two-person paradigms, assert that the therapist cannot avoid revealing the self and influencing the therapeutic encounter so as to create it along with the patient (Levenson, 1995). When viewing the therapeutic relationship as a system, the interaction between the therapist and patient, including the therapists' behaviors and feelings, becomes critically important and should be considered to aid case formulation and planning interventions. Since a change in any part of a system affects the whole of the system (Bertalanffy, 1968), the therapist's attempts to foster a healthy relationship can encourage improved interpersonal functioning in the patient (Levenson, 1995). Second, systems theory gave rise to another popular paradigm for understanding individual and family dysfunction, known as family systems theory. Family systems theory holds that an individual's or family's distress cannot be understood fully by looking at any one person in isolation, but must be viewed as the symptom of problematic patterns of interactions within the larger family structure (Smith-Acuña, 2010). Systems therapists therefore seek to improve the functioning of the family as a unit.

T

Tachycardia

Lois Jane Heller
Department of Biomedical Sciences, University of Minnesota Medical School – Duluth, Duluth, MN, USA

Definition

The word "tachycardia" means rapid heart rate. This condition is more precisely defined as a heart rate that is above the age-adjusted range of normal heart rates (see Table 1). Children normally have higher heart rates than adults and can tolerate rapid heart rates more easily.

Description

Normal Determinants of Heart Rate

Heart rate is normally established by the rate of spontaneous generation of an electrical signal (action potential) by "pacemaker" cells located in the sinoatrial (SA) node of the heart (in the wall of the right atrium near the entry of the superior vena cava) (Mohrman & Heller, 2011). These electrical signals are normally generated at a rate of 60–100 beats per min in a human adult. They are propagated from the SA node through the atrial and ventricular muscle cells in a set pathway that stimulates contraction in a pattern that optimizes pumping of blood from the heart. Most other cardiac muscle cells have the potential to act as pacemakers, but the SA nodal cells drive the heart at a slightly faster rate than any of these other "latent" pacemakers.

The normal fluctuations in heart rate that occur in response to normal changes in the body's metabolic demands are accomplished by altering autonomic neural influences on the SA nodal pacemaker cells from the parasympathetic and sympathetic nervous system. Increased sympathetic activity causes an increase in heart rate whereas increase in parasympathetic activity causes a decrease in heart rate.

Tachycardia, Table 1 Age-associated upper limit to normal human heart rates (Adapted from Greene, 1991)

Less than 1 year	~170 bpm
1–2 years	~150 bpm
3–5 years	~135 bpm
6–12 years	~130 bpm
12–15 years	~120 bpm
15 years through adulthood	~100 bpm

Symptoms of Tachycardia

A person with significant tachycardia may or may not be aware that their heart rate is fast without actually measuring their pulse rate (Valentin, O'Rourke, Walsh, & Poole-Wilson, 2008). However, tachycardia often results in a feeling of light-headedness, dizziness, tunnel vision, or fainting. Other symptoms may include muscle weakness, nervousness, sweating, pallor, or a feeling of fullness in the chest. The cause of

M.D. Gellman & J.R. Turner (eds.), *Encyclopedia of Behavioral Medicine*,
DOI 10.1007/978-1-4419-1005-9,

many of these symptoms is often related to a decrease in arterial blood pressure and therefore blood flow to the brain and other tissues.

Physiological Cause of the Symptoms

The amount of blood that the heart pumps in a minute is called the cardiac output (Mohrman & Heller, 2011). This is determined by the volume of blood ejected in each beat *(stroke volume)* and the number of beats per minute *(heart rate)*:

$$\text{Cardiac output} = \text{stroke volume} \times \text{heart rate}$$

One might predict from this equation that the cardiac output would increase whenever heart rate increased. This is true over the normal range of heart rates. However, when the heart rate exceeds this normal range, the cardiac output may actually fall. There are three primary reasons for this: (1) There is insufficient time between beats to allow the heart to fill adequately. (2) The coronary circulation to the cardiac muscle may be compromised by the compressive forces in the ventricular wall associated with each individual beat. (3) The energy requirements for the heart increase enormously and may not be met by the compromised coronary blood flow.

Physiological Causes of Tachycardia

1. *Atrial Tachycardia or Supraventricular Tachycardia* (i.e., associated with a narrow QRS complex on an ECG) (Valentin, O'Rourke, Walsh, & Poole-Wilson, 2008). This condition is more common than ventricular tachycardia (see below) and can often be successfully treated. It is often uncomfortable and alarming to the individual, but does not usually portend immediate, possibly fatal consequences.
   (a) *Sinus Tachycardia* – Elevated sympathetic neural activity or an increase in circulating catecholamines stimulates the normal pacemaker cells in the SA node to fire at a very rapid rate and this electrical signal is then carried via normal pathways through the entire heart.
   (b) *Ectopic Atrial Pacemakers* – Atrial cells that are not part of the SA node can sometimes become irritable and generate electrical signals that spread throughout the cardiac tissue.
   (c) *AV Nodal Reentrant Tachycardia* – This is a conduction defect rather than a pacemaker defect. In this case, a rapid heart rate may result from an abnormal portion of conduction pathway usually found in the AV node in which the electrical signal circles back on itself to rapidly re-excite the downstream tissue.
   (d) *Atrial Flutter* – An ectopic pacemaker or reentrant pathway in the atria evokes in a very rapid atrial rate such that AV node fails to conduct every signal. The atria may beat three or more times for each ventricular beat. The ventricular rate may be faster than normal or within the normal range but the atrial rate is faster.
   (e) *Atrial Fibrillation* – The atrial conduction pathways become disorganized and the normal synchronized excitation of the atrial tissue is disrupted. Electrical signals are initiated and conducted in bizarre patterns, resulting in unpredictable intermittent conduction through the AV node. This results in an irregular ventricular rhythm that may, on the average, be faster than normal (tachycardia), normal, or slower than normal (bradycardia).
2. *Ventricular Tachycardias* (i.e., associated with wide QRS complex on an ECG). This is a more serious condition than atrial tachycardia and needs immediate attention. The heart is still operating as a pump but the possibility of a sudden deterioration to ventricular fibrillation is high.
   (a) *Ectopic Ventricular Pacemakers* – Ventricular cells can sometimes become irritable and generate electrical signals that spread throughout the cardiac tissue. This may occur if blood flow to a portion of the ventricular wall is inadequate and the tissue becomes ischemic.
   (b) Ventricular Reentrant Pathways – In this case, a rapid heart rate may result from

abnormal conduction of the electrical signal through a small portion of ventricular muscle such that the electrical signal circles back on itself to rapidly re-excite the cardiac tissue. Because all cardiac muscle cells are electrically connected, this rapidly firing small group of cells can drive the ventricles at a fast rate.

Tailored Communications

Celette Sugg Skinner
Clinical Sciences, The University of Texas Southwestern Medical Center at Dallas Harold C. Simmons Cancer Center, Dallas, TX, USA

Synonyms

Tailored health behavior change interventions

Definition

"Tailored communications are any combination of information intended to reach one specific person, based on characteristics unique to that person, related to the outcome of interests, and derived from an individual assessment" (Kreuter & Farrell, 2000).

Description

Background

The field of behavioral medicine studies how behaviors affect health and medical conditions, as well as how behaviors can be changed. Good behavior-change interventions are, of course, guided by strong health behavior theories that elucidate factors (variables) affecting individuals' behaviors. One of most basic of these, the Health Belief Model (HBM), was developed in the 1950s when the US public health service consulted with psychologists to understand why people were not availing themselves of free tuberculosis screenings. This simple model delineates three major factors (or theoretical constructs) affecting whether people take a health action. They must feel susceptible to a health threat serious enough to warrant attempts to reduce the risk, believe that changing their behavior would reduce their risk, and overcome perceived barriers to behavior change (Champion & Skinner, 2008). Individuals can vary widely on these beliefs. One's threat perception may be low whereas another may perceive the threat but not believe the behavior change would have benefit for lowering it. Among those who perceive barriers to behavior change, specific types of barriers may vary widely. For example, not having a ride to a screening site is very different from not being able to afford screening or of being afraid the screen would find a problem.

Message Customization

Face-to-face communications are usually customized for different people. For example, nurses seeking to facilitate medication adherence communicate with different patients differently, depending on factors influencing *that persons'* behavior. The message differs when talking with someone who cannot remember to take the pills versus someone avoiding the medication due to side effects. But only recently did this kind of message customization become possible in mass-produced media such as print and video. From the 1950s through the 1980s, mass-media communications such as brochures and videos were developed to address an array of variables,

with the hope that at least some of the message components would be relevant to most audience members.

Mass-Produced Tailored Communications

In the 1980s, the rise of micro-computing capabilities opened possibilities for mass-producing communications that retained advantages of customized face-to-face interactions. These "tailored communications" are reminiscent of tailor-made clothing that is based on numerous measurements taken by the tailor before beginning his work. Tailored communications begin with measures of people's behavior-influencing factors such as the HBM variables of perceived risks and beliefs about the behavior's benefits and barriers. The "fabric" of tailored communications is distinct text, audio, or graphic components that are "sewn" together to fit the measurements of a particular message recipient.

In their 2000 book, *Tailored Health Messages; Customizing Communication with Computer Technology* Kreuter, Farrell et al. provide this elegant definition of tailored communications: "any combination of information intended to reach one specific person, based on characteristics unique to that person, related to the outcome of interests, and derived from an individual assessment." Continuing the clothing analogy, this definition distinguishes between tailored and targeted communications, as follows. *Tailored communications* – and tailored clothing – are intended to fit one individual. *Targeted communications* – and off-the-rack clothing – are intended to fit any one of a group sharing some common characteristics (e.g., men who wear a size 40 long, like pinstripes, and shop in a certain price range). Targeted messages are usually directed to a particular demographic group (i.e., African American church members) and address factors known to be important for *many* members of that group. In contrast, tailored communications are based on individual-level assessment of theory-based behavior-influencing variables, with a unique combination of messages assembled for each individual within the group (Kreuter & Skinner, 2000).

The original rational for tailoring was that tailored communications would be more noticeable and compelling and less burdensome because they are streamlined to only include content relevant to the recipient. According to Petty and Cacioppo (Petty, Cacioppo, & Goldman, 1981), the more personal involvement with the message, the more careful consideration (i.e., "central processing") and elaboration on the message which, in turn, increases likelihood of attitude and behavior change.

Early Trials of Tailored Print Communications

Several initial randomized trials compared printed communications that were v. were not tailored on theory-derived behavior-influencing variables (Skinner, Campbell, Rimer, Curry, & Prochaska, 1999). Three of these, targeting mammography screening (Skinner, Strecher, & Hospers, 1994), smoking cessation (Strecher et al., 1994), and dietary change (Campbell et al., 1994), were conducted among primary-care patients who completed telephone surveys and were randomly assigned to receive tailored or non-tailored printed newsletters. In addition to age, race, and risk factors, messages in the tailored letters directly addressed variables such as the recipients' perceived risk, benefits and barriers, their stage of behavior adoption, characteristics such as age, race, and risk factors and, for smokers, causal attributions for past failed quite attempts. In each of these three studies, the non-tailored letter version addressed a number of factors that had been shown to influence people's behaviors, in general. For example, the non-tailored mammography letter was adapted from a letter from US Surgeon General's office mailed to women who requested information about breast cancer screening. Because these three trials were designed to compare tailored versus non-tailored *content*, the tailored letters did not include statements such as "the information was prepared especially for you," as have later studies. Tailored and non-tailored letters looked very much alike. They were printed in black and white on two-column 8½ × 11 paper and included a head-and-shoulders line drawing. Therefore, it is remarkable that recipients of the tailored letters

were more likely to report remembering and reading their letters. Receipt of a tailored letter was also associated with behavior change (Campbell et al., 1994), at least among important subgroups (Skinner et al., 1994; Strecher et al., 1994). Indeed, of the seven initial comparisons of tailored versus. non-tailored print communications, six (Skinner et al., 1999) found more behavior change among tailored recipients.

Movement Toward Different Comparisons

Given these impressive results from studies comparing tailored versus similar non-tailored print, and with tailoring technology expanding rapidly, tailoring researchers moved on to different comparisons. Studies tested tailored communications as an adjunct to other intervention components such as self-help smoking manuals, and compared tailored messages delivered through different media, such as tailored print versus tailored telephone counseling (Champion et al., 2007; Rimer et al., 2002), tailored on different types of variables (Kreuter et al., 2005), and with and without booster doses (Skinner, 2006). Even within the tailored print medium, researchers moved beyond the newsletter format to tailored booklets and magazines with tailored features such as cartoons and advice columns (Rimer et al., 2002; Kreuter et al., 2005). Because there were so many kinds of comparisons of different tailoring approaches and for different target behaviors, data do not exist from head-to-head comparisons of every feature (e.g., more vs. less content, fewer vs. more graphics). As reported in a 1998 review of the "first generation" of tailored communications, these various comparisons showed mixed results, and "when (tailored print communications) are only one component of a complex intervention strategy without a factorial design, it is more difficult to isolate their relative contribution to the overall intervention effect" (Skinner et al., 1999, p 296). Nonetheless, this initial review and several others published subsequently (Kreuter & Farrell, 2000; Kroeze, Werkman, & Brug, 2006; Revere & Dunbar, 2001; Rimer & Glassman, 1999) reported that tailoring seems to "work" both for attracting and retaining attention and for facilitating behavior change. Further, delivering tailored messages via print plus another medium such as telephone generally is more effective than tailored print alone.

Interactive "Real-Time" Tailoring

Original print-tailored interventions collected questionnaire data and then used that entire "batch" of data to put together specific messages that, depending on algorithms, were selected from a library of potential messages. More recently, CD-ROMs, DVDs, and the internet have allowed for interactive tailoring based on data collected during program use rather than in questionnaire form before the intervention is delivered. For example, a DVD or CD-ROM can ask a question about barriers to behavior change, then immediately show videos, selected from a tailored video library, that address the specific barriers named by the user (Skinner et al., 2011). Some web-based programs provide tailored content based on predetermined algorithms, others allow users to "self-tailor" by selecting any content of interest to them. As described in Lustria, Cortese, Noar, & Glueckauf, 2009 review of computer-tailored health interventions delivered over the web, these interventions "have involved a great diversity of features and formats," and "further outcome research is needed to enhance our understanding of how and under what conditions computer-tailoring leads to positive health outcomes in online behavioral interventions" (Lustria et al., 2009, p. 156). Therefore, as with the print-tailored communications, it is difficult to draw conclusions across studies.

Conclusions and Challenges

One problem in understanding findings and implications of tailored communication intervention studies is that journals often severely limit the amount of space for intervention descriptions. As a result, we have many statistics associated with the intervention outcomes, but we know little about the interventions themselves. In other words, we may learn that "it worked" without knowing exactly what "it" was or with what "it" was compared. Tailoring researchers have,

therefore, recently called for new reporting standards through which intervention studies will report similar descriptions and metrics, which should help in evaluation and dissemination of best practices in tailored interventions (Harrington & Noar, 2011).

In summary, communication interventions that are tailored to include theory-based messages relevant to individual recipients, based on data collected from them, are generally better than non-tailored communications in drawing the attention of message recipients and facilitating their health behavior change. However, questions still remain about optimal amounts and types of tailoring for different behavioral targets and through different media.

Telomere and Telomerase

A. Janet Tomiyama[1] and Elissa S. Epel[2]
[1]Rutgers University, NJ, USA
[2]University of California, San Francisco, CA, USA

Definition

Telomeres are noncoding repeat DNA sequences (consisting of TTAGGG) that cap the ends of eukaryotic chromosomes. Telomerase is an enzyme that adds basepairs to telomeres.

Description

Like the plastic tips that protect shoelaces from unravelling, telomeres protect DNA material. When cells divide, the enzymes that replicate the chromosomes are unable to do so fully. The main purpose of telomeres is to form a buffer so that genetic material is not lost in this process. With each cell division, telomeres can shorten, and when telomeres become critically short, a cell undergoes senescence (cell arrest). Telomeres also function to protect chromosomes from genomic instability, end-to-end chromosome fusion, less efficient cell division, loss of ability for cell replenishment, and apoptosis or cell death (Blackburn, 2000).

Because of these important functions, telomeres are related to a number of health outcomes and disease states. Shorter telomere length is associated with chronic diseases of aging such as cardiovascular disease, cancer development, and Alzheimer's disease, and is related to earlier mortality. Telomere length is also thought to be an indicator of biological, rather than chronological, age (Epel, 2009).

Telomere length is associated with a number of psychosocial factors. For example, depression, higher perceived stress, longer stress duration, caregiving, lower socioeconomic status, pessimism, childhood adversity, and lower subjective well-being are correlated with shorter telomere length. Health behaviors such as smoking, lack of physical activity, and repeated dieting as well as altered metabolic states such as obesity and insulin resistance are also linked with shorter telomere length (Lin, Epel, & Blackburn, 2009).

Telomerase is the enzyme that adds base pairs back onto telomeres. This serves to protect telomeres from shortening. Recent work suggests telomerase may have future applications for antiaging therapies as evidenced by telomerase knockout mice displaying reversed aging with telomerase treatment (Jaskelioff et al., 2010).

Telomerase, like telomeres, appears to be responsive to psychological states, and may

serve to protect cells under stress. Exposure to acute stress (Epel et al., 2010) as well as states of chronic psychosocial adversity are associated with high telomerase. Because telomerase levels change more dynamically than telomere length, psychosocial interventions such as meditation (Jacobs et al., 2010) and comprehensive lifestyle changes (Ornish et al., 2008) have been tested in preliminary studies as a potential treatment to increase telomerase, with promising results.

Temporal Self-Regulation Theory

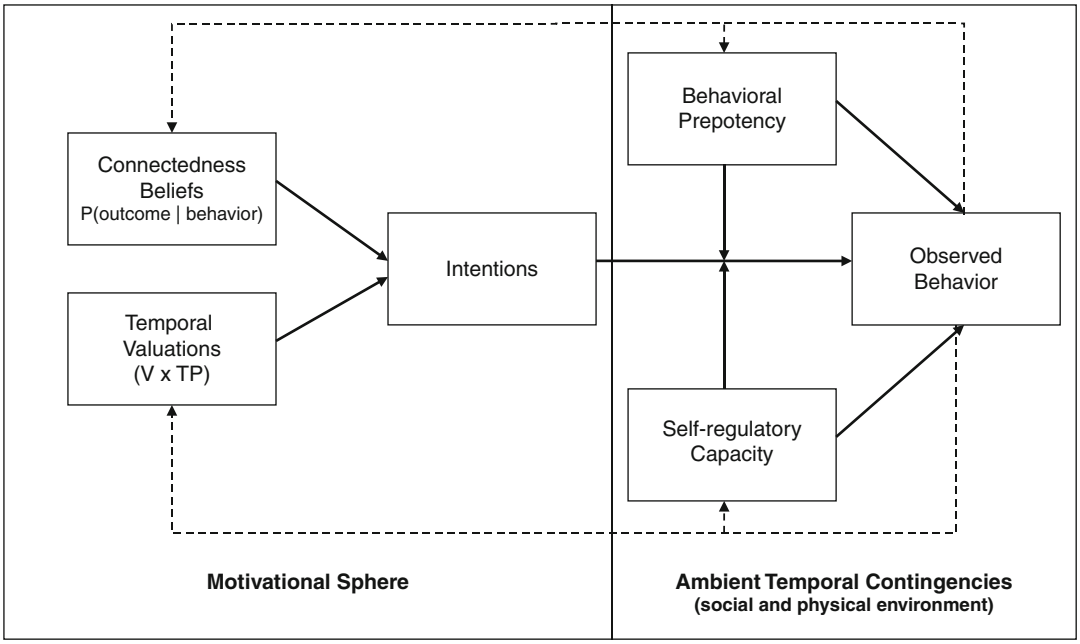
Peter A. Hall
Faculty of Applied Health Sciences, University of Waterloo, Waterloo, ON, Canada

Synonyms

Dual process models of health behavior; Dual systems models

Definition

Temporal self-regulation theory (TST; Hall & Fong, 2007; Fig. 1) is a theoretical framework for explaining individual health behavior. TST posits that health behavior is proximally determined by three factors: *intention strength*, *behavioral prepotency*, and *self-regulatory capacity*. The latter two constructs are theorized to have direct influences on behavior and also to moderate the intention-behavior link. Specifically, intentions are proposed to have a stronger influence on behavioral performance in the presence of stronger self-regulatory capacity and/or when the behavioral prepotency is weak. Also included in the model is consideration of ecological context in the form of contingencies supplied to the behavior by the social and physical environment



Temporal Self-Regulation Theory, Fig. 1 Arrows between Behavioral Prepotency and Self-regulatory Capacity to the Intentions-Behavior arrow implies moderation; V = value; TP = perceived temporal proximity. Broken arrows denote weaker (i.e., secondary) hypothesized effects. Adapted from (Hall & Fong 2007).

(i.e., *ambient temporal contingencies*). In the TST model, *intention strength* is a function of anticipated connections between one's behavior and salient outcomes (i.e., *connectedness beliefs*); the valence of the latter can range from negative (i.e., costs) to positive (i.e., benefits). These beliefs are weighted by temporal proximity (i.e., *temporal valuations*). For example, the perceived self-relevant contingencies for making a healthy dietary choice might include eventual benefits (e.g., improved appearance, better health status), but more temporally proximal – therefore more heavily influential-immediate costs (e.g., inconvenience, monetary costs, time costs). The sum of the perceived contingencies weighted by their respective temporal proximities should determine intention strength to make a healthy dietary choice, according to the TST model.

Description

The aim of the TST is to explain variability in health behavior in a manner that is sensitive to biological capacities for self-control, motivation level, and the ecological context in which the behavior takes place. Given the complexities of the model and the fact that it crosses many levels of analysis (from biological to social to ecological), it is expected that the model is not testable in its entirety. Rather, individual components of the model may be tested individually or in relation to each other (e.g., hypothesized moderating effects).

The TST model was initially offered as an improvement over traditional models of individual health behavior which posited that behavior was most proximally determined by social cognitive variables, without direct or indirect links to neurobiological resources. While TST preserves the central role of intention strength, it adds two important moderating and direct effects on health behavior performance: (1) *self-regulatory capacity* (SRC) and (2) *behavioral prepotency* (BPP).

SRC is composed primarily of executive control resources and therefore ascribed to operation of the prefrontal cortex and associated neural

systems implicated in the neurobiology of self-control (Miller & Cohen, 2001). BPP is the psychological inertia of a given behavior, by virtue of frequent past performance in similar contexts, or via the presence of strong cues (which may be social or visceral in nature) to perform the behavior at a given time. The combination of SRC and BPP determines the likelihood that intentions will be translated into behavior, and each also has direct influences on behavior itself regardless of intention.

Additional components of TST that differentiate it from its predecessors are (1) an explicit focus on temporal proximity of behavioral contingencies as determinants of their relative potency and (2) a consideration of ecological factors as causal agents in health behavior performance. These two components are conceptually linked, as ecological contexts often determine what kinds of consequences (positive, neutral, or negative) are experienced following performance of a behavior, as well as the relative proximity of those consequences (immediate vs. long-term).

The primary contribution of the TST model has been to provide some basis for understanding the possibility of brain-behavior relationships as being partial determinants of health behavior trajectories, and to provide an interface for individual models of health behavior with ecological and social-level determinants of behavior. Given that intention strength (Armitage & Connor 2001) and behavioral prepotency (Ouellette & Wood, 1998) are among the most well-established determinants of behavior in the extant research literature, the construct within TST that has required the most empirical justification is the inclusion of biologically based SRC.

Though few studies of SRC as a determinant of health behavior existed prior to the introduction of the TST model, the early findings have been promising. In recent studies, it has been found that SRC predicts health behavior patterns directly and exerts an additional moderating influence on health behavior performance, both of which are hypothesized by TST (Hall, 2012). In addition, evidence has emerged to indicate that individual differences in SRC may be selectively responsible for the previously demonstrated association between IQ and longevity, and also predicts survival time among those living with chronic illnesses that carry significant self-care demands. Finally, recent research shows that SRC interacts with intentions such that intentions predict various health behaviors, only when SRC is high, not low.

Together these findings provide support for the inclusion of biologically based SRC in contemporary models of health behavior. It is expected that the next generation of research involving TST will include experimental designs that can isolate causal relations between SRC and health behavior performance (both directly and via its intention-moderating effect) in the laboratory setting, and test the efficacy of SRC-augmenting activities in the interventional context. Among the most promising interventions for augmenting SRC is the use of aerobic training, which has been shown to enhance structural and functional components of the brain regions that are known to support self-regulatory processes and self-control (McAuley & Hillman, 2012). One final novelty of this model is its use of various types of assessment methods (self-report and neuropsychological or reaction-time tests), which may overcome problems of shared-method variance and enhance its predictive validity.

Definition

A theory is a coherent set of statements or ideas used to organize, generalize, explain, and predict phenomena. Theories are based on observations, experimentation, and abstract reasoning, and play a fundamental role in scientific research.

Theories must (a) successfully describe and explain existing observations, (b) make predictions about future observations, and (c) be falsifiable, that is, they must be refutable by some conceivable event or observation.

While not directly verifiable, theories gain support as empirical evidence accumulates in their favor, particularly if such evidence results from "risky" predictions where the outcome could conceivably have been different (Popper, 1963/2004). An accumulation of contradictory empirical evidence results in the theory being abandoned, modified, or superseded by a new theory. This dynamic process of testing, evaluation, and change allows research to move forwards toward the "truth." Theories provide a shared language for researchers to use, enabling the development of a cumulative science. The most useful theories are those that make specific and relevant predictions that can be tested in a straightforward manner.

Prominent theories in behavioral medicine cover a range of domains and include the Transactional Theory of Stress and Coping (Lazarus & Folkman, 1984), Type D Personality (Denollet et al., 1996), the Theory of Planned Behavior (Ajzen, 1991), and the Common Sense Model of Self-Regulation of Health and Illness (Leventhal, Diefenbach, & Leventhal, 1992).

Theory of Planned Behavior

- ▶ Theory of Reasoned Action

Theory of Reasoned Action

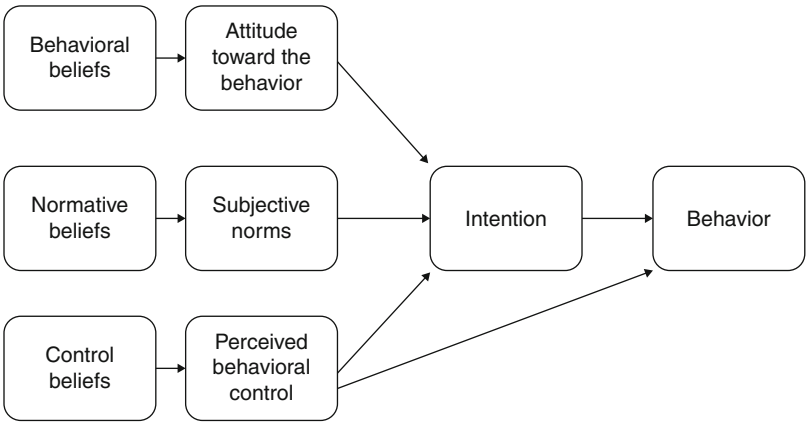
Lara LaCaille
Department of Psychology, University of Minnesota Duluth, Duluth, MN, USA

Definition

The Theory of Reasoned Action (TRA; Ajzen & Fishbein, 1980; Fishbein & Ajzen, 1975) and its extension, the Theory of Planned Behavior (TPB; Ajzen, 1985, 1991), are cognitive theories that offer a conceptual framework for understanding human behavior in specific contexts. In particular, the theory of planned behavior has been widely used to assist in the prediction and explanation of several health behaviors.

Description

According to the initial Theory of Reasoned Action, an *intention* to engage in a certain behavior is considered the best predictor of whether or not a person actually engages in that behavior. Intentions, in turn, are predicted by *attitudes* and *subjective norms*. That is, the more positively a person regards a certain behavior or action and the more they perceive the behavior as being important to their friends, family, or society, the more likely they are to form intentions to engage in the behavior. Azjen, however, noted the importance of a behavior being under volitional control in both forming intentions and engaging in the actual behavior. Therefore, he added *perceived behavioral control* to the model, which is now known as the Theory of Planned Behavior. See Fig. 1.



Theory of Reasoned Action, Fig. 1 Theory of planned behavior

Description of the Theoretical Factors

Behavioral beliefs and attitudes: A person first forms beliefs about the outcomes of a given behavior (e.g., "If I exercise, I will improve my health, lose weight, and be more attractive"). These beliefs contribute to his or her attitude or evaluation of the outcome of the behavior (e.g., "Being healthy and attractive is good/valuable"). The more favorable the attitude, the stronger the intention.

Normative beliefs and subjective norms: Normative beliefs refer to a person's perception about the expectations of important others (e.g., "My friends think I should exercise"). These beliefs contribute to the perception of social pressure and contribute to motivation to comply (e.g., "I feel pressured to exercise and I want to fit in with my friends"). The more powerful the perceived norm/pressure, the stronger the intention.

Control beliefs and perceived behavioral control: A person forms beliefs about the factors that may facilitate or be barriers to engaging in the specific behavior (e.g., "I have time before work, I have access to a gym, and I am physically able to exercise"). These beliefs lead to a perception of behavioral control or sense of ease/difficulty in engaging in the behavior (e.g., "I will be able to exercise"). Although many researchers have used the terms self-efficacy and perceived behavioral control interchangeably, including Ajzen (1991), these concepts are not quite synonymous. Whereas self-efficacy reflects individuals' beliefs about their competence or internal control, perceived behavioral control also incorporates other external/environmental factors (e.g., time, resources, social support). The greater the perceived behavioral control, the stronger the intention and the greater the likelihood of engaging in the behavior.

Intention: Intentions refer to peoples' plan of action and represent their expressed motivation to perform the behavior.

Evaluation of the Model

Meta-analytic reviews have supported the predictive efficacy of the TPB model for both behavioral intentions and behaviors (Armitage & Conner, 2001; Godin & Kok, 1996; Sheeran, 2002). The theory typically accounts for about 40–50% of the variance in intentions and 20–40% of the variance in behavior. The relative importance of each of the three factors (attitudes, norms, perceived behavioral control) varies across behaviors and situations. Subjective norms are usually the weakest predictor, though this may reflect measurement issues or people's denial of the effects of social pressures. With regard to health behaviors, the model is better at predicting some behaviors (exercise, condom use, drug use, and cigarette smoking) than others

(weight loss and dietary behavior, clinical and screening behavior, oral hygiene; see Godin & Kok). Intentions are usually more potent than perceived behavioral control in predicting health behaviors, suggesting that such behaviors are largely driven by personal motivation.

Although TPB is widely used and offers one of the most robust set of predicators of human behavior, it has been criticized for failing to include emotional variables, such as perceptions of threat, mood, and affect, which may limit is predictive power, particularly with certain health behaviors. It has been argued that many behaviors are not rational and that one's affect may be counter to one's cognitions about engaging in a particular behavior. Thus, attitude may be shaped by affect in addition to beliefs. Another criticism of the TRA/TPB model is that the majority of research testing the theory has been correlational (cross-sectional or longitudinal, typically with brief follow-up periods). The experimental studies testing the theory have provided less support for the model (Webb & Sheeran, 2006).

Measurement of the Theory of Planned Behavior Constructs

It is common practice to assess each of the constructs with only one or two items, though multi-item measures are often recommended. Differences in the way the constructs are assessed have led to confusion and may account for some of the variation between studies (see Armitage & Conner (2001) for a meta-analytic review of such differences).

Attitude: Attitude is typically assessed via the use of semantic differential scales that tap into both affective and cognitive attitude. Pairs of adjectives (reflecting a positive and negative component of an attitude) that have relevance to the health behavior being studied are provided as anchors. For example, "To me, engaging in regular exercise is…" [*unpleasant-pleasant; unsatisfying-satisfying*(affective); *harmful-beneficial; useless-useful* (cognitive)].

Subjective norms: When assessing subjective norms, it is recommended to measure both injunctive norms (what others think) and descriptive norms (what others actually do). Social groups are often identified as peers, family, friends, or important people. Examples of items include the following: "People who are important to me think I should exercise regularly" (injunctive); "My friends exercise regularly" (descriptive). Items are usually measured using a 7-point Likert scale.

Perceived behavior control: Perceived behavioral control is often measured with Likert-scale items assessing both internal control (i.e., self-efficacy), such as "I am confident that I can exercise regularly," a perception of ease/difficulty of engaging in the behavior, such as "It is easy for me to exercise," and perception of control, such as "How much personal control do you feel you have over engaging in regular exercise?" In general, measures of self-efficacy account for the most added variance to intentions.

Intentions: Many researchers assess intentions with one Likert-scale item, such as "I intend to engage in regular exercise for the next 3 months." Although intentions tend to be highly reliable, additional items may strengthen the measurement of this construct. Items are sometimes phrased as, "I will try to…," "I plan to…," and "I will make an effort to…." This construct has also been assessed with questions related to self-prediction (e.g., "It is likely that I will engage in regular exercise over the next 3 months"), though such a conceptualization probably incorporates perceived behavioral control.

Behavior: Behavior is often assessed via self-report, but observed behavior is clearly preferred. The TPB model typically predicts more of the variance in self-reported behavior than observed behavior.

Specific recommendations and guidelines for developing questionnaires for use in a particular study are offered by Ajzen (see http://people.umass.edu/aizen/tpb.html), Fishbein and Ajzen (2010), Godin and Kok (1996), and the National Cancer Institute (see http://cancercontrol.cancer.gov/brp/constructs/index.html).

Couple therapy; Family therapy; Interventions therapy

Definition

Both family and marital therapy are branches of psychotherapy that aim to facilitate positive change, by addressing the dyad and family as a whole. Broadly, these branches of psychotherapy help teaching communication and problem-solving techniques in an effort to ameliorate distress.

Description

There are a wide range of therapeutic interventions that work with families and couples during times of distress. The goal of each therapeutic approach is to alleviate the distress, to strengthen dyadic and family resources, and to improve well-being of the couple or family members. Although family and couple therapies can be applied with various techniques or theoretical approaches, there are common approaches that have been shown effective in alleviating family distress, such as behavioral family and couple therapy.

Family Therapy Techniques

Therapeutic techniques for families are grounded in family systems theory, which states that each member of the family is interconnected and one cannot just treat one family member independently (Segrin & Flora, 2005). The most common family therapy techniques address adolescent concerns in respect to the family dynamic.

Below, we review some of the commonly used therapies.

Bowen's family approach. Bowen's family systems theory views behavior within the family as an emotional unit. This theory operates under the balance of two forces: togetherness and individuality, whereby too much of any one force can create an imbalance in the system. Bowen's approach also uses eight concepts that aim to explain family development and functioning: (1) differentiation of self, (2) triangles, (3) nuclear emotional process, (4) family projection process, (5) multigenerational transmission process, (6) sibling position, (7) emotional cutoff, and (8) societal emotion process. Some of the main goals of therapy include reframing the family problem as a multigenerational problem that is caused by factors outside the individual and to lower the family "emotional turmoil" (Bowen, 2004; Bowen Center for the Study of the Family, 2011).

Structural family therapy (*SFT*). SFT is a way to address problems within the family by looking at the invisible rules or boundaries which help its functioning (family rules). The role of the therapist is to manipulate the therapy session in a way to accelerate change in the family, for example, by changing the seating of each family member. This helps the family members see the unbalance of the family system and the dysfunctional patterns that have developed (Minuchin, 1974).

Brief strategic family therapy (*BSFT*). BSFT aims to improve and change the family interaction patterns that have led to the disruptive behaviors in adolescents. Specifically, BSFT targets children between the ages of 6 and 17 that display or are at risk for developing behavior, conduct, and substance abuse problems. Specifically, BSFT focuses on inappropriate family alliances, poor boundaries (open vs. closed), and allows the parents to recognize the adolescent is not necessarily the cause for familial problems but the expression of dysfunctional family patterns (Szapocznik & Williams, 2000).

Functional family therapy (*FFT*). FFT is an intervention program that focuses on adolescents with disruptive behavior problems (conduct, alcohol, and/or substance abuse). The goal is to reduce the problem behavior while using an individualized nonjudgmental attitude, focusing on strengths and protective factors specific to each client. This intervention can be implemented in a variety of settings such as schools, probation and aftercare systems, and well as in mental health facilities (Alexander & Parsons, 1982).

Multisystemic therapy (*MST*). MST is an intensive family- and community-based treatment program that focuses on the entire "world" of chronic and violent juvenile offenders – their homes and families, schools and teachers, neighborhoods and friends (Heneggler, Schoenwald, Borduin, Rowland & Cunningham, 1998).

Other techniques, such as contextual therapy, focal family therapy, systemic therapy, and symbolic-experimental family therapy have also been used in family therapy (see Gurman & Kniskern, 1991, for an overview).

Marital Therapy

Traditional behavioral couple therapy (*TBCT*). TBCT attempts to increase the level of reinforcing exchange between the two partners. This approach classically aims at teaching more effective communication and problem-solving skills that will enhance the ability of the couple to effectively communicate as well as minimize punishment and maximize reward (Jacobson & Christensen, 1994; Jacobson & Margolin, 1979).

Cognitive behavioral couple therapy (*CBCT*). CBCT takes the basic principles of TCBT and incorporates partner's relationship assumptions, standards, expectancies, and attributions that contribute to the relationship distress (Baucom, Shoham, Mueser, Daiuto & Stickle, 1998; Epstein & Baucom, 2002).

Integrated behavioral couple therapy (*IBCT*). ICBT also takes the basic principles of CBCT and expands them to emphasize interventions aimed at increasing acceptance. The three components, empathetic joining, tolerance building, and detachment from the problem, are focused at enhancing the couple's ability to appreciate the differences in their marriage

(Christensen, Jacobson & Babcock, 1995; Jacobson & Christensen, 1998).

Emotion-focused couple therapy (EFCT). EFCT focuses on inner emotional experiences in combination with self-reinforcing interactions, based on adult attachments and attachment bonds. Therapists in this approach try to (1) access and reprocess the emotional experience of the partners' and (2) restructure the partner's interaction patterns. Partners are thought to learn new aspects about themselves and develop a more functional pattern of interaction with their partner that is cohesive with their specific attachment needs (Greenberg & Johnson, 1988; Johnson & Greenberg, 1985).

Integrated systematic couple therapy (*ISCT*). The specific goal of ISCT is not to resolve all of the issues causing distress but rather instigated a reversal of the negative interaction. ISCT is based on procedures from family and marital systems therapy and primarily targets the problem at the interaction level. Specifically, ISCT tries to initiate a reversal in the "fight cycle" by changing the meaning attributed to the situation. Empirical evidence exists for the efficacy of ISCT showing greater maintenance of marital satisfaction and goal attainment after the intervention (Greenberg & Goldman, 1985).

Insight-oriented therapy (*IOMT*). IOMT focuses on the interpretation of underlying intrapersonal and interpersonal dynamics between the couple partners contributing to the marital distress. IOMT also examines developmental issues, interactions, expectations, and maladaptive relationship patterns that may exist in the relationship. The role of the therapist is to guide the couple to gain a better understanding and clarification of each partner's unconscious feelings and beliefs that may be affecting the relationship (Snyder & Wills, 1989; Wills, 1982).

Coping-oriented couple therapy (*COCT*). COCT is based on stress and coping research in couples and cognitive behavioral couple therapy. It aims to enhance communication, problem-solving, and dyadic coping in both partners (Bodenmann, 2007, 2010). A main focus lies on dyadic coping and building mutual intimacy and understanding. A key element of this approach is the three-phase method. By means of this method the therapist aims to enhance mutual understanding for each partner's personal functioning (that becomes most evident in stressful situations) and its impact on the close relationship as well as the enhancement of mutual support that matches personal needs of the partner. Overall, this approach fosters (a) understanding for each partner's personality, (b) mutual dyadic coping, and (c) mutual intimacy, trust in the partner, cohesion, and emotional security (Table 1).

Prevention Programs

Several evidence-based programs aim to prevent marital distress (e.g., Couples Communication Program (CCP); Miller, Wackman & Nunnally, 1983; Premarital-Relationship Enhancement Program (PREP): Markman, Stanley & Blumberg, 1994, Couples Coping Enhancement Training (CCET); Bodenmann & Shantinath, 2004).

Efficacy of Marital and Family Therapy

The efficacy of family and couple therapies are well documented (Dunn & Schwebel, 1995; Shadish & Baldwin, 2005) including substantial mean effect sizes which demonstrate the effectiveness in relieving distress ($d = .74–.95$; Shadish, Montgomery, Wilson, Wilson, Bright & Okwumabua, 1993; $d = .50–1.30$; Shadish & Baldwin, 2003). Prior research has shown that approximately 70% of couples seeking evidence-based couple therapy report an improvement after therapy (Baucom et al., 1998; Christensen & Heavey, 1999), and more recent numbers suggest 46–56% of couples show significant clinical improvement (Christensen, Atkins, Baucom & Yi, 2010).

Application to Behavioral Medicine

Family and marital therapy techniques have been used to alleviate distress within the family, stemming from things such as communication issues or family dynamics. Nevertheless, some of these therapeutic approaches have been used for a range of behavioral and physical health problems (see Snyder, Castellani & Whisman, 2006 for

Therapy, Family and Marital, Table 1 Marital and family therapies

Marital and family therapies	Goal	Content
Family therapies		
Bowenian Family Therapy	Individuals are encouraged to look at the view they play in the family system, patterns of emotional reactivity, and interlocking triangles. In addition, the goal is to decrease anxiety	Examines how the family may operate as an "emotional system" using key concepts such as : triangles, differentiation of the self, emotional cutoff, and sibling position
Structural Family Therapy (SFT)	Address the problem in functioning within a family, in an attempt to restructure the family system's rules to become more flexible (Minuchin, 1974)	Therapist helps to show family how their family system may be unbalanced and to help the family see the dysfunctional patterns they have created. SFT also helps families move toward an understanding of how the behavior has developed into a positive feedback loop
Brief Strategic Family Therapy (BSFT)	Aims to improve family interaction and change family interaction patterns that have led to disruptive behaviors in adolescents (e.g., conduct problems, delinquency, and drug abuse) (Szapocznik & Williams, 2000)	BSFT operates on five basic concepts: (1) *context* – the behavior cannot be understood outside the context to which it occurs; (2) *systems* – the family is an interconnected entity that cannot be understood by just examining one member; (3) *structure* – provides the habitual and repetitive patterns of family interaction; (4) *strategy* – interventions tend to be practical, problem-focused, and planned; and (5) *content versus process* – the therapist's focus is on **how** the family members' interaction, not **what** the family members discuss, is the problem
Functional Family Therapy (FFT)	Family intervention program for adolescents with disrupting behavior problems (conduct, alcohol, and/or substance abuse). The goal is to reduce the problem behavior while using an individualized nonjudgmental attitude, focusing on strength/protective factors that are linked to each client (Alexander & Parsons, 1982; Alexander et al., 2000)	FFT operates on five major components: (1) *engagement phase* – the goal of this phase is to demonstrate a desire to listen and help. The therapist focuses on immediate responsiveness and maintains a strength-based focus; (2) *motivational phase* – the goals of this phase include creating a positive motivational context that will facilitate change, minimizing hopelessness, and changing the meaning of the family context to promote change; (3) *relational assessment* – the focus of this phase is on intra- and extra-familial context (e.g., values, interaction patterns, and sources of resistance, resources, and limitation); (4) *behavior change phase* – this phase helps build coping patterns, such as teaching communication as well as training conflict resolution; and (5) *generalization phase* – this phase focuses on extending positive family functions and helps the family plan for relapse prevention (e.g., using other family and community members for support)
Multisystemic Therapy (MST)	Intensive family and community-based treatment program that focuses on violent and criminal youth behavior (Heneggler et al., 1998)	MST views the child/adolescent embedded within interconnected systems: family, peers, school, neighborhood, and community/culture. Focus is on increasing parenting skills: spending time with children, teaching communication techniques and how to develop boundaries/ discipline, and teaching skills on how to deal with conflict. Help adolescents participate in positive activities (sports or extracurricular clubs) and create a supportive social network among family, peers, and community to maintain change

(*continued*)

Therapy, Family and Marital, Table 1 (continued)

Marital and family therapies	Goal	Content
Couple therapies		
Traditional Behavioral Couple Therapy	Attempts to increase the level of reinforcing exchange between partners Minimize punishment and maximize reinforcement (Jacobson & Margolin, 1979; Jacobson & Christensen, 1994)	Help couples identify positive behaviors that they can do for one another (e.g., show more affection). Help guide couples to engage in these behaviors and acknowledge when they occur (e.g., to give praise)
Cognitive Behavioral Couple Therapy (CBCT)	Examined the evidence about their thoughts about their partner Alter assumptions and standards, couple evaluates consequences of living according to their standards and assumptions about their partner (Baucom et al., 1998; Epstein & Baucom, 2002)	Use of cognitive restructuring strategies to modify different types of dysfunctional cognitions. Examine the interplay between thoughts, emotions, and behavior
Integrated Behavioral Couple Therapy (IBCT)	To help the couple think about the problem and identify feelings associated with that issue before one can accept them (Christensen et al., 1995; Jacobson & Christensen, 1998)	Educate couples that partners need to learn a way to alter negative emotional responses that make them and their partners unhappy Teaches couple new ways to resolve problems and emotions through three steps: (1) Empathetic joining, (2) tolerance building, and (3) detachment from the problem
Emotion-Focused Couple Therapy (EFCT)	Conceptualizes distress in adult romantic relationships in terms of attachment theory. Focus on re-establishing attachment bonds (Johnson & Greenberg, 1985; Greenberg & Johnson, 1988)	(1) Identify the negative interaction cycle of the conflict, (2) access unacknowledged feelings, (3) reframe the problem(s) in terms of underlying feelings, (4) promote identification with disowned needs and aspects of self, (5) promote acceptance by each partner; (6) facilitate the expression of needs and wants to restructure the interaction based on the new understandings, (7) establish the emergence of new solutions (cycles), and (8) consolidate new positions
Integrated Systematic Couple Therapy (ISCT)	Try to change meaning attributed to situation that caused distress. Aims to initiate a reversal in the "fight cycle" (self-perpetuating negative cycles that lead to changes in behavior) (Greenberg & Goldman, 1985)	(1) Define the issue presented, (2) identify the negative interactional cycle, (3) attempt restructuring, (4) reframe the problem using positive connotation followed by prescribing the symptom, (5) restrain using "go slow" and dangers of improvement, (6) consolidate the frame, and (7) prescribe a relapse
Insight-Oriented Marital Therapy (IOMT)	Emphasis is on the interpretation of underlying intra- and interpersonal dynamics that influence relationship distress (Wills, 1982; Snyder et al., 1989)	Focus on expectations, interactions, and maladaptive relationship rules using clarification and interpretation, to highlight unconscious feelings, beliefs, or thoughts causing the marital discord
Copying-Oriented Couple Techniques (COCT)	Teach couples the notion the better the partners *together* can cope with stress, the higher their chance for optimal marital satisfaction and stability. Bodenmann, Plancherel, Beach, Widmer, Gabriel & Meuwly, 2008)	Focus on educating the couple about the effects stress has on the relationship. Couples become aware of the influence of environmental factors on their close relationship. Focus on teaching dyadic copying that goes beyond the traditional models of interpersonal communication and social support in close relationships

a review). Additionally, CanCOPE is an education program developed for people facing cancer (personally or within the family). The focus of this program is to strengthen the resources within the family so that they can more effectively deal with the realities of cancer management (Scott, Halford & Ward, 2004). Family-based obesity treatment programs have also been

developed, and show that child–parent interactions can influence the outcome of obesity treatment (Temple, Wrotniak, Paluch, Roemmich & Epstein, 2006). Osterman, Sher, Hales, Canar, Singla and Tilton (2003) encourage health psychologists to incorporate more of a couple's perspective into illness, so that the partner can facilitate health-promoting attitudes and behaviors.

Therapy, Occupational

Cecilia W. P. Li-Tsang[1], Kit Sinclair[1] and Jennifer Creek[2]
[1]Department of Rehabilitation Sciences, The Hong Kong Polytechnic University, Kowloon, Hong Kong, China
[2]Occupational Therapist, Guisborough, North Yorkshire, UK

Synonyms

Ergotherapist; Occupational therapist

Definition

Therapy with focus on people's occupational performances and behavior that is using occupation as the therapeutic medium is carried out by registered or legitimated occupational therapists (ergotherapists). Major goals of occupational therapy and major roles of occupational therapists are to (a) manage environmental, temporal, and occupational adaptations that facilitate clients' way of life and well-being, (b) teach clients to learn or relearn performance of activities in daily life and work, (c) enable clients to be meaningfully occupied, and (d) promote clients' health and wellness through preventive measures (Söderback, 2009).

Description

Occupational therapy is concerned with the activities and occupations that make up the pattern of people's lives, and with people's capacity to carry out those activities in ways that support their health and well-being. For occupational therapists, the concept of *occupation* encompasses everything that people do in their daily lives, including self-care, domestic activities, interactions with others, work and leisure activities (Fidler & Fidler, 1978; WFOT, 2010).

Occupational therapists understand that occupation is essential to human development and learning, to social relations, to individual health and well-being and to the well-being of communities. Occupation enables the development and integration of bodily systems, promotes socialization, and verifies the individual's identity as a contributing member of society. Further, purposeful activity can mitigate the effects of disease or injury and prevent secondary disability (Creek, 2003). Occupational therapists are concerned with the impact of illness, injury, or disability on people's ability to carry out the activities and occupations that they want to do, need to do, or expect to do. The focus of intervention is not on the client's impairment or diagnosis but on the impact that illness or

disability can have on the individual's ability to carry out his or her expected daily activities. This means that the occupational therapist works not only with the client's functional problems but also with the *meaning* of illness or injury to his or her life. This has been called a two-body practice, because occupational therapy is concerned both with the physical body and with the whole person, including social, cultural, and psychological issues. The knowledge base that supports a two-body practice is necessarily broad and varied (Mattingly, 1994). Occupational therapists have a deep understanding of the importance of activity and occupation in people's lives and they also make use of relevant knowledge from the biological, medical, psychological, social, and technological sciences. Areas of knowledge include theory, research, policy, and legislation. In most countries, occupational therapy education is at bachelors or master's degree level, although the qualification is a diploma in some countries (College of Occupational Therapists, 2009). Occupational therapists are experts in assessing function in the activities of daily life, including personal care, mobility, domestic activities, social interactions, education, leisure, and work. When a person is unable to perform the activities of daily life to an acceptable standard, the occupational therapist can assist him or her to relearn the necessary skills, develop new skills, or adapt activities so that they are within the individual's capabilities. The occupational therapist can also recommend aids, equipment, and environmental modifications to support function or compensate for loss of function.

Occupational therapists practice a set of principles that influence both what is done and how the therapeutic relationship works. These principles include respect for diversity, customs and preferences; recognition of the client's rights; incorporation of the client's perspective at all stages of intervention; promotion of client autonomy and choice, and sharing power with the client and/or carer. Intervention does not follow a standard process but is highly individualized and specific to the client, the context, and the environment. This means that the way in which occupational therapy is practiced is strongly influenced by the social context in which the therapist is working, the work setting, government policies and standards, local norms and procedures, and the available research evidence (White, 2007). Person-centered intervention takes account of the individual's current circumstances, cultural background, social context, educational experiences, employment status, personal beliefs and values, skills, interests, needs, and aspirations. Interventions are designed to suit the person's living environment, family, neighborhood, workplace, financial situation, social networks, and support systems. An expert occupational therapist is able to engage with each service user within his or her own environments, to identify the activities that have meaning and relevance for each person and to work in partnership to devise individually tailored interventions. The occupational therapist works in collaboration with the client, families, caregivers, employers, teachers, coworkers, and colleagues to develop and deliver relevant and effective interventions. As far as possible, the client is engaged as an active partner throughout, and the intervention is carried out within his or her own living or working environments.

The core skills of the occupational therapist are collaboration with the client, assessment of function, problem solving, therapeutic use of activity, group work, and environmental adaptation. Activity is the main tool employed to achieve therapeutic goals: It can be used to develop and maintain skills, to improve occupational performance, to enhance self-esteem, and to increase social participation. Activities are chosen both for their potential to engage client participation and for their potential to meet treatment objectives. Throughout the intervention, activities are monitored and adapted to maintain client interest and therapeutic effectiveness.

Occupational therapists also use environmental adaptation to enhance functional and occupational performance. Changes to the client's environment have to be negotiated and agreed with the client and relevant others, taking into account the dynamics of the household or other setting. Environmental modifications may be made over time, as the client's circumstances

change. The therapist may also recommend the introduction of paid carers to improve the client's functional capacity and quality of life, or to relieve carers.

Occupational therapy has relevance for everyone who is experiencing occupational dysfunction and it is practiced in many countries throughout the world. In most countries, it is regulated as a health profession. The worldwide professional body for occupational therapy is the World Federation of Occupational Therapists: Member countries all have a national professional body and full member countries also have at least one approved program of occupational therapy education (White, 2007; Christiansen & Baum, 1997).

Occupational therapists are working in a wide range of public, private, and voluntary sector settings, although most occupational therapists work in the fields of health and social care. People of all ages, who have functional problems arising from physical, psychological, social, educational, economic, or other difficulties, participate in occupational therapy. Clients may be individuals, groups of people, communities, health and social care agencies, or other organizations. Individual clients may be hospital or community patients, schoolchildren, workers, compensation claimants, caregivers, homeless people, or anyone who is experiencing occupational dysfunction. Group clients can be families, coworkers, paid carers, or groups of patients. Some occupational therapists work in the areas of public health, occupational health, or health promotion. They may work in the field of law as expert witnesses or consultants, for example, carrying out assessments to ascertain the level of disability sustained following an accident (Radomski & Trombly, 2008). Occupational therapy contributes to the treatment of, and early recovery from, injury and disease, and is making an increasing contribution to health promotion and disease prevention. However, the profession's major role is in habilitation and rehabilitation: helping people to gain or regain the ability to perform their occupations and preventing secondary disability. Occupational therapists also work with people who have long-term or deteriorating health conditions, assisting them to remain active for as long as possible and slowing down the decline of functional ability (Christiansen & Baum, 1997).

Tinnitus

Linda C. Baumann and Alyssa Karel
School of Nursing, University of Wisconsin-Madison, Madison, WI, USA

Synonyms

Ringing in the ears

Definition

Tinnitus is a condition characterized by the perception of sound in the ears or head without the presence of an external source. Tinnitus itself is not a disease, but a symptom that can result from a number of different causes. Sounds heard can manifest in many different ways such as low to high pitched, heard in one or both ears, heard as a single noise or competing noises, or be heard intermittently or continuously. Sounds have been described as ringing, buzzing, blowing, humming, hissing, whooshing, hissing, and whistling among many others. Mild forms of tinnitus are very common and experienced by most people at some point in their lives. More severe forms, however, are less common and can lead to chronic sleep disturbance, anxiety, and depression.

Description

Tinnitus is generally categorized into two types: subjective tinnitus and objective tinnitus. Objective tinnitus is the less common of the two types and sound is not only heard by the patient, but also audible to other people, most often a clinician listening with a stethoscope or an ear tube. Pulsatile tinnitus is a common example of objective tinnitus. It is caused by muscle contractions or audible blood flow in arteries or veins (e.g., bruits) close to the inner ear that resonate as rhythmic pulsing in the ear. Subjective tinnitus is the most common form and is heard exclusively by the patient. This type of tinnitus has many causes and pathologies.

Although tinnitus is most often associated with abnormalities of the auditory or central nervous systems, it can also be caused by nonauditory etiologies. These include hypertension and cardiovascular disease, hypo- and hyperthyroidism, stress and fatigue, temporomandibular joint (TMJ) disorder, poor diet and physical inactivity, and wax buildup in the outer ear putting pressure on the tympanic membrane. Exposure to excessive noise is also a common cause of tinnitus, which can precede hearing loss and should therefore be an indicator of the need for protection from excessive noise exposure. Tinnitus associated with abnormalities of the auditory or central nervous systems including middle ear infections, damage to the inner ear, disorders that affect the central nervous system such as meningitis, encephalitis, and stroke; head and neck trauma; surgical injury; and tumors affecting the acoustic nerve (cranial nerve VIII); Meniere's disease (an inner ear disorder characterized by hearing loss vertigo, and tinnitus); and vestibular schwannoma (e.g., acoustic neuroma). Over 200 ototoxic medications are associated with inducing tinnitus. These medications include aspirin, some

antibiotics, diuretics, cancer chemotherapy drugs, and quinine.

With many causes of tinnitus, treatment of the underlying disease often alleviates symptoms. Drug therapies include benzodiazepines, anticonvulsants, antidepressants, vasodilators, tranquilizers, and antihistamines. Acamprosate, a drug used to treat alcohol dependence, has shown to have potential as a treatment, as well as zinc and gabapentin. Antiarrhythmic agents such as lidocaine have also shown to have tinnitus-suppressing qualities.

Hearing aides are another modality shown to benefit patients. Loss of hearing often increases awareness of tinnitus and a hearing aid, which amplifies external sound, often helps mask the perception of tinnitus. Wearable sound generators or tinnitus maskers are also used. These devices fit into the ear much like a hearing aid and deliver low-level sound directly into the ear.

Cochlear implant is a treatment used in patients whose tinnitus is accompanied by severe hearing loss. Electrical and magnetic stimulation treatments include transcranial magnetic stimulation and trans-electrical nerve stimulation. Cognitive behavioral therapy treatments include tinnitus retraining therapy (TRT), tinnitus activities treatment, sound therapies, auditory discrimination therapy, and neurofeedback. Alternative therapies for tinnitus have included acupuncture, hypnosis, craniosacral therapy, antioxidants, vitamin and herbal remedies.

Tinnitus and Cognitive Behavior Therapy

Gerhard Andersson
Department of Behavioural Science and Learning, Linköping University, Linköping, Sweden

Synonyms

Hearing disturbances; Perception of internal noise (false)

Definition

Tinnitus is an auditory perceptual phenomenon that is defined as the conscious perception of internal noises without any outer auditory stimulation. The sounds may be very loud and bizarre, and the most common ones are heard like a high-pitched musical tone or a rushing sound like escaping steam or air. Other descriptions can be more complicated such as metallic sounds, multiple tones of varying frequencies, and mixtures between buzzing and ringing.

Tinnitus is in most cases a temporary sensation, which many people have experienced at least sometime in their life. However, it may develop into a chronic condition, and prevalence figures show that at least 10–15% of the general population have tinnitus. Fortunately, most persons do not have severe tinnitus. Only about 1–3% of the adult population has severe tinnitus, in the sense that it causes marked disruption of everyday activities, mood changes, reduced quality of life, and disrupted sleep patterns. Tinnitus has been reported in children, but in its severe form, it is more common in adults and in particular in the elderly.

Tinnitus is known to occur in association with almost all the dysfunctions that involve the human auditory system. This includes damage to the middle ear, the cochlea, the audiovestibular cranial nerve, and pathways in the brain from cochlear nucleus to primary auditory cortex.

A common distinction is often made between so-called objective (somatosounds, which can actually be heard from the outside) and subjective tinnitus (that are heard only by the afflicted person). Objective tinnitus represents a minority of cases. Subjective tinnitus has been linked to sensorineural hearing loss, caused by various deficits such as age-related hearing loss and noise exposure. Links to other conditions such as temporomandibular joint dysfunction have also been found. Tinnitus has been explained as the result of increased neural activity in the form of increased burst firing or as a result from pathological synchronization of neural activity. Other suggested mechanisms are hypersensitivity and cortical reorganization. With the advent of modern imaging techniques, it has been observed that tinnitus involves certain areas of the brain, particularly those that are related to hearing and processing of sounds. Some involvement of the brain's attentional and emotional systems has also been seen (Cacace, 2003).

Description

Distress and Tinnitus

What distinguishes mild from severe tinnitus is not easily established, apart from variations in subjective ratings of intrusiveness and loudness. In particular, in attempts to determine the handicap caused by tinnitus, it has not been possible to make the determination using the characteristics of the tinnitus itself (e.g., loudness, pitch, etc.). However, psychological factors are of major importance in determining the severity of tinnitus, and this has been observed in both clinical and epidemiological studies.

The problems experienced by tinnitus patients can be divided into four categories: hearing difficulties including noise sensitivity, emotional consequences, concentration problems, and insomnia. In addition, there might be interpersonal consequences and occupational difficulties (e.g., for a musician, admitting tinnitus can be regarded as a sign of weakness).

Hearing loss is the most common symptom that goes together with tinnitus and that can in itself be a great problem. Another common problem is noise sensitivity, which in its severe form can develop into hyperacusis, which is sensitivity to everyday sounds not regarded as loud by most people.

In its severe form, tinnitus is strongly associated with lowered mood and depression. Suicide caused by tinnitus is however rare. Most cases reported have had comorbid psychiatric disturbances. Anxiety, and in particular anxious preoccupation with somatic sensations, is an aggravating factor, and stress is often mentioned as a negative factor for tinnitus and in particular in association with major adverse life events, but the evidence for this notion is weak. Personality factors have been investigated, and associations have been reported between degree of optimism and tinnitus distress (Andersson, 1996) and between perfectionism and tinnitus distress (Andersson Airikka, Buhrman, & Kaldo, 2005).

Tinnitus patients often report difficulties with concentration, for example, with reading. Often this is perceived as auditory intrusions while trying to hold concentration on a task. Until recently, there have been few attempts to measure tinnitus patients' performance on tests of cognitive functioning, but recent research implies a role of the working memory system (Hallam, Shurlock, & McKenna, 2004). Another line of research has focused on the role of selective information processing. Finally, sleep problems represent a significant element in tinnitus patients' complaints and are often a driving reason for seeking help.

Theories

Among the most influential psychological theories on why tinnitus becomes annoying is Hallam et al.'s (1984) habituation model of tinnitus, which presents the notion that tinnitus annoyance is caused by lack of habituation, and the neurophysiological model by Jastreboff and coworkers (Jastreboff, 1990), which is a classical conditioning model where the tinnitus signal is conditioned to aversive reactions such as anxiety and fear. The latter model puts less emphasis on conscious mechanisms involved in tinnitus perception. Other researchers have endorsed

a cognitive-behavioral conceptualization of tinnitus, suggesting a major role for thoughts and beliefs regarding tinnitus (Andersson, 2002).

In clinical settings, management of tinnitus involves taking history of its characteristics such as onset, loudness, character, fluctuations, and severity. Audiological and neuro-otological measurements such as pure-tone audiometry, otoscopy, and brain stem audiometry are also included in routine assessment to exclude treatable conditions (Andersson, Baguley, McKenna, & McFerran, 2005).

Treatments

There is a long history of attempts to cure tinnitus, but surgical and pharmacological interventions have been largely without any success. When the aim is to reduce the suffering, treatment outcome is more promising, and psychologically informed treatments have been found to be helpful in randomized trials (Andersson & Lyttkens, 1999).

Among the psychosocial treatments, cognitive-behavioral therapy (CBT) is the most researched alternative. As for other medical conditions such as chronic pain, CBT for tinnitus distress is directed at identifying and modifying maladaptive behaviors and cognitions by means of behavior change and cognitive restructuring. The focus is on applying techniques such as applied relaxation in real-life settings. An overview of the techniques used in CBT for tinnitus is presented in the Table. There is now evidence from randomized trials that CBT can be effective for alleviating the distress caused by tinnitus in adults (e.g., Hesser, Weise, Zetterqvist Westin, & Andersson, 2011), including a trial on the use of CBT with older adults, and also that it works in a self-help format presented via the Internet (Kaldo et al., 2008). However, while the effects are promising, there is room for more improvement, and tinnitus is a typical example of an area where multidisciplinary input is necessary. Most recent development in CBT for tinnitus is to incorporate treatment procedures from acceptance and commitment therapy (ACT; Hayes, Strosahl, & Wilson, 1999).

Tinnitus and Cognitive Behavior Therapy, Table 1 Overview of cognitive-behavioral treatment for tinnitus

Case formulation
Structured clinical interview following audiological screening
Questionnaire assessment
Treatment rationale and information
Treatment presented in 6–10 sessions
Applied relaxation (1. progressive relaxation, 2. short progressive relaxation, 3. cue-controlled relaxation, and 4. rapid relaxation)
Positive imagery
Sound enrichment by means of external sounds
Hearing tactics and advice regarding noise sensitivity
Modification of negative thoughts and beliefs
Behavioral sleep management
Advice regarding concentration difficulties, exercises of concentration (mindfulness)
Exposure to tinnitus
Advice regarding physical activity
Relapse prevention
Follow-up
Interview and questionnaires

Conclusion

Tinnitus is a poorly understood phenomenon, and while the role of psychological factors is widely acknowledged, there is yet little research on basic mechanisms such as information processing bias, the role of psychopathology, and the influence of the tinnitus sound on working memory capacity. While there are few cases of tinnitus for which surgical and medical interventions might help, in most cases, there is no cure in the sense that the tinnitus sound will not disappear. However, longitudinal fluctuations of both loudness and severity of tinnitus have been observed, and health psychologists could benefit in the pursuit of an explanation why it is that tinnitus becomes bothersome only for a proportion of individuals. When it comes to methods to lessen the distress and to cope with the adverse consequences, such as lowered mood and sleep difficulties, CBT is a promising approach. However, the dissemination of CBT into audiological hospital settings has been slow, and there are very few clinical

psychologists working with tinnitus. Self-help methods are promising and could at least partly solve that problem, and there is also much to be done regarding preventive work as noise-induced hearing loss is the cause of tinnitus in one third of cases with recent onset of tinnitus (Table 1).

Tobacco Advertising

Reiner Hanewinkel and Matthis Morgenstern
Institute for Therapy and Health Research, Kiel, Germany

Synonyms

Tobacco marketing; Tobacco promotion

Definition

Tobacco advertising is a form of communication by the tobacco industry with the aim of promoting tobacco products (typically cigarettes) and use. Different forms of advertising can be classified into "above the line" (ATL) and "below the line" (BTL) advertising. ATL advertising is traditional mass media advertising in print, television, radio, in cinemas, and on billboards. BTL advertising focuses more on specific target groups and uses less traditional advertising methods, such as sponsoring, promotion, event marketing, point-of-sale displays, product placements, direct marketing, ambient marketing, viral marketing, or brand stretching. Most research on the effects of tobacco advertising focuses on ATL advertising. However, the importance of BTL

tobacco advertising is growing in the light of bans or partial bans of traditional tobacco advertising in most countries.

Description

A fundamental premise for the tobacco industry to spend money into tobacco advertising is the assumption that it is effective. The term "effective" can refer to different levels or "outcomes." It can either mean that tobacco advertising increases the market share of a specific brand, given a fixed market size for tobacco products. It can also mean that tobacco advertising increases or stabilizes the market size, by recruiting new smokers and by stimulating current smokers not to quit or ex-smokers to relapse. Empirical research conducted by non-industry-funded researchers has mainly focused on the latter interpretation of effectiveness, which is the one with high impact from a public health perspective.

One type of study in this field has analyzed changes in the global or country-specific tobacco market size dependent on advertising spending or dependent on changes in tobacco policy (e.g. implementation of advertising bans). These studies are usually time series or interrupted time-series designs and use highly aggregated data. While many of the early econometric studies found no association between aggregate cigarette advertising spending and total market sales, there are also studies that found positive relations, especially if the aggregation of the data was reduced (Saffer & Chaloupka, 2000). Studies that compare countries with and without advertising bans or that conduct comparisons within a country before and after an advertising ban often find that bans reduce overall consumption of tobacco (Quentin, Neubauer, Leidl, & Konig, 2007). The effect is stronger in countries with comprehensive bans compared to partial bans.

A second type of studies uses individual-level data, looking at the effects of tobacco advertising on smoking behavior, mostly of young people. These studies are either experimental and quasi-experimental studies or cross-sectional and longitudinal observational studies. The effect of tobacco advertising is usually studied in terms of individual exposure to tobacco advertising. This is some form of induced exposure in the experimental studies or a measure of self-reported advertising exposure in the observational studies. Measures of exposure can be direct (e.g., advertising recall, brand recall, notice of advertising, liking of advertising, ownership of promotional items) or indirect (e.g., television screen times, reception and liking of specific television programs, movies, sports, or magazines). A 2006 systematic review of the empirical evidence based on individual-level studies found 29 studies from 5 continents with more than 300,000 participants (DiFranza et al., 2006). The authors concluded that there is strong evidence for a link between exposure to tobacco promotion and tobacco use of children and adolescents. Applying Hill's criteria for judging the likelihood of a causal relationship between exposure and behavior, the authors found that many of Hill's criteria of causation were fulfilled (Hill, 1965). They found that (1) children are exposed to tobacco promotion before the initiation of tobacco use (criterion temporality), (2) exposure increases the risk for initiation (criterion strength), (3) greater exposure results in higher risk (criterion dose–response), (4) the increased risk is robust (criterion consistency), (5) the risk is scientifically plausible (criterion plausibility), and (6) no other explanation can account for the evidence (criterion analogy). A recent study additionally confirmed the Hill criterion "specificity" (Hanewinkel, Isensee, Sargent, & Morgenstern, 2011).

It is less explicitly studied *how* this effect is mediated, i.e., how tobacco advertising leads to an increase in market size. However, tobacco advertising is not systematically different from other forms of advertising and can, therefore, be conceptualized within broader psychological and marketing theories. Most psychological theories of advertising can be classified as "hierarchy of effects" models (Vakratsas & Ambler, 1999). These models suggest that advertising is not directly influencing behavioral responses, but that the effects are always mediated by a mental process. In the broadest sense, this mental process is a change in object valence, the object being the brand, the product, the product group, or the advertising itself. The most common models used to

explain the effects of advertising are based on the information processing approach (McGuire, 1976). They assume that people are persuaded by the contents of the advertising and consciously follow a cognitive path which is mediated by preferences, attitudes, norms, and beliefs about the advertised object. Newer variants of these models are the so-called dual-process models which conceptualize two routes of information processing, a central route and a peripheral route (Eagly & Chaiken, 1993; Petty & Cacioppo, 1986). The central route is activated if advertising contents are thoughtfully elaborated and recipients have high involvement and attention. On the peripheral route, information is less thoughtfully processed (low involvement) which happens if advertisings are consumed rather casually. Recipients with low involvement are more influenced by peripheral or emotional characteristics of the advertising (e.g., attractiveness of the source, colors, music). Most recent psychological theories even go a step further and assume that conscious mental processes are not a necessary precondition for behavioral influences (Bargh, 2002; Harris, Bargh, & Brownell, 2009). From this perspective, advertising is a form of behavioral priming that automatically affects the perceiver. The term "automatic" implies that the consumer does not have to be aware of having seen the advertising and also does not have to be aware that she/he responded to it. Such conceptions of advertising effects have, of course, strong implications for prevention strategies as it may be very difficult to counteract unconscious advertising effects.

Tobacco Cessation

► Smoking Cessation

Tobacco Control

Pekka Puska
National Institute for Health and Welfare (THL), Helsinki, Finland

Synonyms

Secondhand smoke; Smokeless tobacco; Smoking; Smoking cessation; Smoking prevention; Tobacco policy

Definition

Tobacco control includes all measures aiming at reduction of tobacco use and of its harmful consequences in the population.

Thus, tobacco control includes measures aiming at both prevention and cessation of use of all tobacco products – both smoking and use of smokeless tobacco.

Description

Introduction

The great health risks from smoking have been convincingly shown since the 1950s. It is now known that all forms of tobacco use, i.e., smoking and use of smokeless tobacco, are addictive and potentially lethal. Scientific evidence confirms that smokers have significantly elevated risks of death from many cancers, cardiovascular and respiratory diseases, and many other fatal conditions (US Department of Health and Education and Welfare, 1972). The harmful effects of secondhand smoke have also been convincingly established (Öberg, Jaakkola, Woodward, Peruga, & Prüss-Ustün, 2011).

Tobacco is a highly addictive substance that directly kills half of its users, as well as many nonsmokers exposed to secondhand smoke. There is no safe form of tobacco use or no safe level of exposure to secondhand smoke.

It is estimated that currently about 1 billion of men (nearly 50% of adult men) and about 250 million women (over 10% of women) in the world smoke. Smoking rates among men seem to have peaked, but among women, they are still increasing on global scale.

Tobacco kills currently annually some six million people (about 10% of world deaths), and with current trends some eight million people annually by 2030. Of the tobacco deaths some three fourth occur in low- and middle-income countries, and generally proportionally more among lower socioeconomic segments of the population. The economic costs of tobacco-related harms are enormous: both the direct costs to health services and the indirect societal costs (Shafey, Eriksen, Ross, & Mackay, 2009).

Health professionals started to warn about the harmful consequences of tobacco use already in the 1950s. Because of the disinformation and lobbying of the big tobacco industry, policy actions to reduce tobacco use started much later, generally only in the 1980s and the 1990s. A milestone was the adoption of the WHO Framework Convention on Tobacco Control (FCTC) in 2003 (World Health Organization [WHO], 2003). Currently, over 170 countries have ratified the convention that is a pioneering example of use of international law in the field of public health. FCTC covers all the main elements of tobacco control.

Elements of Tobacco Control

Reduction of Demand for Tobacco

Education and communication: Included are comprehensive educational and public awareness programs on the health risks and on the addictive nature of tobacco products and exposure to tobacco smoke. This includes also effective training programs on tobacco control to health workers, to other professional and community groups dealing potentially with tobacco control, as well as to decision makers.

Tobacco cessation: Stopping tobacco use is often difficult because of strong physical addiction to nicotine and to the psychosocial dependence to the habit. During the last few decades, pharmacological and nonpharmacological (psychological, educational) methods have been developed to effectively help smokers and other tobacco users to quit the habit. Tobacco control policies include measures to provide tobacco users access to cessation services.

Elimination of tobacco advertising and promotion: An important background for the global tobacco epidemic is the powerful push from the multinational tobacco industry in form of effective advertising, promotion, sponsorship, and lobbying of decision makers. Thus, important component of tobacco control is a comprehensive ban on advertising, promotion, and sponsorship. Here an international agreement is

especially important because of the cross-border spreading of advertising. It is also important to eliminate false or misleading messages about the tobacco products.

Price and tax measures: Price is an important aspect of use of any product. Accordingly, price and tax measures are effective and important means of reducing tobacco consumption, in particular among young persons.

Regulation on the contents of tobacco products: Although there is no safe tobacco products, authorities can introduce regulations on testing, measuring and levels of the contents and emissions of tobacco products. This can also include introduction of self-extinguishing cigarettes to reduce fires. National legislation can also regulate tobacco product disclosures.

Smoke-free environments: Exposure to tobacco smoke, especially indoors, is a health risk to everybody and especially to vulnerable population groups like children. At the same time, smoke-free environments discourage initiation and continuation of smoking. Thus, important elements of any tobacco control policies include prohibition of smoking in indoor workplaces, public transport, indoor public places, and also in other public places (e.g., stadia).

Packaging and labeling of tobacco products: Tobacco product packages and labels should not promote the product by any false, misleading, or deceptive messages. Such messages may include terms like "low tar," "light," "ultralight," or "mild." Tobacco products should carry large and clear health warnings in text or in form of pictures. Recently, also generic tobacco packages have been proposed.

Reduction of the Supply of Tobacco

Sale to minors: An important part of tobacco-related health work is prevention of tobacco use among children and youth, and moving the possible initiation to as late as possible. Thus, sale of tobacco to minors should be prohibited, and this legislation well enforced, e.g., by requiring the purchaser to provide appropriate evidence of age. Vending machines should be placed so that minors cannot use them. Regulations should also prohibit sale of tobacco products by minors, as well as sale of individual cigarettes or small cigarette packets.

Illicit trade: Surprisingly, large part of tobacco products used in the world is smuggled, manufactured illicitly, or counterfeited. Thus, elimination of illicit trade of tobacco products is important, and an issue in which international collaboration by authorities is especially needed.

Economic alternatives to tobacco business: Reduction of tobacco use calls also for reduction of tobacco growing. Thus, alternatives for tobacco growing should be encouraged, as well as also other viable alternatives for other tobacco-related occupations.

Other Aspects of Tobacco Control

Research, monitoring, and surveillance: Although the scientific base of tobacco control is very strong, further research is needed in several areas. It is also important that every country has own tobacco research. Monitoring of tobacco use trends in the population and its subgroups is crucial. It is also important to monitor many aspects of determinants and process of tobacco use as well as activities related to tobacco control.

Exchange of information: For the international collaboration and the reporting of the FCTC implementation exchange of tobacco control–related information is needed. This includes, e.g., information on legislative, administrative, and other tobacco control measures, as well information on tobacco use trends.

International collaboration in scientific, technical, and legal fields of tobacco control: Because of the global nature of the tobacco epidemic, also the tobacco control calls for strong international collaboration, much assisted by the international FCTC-related work.

Implementation of International Tobacco Control

The FCTC Convention Secretariat published in 2009 a summary report on the global progress in implementation of the FCTC (FCTC, 2009). The report concluded that the implementation levels vary substantially between different policy

measures. Overall, countries report high implementation rates for measures on packaging and labeling, sales to minors, and education, training, and public awareness. Rates remain low in areas like disclosure of marketing expenditures or programs for tobacco use cessation.

The implementation of tobacco control measures varies across different regions of the world. Also comparability of reports from different countries varies concerning both implementation measures and tobacco use data.

Overall, there seems to be notable progress in introduction and implementation of various tobacco control measures in most parts of the world.

Trail-Making Test

Romola S. Bucks
School of Psychology, The University of Western Australia (M304), Crawley, WA, Australia

Synonyms

Trails

Definition

This term refers to a widely used test assessing organized visual search, planning, attention, set shifting, cognitive flexibility, and divided attention (Rabin, Barr, & Butler, 2005), all capacities thought to be executive in nature. Originally developed by Partington (Brown & Partington, 1942), it was first published as part of the *Army Individual Test Battery* (1984). The test is currently available in public domain (see Lezak, Howieson, Loring, Hannay, & Fischer, 2004; Strauss, Sherman, & Spreen, 2006) and revised versions (e.g., Reynolds, 2002) and as part of a number of assessment batteries (e.g., Delis, Kaplan, & Kramer, 2001).

The standard trail-making test (TMT) contains two parts: Trails A and Trails B, which usually takes no more than 5–10 min to complete. In Trails A, the subject draws lines to connect consecutively numbered circles, drawn on a single A4 sheet (1-2-3. . .). In Trails B, the subject connects consecutively numbered and lettered circles, alternating between them (1-A-2-B-3. . .) on a second sheet. The subject is asked to connect the numbers, or numbers and letters, as fast as possible without lifting the pencil from the sheet. Revised versions (e.g., Delis et al., 2001; Reynolds, 2002) usually contain an equivalent to Trails B, plus up to four other subtests designed to help the assessor distinguish the cause(s) of difficulties in the switching task, such as number or letter sequencing, visual scanning, or motor deficits.

The main performance measure is time taken to complete the sequence, but errors are commonly recorded as they can also be clinically useful (Lezak et al., 2004). Because of the significant motor requirements of the task, normative data must be age-stratified (e.g., Mitrushina, Boone, & D'Elia, 1999; Tombaugh, 2004). Education-based norms are also recommended (Tombaugh, 2004). Generally, Trails B is thought to require more executive skills because it requires shifting between sequences (Kortte, Horner, & Windham, 2002). Evidence suggests that the difference between Trails A and B, or their ratio, may be "cleaner" indices of executive function by controlling for baseline motor, visual tracking, and sequencing abilities (Arbuthnott & Frank, 2000; see e.g., Hester, Kinsella, Ong, & McGregor, 2005, for difference and ratio norms). Indeed, fMRI evidence supports this view: Zakzanis, Mraz, & Graham (2005) found greater left frontal activation in the dorsolateral prefrontal cortex during Trails B than Trails A.

Both parts of the TMT are highly sensitive to dementia and brain injury, including Parkinson's (Goldman, Baty, Buckles, Sahrmann, & Morris, 1998) and Alzheimer's disease (Chen et al., 2000). Importantly, deficits in TMT performance predict everyday activities of daily living difficulties (Bell-McGinty, Podell, Franzen, Baird, & Williams, 2002) and mortality (Vazzana et al., 2010) and may indicate preclinical Alzheimer's dementia (Chen et al., 2000).

Trait Anger

Judith Carroll
Cousins Center for Psychoneuroimmunology, University of California, Los Angeles, CA, USA

Synonyms

Hostile affect; Hostility

Definition

Trait anger is described as a dispositional characteristic where one experiences frequent anger, with varying intensity (e.g., mild irritability, intense rage), and is often accompanied by related negative emotions such as envy, resentment, hate, and disgust (Buss, 1961; Siegman & Smith, 1994). There is considerable construct overlap between hostile dispositions and trait anger, making it difficult to disentangle. Martin, Watson, and Wan (2000) have proposed a three-factor model of trait anger, which includes the anger-related affect, behavior (i.e., aggression), and cognitions (i.e., cynicism), similar to several of the subscales

of the Cook-Medley Hostility Scale (Barefoot, Dodge, Peterson, Dahlstrom, & Williams, 1989). A frequently used measure of trait anger is the Spielberger State-Trait Anger Expression Inventory (STAXI), which measures trait anger as having a proneness to experiencing anger either as a general tendency (*Anger temperament)*, or with provocation (*Anger Reactions*) (Spielberger, 1988, Spielberger & Sydeman, 1994). Furthermore, Speilberger describes three different styles of anger expression: (1) showing anger emotions (*Anger-Out*), (2) preventing anger from being expressed but still experiencing it internally (*Anger-In*), or (3) having the initial affective response but then regulating it well (*Anger-Control*) (Spielberger, 1988).

Behavioral medicine research has documented associations of trait anger, and the related constructs of hostility, with greater cardiovascular disease incidence and progression (al'Absi & Bongard, 2006; Chida & Steptoe, 2009; Miller, Smith, Turner, Guijarro, & Hallet, 1996; Siegman & Smith, 1994; Smith, Glaser, Ruiz, & Gallo, 2004). Although poor health behaviors are thought to partially explain these associations (Everson et al., 1997; Siegman & Smith, 1994), it is also likely that this trait disposition contributes to worse health through the repeated emotionally driven activation of the neuroendocrine stress response and its associated downstream biological effects, including increases in blood pressure, inflammation, and oxidative stress (Carroll et al., 2010, 2011; Greeson et al., 2009; Smith & Gallo, 1999; Suarez, Kuhn, Schanberg, Williams, & Zimmermann, 1998). Further work is needed to better define the mechanisms of this association.

Trait Anxiety

Yori Gidron
Faculty of Medicine & Pharmacy, Free University of Brussels (VUB), Jette, Belgium

Definition

Trait anxiety refers to the stable tendency to attend to, experience, and report negative emotions such as fears, worries, and anxiety across many situations. This is part of the personality dimension of neuroticism versus emotional stability. Trait anxiety also manifests by repeated concerns about and reporting of body symptoms. Trait anxiety is characterized by a stable perception of environmental stimuli (events, others' statements) as threatening. Trait-anxious people often experience and express also state anxiety, in situations in which most people do not experience such responses. This bias is thought to reflect a cognitive-perceptual bias. At the perceptual level, there is an overattentional bias to threatening stimuli. At the cognitive level, there is a distorted negative interpretation of information congruent with and fostering anxious responses. Finally, at the level of memory, there is overrecall of threatening information. These three biases are common in people with a trait-anxious personality type and have important etiological roles in various types of affective disorders (Mathews & Macleod, 2005). Trait anxiety is commonly assessed with the state-trait anxiety inventory – trait version (Spielberger, Gorsuch, & Lushene, 1970), though other instruments exist as well. Trait anxiety is an important predictor and moderator in behavior medicine. For example, trait anxiety predicts functional recovery following spine surgery, risk of posttraumatic stress disorder, as well as adaptation to and risk of death following myocardial infarction (e.g., Szekely et al., 2007). These relationships could occur since trait anxiety is related to various coping strategies and to various neurophysiological responses. For example, high trait-anxious people demonstrate greater activity in the amygdala and reduced activity in the inhibitory dorsal anterior cingulate cortex, during extinction of fear responses (Sehlmeyer et al., 2011). This brain pattern can explain their increased vulnerability for psychological disorders and adaptation problems. As such, this psychological trait deserves attention in research and clinical applications of behavior medicine. The underlying causes, mechanisms for contributing to poor health outcomes, and ways for reducing the consequences of trait anxiety are important avenues of research for the benefit of clinical practice.

Trans fats

Definition

Trans fatty acids are unsaturated fatty acids with one double bond in the *trans* structural configuration as opposed to the *cis* conformation. These differences in conformation likely have consequences in the development of atherosclerosis secondary to diets rich in trans fatty acids. Dyslipidemia and adverse health outcomes have been linked to frequent consumption of *trans* fatty acids. While *trans* fatty acids do appear in nature, the vast majority in industrialized-world diets are manufactured to promote shelf life stability and enhance flavor in prepared foods. Preventative approaches to cardiovascular disease prevention and management include elimination of *trans* fatty acid consumption (Curhan & Mitch, 2007). Certain municipalities, such as New York City, have recently enacted prohibitions against the use of *trans* fatty acids in restaurant food.

Synonyms

Attention training; Concentration; Contemplation; Meditation; Mental training

Definition

Transcendental meditation (TM) is a meditation technique that has its origins in the ancient Vedic tradition of India. In the 1960s, Maharishi Mahesh Yogi introduced this meditative technique to the western world in a simple, nonreligious fashion, and since then TM has been practiced by millions of people worldwide. A considerable amount of research has been conducted on the effects of TM on physiological and psychological outcomes. Overall, the results of this research indicate that the practice of TM has beneficial effects in individuals with chronic health conditions as well as healthy people.

TM is classified as a concentrative meditation technique. The method consists of twice-daily 20 min practice in which the individual focuses on their mantra which is individually prescribed by a certified instructor. The individual is

instructed to sit in a relaxed posture in a quiet environment and focus on the silent repetition of their mantra in their mind to the exclusion of other thoughts or feelings.

As concentration deepens, feelings of calm or tranquility are experienced. Research has shown that when individuals practice this type of meditation, they experience a restful hypometabolic state in which their respiration, heart-rate, blood pressure, muscle tension, and other indicators of sympathetic nervous system activation all decrease. This state of hypometabolic, restful alertness has been termed "the relaxation response." The relaxation response can be reliably elicited by the repetition of a mental stimulus (e.g., a mantra) while the individual adopts a relaxed mental attitude in a quiet environment.

Transducer

Yori Gidron
Faculty of Medicine and Pharmacy, Free University of Brussels (VUB), Jette, Belgium

Definition

In physics, a transducer is a device or system which converts one type of energy to another type. In biology, this term can refer to cells or intracellular elements which transform one form of input into another. Both are applicable for behavior medicine. Looking at devices, transducers are found in any machine which measures bodily parameters and depicts them electronically. A device measuring heart rate or pulse can detect changes in light in blood vessels, which reflect amount of blood as a function of one's heart rate. These changes in light are sensed, for example, by photoresistors, which are then translated to changes in electrical energy (current), which is then translated to digital numbers reflecting the rate of change in heart rate. Such devices are pivotal in medical diagnosis and in psychophysiological research. Another example of a device would be a galvanic skin conductance measure, which detects changes in electrical conductance of the skin, which reflects sympathetic activity and input into the skin. The conductance is translated into a digital representation, to reflect sympathetic activity. This too is used in psychophysiological research on stress responses.

Biologically, numerous transducers exist in the pathways of the sensory system and in cells. In the eyes, for example, the retina contains numerous photoreceptor cells that contain

molecules called opsins. These photoreceptor cells synapse onto neuronal pathways and, via signal transducers, convert light energy detected by the opsins to neuronal energy, for visual processing in the brain. In the auditory system, sound reaches the middle ear after being channeled by the ear's shape. The eardrum and bones carry vibrations to the inner ear, where physical movements are transformed to fluid movement in the cochlea. This fluid movement excites hair cells in the basilar membrane that generates, via transduction, neuronal signals to the auditory cortex for higher auditory processing. Another example is the neuroendocrine transducer, where a neuron, for example, in the pituitary gland, translates electrical stimulation in its input to secretion of hormones at its output. In recent years, the vagus nerve has been found to be a pivotal neuroimmune transducer since its paraganglia express receptors for interleukin-1. Upon signaling by that cytokine, neuronal information is carried to the brain via acetylcholine, thus translating immune to nerve information, which then triggers several negative feedback anti-inflammatory loops (Tracey, 2009). Transducers also play major roles in diseases. In cancer, for example, among multiple intracellular signaling pathways, the signal transducer and activator of transcription 3 (STAT3) is a transcription factor which is active upon extracellular activation by many signals including cytokines and growth factors. STAT3 plays a role in cell apoptosis and growth. In some cancers, constant activity of STAT3 is related to procarcinogenic activity and to poor prognosis (e.g., Alvarez, Greulich, Sellers, Meyerson, & Frank, 2006). Thus, transducers are omnipresent in the body (or in devices) and are crucial for communication between the body and the external world as well as between different types of signals inside the body, in relation to health and disease.

Implementation; Integrated behavioral medicine research, practice, policy; Research to practice translation

Definition

Translational behavioral medicine (TBM) is an approach that concerns the transfer of knowledge

from the psychosocial and biomedical sciences in order to develop behavioral interventions to improve health, evaluate the effectiveness of those interventions, and study and improve their implementation in practice and policy. The overarching objective of TBM is to advance, integrate, and actualize knowledge from the research, practice, and policy arenas to improve the health of individuals and communities. *Translational Behavioral Medicine: Practice, Policy, Research*, a scholarly professional journal devoted to the topic, was established in 2011 by the Society of Behavioral Medicine, with founding editor, Bonnie Spring.

Description

In 2001, the Institute of Medicine (IOM) published a report on the quality of health care in the United States. The IOM perceived a chasm between the health care Americans receive and the kind they could and should receive. They attributed this gap largely to inadequate translation of scientific discoveries into actual practices. An often-cited statistic is that it takes 15–20 years for a scientific discovery to influence clinical practice (Balas and Boren, 2000). Moreover, even when a research-supported treatment does become recognized as a best practice, practitioner adherence is highly variable.

"Translation" is the process of adapting theoretical principles and empirical findings from research so that these can be applied to the worlds of clinical and public health practice (Sung et al., 2003; Westfall, Mold, & Fagnan, 2007; Woolf, 2008). The translation process proceeds through a series of phases, as illustrated in the conceptual model by Westfall et al. (2007), shown in Fig. 1.

T1 Translation

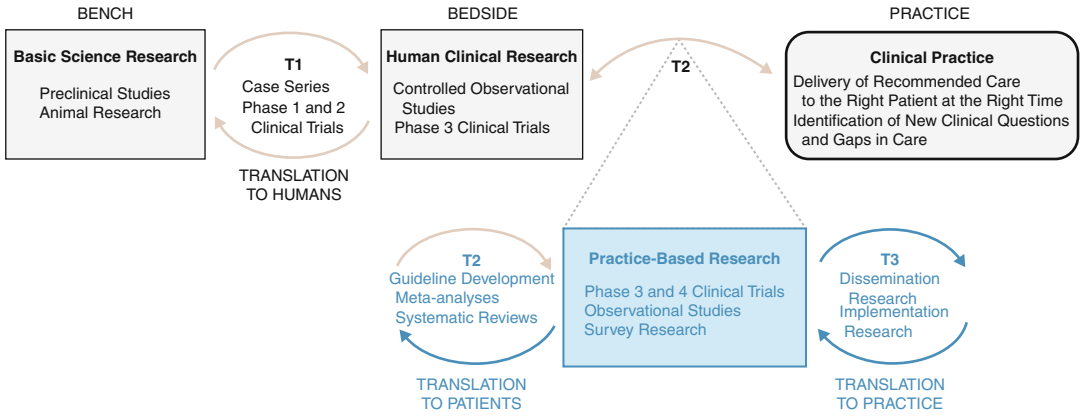
The first translational phase (T1) is focused on using knowledge obtained from the study of basic biological, psychosocial, and behavioral processes to inform the development and refinement of promising interventions for health conditions. T1 research is sometimes called "bench to bedside," as it provides the first link from basic science to human clinical studies. Basic scientists address fundamental questions about mechanisms that underlie human functioning. T1 researchers then apply these understandings of biopsychosocial mechanisms to develop efficacious behavioral interventions and assessments of how they work. T1 research can be performed using a number of different types of research designs.

Case Series

A case series (or clinical series) is a form of observational research design. In a T1 case series to develop a new treatment, a single individual or small group of individuals is observed (either prospectively or retrospectively using recorded information). The aim is to examine whether there is an association between exposure to the treatment elements and a clinical event (e.g., symptom improvement or remission). Usually applied in the earliest phases of treatment development, a series of cases may be gathered to establish "proof of concept" that a new treatment holds sufficient promise to warrant further study. An advantage of case series studies is that they capture clinical events in a naturalistic context. Disadvantages are that they examine small, highly selected samples of people who may be atypical, and can demonstrate only correlation, not causation.

Randomized Controlled Trials

Randomized controlled trials (RCTs) are the gold standard method of testing whether a treatment works. After participants are screened for inclusion and exclusion criteria, they are assigned randomly to two or more groups or conditions. In a two-group design, participants in one group receive the active intervention (e.g., smoking cessation treatment), and participants in the other group receive a control intervention (e.g., general health education) that is comparable in some elements (e.g., credibility, contact time) but inert in the active elements (e.g., specific skills training) thought responsible for the treatment's effect. The primary outcome might be change from baseline in the number of study participants who smoke. Because the group allocation is concealed until randomization has occurred,



Translational Behavioral Medicine, Fig. 1 Translational research phases from the NIH roadmap. Reprinted with permission from Westfall, Mold, & Fagnan (2007)

neither investigator nor patient can influence the treatment assignment, so that participants have an equal chance of being assigned to either the intervention or control group. This enables researchers to eliminate any bias that might otherwise occur in the group assignment.

Two different randomization procedures are employed in RCTs. They are: (1) fixed allocation randomization (which includes simple, blocked, or stratified randomization), and (2) adaptive randomization (which includes baseline adaptive- or response adaptive randomization). Simple randomization is analogous to repeated fair-coin tossing. However, this procedure is prone to creating imbalanced group sizes. Blocked randomization (also referred to as permuted block randomization) instead ensures that at no time during the randomization will the difference between group sizes be large, and at some points, groups will be equal. Stratified randomization helps to ensure the even distribution of certain factors (e.g., gender) between the groups or conditions. In adaptive randomization, the probability of being randomized to different groups changes as the study progresses. Altering the randomization procedure can help to overcome imbalances based on differences in participants' baseline characteristics (i.e., baseline adaptive randomization) or based on their responses at a later point in the study (i.e., response adaptive randomization).

In RCTs testing drug treatments, the use of identical appearing pills to contain active and inactive agents makes it possible to keep both participants and study personnel naïve to group assignment, a state of affairs referred to as double blind. When only participants are naive, the trial is described as being single blind. Blinding participants and personnel to study conditions helps to ensure that treatment effects are due to the intervention, rather than person-level factors (e.g., knowledge or expectancies about the treatment or outcome). However, double blinding is rarely feasible in trials of behavioral interventions: Both patients and interventionists usually know which treatment is being given. One important form of blinding that does remain feasible is blinding of outcome assessors. When blinded, the assessors who evaluate study outcomes are unaware of whether patients belong to the treatment or the control group.

RCTs are the gold standard for evaluating treatments because this design surpasses others in its internal validity. This means that differences between the study groups in their outcome can be attributed to the treatment, because the researchers held constant other extraneous variation between the groups. The presence of the control group enables the researcher to account for shared influences, such as being repeatedly assessed or receiving attention from professionals. Equally important is the need to establish treatment fidelity; that is, that the intended intervention was delivered as planned. Fidelity is induced by training and supervising therapists to

follow a treatment protocol (i.e., a treatment manual or algorithm) and is assessed by monitoring to ensure that critical intervention elements are delivered. The RCT's internal validity permits researchers to make causal inferences; that is, to attribute between group differences in patient outcomes to variation in the treatment. Its drawbacks are that RCTs are expensive and time consuming to implement, and that random assignment of study participants to conditions is not always feasible. Just as an RCT's validity is compromised by low-quality design or execution, its utility is undermined by incomplete reporting. To facilitate comprehensive, uniform reporting of RCTs, most scholarly journals in health have adopted the international CONSORT guidelines which guide the information to be reported when publishing a RCT (Moher et al., 2010).

Intervention Development via Optimization Design

Behavioral medicine interventions usually combine multiple treatment components brought together in a compilation intended to achieve maximal benefit. For example, an exercise intervention may combine individual coaching from an exercise physiologist with peer support groups, a free gym membership, and incentives for monitoring physical activity and reaching behavioral goals. Although the practice of testing a bundled treatment package in an RCT maximizes the likelihood of detecting a treatment effect, it can be inefficient for long-term policy. After a treatment package has been found effective, it remains unclear which treatment components have produced the positive effect, whether some treatment elements are inert and could be eliminated (potentially reducing costs), and whether the dose and timing of other components is optimal. Subsequent "dismantling" trials are needed to answer those questions.

Multiphase optimization strategy (MOST), adapted from engineering science, is a methodology designed to build new interventions from the ground up by first optimizing and evaluating the contribution of multiple intervention components. MOST follows a sequential, stepped approach to intervention development. The first step is to establish a conceptual, theoretical model of how the eventual intervention should produce benefit and apply the model to derive the intervention components to be examined. The second step involves experimentation to examine the impact of individual intervention components. That stage may be followed by further experimentation to refine and optimize the components (e.g., by modifying their dose, timing, format, or delivery channel). Once the individual treatment components have been optimized, the third step is to assemble the treatment package (the beta intervention) and confirm its efficacy via an RCT. If the trial proves successful, the fourth step is that the new intervention can be released and tested further for effectiveness.

Note that the MOST approach delays the RCT of a bundled treatment package until the third step in intervention development. A key feature of the MOST strategy is that each subsequent intervention will have been engineered, and empirically validated to be superior to the previous one on whatever optimization parameter the interventionist desires. For example, a treatment can be optimized to have no inactive components, to produce the maximum change attainable for a given level of financial resource or time, to maximize the number of people that can be exposed to an intervention, etc. By optimizing for a specific context, MOST emphasizes efficiency and careful management of resources to increase the implementation rate of science.

T2 Translation

The second translational phase (T2), sometimes called "bench to trench," is concerned with evaluating the effectiveness of interventions under conditions that become progressively less controlled and more representative of the general population and usual practice settings. For example, the studies conducted during T1 are usually experiments or phase I and phase II clinical trials. These trials are characterized by their strict control of extraneous variables. The intent of a phase I clinical trial is to pilot test the intensity, timing, duration, or format of an intervention, with participant safety being a primary outcome.

Consequently, phase I trials are often conducted with small samples of participants, who are relatively free of complex medical histories. Once patient safety is established, phase II trials are undertaken. The goal of a phase II clinical trial is to evaluate the efficacy of an intervention for the treatment of a specific, circumscribed problem. Efficacy testing is performed under optimal conditions; for example, in an academic medical setting, employing highly trained research staff as interventionists, and involving patients without co-occurring health conditions. The progression to T2 research introduces phase III trials, in which local staff in a community setting may deliver an intervention as part of their regular job duties. Such trials impose few exclusion criteria and enroll patients even if they have comorbidities. Phase III trials are often called studies of effectiveness (in contrast to efficacy) because they involve more "real world," less highly selected settings, interventionists, and patients.

Another component of T2 research involves the creation of systematic evidence reviews and practice guidelines. Unlike primary research, which involves the collection of new data, systematic evidence reviews are secondary research that culls and combines information from prior reports. The science of systematic reviewing is in itself a sophisticated and evolving field with many nuances that surround the unbiased acquisition of publications, extraction and analysis of data, and interpretation of results. Systematic reviews offer a means to evaluate whether the evidence about a treatment's effectiveness is strong and consistent enough to warrant widespread application in practice. If the data are plentiful and the studies sufficiently similar, a systematic review can provide evidence about whether a treatment's effects are broadly generalizable. In other words, the review can indicate whether there are boundary conditions or types of people for whom the treatment is less helpful or even contraindicated. The comprehensive, unbiased evidence base analyzed for a systematic review affords an excellent grounding from which experts can formulate practice guidelines. The dissemination of evidence-based guidelines concludes the T2 translational phase by conveying best research-tested practices to clinicians and policy makers.

T3 Translation

The third translational phase (T3) is also called Dissemination and Implementation (D & I) research. D & I studies examine how to facilitate the uptake of evidence-based (research-supported) interventions into routine, day-to-day provision of clinical care and public health services. In contrast to T1 and T2, which concern determining whether treatments work (and for whom), T3 research examines how to get effective treatments widely implemented in real-world settings. D & I research focuses on identifying and learning how to overcome barriers at the practitioner, institutional, and system levels that keep effective treatments from being used. Barriers may include limitations in clinician training or skills, lack of available resources for training, competing institutional priorities, or policy barriers (e.g., lack of insurance reimbursement).

Quasi-Experimental Designs

Quasi-experimental designs emerged from social science research because true experimentation (i.e., randomization of participants to groups or conditions) was sometimes challenging to implement. These designs gained popularity with the development of advanced statistical procedures to control for the effect of extraneous variables associated with group membership. In essence, these procedures help researchers to overcome some of the limitations of non-randomization. Quasi-experimental designs are often used when randomization of participants to groups or conditions is infeasible (or impossible). Suppose, for example, a researcher wished to study the effect of preventive care reimbursement policy on the frequency with which clinicians counsel patients for smoking and obesity. Ideally, one would randomize practices to different levels of preventive care coverage. However, that will not be feasible. Therefore, instead of being randomized, practices will be grouped into those where most patients have preventive care coverage versus those where most patients lack such coverage. Quasi-experimental designs are more susceptible than

RCTs to confounding variables that may affect the outcomes of interest. For example, universal preventive coverage may prevail in cooperative, single payer systems (e.g., Group Health, Kaiser Permanente) that are geographically and demographically distinct from practices where majority preventive care is rarer. It will not be possible to determine whether these extraneous differences or differences in insurance coverage account for observed variations in clinician counseling behavior.

Examples of quasi-experimental designs include: time-series designs (i.e., following a single group of participants longitudinally to obtain a large number of data points), single group pretest posttest design, and case–control design (i.e., observational design where participants selected for a certain condition, such as insomnia treated with cognitive behavioral therapy, are compared with a control group whose insomnia is untreated). The advantage of quasi-experimental designs is that they are broadly applicable and easy to implement. For policy interventions or other contexts that preclude randomization, quasi-experimental designs may be the only option available. Their disadvantage is that non-randomization prevents researchers from being able to make causal inferences about what generated the outcomes, particularly because confounding variables (both measured and unmeasured) offer alternative explanations.

Transtheoretical Model of Behavior Change

James O. Prochaska
Clinical and Health Psychology, University of Rhode Island, Kingston, RI, USA

Synonyms

Stages-of-change model

Definition

The Transtheoretical Model (TTM) construes behavior change as an intentional process that unfolds over time and involves progress through a series of six stages of change (Prochaska, DiClemente, & Norcross, 1992a). TTM integrates processes and principles of change from across leading theories, hence the name Transtheoretical.

Description

Precontemplation is the initial stage in which individuals are not intending to take action in the foreseeable future, usually assessed as the next 6 months.

People can be in this stage due to a lack of awareness of the health consequences of a behavior.

Or, they can be demoralized about their abilities to change, like millions of people who have tried to lose weight multiple times in multiple ways. This stage is often misunderstood to mean that these people do not want to change.

The history of demoralized individuals indicates that they want to change, but they have given up on their abilities to change.

Contemplation is the stage in which individuals are intending to change in the next 6 months, but not immediately in the next month. These individuals are more aware of the benefits or pros of changing, but can also be acutely aware of the cons, such as having to give up some of their favorite foods or having to risk failure. Decisional conflict between the pros and cons can lead to profound ambivalence reflected in the motto: "When in doubt, don't act." With smokers intending to quit for good in the next 6 months, without help, less than 50% will quit for 24 h in the next 12 months.

In the preparation stage, individuals are intending to take action in the next month. Their number one concern is, "If I act, will I fail?" The emphasis here is helping them to be well-prepared, because people know in growing up, the better prepared they are in academics or athletics, the more likely they are to reach their goal.

In the Action stage, change is typically overt and observable, with individuals having quit smoking, started exercising, or practicing stress management. This is the busiest stage, where people have to work the hardest to keep from regressing or returning to an earlier stage. Many people believe the worst risks for relapse will be over in a few days or few weeks. We find that people who progress through action work the hardest for about 6 months, which happens to represent the steepest part of relapse curves across addictions (Prochaska & DiClemente, 1983). So, Action is defined as 6 months being risk-free and we encourage individuals to think of this time as the behavior medicine equivalent of life-saving surgery. Following such surgery, would they give themselves 6 months to recover? Will they let others know they will not be at their best and will need more support? This is the type of priority needed to progress through this tough time.

Maintenance is the stage in which people are free from their problem for 6 months to 5 years. People are considered cured from cancer after 5 years without symptom remission. For many people, it may take 5 years to get free from behavioral causes of cancer. During this stage, individuals do not have to work as hard, but they do have to be prepared to cope with the most common causes of relapse. These causes are times of distress, when people are anxious, depressed, lonely, bored, or stressed. Average Americans cope with such distress by increasing unhealthy habits. We try to prepare people to cope with such temptations through healthy alternatives, like talking with a supportive person, walking, or relaxing.

Termination is the stage in which people are totally confident that they are never going back to their high-risk behavior and have no temptation to return. We have found that of alcoholics and smokers in their first 5 years of abstinence, about 20% have reached this criteria (Snow, Prochaska, & Ross, 1992). These people can put all of their change efforts into enhancing other aspects of

their lives. But, for many it may mean a lifetime of maintenance. The ideal goal is to have a new healthy behavior be automatic and under stimulus control, like taking their aspirin every day at the same time and place.

Applying TTM usually begins by assessing which stage the patient is in and then helping them set a realistic goal for now, like progressing to the next stage. Research shows that if we try to pressure patients to progress quickly from precontemplation to action, there can be unforeseen consequences of dropping out of treatment, stopping until treatment is over and then quickly relapsing or simply lying.

What are the principles for helping patients progress from precontemplation to contemplation? A meta-analysis of the pros and cons of changing for 48 health behaviors revealed some remarkable results from 140 studies from 10 countries in 9 languages (Hall & Rossi, 2008). The cons are clearly greater than the pros in precontemplation (PC) and the pros are clearly higher in contemplation (C). So, the first principle of progress is to raise the pros. With sedentary individuals, we might ask them if they like bargains and tell them that if so, physical activity (PA) is the bargain basement of behaviors. There is no other behavior from which they can get as many benefits as PA. We would ask them to list all the benefits that they believe they could get from regular PA, chart their list, and then challenge them to try to double the list. Most have five or six and we tell them there are over 60 scientific benefits and we only want them to find five more. If we see the list going up, it is like seeing cholesterol or blood pressure coming down. We know our behavior medicine is working.

In contemplation, the pros and cons are exactly tied, reflecting their profound ambivalence. From C to preparation (P), the cons come down, so the second principle is to help lower the cons. The number one con for PA is time, so some individuals lower this con by riding a lifecycle where they can multitask and read or review an article for work, read a book for pleasure, or catch up on the news. Others may volunteer to help coach their kid's soccer team and at the same time, get some PA, be with their child, do community service, meet more parents, and have fun. Fortunately, the cons have to decrease only half as much as the pros increase, so we put twice as much emphasis on raising the pros.

In the preparation stage, the pros clearly outweigh the cons, so individuals are not encouraged to take action until they have a favorable profile. Once in the action stage, they can use their growing list of pros to put other principles and processes of change into operation. When they write down on their "To-Do" list, "walking for my heart" they are making a daily commitment based on the process of self-liberation from Existential therapy. When they look at the list they are cued to action based on stimulus control from Behavior Therapy. When they scratch off their list, they are reinforcing themselves based on Skinnerian Theory. As they move from one pro to the next each week, like walking for my weight, my sleep, my self-esteem, my immune system, and my sex life, after a while they may be running. Over time, they are using PA to affirm so much of their body, selves, and others based on self-reevaluation from cognitive theory and self-psychology.

This description illustrates how different principles and processes are applied to produce progress at different stages of change. This integrative approach led to the development of computer-tailored interventions (CTIs) by which individuals are assessed on TTM variables related to their current stage. Their assessment is compared to a normative database and they can be given feedback on how they are applying principles and processes compared to peers who make the most progress. Over time, they can be given feedback compared to themselves, such as "Congratulations, you have progressed two stages, which means you have about tripled the chances you will be taking effective action in the next few months."

Such CTIs have been found in randomized population trials to be effective with a growing

range of problems, including smoking, exercise, diet, stress, depression, bullying, partner violence, and medication adherence. The percentage of those in the action or maintenance stage at long-term follow-up ranges from about 25% for smoking (Prochaska, Velicer, Fava, Rossi, & Tsoh, 2001), to about 45% for exercise and diet (Prochaska, Wright, & Velicer, 2008), to over 65% for stress (Evers et al., 2006) and medication adherence (Johnson et al., 2006). These results are with populations in which typically the majority, like 80%, would be labeled as unmotivated or not ready to change when we proactively reached out to them at home, school, work, or in clinics to offer them help matched to their personal needs. The results can be remarkably robust with very comparable outcomes with smoking, for example, with adolescents and older smokers, Hispanic and African-American smokers, and smokers with mental illness (Velicer, Redding, Sun, & Prochaska, 2007).

Similar interventions have been found to be just as effective when we treat populations for three or four behaviors at the same time (Prochaska, Velicer, Prochaska, Deluschi, & Hall, 2006). Individuals working on one behavior are just as effective as those working on two who are just as effective as those working on three. But, very few people are taking action on more than one behavior at a time because they are not ready. So, they can be progressing through early stages on two behaviors, for example, while they are working to maintain action on another single behavior. Over time, the outcome will have much greater impact on populations with multiple health risk behaviors who have the highest risks for morbidity, disability, mortality, lost productivity, and increased health care costs.

Traumatic Brain Injury

Mary Spiers and Emily W. Reid (Deceased)
Department of Psychology, Drexel University, Philadelphia, PA, USA

Synonyms

Brain damage; Brain injury; Brain trauma; Concussion; Head injury

Definition

Traumatic brain injury (TBI) is an acquired brain injury resulting in diffuse brain damage. Injury is caused by the direct impact of an external force or whiplash, which results in a rapid acceleration or deceleration of the brain against the skull. The rapid movement causes neurons to shear and tear, and the impact of the brain against the skull can result in bruising and bleeding. The trauma can cause secondary complications such as ischemia, increased blood pressure, or ruptured blood vessels. The impairments caused by TBI depend on its severity. Due to the diffuse nature of the injury, a variety of cognitive, emotional, and behavioral changes are often seen.

Description

Epidemiology of Traumatic Brain Injury

The CDC estimates that 1.5–2 million people suffer a traumatic brain injury (TBI) every year in the United States (Faul, Xu, Wald, & Coronado, 2010). Of those, an estimated 80% are mild in severity, 10% are moderate, and the remaining 10% have severe injuries (Kraus, McArthur, Silverman, & Jayaraman, 1996). A small proportion (estimated 275,000) are hospitalized, whereas 1.4 million are treated and released (Faul et al., 2010). This is likely to be an underestimate of incidence as many do not go to the emergency room, and it is estimated that 1.6–3.8 million sports-related TBIs occur each year, of which many are treated on the field and do not seek emergency room assistance (Brain Trauma Foundation, 2011). Approximately 2% of the US population currently live with disabilities from TBI and represent a significant public health challenge (Brain Trauma Foundation, 2011).

The majority of TBIs are caused by falls (35.2%), motor vehicle accidents (17.3%), striking or being struck by or against an object (16.5%), and assaults (10%) (Faul et al., 2010). Another common cause for military personnel is blast-related injury. Approximately 52,000 deaths each year are due to traumatic brain injury with motor vehicle accidents resulting in the largest number of fatalities (31.8%) (Faul et al., 2010).

TBI is the leading cause of death and disability for children and adults under the age of 44 (Brain Trauma Foundation, 2011). Those most vulnerable to TBI are children, ages 0–4; older adolescents, ages 15–19; and adults over 65 years old. However, the number of emergency room visits for ages 0–14 is twice as many as those for adults over 65 years of age (Faul et al., 2010). Across all age groups, men sustain at least twice as many head injuries as women (Faul et al., 2010), and males, ages 0–4, have the highest rates of TBI-related emergency visits, hospitalizations, and deaths.

TBI also has a strong economic impact. In a 1998 consensus report from NIH, an estimated $9–10 billion were spent on new TBI cases each year ("Consensus Conference," 1999). Financially, the lifelong care for a person with a TBI is estimated to be between $600,000 and $1.9 million (Elias & Saucier, 2006). The NIH acknowledges that these are likely underestimates of the actual cost, as these numbers do not reflect the lost earnings, costs to social services systems, and the value of time and forgone earnings of family members who care for persons with TBI (Elias & Saucier, 2006). Further complications to care include insurance coverage, access to care, ability to navigate the health system, and available family and community support ("Consensus Conference," 1999).

Mechanism of Injury

Traumatic brain injury results either from object penetration or from rapid acceleration or deceleration of the brain resulting in the classifications of open head and closed head injuries.

Open or Penetrating Head Injury

In an open or penetrating head injury, the skull and the covering of the brain, or meninges, are ruptured. These injuries occur when an object (e.g., bullet, knife, bone fragment) lodges or passes through the brain. Because the brain is exposed, infection is a concern. Also, because penetrating head injuries may create more focal damage than in a closed head injury, the pattern of behavioral deficits is dependent on location of injury. Aftereffects of the initial injury, including swelling and bleeding, may cause more global, though usually time-limited, effects due to intracranial pressure or inflammatory response.

Closed Head Injury

The majority of head injuries are closed head injuries. These injuries occur by either direct impact or whiplash and may be caused by, for example, motor vehicle accidents, sports-related concussions, falls, and war-related blast injuries. The brain undergoes a rapid acceleration or deceleration or both but without skull penetration.

Contusions and/or hematomas may be seen at the location of impact (i.e., coup) and the opposite side of the brain (i.e., contre-coup) owing to the acceleration and deceleration of the brain against the skull. Despite the location of impact, a pattern of diffuse injury is likely to occur, impacting the frontal lobes and temporal poles because of the jagged surface of the tentorial plates that hold those brain structures in place. The physical forces may shear, tear, and rupture neurons, blood vessels, and the meninges, or covering, of the brain.

Diffuse axonal injury (DAI) may occur with shearing or tearing of neurons, often as a result of head rotation or rapid deceleration. Consequently, the axon damage can result in fewer axonal connections and/or less efficient transmission from one axon to another (Lux, 2007). The neurons most vulnerable to this type of strain are those with long axons, usually white-matter tracts that connect distant brain regions. DAI produces two types of cell death, necrosis and apoptosis, which are the leading contributors to brain damage in closed head injuries. Both impede axonal transport, induce atypical metabolic changes, and cause the axon to swell. In DAI, the damage is widespread, regional, multifocal, and at times global, and the course of damage may change over time. The swelling leads to detachment downstream from other neurons. This pattern of deafferentation is considered to affect more neurons than those identified as originally damaged. Although the brain's plasticity does allow for new axonal growth in living neurons, spurious growth can cause additional complications by forming undesirable connections leading to behavioral disturbances.

Consequences of Traumatic Brain Injury

The neuropsychological and behavioral consequences of TBI are related to injury characteristics and severity. The injury characteristics of importance in the acute phase are length of loss of consciousness (LOC) and length of emergence into consciousness with accompanying degree of posttraumatic amnesia (PTA), characterized by confusion and disorientation. For example, LOC ranges from none to brief LOC in concussion and mild traumatic brain injury (MTBI) to weeks in severe head injury. Emergence into consciousness ranges from minutes to hours in MTBI to weeks to days in severe head injury. Corresponding recovery of neuropsychological functioning can range from days to years.

LOC and coma are directly associated with an injury to those areas of the brain, typically the lower brain stem and reticular activating system (RAS), that are involved in maintaining consciousness and arousal. Coma falls along a continuum related to depth of responsiveness and is typically assessed at regular intervals after an injury via the Glasgow Coma Scale (GCS) (Teasdale & Jennett, 1974). The GCS assesses best motor, verbal, and eye opening response at one point in time. Scores range from 15 (can obey motor commands, is oriented, and eyes are open)

to 3 (flaccid motor response, no verbal response, and no eye opening). Medically, coma is defined as a score of 3–8, which typically corresponds to a severe brain injury. Greater mortality is typically associated with scores below 7. Although initial severity of GCS is an important prognostic indicator for survival, other indicators, such as number of days to reach a GCS of 15, and length of PTA are added predictors for long-term neuropsychological outcome. Duration of PTA and education appear to be two of the best predictors of long-term functional outcome. On measures of global functioning and disability, those who had less education preinjury or a longer period of PTA had poorer outcomes 10 years after the injury (Ponsford, Draper, & Schonberger, 2008).

The recovery from coma is a process of "emergence" in which greater awareness of environmental stimuli occurs. Characteristic of traumatic brain injury is a loss of recall for the actual impact event. Since the injured person does not recall the event, he or she cannot usually give a reliable account of the length of LOC. This period of PTA is characterized by confusion and disorientation and typically includes both retrograde and anterograde amnesia. Retrograde amnesia is the impairment in the retrieval of information for events preceding the injury. Conversely, anterograde amnesia is impairment in encoding new memories after the injury.

The difference in diagnosis between mild, moderate and severe head injuries relates both to immediate injury severity as rated by the GCS and time related to resolution of symptoms. For example, MTBI is characterized by a GCS score of 13–15 and a fairly rapid resolution of LOC (less than 30 min) and PTA (less than 24 h). Moderate-level brain injuries are characterized by a GCS of 9–12, LOC between 30 min and 24 h, and PTA between 1 and 7 days. Severe head injuries are those with a GCS of 3–8, LOC longer than a day, and PTA longer than 7 days.

Neuropsychological Consequences of TBI

The neuropsychological consequences of TBI may include a number of deficits. However, those deficits that correspond to frontal and temporal injuries, as well as diffuse axonal injuries are most common. Specifically, these include difficulties in attention, memory, and language functions, executive dysfunction, and emotionality.

Regardless of injury severity, attentional deficits are common after TBI. Reports include a feeling of mental slowness, difficulty following conversations, losing a train of thought, and trouble with multitasking (Gronwall, 1987; Van Zomeren & Brouwer, 1994). The most universal consequence is a reduced ability to process information (McCullagh & Feinstein, 2005). Therefore, when tasks become more complex, reaction time becomes slower. As a result, a TBI sufferer may not appear cognitively impaired in simpler routine assessments, but the deficits may become more evident in the multicomponent tasks of daily life (Granacher, 2008; Lux, 2007). Deficits are seen across all types of attention processing, including selective, sustained, and divided attention with particular problems on tasks that require controlled rather than automatic processing (Park, Moscovitch, & Robertson, 1999).

In addition to attention and working memory difficulties, a deficit in episodic memory is a hallmark feature of TBI (Richardson, 2000). Memory impairment is one of the most frequent (Arcia & Gualtieri, 1993; King, Crawford, Wenden, Moss, & Wade, 1995) and long-lasting complaints with significant deficits found in many people 10 years postinjury (Zec et al., 2001) and poor employment prognosis 7 years postinjury (Brooks, McKinlay, Symington, Beattie, & Campsie, 1987). Furthermore, TBI patients tend to have impairments in prospective memory, or remembering to perform an intended action, which may lead to forgetting appointments, payment of bills, and medication taking (Kinsella et al., 1996). Adding further difficulty, patients tend to be less aware of their memory difficulties than those around them (McCullagh & Feinstein, 2005).

Those with TBI may also experience language and communication difficulties. Speech tends to be less productive and efficient, with less content in longer discourse, and with greater fragmentation (Hartley & Jensen, 1991). Additionally,

language difficulties may include trouble naming objects and, to a lesser extent, comprehension of complex commands (Levin, Grossman, & Kelly, 1976; Sarno, Buonaguro, & Levita, 1986).

Deficits in executive functioning influence functional, emotional, and social outcomes after TBI. The term "executive functioning" refers to higher-order capabilities that include goal setting, planning, initiating, sequencing, reasoning abilities, decision making, inhibiting responses, self-monitoring, and self-regulation (Stuss & Levine, 2002). Since these processes underlie many daily and social skills, such as impulse control, judgment, creativity, emotional regulation, and moral judgment, routine testing might not detect the degree of impairment evident in these areas (Zillmer, Spiers, & Culbertson, 2008). Verbal fluency tests, as a measure of executive dysfunction, however, consistently show impairment for TBI patients because they require organization of verbal retrieval and recall, self-monitoring aspects of cognition, and effortful self-initiation and inhibition of responses. (Henry & Crawford, 2004)

Emotional and behavioral complications are common after TBI and often lead to depressed and anxious mood, impulsivity, agitation, and amotivation (Vaishnavi, Rao, & Fann, 2009). Mood disturbances are considered the most common psychiatric complication of TBI and are often the most difficult adjustment for those who care for the TBI patient (Rosenthal, Christensen, & Ross, 1998). Approximately 10–60% of patients are depressed, reporting feelings of hopelessness, worthlessness, and anhedonia (Hurley & Taber, 2002). Also, they display somatic symptoms, such as sleep disturbances, reduced initiation, fatigue, and changes in appetite. TBI patients have reduced participation in leisure activities and have difficulty engaging in new hobbies (Rosenthal et al., 1998). Mood disturbances can cause significant emotional distress in patients with TBI, contributing to the disruption of social relationships.

In sum, while a pattern of neuropsychological deficits in TBI may show common features, the evaluation of any particular individual should include a consideration of the unique injury location and severity features in a context of previous levels of education, work, and social history.

Trier Social Stress Test

Robert Miller and Clemens Kirschbaum
Chair of Biopsychology, Technische Universität Dresden, Dresden, Saxony, Germany

Synonyms

Laboratory stress protocol; Psychosocial stress; TSST

Definition

The Trier Social Stress Test (TSST) is a procedure for induction of moderate psychosocial stress under laboratory conditions. It was introduced in 1993 by Kirschbaum, Pirke, and Hellhammer.

Description

Stress is one of the presumably most significant health problems of the twenty-first century (World Health Organization, 2001). Thus it has been of growing importance to gain insight into its underlying components using standardized methods, which reliably induce self-reported, behavioral, and biological stress responses in laboratory settings.

Two major biological systems significantly drive stress responses in mammals: the sympathetic-adrenal-medullary (SAM) axis and the hypothalamic-pituitary-adrenal (HPA) axis. Adequate methods and protocols are needed for reliable stimulation of biomarkers for these systems, to allow for investigations of psychosocial stress effects on the brain and peripheral tissues. While already an effort-driven response suffices for a sufficiently large SAM response, effective HPA psychological stressors, however, need to exert significant social-evaluative threat and uncontrollability upon the tested individual (Dickerson & Kemeny, 2004).

With the development of the Trier Social Stress Test (TSST; Kirschbaum, Pirke, & Hellhammer, 1993), a laboratory protocol with social-evaluative threat, uncontrollability, and effort components became available for rapid and reliable activation of SAM, HPA axis, and other biological stress pathways. Over the past two decades, the TSST has been employed in many laboratories around the globe in stress research of healthy subjects and various clinical samples.

The TSST is a motivated performance task protocol being disguised as a job interview, which consists of a brief preparation period followed by two 5-min test periods during which a subject has to perform a free speech and solve an arithmetic problem, respectively. Upon arrival the subject is informed that he/she is supposed to take over the role of a job applicant who is invited for a personal interview with a selection committee. After ensuring that the subject fully understood the instructions, he/she is guided into a separate room where the selection committee is already seated at a desk upon entrance of the subject. The committee members (male and female confederates) wear white lab coats and are specially trained to withhold any positive or negative feedback during the whole procedure. Furthermore, the room is equipped with a separate desk and chair, a video camera, and a microphone being located approximately 2 m in front of the selection committee. After the initial 3-min preparation phase, during which the subject has the opportunity to structure the upcoming free speech on personal job-relevant traits, the committee asks the subject to step in front of the microphone and begin with the presentation. Most test subjects finish their talk after about 2–3 min of speech time and are encouraged to continue with their speech by one member of the committee. Upon the second speech interruption, the committee silently focuses their gaze on the subject for 20 s, before they begin to ask standard personal questions. After exactly 5 min the subject is asked to stop the speech and continue with the second task, which comprises continuous serial subtractions. The subject is told that upon each error, the committee would ask to start anew from the initial number. After another 5 min, the subject is asked to return to the experimenter who is already waiting outside the testing room to continue with study protocol and the assessment of relevant biomarkers.

With proper completion of the TSST about 70–85% (Kudielka, Hellhammer, & Kirschbaum, 2007) of all subjects reveal an increase in HPA activity as indicated by corticotropin-releasing hormone, adrenocorticotropic hormone (ACTH), serum, and salivary cortisol (Kirschbaum et al., 1993). While ACTH levels peak at or shortly after stress cessation, cortisol levels reach maximum values between 10 and 20 min thereafter. The TSST also activates the SAM, with significant responses in norepinephrine, epinephrine, salivary amylase, heart rate, blood pressure levels, and electrodermal activity. In addition, hemoconcentration, blood coagulation indicators, and transcription factor activation is seen after the TSST (Kudielka et al., 2007). Evaluation of

perceived stress level changes as measured with self-report scales also supports the validity of the protocol.

The methodological advantages of the TSST have led to its widespread use in psychoneuroendocrinological research and stimulated the development of adaptions for children (TSST-C; Buske-Kirschbaum et al., 1997), retirees (Kudielka et al., 1998), psychiatric patients (Brenner et al., 2009), and groups (TSST-G; von Dawans, Kirschbaum, & Heinrichs, 2011). Furthermore, a TSST-like placebo protocol has been developed, which is especially useful in studies with control group designs (Het, Rohleder, Schoofs, Kirschbaum, & Wolf, 2009). Apart from these, variations of the TSST have been employed with mixed results (i.e., insufficient/unreliable stress responses; Gold, Zakowski, Valdimarsdottir, & Bovbjerg, 2004; Gunnar, Frenn, Wewerka, & Van Ryzin, 2009; Kelly, Matheson, Martinez, Merali, & Anisman, 2007; Simoens et al., 2007).

Even with complete adherence to the standard TSST protocol, there is considerable intra- and interindividual variation in the stress response patterns. Certain demographic, biological, and psychological variables can change the magnitude and course of the biomarkers. Among other variables, chronic and acute nicotine or alcohol consumption, dietary status, pregnancy, lactation, physical exercise, or personality traits can lead to differences in HPA activation by the TSST. For a detailed review on potential confounds, Foley and Kirschbaum (2010) recently summarized the TSST literature with a special focus on genetic factors.

In within-subject experimental designs, the TSST may be used repeatedly. Although prior knowledge about the protocol, as well as repeated exposure with days, weeks, or months between sessions can lead to HPA response habituation (Kirschbaum et al., 1995), these effects can be bypassed by changing setting variables, i.e., the selection committee, and the test location with each session. For the assessment of SAM activity with repeated TSST exposure such adaptations are not necessary, since SAM biomarkers show comparable activation patterns even with five identical TSST repetitions. The same seems to apply to cytokines, blood coagulation indices, and parameters of hemoconcentration (Kudielka et al., 2007).

While the TSST has become a research tool frequently employed in many different areas of basic science and clinical research, a powerful stress protocol for use in imaging studies is still missing. Although an adapted version of a computer-based stress task, the "Montreal Imaging Stress Task" (Dedovic et al., 2005) was created for this purpose, numerous subjects show only small HPA responses or no significant cortisol rises at all with this protocol. A scanner-adapted version of the TSST may therefore prove useful to advance our understanding how stress affects the brain and peripheral tissues.

Triglyceride

Chad Barrett
Department of Psychology, University of Colorado Denver, Denver, CO, USA

Synonyms

Lipid

Definition

Triglycerides are a type of lipid (fat) which consist of glycerol and three molecules of fatty acid and are found in blood plasma and fat tissue. They are derived from fats and carbohydrates that are consumed. When calories are consumed, the body converts any calories not immediately used by tissues into triglycerides and transports them into fat cells for storage. Hormones regulate the release of triglycerides from fat tissues in order to provide energy for the body between meals. If the body uses fewer calories than are consumed in a day, then the surplus of calories can cause elevated levels of triglycerides (Welson, 2006).

According to the American Heart Association, the normal level of triglycerides is less than 150 mg/dL and the optimal level of triglycerides is 100 mg/dL or lower. Borderline high levels range from 150 to 199 mg/dL; high levels range from 200 to 499 mg/dL; very high levels range from 500 mg/dL and above. Elevated levels of triglycerides are often the result of being overweight, physically inactive, smoking, excessive consumption of alcohol, and diets high in fat and carbohydrates. High levels of triglycerides have been linked to atherosclerosis (hardening of the arteries) and increased risk of heart disease, stroke, metabolic syndrome (Triglycerides, 2010; What Your Cholesterol Levels Mean, 2011), and Alzheimer's disease (Altman & Rutledge, 2010). Interventions to lower triglycerides typically involve changes in lifestyle such as losing weight, adopting a more heart-healthy diet consisting of less fats and foods with added

sugars, engaging in regular exercise, quitting smoking, and reducing alcohol consumption (Haffner et al., 2005; Graves & Miller, 2003; Triglycerides, 2010). Omega-3 fatty acids can also help reduce triglyceride levels and reduce the risk of cardiovascular diseases and possibly even strokes (Kris-Etherton, Harris, & Appel, 2002).

Tumor Necrosis Factor-Alpha (TNF-Alpha)

Nicolas Rohleder
Department of Psychology, Brandeis University, Waltham, MA, USA

Synonyms

Cachectin

Definition

Tumor necrosis factor-alpha (TNF-alpha) belongs to the group of pro-inflammatory cytokines. Cytokines are chemical messenger molecules of the immune system, and the group of pro-inflammatory cytokines characterizes molecules that are secreted in response to inflammatory stimuli, and further promote inflammatory responses in target cells. The cytokine now known as tumor necrosis factor-alpha was first discovered as a molecule that appeared to be essential in the wasting syndrome associated with bacterial infection, and therefore initially referred to as cachectin. At the same time, another molecule was discovered that induced pronounced necrosis of certain tumors in organisms infected by gram-negative bacteria. This molecule turned out to be identical to cachectin, and both were then called tumor necrosis factor-alpha (Beutler & Cerami, 1989; Pennica et al., 1984).

TNF-alpha is one of the major products secreted by macrophages that are activated by inflammatory stimuli, and it acts through a family of different receptors that have some structural similarities and are present as

transmembrane proteins on a variety of target cells. There are two different categories of receptors, based on their effect on the target cell. The first category is characterized by intracellular signals preceding programmed cell death; these are most likely the receptors that mediate the tumor necrotic effects of TNF. The second category induces pro-inflammatory effects, for example, by stimulation of proliferation or transcription of further inflammatory mediators. On a systemic level, TNF-alpha plays a notable role in sepsis and in the induction of septic shock. Similar to the interleukins (IL)-6 and -18, TNF-alpha does also act on nonimmune tissues such as endothelial cells, adipocytes, muscle cells, the liver, and the gastrointestinal tract (Beutler & Bazzoni, 1998; Hehlgans & Pfeffer, 2005).

Of note, along with IL-1, TNF-alpha is an important mediator of CNS effects of peripheral inflammation. TNF-signaling into the CNS has been shown to activate the hypothalamus-pituitary-adrenal axis, to induce hyperalgesia, to reduce food intake, and to contribute to the well-described sickness behavior response (e.g., Besedovsky et al., 1991; Watkins, Goehler, Relton, Brewer, & Maier, 1995). This immune-to-CNS signaling function of TNF-alpha and other inflammatory cytokines plays an essential role in the control of peripheral inflammation during infectious and inflammatory diseases, and disruption of this loop leads to death in animal models of inflammatory diseases (Sternberg, 2006).

TNF-alpha and other inflammatory cytokines are further important as targets of CNS-to-immune signaling, and serve as a link between CNS states with disease-relevant pathophysiological factors. Inflammatory cytokine production is modulated by the sympathetic nervous system and the hypothalamus-pituitary-adrenal axis, and pro-inflammatory cytokines in blood are sensitive to acute and chronic stress, and found increased in depression and posttraumatic stress disorder (e.g., Rohleder, Marin, Ma, & Miller, 2009; Rohleder, Wolf, & Wolf, 2010; Steptoe, Hamer, & Chida, 2007). Inflammatory cytokines also increase with age and have been found to predict later life morbidity and mortality (e.g., Bruunsgaard et al., 2003).

Twin Studies

Jennifer Wessel
Public Health, School of Medicine, Indiana University, Indianapolis, IN, USA

Definition

The classic twin study builds on the fact that there are two kinds of twins that provide contrasting degrees of genetic relationship in siblings of the same age and family circumstances. Monozygotic (MZ) twins, or identical twins, have identical copies of all their genes. In contrast, dizygotic (DZ) twins, or fraternal twins, share, on average, only half of their genes by descent, as do ordinary siblings.

If there are genetic influences on the phenotype of interest, the MZ correlation will exceed that for the DZ twins. The greater the influence of the genes in determining individual differences in the phenotype, i.e., the greater the proportion of phenotypic variance attributable to genetic differences, the greater the difference between the MZ and DZ correlations will be. With some simplification of assumptions, twice the difference between the MZ and DZ correlations can be taken as an estimate of the heritability of the trait.

If genetic influences are the only cause of familial aggregation, if there is no nonadditive genetic variation, and if mating is random with respect to the characteristic under study, the correlation for DZ twins would be expected to be half that for MZ twins. However, if there are significant nonadditive genetic influences or there is significant competition between the twins or other contrast effects that accentuate the genetic differences of siblings, the DZ correlation may be less than half the MZ correlation. Conversely, assortative mating (like marrying like) or imitative or cooperative effects within the sibship, e.g., cooperative involvement in smoking or drinking behavior, may cause the DZ correlation to exceed half the MZ correlation.

Environmental influences on the phenotype of interest have two distinct characteristic consequences. First, if there are environmental influences that are shared by siblings growing up in the same home, e.g., socioeconomic status or parenting style, the MZ and DZ correlations will reflect this source of familial aggregation to the same extent. In the absence of genetic influences, these shared environmental influences would lead to equal MZ and DZ correlations. If there are genetic influences present, the shared environment will raise the DZ correlation relative to the MZ correlation. Another point to consider is individual environmental influences. If there are significant environmental influences that are unique to individuals, e.g., significant personal life events, familial aggregation will be attenuated and the MZ and DZ correlations will be reduced, although their relative magnitudes will continue to reflect the importance of genetic versus shared environmental causes of familial aggregation.

Historically, the twin study design has been a key tool for understanding behavioral genetics, but the use of twins has expanded to facilitate our understanding of the genetic contribution to a number of complex traits and diseases.

Type 1 Diabetes

► Insulin-Dependent Diabetes Mellitus (IDDM)

Type 1 Diabetes Mellitus

Luigi Meneghini
Diabetes Research Institute, University of Miami, Miami, FL, USA

Synonyms

Autoimmune diabetes mellitus; Insulin-dependent diabetes mellitus (IDDM); Juvenile diabetes

Definition

Type 1 diabetes (T1DM) is an elevation in blood glucose due to insufficient production of insulin thought to result from cell-mediated autoimmune destruction of insulin-producing pancreatic beta cells. Autoimmunity is manifested by mononuclear cell invasion of islets (insulitis) and the production of islet-specific antibodies, such as GAD (Glutamic Acid Decarboxylase), IA-2 autoantibodies and ICA (Islet Cell Antibodies), detectable in ~85% of newly diagnosed patients. Genetic, environmental, and possibly other unknown factors contribute to disease susceptibility, which is most commonly manifested in the teenage years (hence the former designation of juvenile diabetes).

If not replaced, absolute insulin deficiency in T1DM results in severe hyperglycemia and diabetic ketoacidosis (DKA), which if left untreated can prove fatal (hence the designation insulin-dependent diabetes mellitus). Insulin replacement ideally takes the form of basal/bolus insulin therapy, delivered either via multiple daily insulin injections or an insulin pump infusion. Poorly controlled type 1 diabetes can lead to, among other complications, nephropathy (kidney damage manifested by excess protein in the urine) and end-stage kidney failure, retinopathy potentially leading to decreased visual acuity, and neuropathy and the risk of diabetic foot infections or ulcerations. Long-standing diabetes is also associated with increased risk for heart disease, stroke, and peripheral vascular disease. Maintaining good glycemic control, as reflected by an HbA1c of less than 7%, will prevent many of the chronic complications of the disease.

Non-insulin-dependent diabetes mellitus; Type 2 diabetes

Definition

In type 2 diabetes mellitus (T2D), high blood glucose (or hyperglycemia) is the result of the

pancreas producing insufficient quantities of insulin due to beta-cell dysfunction, as well as insulin resistance. Peripheral insulin resistance, in which cells resist the action of insulin at the receptor level, occurs early in the disease course. Initially this is compensated for by increased production of insulin, or hyperinsulinemia. Over time, however, insulin secretion declines, and hyperglycemia results. There is no single cause of T2D, although it is generally accepted to be the result of genetic, physiologic, and lifestyle factors, including obesity and physical inactivity.

Most cases of diabetes worldwide are due to T2D. Obesity and family history are well-known correlates of T2D, with over 85% of individuals being either overweight or obese at diagnosis, and most having a positive family history of T2D. The incidence of T2D is increasing dramatically, particularly among children and youth, most likely attributable to the increase in obesity among youth. This increasing incidence is expected to continue in the future unless significant prevention efforts are successfully implemented at the population level.

T2D is generally managed by prescription of oral medications such as Metformin to help reduce blood glucose, but insulin is also used in the treatment of T2D. Because of the association of obesity with insulin resistance, weight loss is another important goal of treatment, achieved through lifestyle modification of dietary habits and physical activity. The health complications associated with poorly controlled diabetes, whether from type 1 or T2D, include cardiovascular disease, renal disease, blindness, and limb amputations. Thus, management of T2D constitutes an important public health issue. In the past, T2D was referred to as non-insulin-dependent diabetes or adult onset diabetes. However, now that T2D is diagnosed at earlier ages in the life course and treatment often does utilize insulin, T2D is the accepted term.

Definition

The type A behavior pattern is a personality type which is a risk factor for coronary artery disease. It was described by Friedman and Rosenman in 1959. The type A behavior pattern is defined as a complex set of action and emotion including floating hostility, sense of time urgency, impatience, intense achievement drive, and a desire for recognition and advancement. It has been reported that the type A behavior pattern associates with inadequacy and low self-esteem.

The association between type A behavior pattern and coronary artery disease has been examined for more than a few decades and strong epidemiological evidences in this association have appeared. However, successive studies have failed to find the association between type A behavior pattern and coronary artery disease. From these findings, hostility has been supposed to be the main psychosocial predictor of coronary artery disease instead of global type A behavior

pattern (Razzini et al., 2008; Trigo, Silva, & Rocha, 2005).

The type A behavior pattern is originally assessed by the structured interview. The interviewer must have training to be able to ask the question in an interview format before administering the structured interview. Also, some self-report questionnaires have been developed. For example, the Bortner Rating Scale and Framingham Type A Scale assess the type A behavior pattern. Although self-report questionnaires have been used widely, Friedman (1996) pointed out that inconsistencies of the association between type A behavior pattern and coronary artery disease were caused by the assessment method including the such as self-report questionnaires and the structured interview. Friedman proposed the type A videotaped clinical examination (VCE), which can detect the physical signs of type A behavior pattern and was valid for diagnosis of type A behavior pattern. The VCE method has predictive validity for myocardial infarctions.

The modification of type A behavior pattern has been proposed and summarized by Friedman (1996). The modification of type A behavior pattern consist of some components including the enhancement of self-esteem and the modification of floating hostility and sense of time urgency. Friedman et al. (1986) conducted a large randomized clinical trial to examine the effect of type A modification group therapy for myocardial infarction male patients. Their results showed that the coronary artery disease recurrence rate in treatment group was lower than that of control group.

Type D Personality

Johan Denollet
CoRPS – Center of Research on Psychology in Somatic diseases, Tilburg University, Tilburg, The Netherlands

Synonyms

Distressed personality type

Definition

The Type D (distressed) personality refers to *a general propensity to psychological distress* (Denollet, Schiffer, & Spek, 2010) *that is defined by elevated scores on two broad personality traits*, *negative affectivity* (NA), and *social inhibition* (SI). NA refers to the tendency to experience negative emotions across time and

situations, and SI to the tendency to inhibit the expression of emotions and behaviors in social interaction (Denollet, 2005).

Description

Individuals with a Type D personality are more likely to report *feelings of dysphoria, tension, and worry* (Denollet, 2005). On an interpersonal level, Type D individuals tend to feel *insecure and inhibited* in the company of others, fearing rejection and disapproval (Denollet). Although these individuals may experience emotional difficulties, this may not be acknowledged by others given their inhibited behavior. Type D individuals are less likely to express their true thoughts and feelings and may keep other people at a distance.

A number of studies have reported that Type D was associated with an increased risk of *mortality and other adverse events in cardiac patients*, even after statistical adjustment for measures of depression or anxiety. In 1996, a paper published in the Lancet was one of the first reports on Type D personality as an independent predictor of mortality in patients with heart disease (Denollet et al., 1996). A meta-analytic review that summarized the findings from Type D studies that were published over a 15-year period (1995–2009) concluded that this personality profile may be related to adverse health outcomes in patients with a cardiovascular condition (Denollet et al., 2010). Another independent meta-analytic review confirmed that Type D was associated with adverse health outcomes among patients with cardiovascular disorder (O'Dell, Masters, Spielmans, & Maisto, 2011). There are also null studies that found no effect of Type D personality on mortality in patients with heart failure (Coyne et al., 2011; Pelle et al., 2010) or other cardiac conditions (Grande et al., 2011). However, depression or anxiety also failed to predict prognosis in these null studies.

The *prevalence* of Type D among patients with cardiovascular disease largely ranges between 25% and 35%. Type D personality and its two components, NA and SI, can be reliably assessed with the *DS14 self-report scale* (Denollet, 2005). The 14 items of the DS14 are rated on a five-point Likert scale, ranging from 0 (false) to 4 (true) and are divided into NA and SI subscales. The seven NA items cover the tendency to experience feelings of dysphoria, anxiety, and irritability. The seven SI items cover social discomfort, reticence, and lack of social poise. These personality measures have good internal consistency and are stable over time. Due to its brevity and the simplicity of the items, completing the DS14 takes only a few minutes and comprises little burden to patients. The DS14 has been validated in multiple languages, making it widely applicable. In the International HeartQoL study of 6,222 patients with ischemic heart disease, cross-cultural measurement equivalence was demonstrated for the Type D scale in 21 countries (Kupper et al., 2012).

Type D research is based on the notion that (a) research should examine *the way traits combine* in the determination of disease, and that (b) the *delineation of subtypes* may help to identify groups of patients who share a set of relevant characteristics in terms of clinical course. Only those individuals scoring positive on both NA and SI are classified as "Type D." Type D caseness is determined by a cutoff score $\geq$10 on both the NA and SI subscales. Some have argued that Type D personality is more accurately represented as a *dimensional* rather than as a *categorical* construct (Ferguson et al., 2009). The Type D construct does not infer a true taxon that is defined by discontinuity between groups on an underlying dimension; rather, individuals belong only probabilistically to Type D and non-Type D subgroups (Denollet et al., 2010). Therefore, dimensional and categorical approaches to Type D personality do not need to be mutually exclusive, but rather represent two different ways of capturing psychological tendencies of individuals (Chapman, Duberstein, & Lyness, 2007).

General distress, shared across anger, depression, and anxiety, partly accounts for the link between mind and heart (Denollet & Pedersen, 2009). The Type D personality profile identifies

individuals who are particularly vulnerable to this adverse effect of general distress. Hence, Type D personality is not a concurrent of standard psychological risk factors such depression, anxiety, or stress, but rather aims at the early identification of individuals who are inclined to experience these manifestations of distress over a longer period of time. At first glance, depression and Type D personality may appear quite similar, but there are some clear differences. While depression reflects psychopathology, Type D represents a normal personality construct. Accordingly, a narrative review of 29 studies showed that Type D personality and depression are distinct manifestations of psychological distress, with different and independent cardiovascular effects (Denollet et al., 2010). It is not surprising that there is some overlap between Type D and the neuroticism and extraversion traits of the Five Factor Model of personality. However, Type D still predicts health outcomes after controlling for these traits (Denollet et al.), and both the Five Factor and Type D models are related to health outcomes in primary care patients (Chapman et al., 2007).

Several biological and behavioral pathways may *explain the link* between Type D and health outcomes. Potential *biological pathways* associated with Type D personality include elevated levels of the stress hormone cortisol (Molloy et al., 2008), elevated biomarkers of inflammation (Conraads et al., 2006; Einvik et al., 2011), decreased capacity to repair vascular damage (Van Craenenbroeck et al., 2009), and reduced heart rate recovery after exercise (von Känel et al., 2009). Type D has also been related to cardiovascular effects during experimental stress, including higher cardiac output (Williams, O'Carroll, & O'Connor, 2009) and blood pressure (Habra, Linden, Anderson, & Weinberg, 2003), and lower heart rate variability (Martin et al., 2010).

Behavioral pathways may also mediate the relationship between Type D personality and adverse health outcomes (Williams et al., 2008). In the International HeartQoL study of cardiac patients from 21 different countries, Type D was associated with a higher prevalence of hypertension, smoking, and a sedentary lifestyle (Kupper et al., 2012). In the general population, Type D has also been linked to unhealthy behaviors such as smoking and physical inactivity (Einvik et al., 2011; Hausteiner et al., 2010). Type D individuals may show reluctance to consult clinical staff for cardiovascular symptoms (Schiffer, Denollet, Widdershoven, Hendriks, & Smith, 2007), and are not likely to seek care for their mental problems (Williams et al., 2008). In the medical care for patients with chronic condition, *adherence to treatment* may be of particular importance. Type D has been associated with poor adherence to treatment in patients with cardiac (Williams, O'Connor, Grubb, & O'Carroll, 2011) and sleep (Broström et al., 2007) disorders.

Type D personality has been mainly studied in cardiovascular patients, but there is evidence to suggest that Type D personality can also provide relevant information in *other populations* as well. Type D has been related to poor patient-reported health outcomes in patients with *other conditions*. In cancer survivors, for example, Type D personality has been associated with impaired quality of life and poor mental health (Mols, Thong, de Poll-Franse, Roukema, & Denollet, 2012). In the *general population*, Type D individuals have been shown to have an increased risk for clinically significant depression, panic disorder, and alcohol abuse (Michal, Wiltink, Grande, Beutel, & Brähler, 2011). In this study, Type D was also robustly associated with major stressors such as traumatic events and social isolation. These authors concluded that Type D as a frequent disposition is of high relevance for health care (Michal et al., 2011). In other studies of individuals without cardiovascular disease, Type D personality was related to unhealthy behaviors such as smoking and low physical activity (Einvik et al., 2011; Hausteiner et al., 2010).

The evidence so far seems to indicate that patients with a Type D personality profile are at increased risk of for a multitude of adverse health outcomes, particularly in the context of cardiac disease. However, there still are a number of unresolved issues. Evidence suggests that social inhibition modulates the adverse effect of

negative emotions on cardiac prognosis (Denollet et al., 2006) but more research is needed to test this model. Although to date the optimal treatment and the applicability of counseling options for Type D individuals are still unknown, screening may identify these high-risk patients. Overall, the findings of Type D research support the simultaneous use of specific and general measures of distress in cardiovascular research and practice. In this context, *screening for Type D personality with the DS14* (Denollet, 2005) may be useful to improve clinical research and practice in the context of cardiovascular disease and other chronic conditions.

Unintentional Nonadherence

Tavis S. Campbell, Jillian A. Johnson and Kristin A. Zernicke
Department of Psychology, University of Calgary, Calgary, AB, Canada

Synonyms

Noncompliance

Definition

Unintentional nonadherence refers to a non-deliberate alteration in treatment (e.g., medications, exercise, diet). Unintentional nonadherence includes forgetting, poor manual dexterity, lack of understanding of requirements, losing medications, or not being able to afford treatment (DiMatteo, 2004). Unlike intentional nonadherence that is more strongly related to individuals' beliefs, unintentional nonadherence is more strongly related to demographics and clinical variables, such as age, socioeconomic factors, and stage of illness (DiMatteo, 2004).

Unipolar Depression

Amy Wachholtz
Department of Psychiatry, University of Massachusetts Medical School, Worcester, MA, USA

Synonyms

Major depressive disorder

M.D. Gellman & J.R. Turner (eds.), *Encyclopedia of Behavioral Medicine*,
DOI 10.1007/978-1-4419-1005-9,

Definition

Unipolar depression is characterized by a combination of two types of symptoms: neurovegetative and emotional-cognitive. Neurovegetative symptoms are those symptoms that are directly related to the body (e.g., insomnia/hypersomnia, dysregulated eating, fatigue, and decreased energy). Emotional-cognitive symptoms involve those symptoms that are related to how a person processes information (e.g., suicidal ideation, decreased concentration, feeling worthless, anhedonia, and depressed mood). A combination of these depression symptoms must be unremitting for more than 2 weeks in order to be diagnosed with depression. Common treatments for depression include cognitive-behavioral psychotherapy, antidepressant medications, or a combination of these treatments. There are also a number of complementary treatments that are gaining empirical research support for use in combination with traditional approaches to enhance treatment outcomes. These include treatments such as exercise therapy, light therapy, and vitamin B and D supplements.

Unipolar depression may be seen in conjunction with a number of physical health issues (see ▶ Comorbidity) including chronic pain, cancer, physical trauma, cardiac issues (heart attack), chronic health concerns and terminal stage illnesses. Additionally, some medications used to treat medical disorders can mimic or trigger depressive symptoms such as beta-blockers and interferon treatments.

The term *unipolar depression* is used to differentiate between this disorder and *bipolar depression* which involves periods of mania in addition to depression. The term depression is also differentiated from an, which may include feeling depressive symptoms due to a specific life change (e.g., job loss, divorce, recent cancer diagnosis), or *bereavement* due to the loss of a loved one. However, both adjustment disorder and bereavement may progress to unipolar depression if symptoms are present for a prolonged period of time.

Control group of a randomized trial; Usual care arm

Definition

Although the definition of usual care has not been standardized, it can include the routine care received by patients for prevention or treatment of diseases.

Description

In cardiology, the type of routine care can vary by disease type and severity, the practice in which the patient is seen, health care system, and individual physician. Major task forces such from the American College of Cardiology and American Heart Association have published guidelines on the diagnosis, prevention, and treatment of several cardiovascular diseases. These guidelines are based on expert opinion as well as on the strength of the evidence. The purpose of these guidelines is to ensure that these recommendations are disseminated to the practicing cardiology community, as the type and quality of diagnostic, preventive, and treatment strategies widely varies.

In randomized trials, there has been some debate about the advantages and disadvantages of including a usual care arm as a control group. The Declaration of Helsinki states that the "benefits, risks, burdens, and effectiveness of a new method should be tested against those of the best current prophylactic, diagnostic, and therapeutic methods." In theory, it makes sense that in a randomized controlled trial, the usual care arm should be defined by the "best current" method available. The main advantage, of course, is to test the intervention against what is currently available in evidence-based clinical practice. However, there has been disagreement on what should constitute "usual" care in a randomized controlled trial. First, in the community, usual care can sometimes include suboptimal or older practices. Thus, whether "usual care" should really be changed to "optimal care" or "evidence-based care" remains unclear. Second, the outcome in the usual care arm may be affected by the Hawthorne effect. It is difficult to blind the physicians and the patients to being in the usual care arm. The physicians or the patients may improve or modify their behavior after finding out that they are not in the active intervention arm. Third, because physician treatment patterns

vary, the components of the usual care arm and their effects on the outcome are difficult to quantify. Some investigators have advocated for proposing a standardized treatment plan for patients randomized to the usual care arm. Further, differences between the active intervention arm and the usual care arm could be minimized if the usual care arm contains the proposed intervention. Finally, the types and nature of treatment typically given by physicians in the usual care arm could change during the study period.

For example, in the Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT-LLT), 10,355 persons, aged 55 years or older with hypertension and moderately elevated low-density lipoprotein cholesterol levels, were randomized in an unblinded fashion to pravastatin (a statin) or to usual care. During a mean follow-up of 5 years, there was no significant difference in all-cause mortality or coronary heart disease events. ALLHAT-LLT was unique as it was one of the few trials that did not show the beneficial effects of statin therapy on cardiovascular events in patients who were at risk for future events. The reasons for the lack of difference in outcomes between the two arms are unknown, but the inclusion of a usual care arm as a control group may have played a role. For example, ALLHAT-LLT was conducted during a period that several other randomized trials of statin therapy were published. Thus, over time, physicians could have treated patients in the control arm with statin therapy. In fact, there was a steady increase in the use of statins in the usual care arm: 8.2% at year 2, 17.1% at year 4, and 26.1% at year 6. In addition to statins, other treatments in the usual care arm could have played a role. For example, physicians could have disproportionately recommended non-pharmacologic strategies (i.e., exercise, diet, and weight reduction) to their patients in the usual care arm as well. Given that the types of and intensity of the treatments in the usual care arm were likely variable, ultimately, these reasons remain speculative. Overall, ALLHAT-LLT is one example of the potential limitations, described above that may be associated with a usual care arm.

Uutela, Antti

Antti Uutela
Department for Lifestyle and Health, National Institute for Health and Welfare (THL), Helsinki, Finland

Biographical Information

Antti Uutela was born in Tammela, Finland, on March 27, 1946. He is Doctor of Social Sciences

(social psychology) and works as research professor and department director at the National Public Health Institute THL Department of Lifestyle and Participation, and also as professor of public health at the University of Tampere, Finland. Before the current positions, he worked as researcher at the Academy of Finland, as lecturer and assistant professor at University of Helsinki, and chief of laboratory at the National Public Health Institute KTL, respectively.

Uutela was educated as a cognitive social psychologist with a special interest in the link of attitudes and behavior. The latter and interest in practical applications of social psychology led him to start working with health-related applications in 1975, first at the Department of Social Psychology, and from 1980 at the Department of Public Health of the Helsinki University. In 1986, Uutela established a connection to the National Institute of Public Health KTL and to the Finrisk study. This contact was to become a signpost for his later professional career, which also included project membership in the Health 2000 Study.

When accepting the position of chief of the new Health Behavior Research Unit at National Public Health Institute KTL in 1994, Uutela started to look for possibilities of establishing a national member society associated to the International Society of Behavioral Medicine. This emerged rapidly, and he became the founding President of the Finnish Section of Behavioral Medicine, a section of Finnish Society of Social Medicine in 1994, the year when the section was also accepted as a full member of ISBM.

Uutela has been a member of the Board of the Finnish section ever since; he is also a member of the Swedish Society of Behavioral Medicine, and the Society of Behavioral Medicine. He has been active in the International Society of Behavioral Medicine in officer positions and organization of international meetings since 1996. He was the President of ISBM from 2004 to 2006, President-elect from 2002 to 2004, and immediate Past President and chair of the Awards committee from 2006 to 2008. He started his officer career in ISBM by becoming the treasurer of society for the period 1996–2002. He is the current Chair of the Finance Committee of ISBM (2008–2012). On several occasions, he has represented the Finnish section in the Governing Council. Dr. Uutela has belonged to the Editorial Board of IJBM from 1996 onward, been a program committee member for ISBM international congresses in 1996–2006, chair of the local organizing committee (ICBM, Helsinki 2002), and program track chair (1996–2000). He was the Poster session chair for the 2008 and 2010 meetings.

In addition to his work in behavioral medicine, Uutela has been involved in academic research and education, in several national and international committees and expert duties in health promotion, including program chair of the Nordic Public Health Conference in 2011. He is currently President of the Finnish Society of Sport Sciences LTS and a Board member of the Foundation for Sport and Health Sciences LIKES.

Major Accomplishments

Upon becoming the Unit chief at KTL, Uutela assumed leadership of the working age and senior citizens' lifestyle monitoring research, which produced information for public health planning and evaluation in the general population, its subgroups and regionally. This monitoring system is one of the oldest in the world, an excellent basis for evaluation and planning of national health policy, and national and international lifestyle statistics. The system has given rise to similar systems, e.g., in the Baltic countries of Europe. Uutela led study several projects funded by the Academy of Finland related to socioeconomic health inequalities and health promotion. From 2001 onward, he has participated and led intervention studies in the Good Old Age in Lahti region (GOAL) community intervention framework aimed at improving functional capacity of the aging population and preventing type 2 diabetes. He has been in charge of the nutrition intervention study focusing on Finnish male conscripts and also contributed to the upper primary school nutrition intervention at the National Public Health Institute. He has more than 300 publications.

During his ISBM presidency, Uutela worked actively to broaden the global basis of the Society: Asia, Central and Eastern Europe, and Middle and Southern America were especially targeted. In June 2005, the Governing Council of ISBM gathered in Mexico City in association with the Latin-American Regional Meeting in Behavioral Medicine. The Central European Society of Behavioral Medicine to started form with a network meeting in Targu-Mures, Romania, in November 2005. Contacts between ISBM and South America were strengthened during the President's visit to Caracas, Venezuela, in association to the Third Venezuelan Congress of Behavioral Medicine in October. A Thai Forum of Behavioral Medicine was held in Bangkok in December 2005 as a gateway to the 2006 ICBM there. Uutela with his fellow executives worked toward improvement of the administration and budgeting of ISBM. As an important item, in 2006, special funds in ISBM budgeting were devoted to developmental funds of ISBM to increase chances for global development and participation of behavioral medicine. The highly successful Bangkok ICBM, with Brian Oldenburg and Marc Gellman as program chairs, and Naiphinich Kotchabhakdi as chair of local organization, led to acceptance of the Central-Eastern Society of Behavioral Medicine as an ISBM member, and in a change of by-laws regarding individual membership.

V

Validity

J. Rick Turner
Cardiovascular Safety, Quintiles, Durham, NC, USA

Definition

The primary objective of an experimental or nonexperimental research study is to obtain a valid estimate of the treatment effect of interest. Validity can be divided into considerations of internal validity and external validity (Rothman, Greenland, & Lash, 2008).

Both experimental and nonexperimental studies require consideration to be paid to study design, data acquisition, data management, and analysis. If all of these are of optimum quality and there are no imperfections in the study, the study is deemed valid and the correct result is provided. Any imperfections lead to bias of various types.

Internal validity addresses the validity of inferences concerning the source population, and external validity addresses the validity of inferences to the general population, an issue also known as generalizability.

Variability

Definition

Variance is a sophisticated measure of dispersion that takes into account the position of every data

M.D. Gellman & J.R. Turner (eds.), *Encyclopedia of Behavioral Medicine*,
DOI 10.1007/978-1-4419-1005-9,

point about a central value, typically the mean. It is therefore a measure of the variability within a data set.

Imagine the following data set: 6, 8, 10, 12, and 14. The mean is the sum of all the values divided by the total number of values, i.e., $50/5 = 10$. How can we find a measure that will capture the totality of the dispersion of the numbers around the mean? An initial thought is to calculate the arithmetic distance each number, or score, lies from the mean, and sum these values. This leads to the following: -4, -2, 0, 2, and 4, the sum of which is 0. That is, the total deviation of the scores from the mean is 0.

This is actually true for any such calculation for any data set. The mathematics of calculating the mean ensures that the sum of the deviations of any set of scores from its mean is always zero. So, this strategy does not help convey the degree of dispersion around a central value.

However, one extra step takes us to a useful strategy: This involves squaring all of the deviations. Given that a negative number multiplied by another negative number produces a positive value, we now get the following for our original data set: 16, 4, 0, 4, and 16, which sum to 40. This value is known as the sum of squares. If most of the scores in a data set tend to be close to the mean, the sum of squares (the variance) will be relatively low. The converse is true when most of the scores tend to be relatively further away from the mean. It is therefore possible to have two data sets with identical means and yet very different sums of squares.

One further step is required to calculate the variance: The sum of squares is divided by the value that is one less than the number of scores in the data set. This value is called the degrees of freedom, and is discussed in the entry titled "▶ Degrees of Freedom." In this case, the sum of squares, 40, is divided by $(5 - 1)$, i.e., 4. The variance is therefore 10, which is coincidentally the same as the mean in this case.

In most cases, one further step will be taken: the standard deviation will be calculated as the square root of the variance, as discussed in the entry titled "▶ Standard deviation."

Vascular Abnormalities, Function

Jonathan Newman
Columbia University, New York, NY, USA

Description

Vascular function can be described as the function of the vascular endothelium, the monolayer of cells lining the intimal surface of the entire circulatory system. The surface of the vascular endothelium in one individual is enormous and has been estimated to contain roughly 3×10^{13} cells, covering the surface of more than six tennis courts. This section will review the cardinal domains of vascular function in cardiovascular disease; will describe putative pathogenic abnormalities in vascular function, and will briefly review measures to assess vascular function.

The regulation of vascular tone and hemostasis/coagulation are two primary domains of vascular function important in the pathogenesis of cardiovascular disease (CVD). There are other physiologically important vascular functions, including complex metabolic properties and the regulation of vascular permeability, but these domains are outside of this review. The regulation of vascular tone is a delicate balance of opposing vasoconstrictive and vasodilatory functions. The endothelial cells lining the vasculature have vasodilatory and vasoconstrictive properties and synthesize some local active molecules that have both local and systemic effects on vascular tone. The vasoconstrictive and vasodilatory properties of the endothelium that help maintain normal hemodynamics are a crucial portion of the response to local (vascular trauma, compromise) or systemic (congestive heart failure, hypertension) abnormalities. Vasodilation and

vasodilatory function is reviewed elsewhere (see ▶ Vasodilation, Vasodilatory Functions). Vasoconstriction is mediated in part by the endothelium-derived molecules endothelin-1, thromboxane-A_2, and platelet activating factor. Importantly, the vasodilatory and vasoconstrictive properties of the endothelium also have anti- and prothrombotic activities, respectively. This leads to delicate balance of vascular function in which the vasodilatory properties also promote blood fluidity through the inhibition of coagulation, whereas the vasoconstrictive properties of the endothelium promote platelet activation and hemostasis. Thus, the regulation of vascular tone interacts crucially with the other primary domain of vascular function, coagulation, and hemostasis, and in most normal circumstances, the endothelium constitutively expresses an antithrombotic surface to the blood that inhibits platelet aggregation and clot formation. When the endothelium is activated or compromised, however, it is capable of quickly becoming prothrombotic, activating platelets and promoting coagulation.

Given its importance, a number of different modalities have been developed and investigated to assess vascular function.

There are, however, two main categories of assessment.

The first and "gold standard" methodology is coronary angiography (catheterization) to measure coronary circulation with infusion of vasoactive medications, such as adenosine, to measure coronary blood flow and resistance.

However, this technique is invasive, expensive, and not without risk.

Therefore, relying on the principle that endothelial dysfunction is a systemic disorder, vascular function can be measured in other arterial beds in a less invasive manner.

The most widely studied method is flow-mediated dilation (FMD) of the brachial artery using high-resolution ultrasound.

During the measurement of FMD, brachial artery diameter is measured before and after an increase in wall stress induced by reactive hyperemia (increased blood flow) seen following inflation of a sphygmomanometer cuff proximal to the brachial artery for 5 min at high pressures, up to 200 mmHg.

The amount of dilation seen largely reflects endothelial function and the availability of important vasodilatory molecules, such as nitric oxide (NO).

FMD is predictive of the extent and severity of coronary atherosclerosis and is an independent predictor of prognosis.

Brachial artery FMD is also moderately correlated with coronary artery FMD.

However, FMD is operator dependent and requires significant training.

It is also influenced by catecholamines, levels of hormones such as estrogen and progesterone, stress level, and sleep deprivation.

Further, it remains unclear whether the assessment of FMD provides information that is additional to traditional risk factors.

A recent technology that utilizes similar methods of assessing changes following reactive hyperemia is finger-pulse plethysmography.

This technology relies on changes in pulse wave amplitude following reactive hyperemia in the finger.

These changes in amplitude are filtered, amplified, displayed, and stored, and a threshold has been identified that may have utility in identifying endothelial dysfunction within the coronary circulation.

Measurement of both brachial FMD and finger-pulse plethysmography has largely been restricted to research use, but investigation into the potential clinical applications of these modalities is ongoing.

Vascular Endothelial Growth Factor (VEGF)

Alexandra Erdmann and Erin Costanzo
Department of Psychiatry, Carbone Cancer Center, University of Wisconsin-Madison, Madison, WI, USA

Definition

Vascular endothelial growth factor (VEGF) is a key regulatory molecule that promotes growth of new blood vessels. VEGF plays an important role in normal physiological processes that require increased vascularization to bring oxygen and nutrients to tissues, including embryonic and postnatal development and wound healing (Ferrara, Gerber, & LeCouter, 2003). VEGF can also contribute to disease processes. For example, upregulation of VEGF has been linked to development of intraocular neovascular syndromes, inflammatory disorders, and brain edema, among others (Ferrara et al., 2003). VEGF also plays a critical role in tumor growth and development. Specifically, VEGF recruits endothelial cells to the tumor site, allowing for growth of capillary networks that enable tumor development by increasing the supply of oxygen and nutrients essential for cell division and growth (Antoni et al., 2006; Ferrara et al., 2003). The vascularization of a tumor in its early stages allows the mass to grow beyond a critical point and to eventually metastasize, or spread through the circulatory system to other tissues and organs (Kerbel, 2000). Consequently, anti-VEGF agents have been developed for cancer treatment, with promising results from recent clinical trials (e.g., Escudier et al., 2007).

Of relevance to behavioral medicine, there is evidence that stress can affect VEGF production. Specifically, stimulation of in vitro ovarian, melanoma, and nasopharyngeal tumor cell lines with stress hormones such as norepinephrine, epinephrine, and cortisol leads to increased production of VEGF. Effects appear to occur via β-adrenergic signaling pathways and can be moderated by β-blockers, such as propranolol (Lutgendorf et al., 2003; Yang et al., 2006, 2009). These results suggest a potential pathway by which stress-related psychosocial factors may affect tumor development and progression. New investigations are determining the extent to which β-blockers may be promising therapeutic options (Costanzo, Sood, & Lutgendorf, 2011). These studies pinpoint a physiological pathway by which behavioral interventions targeting stress may have the potential to improve cancer outcomes.

Vascular Headache

► Migraine Headache

Vasoconstriction

Leah Rosenberg
Department of Medicine, School of Medicine, Duke University, Durham, NC, USA

Definition

Vasoconstriction is the process by which smooth muscle causes contraction and narrowing along the vessel length. The mechanism of vasoconstriction is mediated by intracellular calcium levels and a variety of calcium-binding proteins, particularly calmodulin (Barrett, Barman, Boitano, & Brooks, 2010).

Vasoconstriction is a physiologic cardiovascular regulatory mechanism that has essential functions throughout the body. Vasoconstriction may be triggered locally in the vasculature or from afar by upstream mediators in response to a variety of physical and emotional stimuli. It is also an example of autoregulation, when organism homeostasis is maintained through balance of vasoconstriction and vasodilatory mechanisms. While most changes are in response to blood flow of the vascular bed or an intrinsic reaction to stretch, there are many other stimuli that induce acute and chronic changes. In the event of vascular injury or compression, there is local response thought to be mediated by serotonin released by platelets that have accumulated proximate to the injured tissue. In addition to serotonin, there are a variety of other vasoconstrictor proteins that have systemic effects.

Several mechanisms have been developed to measure vasoconstriction in the central as well as peripheral vasculature. These are mostly utilized in research settings and have been put into mainstream clinical practice. However, the noninvasive measurement of vascular tone may soon prove to have indications for identifying patients at increased risk for complications like heart attack and stroke.

Vasodilation, Vasodilatory Functions

Jonathan Newman
Columbia University, New York, NY, USA

Definition

Vasodilation refers to the opening or enlargement of blood vessels as a result of relaxation in the smooth muscle cells lining the arteries and to a lesser extent, the veins of the human body. Vasodilation is largely the reverse of the vasoconstriction, which refers to the narrowing of the same blood vessels throughout the human body.

Description

In general, vasodilation leads to a decrease in resistance in that vascular structure and a subsequent

increase in blood flow. This relationship can be illustrated by examining the hemodynamic relationships of total peripheral resistance (TPR). Total peripheral resistance is equal to the difference between mean arterial pressure (MAP) and mean venous pressure (MVP), divided by the cardiac output (CO), represented by the equation: TPR = (MAP − MVP)/CO. In general, resistance in tubular structures, like blood vessels, is inversely proportional to the radius of that tube (blood vessel) raised to the 4th power (Resistance = $1/\text{radius}^4$). Therefore, any increase in the radius of a blood vessel produces a significant decrease in the resistance of the vessel in question. In general, vasodilation works to decrease TPR through the actions of local and systemic factors that relax the smooth muscle cells in and around arteries and arterioles, increasing the size of blood vessels through a change in their radius.

Vasodilation plays an important role in the maintenance of body temperature through the vasodilation of superficial blood vessels and the release of heat into the cooler air surface surrounding the human body. Vasodilation is mediated by local or paracrine factors secreted by the endothelial cells themselves such as nitric oxide, bradykinin, potassium, and adenosine diphosphate (a breakdown product of working muscles). Vasodilatory function has an important role in the pathophysiology and treatment of cardiovascular disease and impaired vasodilation, and vasodilatory function has been demonstrated to be an important component of atherosclerotic coronary artery disease (see ▶ Vascular Abnormalities, Function). Impaired vasodilation is thought to reflect reduced nitric oxide bioavailability. Further, the promotion or stimulation of vasodilation with different cardioactive medications has proven therapeutic benefit in conditions such as mitral regurgitation, aortic regurgitation, hypertension, coronary artery disease, and congestive heart failure.

In general, the stimulation of vasodilation may help to reduce the amount of regurgitant blood flow seen in aortic and mitral regurgitation. Acutely, intravenous vasodilation in these conditions may reduce ventricular pressures and increase forward flow, potentially improving ventricular function. It is not clear if the hemodynamic improvement seen with vasodilator use in regurgitant valvular lesions is due to the reductions in blood pressure alone or through a combination of factors. In heart failure, the use of vasodilators encompasses both arterial and venous vasodilation, typically with agents such as hydralazine (arteriolar dilation) and nitrates (venodilation). The next effect of the use of these two vasodilators is to reduce the amount of a forward (preload) and "backward" (afterload) pressure on the heart, thereby reducing myocardial work and improving function. The antihypertensive effect of vasodilators is due mostly to the reduction arterial tone and therefore blood pressure. In coronary disease, nitrates can have profound anti-ischemic effects through their actions as both arterio- and venodilators, though the main effects of vasodilation in patients with coronary disease may be through decreasing ventricular filling (preload) which decreases wall tension, cardiac work, and hence myocardial oxygen demand, and may in turn lessen anginal symptoms.

In conclusion, vasodilation and vasodilatory function is an important component in both normal cardiovascular function and in the pathogenesis of disease. As described, the promotion of vasodilation is a useful therapeutic target for the treatment of a wide range of cardiovascular diseases.

Vasopressin

George J. Trachte
Academic Health Center, School of Medicine-Duluth Campus, University of Minnesota, Duluth, MN, USA

Synonyms

Antidiuretic hormone

Definition

Background: Vasopressin (antidiuretic hormone) is essential for regulating the osmolarity of blood

and also influences blood pressure. It has numerous behavioral influences such as reinforcing bonding between mating pairs, enhancing memory, and promoting aggressive behavior.

Physiological Relevance: Vasopressin is required for concentration of urine. It is present in all terrestrial animals, presumably to allow water retention. The absence of vasopressin results in a condition called diabetes insipidus, characterized by excretion of large volumes of dilute urine and the need to consume large quantities of water to survive. Vasopressin typically influences cells in the collecting duct of the kidney to promote water retention and concentrate the urine. Urine concentration cannot occur naturally in its absence.

Vasopressin also is essential for bond formation in a number of species. Mating bonds occurring in normally monogamous rodents are prevented by blockade of vasopressin V1a receptors in the brain. It is suspected to have a similar role in humans. Memory also is enhanced by vasopressin in a number of species but the physiological relevance of this potential action remains to be determined in humans. Finally, vasopressin constricts blood vessels to elevate blood pressure and this action might be important in hypovolemic states such as hemorrhagic shock.

Vasopressin actions are mediated by at least three separate receptors termed V1a, V1b, and V2. The V1a receptor mediates vasoconstrictor effects of vasopressin whereas V2 receptors mediate the renal effects to concentrate urine. The exact role of V1b receptors has not been determined at this point.

Control of Release/Secretion: Vasopressin is synthesized in the supraoptic and paraventricular nuclei of the hypothalamus and is transported to the posterior pituitary gland within magnocellular neurons. Vasopressin is synthesized as a 168 amino acid preprohormone that is converted to a 145 amino acid prohormone with the nine amino acids of the amino terminal representing the final vasopressin molecule. Vasopressin is stored in the posterior pituitary and released in response to plasma osmolarity exceeding 280 mM, sexual activity, or hypotension.

Localization/Molecular Biology: The preprovasopressin gene is located on chromosome 20 in humans. It is expressed in the supraoptic and paraventricular nuclei of the hypothalamus. Another site of synthesis is the heart, although the hypothalamic nuclei are believed to be the primary sites of synthesis.

Behavioral Actions: Vasopressin has at least three prominent behavioral actions, including: promotion of pair bonding; improvement of memory; and increased aggression toward sexual rivals. The pair bonding data are derived primarily from monogamous rodents who fail to develop pair bonds when vasopressin V1a receptors are blocked. Similar actions are suspected in humans and vasopressin is referred to as a "bonding" hormone. Memory also is improved in humans and other species by infusions of vasopressin and V1a receptor antagonists can impair memory in some species. Finally, vasopressin increases aggression in males toward other males. It is viewed as a monogamy hormone, enhancing bonding with a mate and children while reinforcing protective behaviors.

Vital Exhaustion

Douglas Carroll
School of Sport and Exercise Sciences, University of Birmingham, Edgbaston, Birmingham, UK

Definition

Vital exhaustion is a prodromal constellation of symptoms including physical exhaustion and feelings of hopelessness preceding major coronary heart disease events such as myocardial infarction.

Description

Vital exhaustion was a concept first proposed by Appels some 25 years ago. Appels argued that exhaustion was not simply premonitory to cardiac events, reflecting established pathology and representing early warnings, the historic clinical view. Rather, he contended that the syndrome of vital exhaustion was casually related to subsequent events. The causal pathway was hypothesized to be the neuroendocrine mechanisms typically invoked as the link between psychosocial exposures and heart disease. Support for a causal role for vital exhaustion was gleaned from a number of subsequent observational epidemiological studies demonstrating an association between measure of exhaustion and subsequent all-cause mortality and cardiac disease mortality and morbidity. Unfortunately, such evidence is necessarily only indicative and provides insufficient surety of the direction of causation. Reverse causation, where heart disease that has not yet been formally diagnosed leads to symptoms of exhaustion, must remain a possibility. A growing literature illustrates how the inflammatory processes implicated in atherosclerosis may contribute to feeling of fatigue and depression. In addition, confounding by some unmeasured or poorly measured variable in these observational studies cannot be wholly dismissed.

The proper test of causation is intervention: a randomized control trial, whether patients are randomly allocated to a exhaustion treatment invention or to a condition in which no such treatment is available. Some 5 years ago, Appels and his colleagues reported the outcome of such an intervention. Participants were over 700 cardiac disease patients who had undergone successful angioplasty, a procedure for the surgical repair of block coronary arteries. Patients were randomized to a 6-month exhaustion intervention comprising among other things relaxation training and stress management, or to usual care. At the 18-month, but not the 6-month, follow-up, fewer intervention than usual care patients reported feeling exhausted and fewer were depressed. However, the intervention did not reduce the likelihood of patients having a recurrent cardiac disease event.

Definition

The concept of active life expectancy revolves around the fundamental question of how many of the years added to life through advances in average life expectancy are spent in reasonably good health. A comprehensive and multifaceted view of health considers a variety of different physical, mental, and psychological health aspects.

Description

Overview

Human life expectancies have almost doubled over the last century. As a result, an unprecedented number of individuals can expect to reach old age. This historically new situation challenges us to better understand the factors that may contribute to vitality in old age. This entry aims to shed light on two important questions: First, it introduces the concept of active life expectancy to address the fundamental question of how many of those years added to life are spent in reasonably good health. Second, it argues for a comprehensive multifaceted view on vitality in old age that takes into account important psychological variables, including well-being, social engagement, and cognitive functioning. It concludes by alluding to key challenges that this line of work has to confront in the future.

Active Life Expectancy

Recent increases in human life expectancies and longevity are a great achievement, due to many different factors including improved public health and medical advances in Western countries (► Longevity). Those demographic trends also pose important societal challenges such as the question whether the gains in quantity of life are accompanied by gains in (or at least maintenance of) quality of life. A central construct in this regard is active (or healthy) life expectancy, which is frequently defined as the number of years individuals can expect to live without chronic disability (Crimmins, Hayward, & Saito, 1996). Research using this concept has advanced our knowledge regarding segments of the population who benefit or who are excluded from such trends. This line of inquiry has also helped put some of the earlier enthusiasm about increasing longevity into perspective. For example, although women can typically expect to live longer than men, they often spend a greater portion of their lives in disabling conditions. Likewise, individuals with higher socioeconomic status do not only live longer, but they also enjoy old age in better health than individuals with lower socioeconomic status. Moreover, there are notable racial differences in active life expectancies with African Americans typically spending more years with disabilities than non-Blacks in the United States (Crimmins et al., 1996). More generally, research on active life expectancy has revealed important insights into which demographic strata can be expected to spend the years added to life in reasonably good health and which strata do not.

Apart from identifying key population-level predictors of vitality, this line of research has also fueled important discussions about big-picture trends. Different propositions have been put forward regarding future changes in morbidity-mortality dynamics. The probably most prominent example is the compression of morbidity hypothesis (Fries, 1980), according to which increases in active life expectancy occur at a faster rate than increases in life expectancy. As a consequence, the years people spend in ill health are compressed into an increasingly shorter period at the very end of life. Conversely, other scholars have proposed that further increases in longevity would result in increased disease prevalence, ultimately leading to an expansion of morbidity (Gruenberg, 1977). Thirty years later, the verdict is still out. It appears as if individual perceptions of the years spent in good health are indeed increasing at the population level. In contrast, trends for the years spent in disability differ by severity. Years spent with severe disabilities are declining, whereas years spent with less severe forms are on the rise (Christensen, Doblhammer, Rau, & Vaupel, 2009). More generally, some researchers are skeptical about the possibility to successfully compress morbidity (e.g., Crimmins et al., 1996) whereas others report promising findings regarding delayed disabilities among more recently born cohorts of older adults (e.g., Manton, Gu, & Lowrimore, 2008). Taken together, the epidemiological literature has posed big-picture questions regarding how increasing longevity impacts disease prevalence and has raised awareness to tremendous heterogeneity in how well older adults from different backgrounds can expect to live their last years of life.

Psychological Indicators of Vitality

A comprehensive understanding of vitality in old age fundamentally depends on how health is defined. Specifically, it has been proposed that the time is due to move away from disease-centered definitions of health (Ryff & Singer, 2000). For example, the WHO defines health as "a state of complete physical, mental and social well-being" (Official Records of the World Health Organization, 1948). This definition dovetails with notions of successful aging that emphasize the importance of older adults maintaining their cognitive and physical functioning as well as actively engaging with life (Rowe & Kahn, 1997). To provide a more holistic account of health with aging, social scientists have thus embarked on a search for psychological factors that contribute to a more comprehensive understanding of vitality in old age that goes beyond the mere absence of disease. For example, it has been shown that emotional well-being is closely linked with physical health (Pressman & Cohen, 2005). In a similar vein, social relationships seem to be associated with older adults' physical and mental health (Hoppmann & Gerstorf, 2009), and associations between cognitive functioning and physical health in old age are a well-established research finding (Schaie, 2005). Hence, psychological research promises to broaden the scope of what constitutes vitality in old age by pointing to the important role of such diverse factors as emotional well-being, motivational processes, and cognition.

In addition to such normative accounts of vitality, there is also a rich literature on interindividual differences in self-regulatory processes. Importantly, this line of research takes into account that older adults may be able to maintain their well-being when confronted with losses in functional health. For example, it has been shown that strategies of selective optimization with compensation, self-efficacy, and control processes are positively associated with health in old age (e.g., Baltes & Smith, 2004; Seeman, Unger, McAvay, & Mendes de Leon, 1999; Wrosch, Schulz, & Heckhausen, 2004).

Identifying key psychological factors that distinguish older adults who spend their final years in reasonably good health from those who suffer from disease is important because it allows us to move beyond a recognition of well-established risk factors of late-life disability (e.g., being male, low socioeconomic status, member of a minority) that are in fact unalterable. Hence, recognizing that psychological constructs are key ingredients of or central contributors to vitality in old age may offer important insight into factors

that may be amenable to intervention and where growth might be possible until old age (Ryff & Singer, 2000).

Future Directions

In a final step, we would like to highlight two key societal challenges that are intrinsically linked with the concept of vitality. First, it is going to become increasingly important to recognize the practical implications of (changes in) vitality. For example, many developed countries currently face a heated debate about whether or not to increase mandatory retirement age. Importantly, it seems as if more flexible and individualized retirement decisions are necessary so as to accommodate the specific needs of the aging population. Some older adults may simply not be well enough to continue working beyond age 65, whereas other 65+ year olds may benefit from staying in the work force for longer and would profit from work-related cognitive stimulation and social participation (Pinquart & Schindler, 2007).

Second, it is well possible that positive secular trends that have repeatedly been reported for earlier points in life such as retirement age may be offset or even reversed in more advanced ages or at the end of life. In fact, there is empirical evidence that later-born cohorts may experience steeper end-of-life declines in cognitive abilities than earlier-born cohorts (Gerstorf, Ram, Hoppmann, Willis, & Schaie, 2011). One way to interpret such results is that members of later-born cohorts may have survived diseases that would have resulted in death among members of earlier-born cohorts. However, the previously higher levels of (cognitive) functioning were not maintained for this manufactured survival time (Olshansky, Hayflick, & Carnes, 2002). More generally, it remains unclear if it will ultimately be possible to successfully compress morbidity into increasingly shorter time periods at the end of life. We have to keep in mind that humans were not designed to enjoy such long post-reproductive lives as it is often the case today and that chance plays a much greater role in determining health during the post-reproductive as compared to the reproductive years of life (Finch & Kirkwood, 2000).

Definition

Waist circumference (WC) is considered a measure of the relative health risk associated with excess abdominal fat. Abdominal fat contains higher amounts of visceral fat, a fat that is produced by the liver, turned into ► cholesterol, and released into the bloodstream where it can form plaque on artery walls. Excess abdominal fat is associated with high ► cholesterol, ► high blood pressure, and ► cardiovascular disease.

Waist circumference may be a better indicator of obesity-related diseases than ► body mass index (BMI) (Cawley, 2006), especially among certain populations (e.g., elderly persons). Certain ethnic groups are genetically predisposed to store more fat in the abdomen, even at healthy weights (e.g., non-Hispanic blacks, people of Asian descent).

It is measured by first locating the upper hipbone and lowest rib, followed by placing the end of a measuring tape between these two points and wrapping horizontally around the abdomen.

Men with a waist circumference greater than 102 cm (40 in.) and women with a waist circumference exceeding 88 cm (35 in.) are considered to be at increased risk for developing obesity-related health problems, including type II ► diabetes, ► hypertension, and ► cardiovascular disease.

Definition

Waist girth is related to abdominal visceral fat and predicts a number of disease risk factors associated with obesity.

Description

Obesity which is explained by an increase in body fat is associated with a clustering of risk factors known as the metabolic syndrome and originates from an imbalance between energy intake and energy expenditure. However, there is substantial evidence that body fat distribution rather than total fat mass per se plays a more important role in the development of such risk factors. Gynoid obesity (commonly referred to as "pear shaped") reflects adipose tissue accumulation around the hips and buttocks, whereas android obesity (more commonly referred to as "apple shaped") reflects increased abdominal fat deposition. Android obesity increases with age, is more prominent in males, and poses a significantly greater risk for the development of hypertension, dyslipidemia, insulin resistance, atherosclerosis, type 2 diabetes, coronary artery disease, and certain types of cancer and higher rates of mortality than gynoid obesity. Girth measurements can be used to assess such differences in body fat distribution, and measurement of waist girth specifically represents abdominal obesity. Therefore, it may be a more relevant measure for anyone looking to use simple anthropometric measurements to predict the risk of obesity-related diseases across populations or in response to interventions over time. A variety of gender and age-specific equations are also available to predict body fat percentage from waist girth measurements.

The measurement of waist girth can be used in conjunction with hip circumference to measure waist-hip ratio which is a common method used to predict many health hazards associated with obesity. However, waist girth is more predictive of obesity-related risk factors than waist-to-hip ratio as it is a more accurate reflection of deep visceral adipose tissue (Roche, Heymsfield, & Lohman, 1996). Furthermore, waist girth measurements also correlate well with the gold standard CT or MRI techniques for the measurement of visceral abdominal fat. The reason that this adipose tissue site is such a risk factor is complex but is likely related to it being more active to lipolytic stimuli such as catecholamines, expression of adrenoreceptors and receptors for insulin, glucocorticoids, and testosterone. Abdominal fat also expresses and releases a multitude of peptides and inflammatory cytokines which are also likely to be involved.

The standardized measurement of waist girth is described by the American College of Sports Medicine (*ACSM's Guidelines for Exercise Testing and Prescription*, 2006). Measurements should be made with a flexible, inelastic tape without compression of the subcutaneous adipose tissue. Measurements should be performed with the participant standing with their feet together and arms by their side. A horizontal measure is then taken at the narrowest part of the torso, typically between the bottom of the ribs and the iliac crest. Duplicate measures should be taken and repeated if the variation exceeds 5 mm.

Waist girth alone, or in combination with other anthropometric measures, has been used to classify and evaluate disease risk. However, different cut off points have been suggested depending on the specific population studied. For example, a waist circumference over 99 cm for males and over 89 cm for females is associated with a high risk for the development of obesity-related disease (American College of Sports Medicine, 2006). Further, a disease risk classification is also available taking into account both BMI and waist

circumference (see McArdle, Katch, & Katch, 2001). This describes a higher risk of disease when a BMI over 25 kg/m^2 is combined with a waist circumference greater than 102 or 88 cm for males and females, respectively.

Waist Size

Kazuo Hara
Department of Metabolic Diseases, Graduate School of Medicine, The University of Tokyo, Bunkyo-ku, Tokyo, Japan

Synonyms

Waist circumference

Definition

There are several lines of evidence that suggest subjects with a large waist size are at increased risk of developing type 2 diabetes and cardiovascular diseases, even after adjustment for body mass index (BMI), an indicator of total adiposity (Hu et al., 2007; Winter et al., 2008; Yusuf et al., 2005). The large waist size reflects accumulation of excess abdominal fat, also known as central obesity, and is reported to be a primary risk factor for glucose intolerance, dyslipidemia, and high blood pressure, which together is now defined as metabolic syndrome (Kadowaki et al., 2006). Therefore, the measurement of waist size is essential for the screening of metabolic syndrome. Two international definitions for metabolic syndrome are currently used in daily practice, one provided by the International Diabetes Federation (IDF) (IDF Worldwide Definition of the Metabolic Syndrome) and the other by the National Cholesterol Education Program (NCEP) (Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults, 2001). The former criterion requires waist size above a certain cut point for a diagnosis of metabolic syndrome, whereas the latter one does not require a large waist size if the subject has three or more of the following: raised fasting plasma glucose concentrations, elevated blood pressure, elevated levels of triglycerides, and/or reduced levels of high-density lipoproteins.

The IDF recommends that the cut point for waist size used to define central obesity should vary according to ethnic group, and they proposed the following European-specific cut points for waist size: 94 and 80 cm for men and women, respectively (Alberti, Zimmet, Shaw, & IDF Epidemiology Task Force Consensus Group, 2005). Nonetheless, further extensive investigations must be performed before more suitable cut points can be established for use in clinical practice to accurately predict cardiovascular diseases.

The method of measurement must also be standardized. Waist size is usually measured at a level midway between the lowest rib and the iliac crest (Han, van Leer, Seidell, & Lean, 1995). However, the waist size is measured at the umbilical level in some countries, such as Japan, for screening metabolic syndrome (Matsuzawa, 2005). It is essential that the subjects being measured are not holding their breath and that the tape measure is not at an angle around their waist.

Waist to Hip Ratio

Kazuo Hara
Department of Metabolic Diseases, Graduate School of Medicine, The University of Tokyo, Bunkyo-ku, Tokyo, Japan

Synonyms

WHR

Definition

The waist hip ratio (WHR) is the ratio of waist circumference to hip circumference. It was reported that the mortality and the risk of coronary artery disease are positively correlated with WHR both in men and women (Lapidus et al., 1984; Larsson et al., 1984). It is well documented that subjects with high WHR and upper body obesity present insulin resistance (Peiris, Mueller, Smith, Struve, & Kissebah, 1986). According to the standard defined by World Health Organization (WHO) in 1999 about metabolic syndrome, in which type 2 diabetes mellitus, glucose tolerance, and insulin resistance are required items, obesity is defined as WHR >0.9 in men and WHR >0.85 in women (World Health Organization, 1999).

Ways of Coping Checklist (WCCL)

Susan Folkman
Department of Medicine, School of Medicine, University of California San Francisco, San Mateo, CA, USA

Definition

The Ways of Coping Checklist (WCCL) is a measure of coping based on Lazarus and Folkman's (1984) stress and coping theory. The WCCL contains 66 items that describe thoughts and acts that people use to deal with the internal and/or external demands of specific stressful encounters. Usually the encounter is described by the subject in an interview or in a brief written description saying who was involved, where it took place, and what happened. Sometimes a particular encounter, such as a medical treatment or an academic examination, is selected by the investigator as the focus of the questionnaire. Subjects respond on a 4-point Likert scale (0 = does not apply and/or not used; 3 = used a great deal), the extent to which the item was used in the specific stressful encounter.

Subscales

Factor analysis of data from a study of stressful encounters reported by a community sample of middle-aged married couples indicated eight scales: planful problem-solving, positive reappraisal, seeking social support, distancing, self-controlling, escape-avoidance, accepting responsibility, and confrontive coping (Folkman, Lazarus, Gruen, & DeLongis, 1986). The eight scales use 50 of the 66 items. The additional items are retained on the WCCL because some investigators find them useful. Subsequent factor analyses indicated variability in factor structure. Some factors such as planful problem-solving, positive reappraisal, escape-avoidance, and distancing are relatively stable. Other factors such as self-controlling, accepting responsibility, seeking social support, and confrontive coping are less stable. For a critical review of the WCCL, see Schwarzer & Schwarzer (1996).

Scoring

There are two systems for scoring the WCCL. The "Raw Score" method is to sum the ratings for each scale. This method provides a score for amount of each type of coping used in the specified event.

The "Relative Score" method, introduced by Vitaliano, Maiuro, Russo, and Becker (1987), controls for the variability in scale length. Relative scores are computed by first obtaining the mean item score for each scale. Once the mean effort (ME) is obtained for each scale, the relative effort is calculated by dividing the ME for the particular scale by the sum of the MEs for each of the scales.

Interpretation

The WCCL is descriptive, not diagnostic. Typically, scores are correlated with outcomes of interest, such as depressive symptoms, distress, positive mood, or a relevant behavior.

Investigators ask if there are population norms for comparison purposes. Stress and coping theory (Lazarus & Folkman, 1984) views coping as contextual, which means that there is no "standard" amount of coping that can be used as a norm. For example, certain types of coping (e.g., planful problem-solving) are used more in situations that are controllable while other types (e.g., distancing) are used more in situations that have to be accepted.

The Ways of Coping Checklist can be obtained through Mind Garden Publishers (www.mindgarden.com).

Weight: Control, Gain/Loss/ Reduction, Maintenance, Monitoring

Shuji Inada
Department of Stress Science and Psychosomatic Medicine, Graduate School of Medicine, The University of Tokyo, Tokyo, Japan

Definition

Weight is the mass of one's body. Weight is usually measured by a scale in kilograms, which are base units of mass in the international systems of unit. Weight is used as barometer of adiposity or condition of nutrition or index of growth in children. Weight is useful for intrapersonal comparisons, while body mass index (in adults) or Rohrer's index (in children), which is adjusted for body height, is used for interpersonal comparisons. Weight is also applied for index of water balance in patients who have water imbalance such as congestive heart failure or renal failure.

Since weight measured by a scale is affected by meal, urine, and stool, it is better to measure on the same time after bladder emptying and defecation.

Description

Weight Control

Weight control is to keep, increase, or decrease one's weight within a certain range. Weight category is classified with body mass index as follows (also see ▶ Body Mass Index) (Table 1).

Since overweight and obese population is increasing, "weight control" often means "weight loss." Weight control is essential to prevention and treatment of many diseases, especially of metabolic disease (Must et al., 1999; Strazzullo et al., 2010).

Weight Gain/Loss/Reduction/Maintenance

Weight gain/loss depends on an energy balance under a normal water balance. Energy intake is usually derived from food intake. Energy consumption includes basal metabolism, consumption for physical activity, and consumption for thermogenesis. Energy intake exceeding energy consumption results weight gain, and energy consumption exceeding energy intake results weight loss.

Diet is the most important for weight reduction, and exercise is often combined with diet. Exercise alone has minimal effect for body weight (Franz et al., 2007). Sibtramine and Orlistat are approved by FDA for use in obesity patients (see ▶ Obesity: Prevention and Treatment). Bariatric surgery is performed to severe obese patients (see ▶ Bariatric Surgery).

Weight: Control, Gain/Loss/Reduction, Maintenance, Monitoring, Table 1 The international classification of adult underweight, overweight, and obesity according to BMI (WHO, 2006)

Classification	Principal cutoff point
Underweight	<18.5
Normal	18.5–24.99
Overweight	25–29.99
Obese class I	30–34.99
Obese class II	35–39.99
Obese class III	>40

Behavioral therapy is applied to weight management and achieves preferable short-term outcome. Behavioral management of obesity includes self-monitoring of diet, physical activity, and/or body weight; stimulus control; cognitive restructuring; goal setting; and problem solving (Johnston, Tyler, & Foreyt, 2007).

Maintenance of reduced weight is more difficult than weight reduction. Some regain of weight is inevitable for nonsurgical weight-loss therapy (Franz et al., 2007).

Monitoring

Self-monitoring is an important element of behavioral weight-loss program. Self-monitoring of dietary intake, physical activity, and/or body weight achieves self-evaluation of the weight-loss behavior, one's awareness of weight and behavior, and self-reinforcement of preferable behavior (Burke, Wang, & Sevick, 2011). While paper-pencil diaries are conventionally used for self-monitoring, internet-based diaries or PDA-based diaries are recently developed for easier recording and less-biased data recording (Burke et al., 2011; Fukuo et al., 2009).

Weighted Sample

Jane Monaco
Department of Biostatistics, The University of North Carolina at Chapel Hill, Chapel Hill, NC, USA

Definition

In a weighted sample, not all sample observations contribute equally to the estimate of a population parameter.

Investigators are often interested in estimating quantities (such as means, counts, or proportions) in a population by using a representative sample selected from that population. Probability samples, defined as samples in which each sampling unit has

a known, nonzero probability of selection based on the sampling design, allow investigators to compute estimates of population parameters. The most straightforward type of probability sampling design, a simple random sample (SRS), is a selection method in which each sample has the same probability of being selected. In an SRS, the probability of selection of each member in the population is the same.

The estimation of the population mean is straightforward for the SRS design. Let n = sample size, N = population size. Also, let $\{Y_1, \ldots, Y_N\}$ be the population values and $\{y_1, \ldots, y_n\}$ be the sample values. We define the overall sampling fraction as $f = \frac{n}{N}$. Then $\bar{Y} = \frac{1}{N}\sum_{i=1}^{N} Y_i$ the population mean, can be estimated by the statistic,

$$\bar{y} = \frac{1}{n}\sum_{i=1}^{n} y_i$$

Under this SRS design, each sample observation, y_i, contributes equally to the estimate, $\bar{y}$, of the population mean.

More complicated sampling designs, such as stratified sampling, may be chosen by investigators for various reasons including potential efficiency and the ability to use different sampling methods for different strata. In stratified sampling, the population is grouped by some characteristic (such as gender, geographic location, or age category), and a sample is selected within each subgroup separately. In this stratified design, the probability of selecting an individual is likely not the same for all individuals, but rather depends on the individual's subgroup (stratum). For example, in a study of illicit drug use among adolescents in a particular city, the population could be stratified into two age groups, middle school and high school. The probability of selection of a particular student will depend on the sample size and population size within that student's age group. Therefore, the sample statistics using a stratified design must be weighted to account for the unequal selection probability of observations.

To compute a weighted sample mean for a stratified sample, first consider the partition of the population into H mutually exclusive strata. Let N_h = the population size in the h^{th} stratum, n_h = the sample size in the h^{th} stratum so that $N = \sum_{h=1}^{H} N_h$ and $n = \sum_{h=1}^{H} n_h$. The stratum specific sampling fraction is $f_h = \frac{n_h}{N_h}$. We can compute each stratum-specific mean, $\bar{y}_h$, as the average of the n_h units in the h^{th} stratum. The weighted sample mean is computed as weighted sum of the stratum specific means: $\bar{y}_w = \frac{1}{N}\sum_{h=1}^{H} N_h \bar{y}_h$. This weighted sample mean can be shown to provide an unbiased estimate of the population mean, $\bar{Y}$.

Weiss, Stephen M.

Stephen M. Weiss
Department of Psychiatry and Behavioral Sciences, Miller School of Medicine, University of Miami, Miami, FL, USA

Biographical Information

Stephen Weiss was born in northern New Jersey on June 17, 1937. He received his B.A. in Psychology from the University of Maryland (1959) and his Master's (AM) in Psychology

from Temple University (1961). He completed his clinical psychology internship and residency in the Department of Medical Psychology at the University of Oregon Medical School (1962–1963) and received his PhD in Psychology (doctoral minor: Cultural Anthropology) from the University of Arizona (1965). Returning to school after nearly 30 years, he completed his MPH in International Health at Johns Hopkins University School of Hygiene and Public Health in 1993.

Weiss has had several "careers" over the past 45+ years. He began his academic career with appointments including the following: assistant professor, University of Arizona (1964–1967); assistant professor, Johns Hopkins University School of Medicine (1967–1970); associate professor and professor (adjunct), Uniformed Services University of the Health Sciences (1978–1993); and adjunct appointments at the Johns Hopkins University School of Hygiene and Public Health (1976–1998) and the NIH Graduate School (Foundation for Advanced Education in the Sciences) (1979–1994). During "intermissions" in his academic career, Weiss spent 5 years (1969–1974) with the US peace corps (including 2 years in the Ivory Coast in West Africa as director of Training for Africa) as deputy director to the Family Health International AIDS Control and Prevention Project (1991–1993) and nearly 20 years at NIH, directing the behavioral medicine program at the National Heart, Lung and Blood Institute (NHLBI: 1974–1991) and as senior advisor at the National Institute of Mental Health (1993). He joined the faculty of the University of Miami School of Medicine in late 1993 as professor in the Department of Psychiatry and Behavioral Sciences, serving as vice chair for research from 2002 to 2009.

Major Accomplishments

Throughout his career(s), Weiss has focused his professional and scientific energies on one principal issue: to better understand how biological, behavioral, and psychosocial factors *interact* in the etiology, treatment, and prevention of chronic illness.

The first 30 years were focused on cardiovascular health and disease. Beginning with his doctoral dissertation, "Psychological Adjustment Following Open Heart Surgery," he continued this work at Johns Hopkins University School of Medicine and subsequently at NHLBI. His program development mandate at NIH enabled him to advance the "biobehavioral" perspective in behavioral and biomedical science venues. For example, when he arrived at NIH (1974), there was *very* little biobehavioral research related to the prevention and control of chronic disease. Upon becoming acquainted with the NIH system of "peer review," it became obvious that one of the principal reasons for this concerned the *lack* of "peer review" for grant applications attempting to combine biological and behavioral perspectives. He demonstrated the need for a "Behavioral Medicine" study section to the senior officials responsible for grant review by screening over 7,000 grant applications from a single review cycle and identifying over 50 applications requiring both behavioral and biomedical review expertise. Established the following year (Joseph Matarazzo was the first Chair), the Behavioral Medicine study section soon proved its relevance to the NIH mission and was permanently chartered after a 3-year trial period.

During this same period, Weiss, with the active participation of a small group of similarly inclined "biobehaviorists" (e.g., Neal Miller, Joseph Matarazzo, Redford Williams, Neil Schneiderman, Gary Schwartz, Herbert Benson, Margaret Chesney, Thomas Coates, and Judith Rodin to name but a few), convened several conferences and workshops which stimulated the establishment of the fields of behavioral medicine (e.g., the Yale Conference on Behavioral Medicine; the Institute of Medicine/National Academy of Sciences Working Group on Behavioral Medicine) and health psychology (e.g., the Arden House Conference on Education and Training in Health Psychology).

These activities led to the formation and growth of several professional organizations (including the Society of Behavioral Medicine;

the Academy of Behavioral Medicine Research; the Division of Health Psychology of the American Psychological Association; the International Society of Behavioral Medicine). He served as President of each of these organizations and was instrumental in establishing new scientific journals representing these areas during his stewardship of these organizations (e.g., *Journal of Behavioral Medicine; Annals of Behavioral Medicine; Health Psychology; International Journal of Behavioral Medicine*).

Discussions between Weiss and David Hamburg, president of the Institute of Medicine of the National Academy of Sciences, in the late 1970s concerning the importance of the biobehavioral perspective in understanding the multifaceted, multilayered nature of chronic illness stimulated two major "health and behavior" efforts by the Institute of Medicine (IOM) to highlight the need for expanding NIH research efforts in this area. Two seminal volumes were published by the IOM Committee on Health and Behavior over a 20-year period synthesizing important scientific findings and providing direction for future research. Weiss served as consultant to this Committee, as well as being invited to provide testimony to several related IOM committees in the ensuing years.

During the 1980s, Weiss became active in international health scientific exchanges, participating as scientific liaison to the US-USSR Scientific Exchange in Cardiovascular Behavioral Medicine for over 10 years, and in a similar capacity with the US-Israel Scientific Exchanges on Hypertension and Coronary Heart Disease. He returned to the Johns Hopkins University School of Hygiene and Public Health to complete the MPH in International Health, a course of study that had important implications for his professional career direction. During this program, he became acutely aware of the growing catastrophe of the HIV/AIDS pandemic, particularly in the developing world. Based on this experience (and his newly minted MPH degree), he set out to explore what role he might play in challenging this public health disaster in Africa, where he had spent 2 years in the early 1970s working with the US peace corps.

Retiring from the NIH in 1991, Dr. Weiss began to search for a meaningful professional direction in HIV/AIDS. He spent 2 years with Family Health International and NIMH in HIV/AIDS administrative and program advisory capacities. Recognizing the major differences in the epidemics in the developed vs. developing worlds, he realized that new and unique approaches would be required to establish effective prevention strategies for HIV transmission. It took several years, however, before sufficient momentum was achieved in scientific circles to stimulate the NIH to establish an aggressive extramural research program in the search for new barriers to sexual transmission of the virus.

The advent of the female condom and growing interest in chemical barriers (microbicides) stimulated the need for a "critical mass" of research to answer important questions of safety, efficacy, acceptability, and effectiveness of these new sexual barrier products. Designation of HIV/AIDS as a "threat to our national security" by former President Clinton produced a "sea change" in the federal government's willingness to invest in international studies and demonstration projects to contain the epidemic in the developing world.

The critical need to develop *acceptable* barrier products for the varied populations at high risk of HIV infection suggested that biological efficacy must be coupled with product acceptability studies to ultimately demonstrate the effectiveness and impact of such strategies in containing the epidemic. He received NIH funding to address many of these issues in the USA, Africa, and India. In addition to being P.I. on two large-scale US trials of behavioral interventions with HIV+ women, over the last 16 years, he also has been funded to conduct several studies in Zambia with HIV+ and HIV− men, women, and couples and also to serve as PI, Co-PI, Protocol Co-Chair, and site investigator for an additional five studies on sexual risk reduction and medication adherence in Zambia, South Africa, and India.

Since settling in Miami nearly 20 years ago, Weiss has continued to lead an active professional life. Nonetheless, he still has made time for his passion for flying (commercial license, instrument, multiengine, with over 5,600 flight hours), as well as the occasional fishing trip on

his small boat. He has four grown children and nine growing grandchildren, whom he and his wife, Deborah, visit regularly, thanks to his aging, but trusty, Beech Bonanza. He has served as mentor to many junior faculty, residents, and fellows within the medical school through his "Grantsmanship 101" seminar and open invitations to join his research program. He has authored/coauthored over 120 papers, monographs, and scientific reviews, in addition to 10 edited volumes on health and behavior. He currently serves on the editorial boards of several scientific journals and health publications and regularly participates as a reviewer on NIH study sections.

When asked what the single most influential factor in his professional preparation was, Weiss answered with one word: *mentorship*. He attributes the guidance he received from strong mentors like Joe Matarazzo and Neal Miller, his psychologist role models during graduate training, as instrumental in preparing him for the many challenges he has faced in his varied, multifaceted professional journey.

Happiness; Health; Positive emotions; Welfare; Wellness

Definition

Well-being is a multi-faceted construct best described as a state of physical, psychological, and social health.

Description

Well-being is a broad term that encompasses what it means to be functioning as a healthy person across multiple domains. Although words like "well-being (WB)," "health," and "happiness" permeate scientific literature, they are frequently variably defined from one study to the next, with many researchers relying on a single construct, such as "happiness" or "high quality of life" to provide an adequate definition. Rather than constricting WB to one equivocal definition, a review of the literature suggests that it is most comprehensively defined and productively discussed as a combination of the following three components: psychological well-being (PsWB), social well-being (SWB), and physical well-being (PWB).

Psychological Well-Being (PsWB)

Psychological well-being (PsWB) and "happiness" have historically been synonymous and equally indefinite in literature across academic disciplines. Contemporary scientific definitions of PsWB, however, encompass three substantial, coherent domains: emotional experience, cognitive evaluation of life satisfaction, and human flourishing (e.g., Diener, Lucas, & Oishi, 2002; Keyes, Shmotkin, & Ryff, 2002). Although PsWB is frequently referred to as synonymous with Subjective WB (a cognitive evaluation of satisfaction with life), some models of PsWB consider cognitive evaluation a related yet distinct subcomponent of a larger construct of PsWB. Both models will be further discussed below.

Early in the study of emotion, Bradburn (1969) clarified that the absence of negative emotion does not indicate the presence of positive emotion; thus, experiencing both frequent positive emotion and infrequent negative emotion are essential to *feeling* "happy." Instruments to measure positive and negative emotion at both the short-term "state" and long-term "trait" level ask individuals to rate the degree to which they experience a range of emotions, varying in valence (e.g., happy vs. sad) and arousal (e.g., excitement vs. calm) and have led to valuable research on emotion. For example, Fredrickson's (2001) notable "Broaden and Build" theory states that positive emotions increase WB by broadening our cognitive range and building lasting resources that can be utilized in times of need. For example, when experiencing positive emotion, individuals are able to identify a wider range of activities they would like to engage in and are more likely to set and reach goals. Furthermore, the manipulation and natural expression of positive emotion in experimental settings has been shown to improve post-stress cardiovascular recovery, possibly resulting in protective effects against the negative physiological consequences of stress.

As outlined above, PsWB frequently involves and is debatably defined as a cognitive evaluation of satisfaction with life (for a review, see Diener, Suh, Lucas, & Smith, 1999) partnered with positive and negative emotion ratings. This model of PsWB is based on ratings of WB from the respondent's own perspective. For example, although an outside person may judge circumstances to be unfortunate, if a respondent reports high life satisfaction, he or she has high Subjective WB. Furthermore, this model assumes that this report has some amount of stability over time; however, reports can vary with momentary experience and events. Measures connecting these two evaluative components are associated with many positive outcomes, such as hope, optimism, and greater income. Interestingly, twin studies have revealed correlations between genes and PsWB, indicating a possible genetic influence on the "set point" for happiness. Since a variety of factors (e.g., genetics, culture, age, gender, emotional experience) can influence life satisfaction ratings, Diener and colleagues have suggested that "happiness" is best understood through a discussion of the factors that influence Subjective WB.

Ryff (1989) has differentially argued that PsWB includes happiness ("hedonic" WB, or the experience of pleasure) and "eudaimonic" WB. Eudaimonic WB is concerned with human flourishing and encompasses constructs related to engagement with and evaluation of challenging life events, including self-acceptance, purpose and meaning in life, sense of mastery over one's

environment, positive interpersonal relationships, personal growth, and autonomy. Proponents of this approach argue that this combination of factors provides a more complete picture of happiness, or "optimal" WB than emotional or cognitive/evaluative WB components alone and have found this optimal balance to increase with age, education, and the presence of certain personality characteristics (i.e., high extraversion and conscientiousness). While Ryff's work suggests that a comprehensive discussion of PsWB must consider the combination of factors that influence both Subjective WB and human flourishing more broadly, it is somewhat problematic when contemplating research questions attempting to determine the critical components of WB. For example, interpersonal relationships (a component of eudaimonic WB) may have independent pathways (e.g., neuroanatomy, hormonal) to PWB as compared to more emotional constructs within eudaimonia (e.g., autonomy, acceptance) whose paths may have more in common with hedonic measures. It seems important then to consider these subcomponents and their differential mechanisms separately in order to understand how PsWB "gets under the skin" to alter physical health.

Social Well-Being (SWB)

Humans are inherently social creatures who evolved in groups that helped ensure the survival of the species. As a result, there is a deeply engrained need to belong and feel supported. When these social needs are met, individuals experience SWB. There is no firmly agreed upon definition of SWB, but generally it can be considered to be a *multifactorial* construct that includes different components of the social environment that when evaluated together result in an overall positive assessment of one's social life. No single measure completely captures SWB, and as a result, many different types of social characteristics must be considered.

The most basic measures of the social environment are collected via integration measures that assess the extent to which people feel like they belong to their communities. This is typically measured by measures that enumerate important social roles (e.g., spouse, close friend). This work has a rich history dating back to the industrial revolution when Durkheim noted that individuals were more likely to commit suicide upon leaving their families for industrial positions in other cities. Since then, the finding that isolated individuals are at risk for detrimental health outcomes is one of the most pervasive and robust in health psychology. For example, an early study from Alameda County, CA (Berkman & Syme, 1979) revealed that those who lacked ties to others were up to three times more likely to die over a 9-year follow-up. Broader social networks (e.g., online networks of friends) are generally less strongly tied to WB since the presence of distant social contacts has less of an immediate and regular impact on one's life. What seems to be critical is the support and resources that your network provides. Related then is the concept of social support, or the perception that emotional and objective resources (e.g., information, tangible aid) are available if and when negative events occur. Research has indicated that those who report having support in times of need have lower physiological stress responses, better immune function, and overall better health and resilience to health problems, resulting in broad WB benefits.

Other work focuses more closely on the perception and quality of social ties. For example, loneliness is an indicator of low SWB but can be relatively independent from objective network size. The hallmark of loneliness is not being alone but the accompanying distress related to the *perception* of isolation. The relationships approach would state that SWB is present when an individual can have satisfactory close relationships and also shows evidence of secure attachment (i.e., a strong emotional bond between two people). If a romantic partner is missing or an individual is insecurely attached, then high SWB would not be expected. There are a number of other related constructs, such as feelings of love and intimacy, social acceptance, and measures of social conflict and hostility, that are also tied to positive and negative appraisals of WB. When considering these feelings and perceptions or relationships, it is critical to also consider

differences in social needs. For example, individuals high in extraversion will have greater needs for regular social contact than someone low on this personality trait. By definition, extraverts feel "better" when in the presence of social others and may therefore require greater interaction to achieve SWB as compared to their more introverted counterparts.

Finally, the social milieu contributes to SWB. Groups (e.g., clubs, volunteer groups, religious organizations) provide important feelings of belongingness, support, and contribution, which promote SWB. Those individuals who endorse group membership roles as well as those who report engaging in various social activities generally have higher WB. Beyond close groups, the broader environment also impacts SWB. Social capital describes the resources available to individuals through their membership in their community (e.g., civic associations, civic engagement, perceptions of trust and sharing in the community). Higher social capital leads to belonging, increased social participation, and has been tied to crime prevention and better societal health. This type of social engagement is critical for SWB as it likely has a trickle-down effect onto many of the previously discussed measures.

From the above examples, it is clear that SWB arises from a number of places. It is unlikely that any one characteristic uniquely predicts SWB. It is also important to consider the interaction between internal factors (e.g., attachment style, personality) and external characteristics of the social environment. Two individuals may live in the same social environment yet experience their social world in different manners, illustrating the importance of individual perception. Future research should consider which components are most critical to SWB and study more closely the interactions between different measurement types in terms of how they predict WB outcomes.

Physical Well-Being

Physical health researchers generally adhere to a medical model that conceptualizes health as the absence of disease, despite the definition in 1948 by the World Health Organization for health as "a state of complete physical, mental and social WB and *not* merely the absence of disease or infirmity." Physical well-being (PWB) then, is something more than "not sick" and may even reflect individuals realizing their fullest wellness potential, as echoed by the model of positive health by Seligman (2008). Compatible with the PWB model, the wellness continuum model (Sheridan & Radmacher, 1992) anchors one end of their model by disease, disability, and death and the other end by optimal human functioning where a person is maximally healthy, has resources for resisting disease, and is capable of experiencing joy (Sheridan & Radmacher, 2003). If the medical model idea of health were captured in the continuum model, it would end at the neutral/zero point with no room or definition of WB beyond "disease-absent." Despite multiple models suggesting that there is something beyond the absence of illness, health is still primarily measured by the presence or absence of symptoms, illness and disease, physiological markers, and reports of physical health typically topping off at "I feel very healthy." Reports of positive physical functioning beyond this "zero" mark are not typically gathered by health practitioners or researchers.

To determine *objective* wellness, researchers and practitioners frequently rely on assessments of biomarkers to determine disease status and risk. These might include factors like immune function, endocrine hormones, or cardiovascular function, which are important indicators of disease status. While there are general guidelines about what levels indicate "healthy" functioning, these are not frequently tied to current WB. For example, someone may be hypertensive as assessed by blood pressure readings, be a genetic carrier of a serious disease, or even have a blocked artery, but still report feeling healthy and asymptomatic. Furthermore, while biological markers are *possible* correlates of physical health, conclusive statements often cannot be drawn based on physiological measures alone (e.g., lowered immune cell counts). This raises the importance of *subjective* assessments of health when considering PWB.

Self-rated health (SRH), a formalized measure of subjective health, has been used in research

studies and suggests that individuals have insight into their health beyond the capabilities of biological measurement tools. Specifically, the commonly used Short-Form Health Survey (SF-36; Ware & Sherbourne, 1992) asks questions such as, "In general, would you say your health is excellent, very good, fair, or poor?" Several of these questions take into account individual perspectives concerning what "health" means to the individual, and even ask for reports comparative to the past. Additionally, questions such as "Have you felt calm/peaceful/full of pep/happy?" are tapping physical health via constructs that influence reports of PWB but are not direct physical measures. Interestingly, poor SRH is independently associated with increased mortality in diverse socioeconomic groups, age groups, in men and women, over time, even after accounting for objective health status at baseline (e.g., Lekander, Elofsson, Neve, Hansson, & Unden, 2004). Researchers are now investigating whether these nonspecific "sickness" symptoms (weakness, listlessness, decreased motivation) are mediated by stress-induced dysfunctional immune patterns (e.g., high inflammation). Given that positive traits and events are tied to healthy immune function (for further reading, see Pressman & Cohen, 2005), it is plausible that positive reports of SRH are occurring via generalized positive feelings that alter the perception of the body and that these positive feelings are representative of an objectively healthy physiology. At this point, the full mapping of these connections with SRH, biomarkers, emotion, and objective longitudinal health outcomes has not been done.

Problematic in definitions based on biomarkers and disease indicators is determining whether individuals suffering from chronic illness can have high PWB. Based on biological assessment, if an individual is diagnosed with cancer, they have low PWB. However, cancer patients frequently survive their cancer, find benefit in the experience of their illness, build relationships with others, and become optimistic about their future. During treatment, they will clearly experience poor PWB (e.g., side effects of radiation or chemotherapy); however, at some point, they will begin to recover. Self-report measures of PWB may be able to track this based on changes in perceptions of symptoms and health; however, biological measures may be more deficient at determining at what point the person's PWB is on the positive end of the spectrum (i.e., it is unlikely that PWB can be measured by a simple assessment of circulating cancer cells). To truly understand WB in this population and many others, it is clear that there is a need for PWB tools that assess both "harder" biological outcomes partnered with "softer" self-report measures.

Conclusions and Future Directions

Although themes of happiness, physical health, and social involvement have long been studied in philosophy, social psychology theory, and cultural analysis, it has only been in the last 10 years that WB has seen an upswing in interdisciplinary scientific study. Because of this, the scientific community is still working on definitions and operationalizations of critical constructs in the field. Currently, significant overlap exists between WB measures making it difficult to separate and understand these constructs. For example, individuals with serious illness by definition have poor PWB, but it is also likely that PsWB and SWB additionally suffer since illness will block engagement in activities that promote these WB types. Similarly, current measures of depression and loneliness frequently include questions tapping *both* PsWB and SWB revealing the extent to which these constructs overlap. Measures need to be improved to reflect the specific underlying components of WB in order to better understand the unique ways that these different WBs impact one another as well as outside outcomes. Finally, it is also critical to consider that in many cases, there is benefit to the overlap of these constructs. When considering interventions to improve PWB, it is frequently via SWB (e.g., support) and PsWB (e.g., relaxation) that impressive improvements are seen, ranging from physiological alterations to increased life span. There is clearly therapeutic value to considering

ALL types of WB and the interrelations that they have with one another. A thorough understanding of the underlying constructs of WB will enable scientists, health professionals, and individuals of all walks of life to better promote and increase WB at multiple levels, with implications for both personal health and public policy decisions.

Whitehall Study

Mark Hamer
Epidemiology and Public Health, Division of Population Health, University College London, London, UK

Definition

The original Whitehall study of British civil servants began in 1967 and showed a steep inverse

association between social class, as assessed by grade of employment, and mortality from a wide range of diseases. The Whitehall II study was later established in 1985 to identify causal pathways linking socioeconomic position to pathophysiological changes and clinical disease. The Whitehall II is an ongoing prospective cohort study of 10,308 British white-collar workers employed in the civil service (Marmot et al., 1991). The study is primarily interested in the pathways explaining social inequalities via characteristics of the work environment, such as job strain, and health-related behaviors including physical activity, smoking, and diet. Data are collected at regular intervals through a combination of self-administered questionnaires and clinical examination. In the 20 years separating the two studies, there has been no diminution in social class difference in morbidity: there remains an inverse association between employment grade and prevalence of common diseases such as heart disease, cancer, and respiratory diseases. Self-perceived health status and symptoms are worse in participants from lower-status jobs. There are also clear employment-grade differences in health-risk behaviors including smoking, diet, and exercise, in economic circumstances, in possible effects of early-life environment as reflected by height, in social circumstances at work (e.g., monotonous work characterized by low control and low satisfaction), and in social supports. These key findings appear to partly explain the social disparities in health (Stringhini et al., 2010). The Whitehall II study currently has available data for nearly 30 years of follow-up, and many of the participants are now in their seventh and eighth decades of life. Thus, the focus of the study is gradually shifting toward aging since many of the participants are now retired from full-time employment.

Social position can be viewed as an indicator of chronic lifetime stress exposure since people of lower social status tend to experience adverse psychosocial factors including greater financial strain, lower control at work, chronic neighborhood and domestic stresses, and more limited social networks. The Whitehall psychobiology studies have been conducted in healthy subsamples ($N = 250–500$) of the main study cohort, in 2001 and 2006, and were specifically undertaken to examine the biological processes that might explain the association between psychosocial stress and coronary heart disease (Hamer, O'Donnell, Lahiri, & Steptoe, 2010; Steptoe et al., 2002). In these studies, healthy men and women from the Whitehall II cohort (stratified by grade of employment as a marker of social status) underwent psychophysiological stress testing involving measurement of cardiovascular and biological responses to laboratory-induced mental stressors. Results suggested that lower social status individuals were characterized not so much by heightened cardiovascular responsiveness, but by impaired poststress recovery, or sustained activation after termination of stressors. Results from the most recent study have suggested that stress responsivity is also associated with subclinical coronary atherosclerosis. Population-based psychophysiological studies with detailed biological measures have contributed to a better understanding about stress and disease pathways.

Definition

Williams LifeSkills is a protocol-driven manualized training program that aims to improve stress coping and interpersonal relationship skills. It focuses on acquiring ten skills in two categories: (1) six skills for handling problematic situations: logkeeping, think before you act to decide between action and deflection, deflection, problem solving, assertion, and saying no; and (2) four skills for improving relationships with others and oneself: speaking, listening, empathy, and increasing positives over negatives. The program has been evaluated in several clinical trials, with resulting evidence of its efficacy on psychosocial and biological markers. There are several delivery options. The initial standard was face-to-face workshops of 5–12 participants, with a trained facilitator. The video version consists of a 70-minute video covering the ten skills, with an accompanying workbook; this video/workshop can be incorporated into a workshop or used as a stand-alone intervention, with or without telephone coaching by a trained facilitator. There is also an online version, either freestanding or with submission of exercises. One-on-one coaching is another option. The initial program has been expanded to include a number of specialized versions that maintain focus on the ten skills: for caregivers with a relative with Alzheimer's, teens delivered by high school teachers, a specialized teen version for incarcerated youths, pastors who otherwise are usually supporting others, and heart patients.

Description

The Williams LifeSkills copyrighted program evolved over the last two decades as a means of translating research by Redford Williams and others (Williams, 2008) that has documented the health-damaging effects of psychosocial factors like hostility/anger, depression, social isolation, job stress, and stressful life situations into a behavioral intervention that can reduce levels, and hopefully the health-damaging effects, of these psychosocial risk factors. Williams LifeSkills, Inc., was founded as a commercial entity in 1996 by Redford and Virginia Williams with the goals of developing and refining this behavioral intervention, doing research to test its efficacy and effectiveness in both controlled and observational clinical trials, and marketing behavioral intervention products shown to work in this research. The founders of Williams LifeSkills have written three books for a lay audience that also serve to describe the program as it evolved (Williams & Williams, 1993, 1997, 2006). While the programs are presented as wellness training for increasing participants' effectiveness in the increasingly stress-filled modern world, they also provide a first-level intervention for individuals with mild to moderate anxiety,

depression, and hostility. The intervention has also been used with outpatients with a wide variety of diagnoses, both to help them cope with their illness and to reduce distress over other issues in their lives.

The face-to-face workshop has been used extensively in the United States, Brazil, Singapore, Hungary, and China. Intervention groups are quite varied in these varied settings: some examples are general stress management, patients with oncological problems, medical students, college students; heart patients, corporations, pastors, and health professionals. It also has been incorporated into a general intervention for heart patients in Germany. Facilitators are initially trained for at least five days, spending the first two days as participants and the last three focusing on practicing supervision of the interactive sections of the program. There is an accompanying participant text (about 40 pages long) and a workbook (about 15 pages long), so the text can either be given to a participant or used again. Participants begin by learning to write up log entries, emphasizing the objective facts, their thoughts and feelings, behaviors, and consequences. They then apply their own examples to practice the other skills. The program thus involves iteration without repetition, since new layers of training are being added. Facilitators are trained to encourage participation, within a set of ground rules, and to emphasize improvement through practice, rather than aiming for perfection. The entire program is designed to fit together, with algorithms to address which skills to apply. As a result, the program can be used in almost any situation a participant might face.

The generic LifeSkills program has also been adapted for specific groups. The LifeSkills course for caregivers focuses on a special video created to address problems particular to caring for someone with a disabling memory disorder. A 121-page workbook accompanies the video. Also part of the program is a manual for five sessions of telephone coaching by a LifeSkills facilitator. All of the materials are oriented to the ten LifeSkills. There is an adaptation for teens in which the emphasis is on issues faced by teens. There is an extensive Facilitator's Manual for high school teachers, which is incorporated into the week-long training that prepares them to deliver the training to students in the high school setting. Teens can either report a personal log entry or draw a role-playing card. Separate packets of cards accompany each skill. Teens have a special text and workbook. The teen program has been modified for incarcerated teens. The same general format is used as in the school program, but the role-playing cards are different. Some of the illustrations and workbook examples also are modified. In the United States, prison educators are trained to be the facilitators. In China, the program is being tested, using psychiatrists and psychologists as facilitators. The program for medical personnel has assumed different forms in the United States, Hungary, and China. The program for heart patients also has assumed different forms in the United States and Singapore (also adapted a number of clinical trials have documented the efficacy of the LifeSkills program in its various forms in the United States and Canada). The first study to document benefits of an early version – based on *Anger Kills* (Williams & Williams, 1993) – of the LifeSkills workshop was a small randomized controlled trial (RCT) in males following a heart attack. Results showed that hostility after the end of training as assessed by both structured interview and questionnaire as well as resting diastolic blood pressure were reduced significantly more in patients in the active arm than those randomized to usual care (Gidron, Davidson, & Bata, 1999). Both these improvements were maintained or enhanced at follow-up two months later. Because this study was conducted in Canada, it was possible to do a follow-up assessment of the clinical course over the six months post-training. Compared to usual care, men in the active arm showed significant reductions in both hospital stay and medical care costs over the six months follow-up (Davidson, Gidron, Mostofsky, & Trudeau, 2007). Another RCT evaluating benefits of the LifeSkills video found significantly larger reductions in both trait anxiety and perceived stress among the active arm participants compared to those randomized to wait list control, both two weeks after the end of training and

after six months follow-up (Kirby, Williams, Hocking, Lane, & Williams, 2006). In an RCT evaluating the LifeSkills workshop augmented by the LifeSkills video, hypertensive employees of a large urban medical center who were randomized to LifeSkills training showed significantly larger, clinically significant decreases in systolic blood pressure compared to those receiving usual care according to JNC-7 guidelines (Clemow, Pickering, Davidson, & Liriano, 2009). A controlled (alternating assignment to active vs. wait list arms), clinical trial of the LifeSkills video adapted for use by caregivers of a relative with Alzheimer's disease showed that those in the LifeSkills for Caregivers video arm, who also received weekly telephone coaching calls, showed significantly larger decreases in depressive symptoms, trait anxiety, perceived stress, and systolic and diastolic blood pressure that were maintained or enhanced at 6 months follow-up (Williams et al., 2010). In addition to replicating findings of psychosocial improvement following LifeSkills training, this study extends the demonstration of benefits to include a potential biological mechanism whereby stress damages health – higher blood pressure.

The LifeSkills program has also been adapted for use in Singapore and Hungary. In Singapore, Bishop, Kaur, and Tan (2005) conducted a RCT of the LifeSkills workshop in a sample of 59 male Singaporean (60% Chinese) patients following coronary bypass surgery. In addition to robust improvements with regard to both negative and positive psychosocial risk factors, blood pressure and heart rate at both rest and in response to anger recall were significantly decreased in the men randomized to LifeSkills workshop training, with all improvements maintained or enhanced at three months follow-up. Effect sizes for these psychosocial and cardiovascular improvements in the LifeSkills workshop arm were moderate to large. In Hungary, an observational trial of the LifeSkills workshop by Stauder et al. (2010) found that distressed persons in the Budapest metro area who participated in the workshop showed a pattern of psychosocial improvements that is remarkably similar to those observed by Bishop et al. (2005) on the other side of the world. Effect sizes in Hungary were similarly moderate to large. Dr. Stauder and colleagues at Semmelweis University in Budapest are now conducting RCTs of the LifeSkills workshop in workplace settings in Hungary.

Evidence for the effectiveness of Williams LifeSkills products in real-world settings comes from two observational trials. In one, conducted by Campo et al. (2008), second-year medical students who participated in the WLSR workshop over a two-day period showed significant reductions in hostility and in the use of placating and avoidant responses in difficult patient scenarios following the training. In contrast, a comparison group of second-year students the following year who did not receive WLSR training showed slight increases in both hostility and placating and avoidant responses. In an observational trial of the LifeSkills workshop among employees of one of our corporate clients, at the end of training, there were significant decreases in depressive symptoms and state and trait anxiety and increased social support; except for social support, all these improvements were maintained or enhanced at follow-up six months later (Williams, Brenner, Helms, & Williams, 2009).

The LifeSkills reach continues to expand, since the skills acquired contribute to resiliency and hence can be applied in situations where potential high stress needs to be inoculated against.

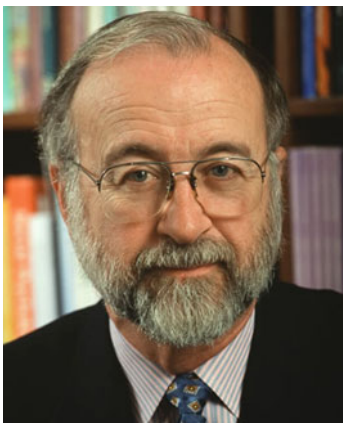
Redford B. Williams
Department of Psychiatry and Behavioral Sciences, Division of Behavioral Medicine, Duke University, Durham, NC, USA

Biographical Information



Redford B. Williams, Jr., was born in Raleigh, NC, on December 14, 1940. Following graduation from Northampton High School in Eastville, Virginia, in June 1959, he entered Harvard College, receiving his A.B. degree in 1963. He married Virginia Carter Parrott in 1963, and they have two children and three grandchildren. Williams received his M.D. degree from Yale in 1967, where he completed his internship and residency in internal medicine in 1970. Following 2 years as a clinical associate at NIMH in Bethesda, MD, he was appointed assistant professor in the Departments of Psychiatry and Medicine at Duke University Medical Center, Durham, NC, in 1972, advancing to the rank of professor in 1978. Since 1985, he has been director of the Behavioral Medicine Research Center at Duke. He was named Head, Division of Behavioral Medicine in the Department of Psychiatry and Behavioral Sciences at Duke in 1990. In 1991, he was appointed professor of Psychology at Duke and adjunct professor of Epidemiology in

the School of Public Health at the University of North Carolina, Chapel Hill. He has served on several Medical Center committees over the years, including the Awards Committee (Chair), the Conflict of Interest Committee, and the Department of Psychiatry and Behavioral Sciences Appointments, Promotion, and Tenure Committee. Williams has been continuously funded by the NIH since receiving a Research Scientist Development Award from NIMH in 1974; he has been principal investigator on a program project grant from the NHLBI that began in 1986, continuing till April, 2015. In 1996, he collaborated with Virginia Parrott Williams to found Williams LifeSkills, Inc., a company with the mission of developing, testing, and marketing behavioral intervention products aimed at reducing the health-damaging effects of psychosocial risk factors such as hostility, depression, and social isolation. Williams has served as the president of the leading scientific societies in the field of psychosomatic/behavioral medicine, including the Society of Behavioral Medicine (1983–1984), the American Psychosomatic Society (1992–1993), the Academy of Behavioral Medicine Research (1995–1996), and the International Society of Behavioral Medicine (2006–2008). He was the inaugural recipient of the Society of Behavioral Medicine's Distinguished Scientist Award (1992). Williams is grateful for the mentorship he has received from George Goethals, Stan King, and John Spiegel at Harvard; Pat McKegney and Mickey Willard at Yale; Irv Kopin and Lyman Wynne at NIMH; Bud Busse and Saul Schanberg at Duke; and numerous colleagues and students at each step along the way over the years.

Major Accomplishments

Beginning with publication of two papers in 1965–1967 reporting effects of interview variables on blood pressure reactivity that were found in his research as a medical student at Yale, Williams has been continuously engaged in research aimed at identifying psychosocial factors that increase risk of cardiovascular disease and the biobehavioral mechanisms that mediate that risk. In the mid-1970s, following training in the assessment of type A behavior by Ray Rosenman and Meyer Friedman, Williams began a still ongoing project that initially pinpointed hostility as the toxic core of the type A behavior pattern. Working over the ensuing years with his Duke psychiatry and cardiology colleagues, Williams has made important contributions to our understanding of the role played by psychosocial factors such as hostility, depression, social isolation, and low socioeconomic status in the pathogenesis and course of cardiovascular disease, as well as the role of mediators such as increased sympathetic and HPA axis function, decreased parasympathetic function, and unhealthy lifestyle behaviors.

In the mid-1980s, Williams began the process of translating research findings on the health-damaging effects of psychosocial risk factors into behavioral interventions to prevent and/or ameliorate those effects. He has collaborated with his spouse of 48 years, Virginia Parrott Williams, to develop the Williams LifeSkills coping skills training program and evaluate its effects on psychosocial risk factors and biobehavioral mechanisms. Published clinical trials have documented a broad range of benefits of this program: decreased levels of hostility, anger, depression, anxiety, and perceived stress; decreased levels of blood pressure and heart rate at rest and during lab challenge; and increased levels of satisfaction with social support and satisfaction with life. These benefits persist over 6 months after the end of training and have been observed in distressed groups like patients following coronary artery bypass surgery and caregivers of a relative with Alzheimer's disease and in diverse cultural settings ranging from the USA to Singapore, to China, and to Hungary.

Beginning in the late 1990s, Williams has extended the focus of his research to include a search for genetic variants that increase one's vulnerability to the effects of environmental stressors on psychosocial risk factors and biobehavioral mechanisms. Based on his hypothesis that dysregulated central nervous system, serotonin plays an important role in the clustering of

psychosocial and biobehavioral risk factors in certain individuals; this work focused initially on genes that regulate serotonin functions. A typical finding emerging in this ongoing work is an association between the more functional long allele of the serotonin promoter 5HTTLPR polymorphism and increased cardiovascular reactivity to acute mental stress, suggesting that the long allele will be associated with increased risk of coronary heart disease – a prediction that has been confirmed in three independent case-control studies in Asia and Europe. Williams and his colleagues at Duke and elsewhere are currently working to test the hypothesis that genetic variants found associated – whether directly or via gene x environment interactions – with predisease endophenotypes such as increased neuroendocrine, sympathetic nervous system, and cardiovascular reactivity to stress, and increased expression of the metabolic syndrome are also associated with incidence of cardiovascular disease and/or type 2 diabetes in large cohorts of both healthy persons and persons with coronary heart disease.

Another important contribution over the years has been Williams' mentoring of students and postdoctoral fellows who have gone on to make their own important contributions to the field of behavioral medicine: Norman Anderson, Gary Bennett, James Blumenthal, Beverly Brummett, Shin Fukudo, Jim Lane, Linda Luecken, Marcellus Merritt, Len Poon, and Ed Suarez.

Women's Health

Michael O'Hara
Department of Psychology, University of Iowa, Iowa City, IA, USA

Synonyms

Women's cardiovascular health; Women's mental health; Women's reproductive health; Women's well-being

Definition

A recent Institute of Medicine committee approached women's health as a concept that has expanded beyond the reproductive system and includes "... health conditions that are specific to women, are more common or more serious in women, have distinct causes or manifestations in women, have different outcomes or treatments in women, or have high morbidity or mortality in women (pp. 2–3)"

(Institute of Medicine [IOM], 2010). Examples of these conditions include breast cancer, cardiovascular disease, cervical cancer, depression, HIV/AIDS, and osteoporosis, among others.

Description

History

Historically, women's health referred to women's reproductive health – the menstrual cycle, ▶ pregnancy, labor, delivery, and ▶ menopause. It is only in the past three decades that women's health has been understood to include the full complement of women's health concerns. For example, it was common for women of reproductive potential to be excluded from clinical trials because of the possibility of unknown teratogenic effects of the medication under study. In fact, in 1977, the FDA restricted women of childbearing potential from being in clinical trials. This policy was only reversed in 1993. Moreover, it was assumed that results of clinical trials with men could be extrapolated to women. This was an untested assumption that is now known to be untrue. Additionally, investigators were concerned that the hormonal fluctuations associated with the menstrual cycle would influence study findings in unknown ways. For all of these reasons, the great bulk of health research until recently has either excluded women or included them in small numbers or has not analyzed the data for sex differences. These deficiencies are slowly being remedied.

There have been a number of important milestones in women's health. For example, the publication of *Our Bodies, Ourselves* in 1970 by the Boston Women's Health Book Collective was a landmark event in women advocating for women's health. This organization and its work continue today. It argues that it has brought several key ideas into the public discourse on women's health (Our Bodies Ourselves [OBOS], 2011).

- "That women, as informed health consumers, are catalysts for social change
- That women can become their own health experts, particularly through discussing issues of health and sexuality with each other
- That health consumers have a right to know about controversies surrounding medical practices and about where consensus among medical experts may be forming
- That women comprise the largest segment of health workers, health consumers, and health decision-makers for their families and communities, but are underrepresented in positions of influence and policy making
- That a pathology/disease approach to normal life events (birthing, menopause, aging, death) is not an effective way in which to consider health or structure a health system"

Change in traditional concepts of women's health did not occur quickly, and it was not until 1980s that clear recognition of the importance of a women's health perspective came into focus. In the forward to a seminal 1985 Public Health Service Task Force report on women's health, Edward Brandt, assistant secretary for health said "This report does not focus strictly on the diseases and problems unique to women in the traditional sense, that is, reproductive problems, but rather is devoted to assessing the problems of women's health, in the context of the lives women in America lead today (p. 74)." Going on the report states: "Good health requires a safe and healthful physical and social environment, an adequate income, safe housing, good nutrition, access to preventive and treatment services appropriate to the persons to be served, and a population that is educated and motivated to maintain healthful behaviors" (p. 77).

In 1990, the Congressional Caucus for Women's Issues (CCWI) pushed through legislation entitled the Women's Health Equity Act. This act created the Office for Women's Health Research at the NIH. It also created a gynecology research program and a Center for Women's Health Research at the NIH. Finally, it required the NIH director to report on progress on women's health and research and that a database be developed of research on women's health and to require the inclusion of women and minorities in NIH trials. The authors of the bill pointed to the then recent Harvard study of 22,000 men (and no women), which demonstrated that daily aspirin could prevent heart attacks as a case of blatant

discrimination against women. The CCWI continued to be very active in subsequent congressional sessions in pushing through many additional laws aimed at improving women's health and including women in biomedical research.

Subsequent to the to the Women's Health Equity Act, there has been a great deal of legislation that bears on improving women's health through improved services and research. Most recently, the Patient Protection and Affordable Care Act (Public Law 111–148) formally codified the Office of Women's Health Research at the NIH, and it formally established an Office of Women's Health in the director's office of the Agency for Health Care Research and Quality (AHRQ), Centers for Disease Control and Prevention (CDC), Food and Drug Administration (FDA), Health Resources and Services Administration (HRSA), and Substance Abuse and Mental Health Services Administration (SAMSA). Additionally, it also established a Department of Health and Human Services Coordinating Committee on Women's Health and a National Women's Health Information Center.

Advocacy Matters: The Example of Breast Cancer

Until the 1970s, there was very little public discussion of breast cancer. Often, it was a cause of shame in families. There were several important landmarks in the 1970s that set the stage for the current strong advocacy around breast cancer prevention and treatment. Already mentioned, *Our Body, Ourselves*, helped set the stage for women taking control of their health. In 1974, the first lady, Betty Ford, was diagnosed with breast cancer. She spoke about her experiences in public, and this encouraged others to do the same. At about the time, Rose Kushner, a journalist, was diagnosed with breast cancer. She objected to the then common practice in which a tumor biopsy and radical mastectomy were performed in a single surgical operation while the patient was under anesthesia. Instead she insisted on a two-step procedure in which biopsies and surgery were undertaken as separate procedures, allowing a woman time to consider her options. This was very unpopular with the medical establishment. However, through persistent advocacy, her efforts resulted in a 1977 NIH panel (of which she was a member), concluding that the two-step procedure that she recommended should be adopted, and that in primary breast cancer, the standard treatment should be a total simple mastectomy rather than the more common radical mastectomy.

The first major advocacy organization was the Susan G. Komen Breast Cancer Foundation in 1982. The work of the Foundation has been described as priming the market (step 1), which means drawing attention to breast cancer through personal stories and by communicating the impact of breast cancer in stark and concrete terms (Braun, 2003). Important in this effort was portraying that there was hope in the form of prevention and effective treatment. In a related manner, efforts were made to engage consumers (step 2) by sponsoring activities, such as the "Race for the Cure" established in 1983. These activities brought positive media attention and raised money for further advocacy. Political action (step 3) in 1980s and 1990s led to a number of legislative, regulatory, and funding accomplishments, for example, the army took on the task of breast cancer research; the Breast and Cervical Cancer Early Detection Program was established; and federal funding for breast cancer research increased fivefold in the 1990s. Currently, over $700,000,000 dollars in federal funds is allocated to breast cancer research each year. The final step in breast cancer advocacy is that the movement has gone mainstream (step 4). There is little question that breast cancer is firmly entrenched in the American consciousness. The ubiquitous pink ribbons and strong support for breast cancer research in the congress and the strong corporate support and the continuing proliferation of strong national and local advocacy groups speak to the effectiveness of breast cancer advocacy by women over the past 30 years.

Progress in Women's Health Research

In 2010, the Institute of Medicine released a report entitled *Women's Health Research: Progress,*

Pitfalls, and Priorities. The committee considered some select diseases of importance to women and characterized the nature of progress that has been made in prevention and treatment. Breast cancer, cervical cancer, and cardiovascular disease are conditions on which research has contributed to major progress. For example, the age-adjusted mortality from invasive breast cancer dropped from 33.1 per 100,000 women in 1990 to 22.8 per 100,000 in 2007 due to increased screening and improved adjuvant therapies. Despite these gains, the incidence of breast cancer is higher today than in 1975. However, there has been a significant decrease in estrogen-positive breast cancers since 2002, probably because of the large decline in hormone replacement therapy for menopause.

HIV/AIDS is an example of a condition in which scientific research has led to some progress in women's health despite the early heavy research emphasis on men. The proportion of AIDS cases represented by women has been increasing steadily since 1985, and women now represent about 27% of cases. Like the case for men, prevention entails decreasing high-risk sexual behavior. However, women suffer from their own high-risk sexual behavior as well as that of their partner, which makes prevention more challenging. Antiretroviral therapy has made a tremendous impact for women (as well as men). However, women seem to be less tolerant of the side effects of these therapies, and treatment toxicity remains a significant problem for women suffering from HIV/AIDs. Treatment and side effects for pregnant women and the offspring can also be problematic.

Autoimmune disorders as a group are common (third only to ▶ cardiovascular disease and cancer). Examples of autoimmune disorders include ▶ diabetes, thyroid disease, Graves' disease, lupus, rheumatoid arthritis, and multiple sclerosis. They affect 5–8% of population, but over 78% of those affected are women. Advances in knowledge have occurred over the past 20 years, but these advances have not led to treatment advances beyond the treatment of symptoms. These disorders do not have the mortality associated with cardiovascular disease and cancer, but they are associated with significant morbidity and reduced quality of life.

Women's Mental Health

Mental health problems represent a significant burden for women. For example, globally, among women aged 15–44 years, unipolar depressive disorders are the second leading cause of disability (measured in disability-adjusted life years) after HIV/AIDS. Moreover, schizophrenia, bipolar affective disorder, suicide attempts, and ▶ panic disorder are in the top 15 conditions causing disability in young women. Depressive and anxiety disorders are much more common in women than men – for depression, the ratio is approximately 2 to 1 around the world. These disorders are found in all societies, not just the societies in the developed nations. In addition to the suffering experienced by women due to mental health problems, there is a large and increasing literature linking maternal mental health problems to behavioral and mental health problems in the offspring. Effective pharmacological and psychotherapeutic interventions exist for depressive and anxiety disorders. Nevertheless, women often go untreated in part because of lack of access but also because the women's depressive and anxiety disorders are often undetected in primary care settings such as prenatal and postnatal health care and routine gynecological care. Major initiatives are underway to develop more effective methods of detecting ▶ depression and anxiety among women and primary care and to provide more efficacious and accessible treatment for these women.

Women's Health Initiative (WHI)

Jonathan Newman
Columbia University, New York, NY, USA

Definition

The Women's Health Initiative (WHI) is a long-term, domestic health study that has focused on preventing heart disease, colorectal cancer, and osteoporotic fractures in post-menopausal women, all of which are major causes of death and disability in older women.

Description

The WHI is a multimillion-dollar study sponsored by the National Institutes of Health (NIH) and the National Heart, Lung, and Blood Institute, involving 161,308 women aged 50–79. The study has two major parts: a set of randomized clinical trials and an observational component. The WHI clinical trials (CT) include three overlapping components: the hormone therapy (HT) trials, dietary modification (DM) trials, and the calcium and vitamin D (CaD) trial. Each trial is a randomized comparison among post-menopausal women, age 50–79 at enrollment, who could be randomized into one, two, or three of the CT trials. Women who declined or were unable to participate were invited to participate in the observational study (OS), including 93,976 participants.

The HT trial is one of the most noteworthy within the WHI, and it consists of two separate trials, one for women who were post-hysterectomy at the time randomization (estrogen-alone trial) and one for women with a uterus (estrogen plus progestin trial). Both the hormone therapy trials and the CaD trial had a 1:1 double-blinded, placebo-controlled randomization, while the DM trial randomized 40% of women to a sustained low-fat diet and 60% to self-selected dietary behavior.

After 5.6 years of follow-up, the estrogen plus progestin (E+P) trial was stopped in 2002 because of increased risks of cardiovascular disease and breast cancer among women randomized to active treatment. While at a lower risk for colon cancer and fracture, women on estrogen and progestin had a higher risk of heart disease, stroke, blood clots, and certain types of breast cancer. After stopping the E+P trial, the WHI continued to follow up the women involved. Three years after stopping hormone therapy with estrogen and progestin, the women no longer had an increased risk of cardiovascular disease nor a lower risk of colon cancer compared to women who were randomized to placebo. Further follow-up revealed a nearly twofold increase in the incidence of breast cancer among women who had taken this hormone combination for 5 or more years. However, once estrogen and progestin hormone therapy was stopped, the risk of breast cancer decreased significantly,

independent of rates of mammography in the population as a whole during this time.

The estrogen-alone trial was stopped in 2004 after 6.8 years of follow-up. It was found that estrogen alone did not affect the risk of heart disease; however, the risk of stroke was increased by 12 cases per 10,000 women taking estrogen alone and tended to increase the incidence of deep vein thrombosis as well. Similar to the results of the E+P HT trial, estrogen alone decreased the occurrence of both hip and total bone fractures. Colorectal cancer rates were unaffected, and there was a small suggestion of a reduction in breast cancer incidence. In a follow-up study, there was an indication that estrogen alone might decrease the amount of coronary artery calcium, a useful subclinical marker of atherosclerotic risk. Taking into account all the diseases studied during the estrogen-alone trial, the WHI investigators concluded that estrogen should not be used to prevent heart disease specifically, nor chronic diseases overall in postmenopausal women without a uterus.

The DM trials, while largely negative in terms of the effects of fat and caloric restriction on either breast or colorectal cancer in postmenopausal women, did suggest that reductions in saturated and trans fat, along with higher intakes of fruit and vegetables, may have a protective effect on the incidence of cardiovascular disease in these women. The separate CaD trials, while failing to show a protective effect of calcium and vitamin D on the occurrence of hip fracture in all postmenopausal women, did find a protective effect on the occurrence of hip fractures in women over the age of 60. The WHI trialists have recognized that the dose of calcium and vitamin D may have been insufficient to prevent hip fractures and may have contributed to the largely negative findings of this trial. Further, in the CaD trial, there were no beneficial effects of calcium and vitamin D on the occurrence of colon cancer. However, there were small (1%) but significant protective effects on maintenance of bone mineral density seen in women taking calcium plus vitamin D supplements.

Work, Lipids, and Fibrinogen (WOLF) Study

William Whang
Division of Cardiology, Columbia University Medical Center, New York, NY, USA

Definition

The WOLF study is a prospective cohort study that was started to analyze the role of adverse occupational conditions in cardiovascular risk and disease development in employed Swedish men and women. Occupational health units carried out baseline screening of employees from approximately 60 companies from 1992 to 1998, including a clinical exam and blood samples. The initial study of 10,382 subjects from WOLF found no associations between job strain and serum total cholesterol and plasma fibrinogen (Alfredsson et al., 2002). Additional studies have examined relationships between cardiac risk and leisure time (Fransson, Alfredsson, de Faire, Knutsson, & Westerholm, 2003) and managerial leadership behaviors (Nyberg et al., 2009).

Working Memory

David Pearson
School of Psychology, University of Aberdeen, Aberdeen, UK

Definition

The term “working memory” describes temporary memory systems involved in tasks such as reasoning, learning, and understanding. Examples of everyday tasks that rely on working memory include performing mental arithmetic or

remembering a shopping list. While linked to the concept of short-term memory (STM), theories of working memory place greater emphasis on simultaneous storage and processing of information. Memory systems responsible for STM can be regarded as forming part of an overall working memory system. Working memory not only temporarily stores information but also manipulates it during complex cognitive activities. Theories of working memory are highly influential in the fields of cognitive psychology, neuroscience, and behavioral medicine.

Description

An influential model of working memory is the multicomponent approach first proposed by Baddeley and Hitch in 1974. The original model was tripartite in nature and comprised three separate, limited-capacity components: the phonological loop, the visuospatial sketchpad, and the central executive. The phonological loop and sketchpad are modality-specific "slave systems" that enable individuals to retain verbal speech-based material and visuospatial material, respectively. The phonological loop consists of a passive phonological store containing information that is rehearsed by an active articulatory mechanism closely linked to the production of speech (Baddeley, 2007). A similar distinction has been made within the visuospatial component between a passive visual store and an active spatial mechanism involved during the planning and execution of movement (Logie, 2003; Pearson, 2007). Both the phonological loop and sketchpad are controlled by the central executive, a modality-free system responsible for strategic cognitive control, the coordination of tasks carried out in parallel, and scheduling and planning during multitasking (Law, Logie, & Pearson, 2006; Logie, Cocchini, Della Sala, & Baddeley, 2004). The original tripartite model was subsequently modified with the addition of a fourth component, the episodic buffer, which functions to bind together information from working memory and long-term memory into unitary multimodal representations (Baddeley, 2000).

An alternative to the multicomponent approach regards working memory as an activated portion of long-term memory rather than as a separate system. According to Cowan (1999), working memory comprises a set of cognitive processes that maintain information in a highly accessible state. Working memory representations are embedded within long-term memory, with the activation of representations controlled by attentional processes. The focus of attention is capacity limited and able to hold up to four activated representations (Cowan, 2005). The temporary activation of representations in working memory can be maintained by either continued attention or rehearsal in a verbal subsystem (Cowan, 1999).

The interaction between storage and processing in working memory is further explored by the time-based resource sharing model proposed by Barrouillet, Bernadin, & Camos (2004). In this model, rehearsal in working memory is carried out by an attentional mechanism also implicated during concurrent processing. Rehearsal must therefore take place during small time intervals in which task processing does not place demands upon attention. Forgetting in working memory is predicted by the model to increase with overall cognitive load, in which both the rate of individual processing steps during a task and their duration have a high density.

Theories of working memory have widespread application in behavioral medicine. Evidence suggests that schizophrenia is linked to a reduced ability to maintain information in working memory (Park & Holzman, 1992), with deficits also being found in patients' biological relatives (Myles-Worsley & Park, 2002). Working memory deficits have also been documented in patients suffering from bipolar affective disorder (Hammar & Ardal, 2009), Asperger's syndrome (Cui, Gao, Chen, Zou, & Wang, 2010), multiple sclerosis (McCarthy, Beaumont, Thompson, & Peacock, 2005), Alzheimer's disease (MacPherson, Della Sala, Logie, & Wilcock, 2007), and attention deficit hyperactivity disorder (Holmes, Gathercole, Place, Alloway, Elliott, & Hilton, 2010). Working memory has also been linked with theories of craving and addiction

(Kavanagh, Andrade, & May, 2005) and the occurrence of intrusive memories associated with post-traumatic stress disorder (Holmes, Brewin, & Hennessey, 2004; Pearson, Ross, & Webster, 2012; Pearson & Sawyer, 2011).

Work tasks

Definition

There is no one widely accepted definition of workload. Hart and Staveland (1988) describe workload as "the perceived relationship between the amount of mental processing capability or resources and the amount required by the task." Another definition is that it represents the relationship between a group or individual human operator and task demands. In simpler terms, it is the volume of work expected of a person. According to Wickens (1984), "the main objective of assessing and predicting workload is to achieve evenly distributed, manageable workload and to avoid overload or underload."

It can be measured in terms of many factors such as the amount of work accomplished over a period of time (number of hours worked or the number of assignments in a course), level of production, or the physical or cognitive demands of the work being performed (working with a person who speaks a different language than your own). There can be constraints to reaching one's workload such as lack of resources, motivation, and sufficient amount of time.

Worksite Health Promotion

Ellinor K. Olander
Applied Research Centre in Health and Lifestyle Interventions, Coventry University, Coventry, West Midlands, UK

Synonyms

Organizational health promotion

Definition

Worksite health promotion refers to interventions/programs implemented in the workplace that aim to promote health and improve employee well-being.

There are numerous benefits associated with implementing interventions/programs in the worksite setting including a great potential to reach a large number of individuals, provision of existing social support for behavior change or existing infrastructure making it easy to contact individuals or assess their behavior/health. Examples of worksite health promotion programs include those that target smoking, physical activity, stress management, weight reduction, and nutrition. Most worksite health promotion programs target individual behavior (such as encouraging individuals to stop smoking); others may target the physical environment (e.g., encouraging stair instead of elevator use) or organizational change/policy (such as not selling unhealthy food in the worksite restaurant).

World Health Organization (WHO)

Shekhar Saxena and M. Taghi Yasamy
Department of Mental Health and
Substance Abuse, World Health Organization,
Geneva 27, Switzerland

Basic Information

The World Health Organization (WHO) was established in 1948 and is the directing and coordinating authority on international health within the United Nation's system (World Health Organization, 2006). It is responsible for providing leadership on global health matters, shaping the health research agenda, setting norms and standards, articulating evidence-based policy options, providing technical support to countries, and monitoring and assessing health trends (About WHO).

WHO's constitution echoes a clear understanding about psychosocial aspects of health. It states that "Health is a state of complete physical, mental and social well-being and not merely the absence of disease or infirmity" (World Health Organization, 2007). It also lays emphasis from the beginning on the "happiness, harmonious relations and security to all people…" (World Health Organization, 2007).

Major Impact on the Field

WHO has a strong relationship with the Ministries of Health of the member states and this provides an opportunity for advocating for mental health and integration of mental health into general health care systems of countries.

For decades WHO has been generating tools and data on epidemiology of mental disorders, classification of mental disorders, and mapping available resources and services. WHO's ATLAS Mental Health and the WHO Assessment Instrument for Mental Health systems (WHO_AIMS) are well-known resources which are being widely used by mental health planners and policy makers across the globe (http://www.who.int/mental_health/evidence/atlas/en/; Saxena, Sharan, & Garrido, Saraceno, 2006; WHO_AIMS).

In 2001, when Dr. Gro Harlem Brutland was the Director General, WHO's theme was chosen "mental health, stop exclusion, dare to care." The World Health Report title was selected as "Mental Health: New Understanding, New Hope." The report focused on the fact that mental health is crucial to the overall well-being of individuals, societies, and countries. The report advocated the policies that were required to ensure that stigma and discrimination are broken down and that effective intervention and treatment are put in place (WHO, 2001).

WHO promotes the rights of people with mental illness and supports participation of service users at all stages of planning, implementation, and evaluation of mental health interventions (Funk, 2005). WHO has also produced intervention guidelines for a wide range of mental, neurological, and substance abuse disorders. In 2008, WHO's Director General launched the Mental Health Gap Action Programme (mhGAP) (World Health Organization, 2008), and in 2010 the mhGAP Intervention Guide (World Health Organization, 2010). The program and the related guidelines and tools will help poor resource countries in providing basic evidence-based mental health care through non-specialized health providers.

WHO is also currently developing the International Classification of Diseases (ICD-11) and is

collaborating with a wide group of professionals including psychologists to develop the mental and behavioral disorders chapter in ICD-11.

- ▶ Meaning (Purpose)

Worry

J. F. Brosschot and Bart Verkuil
Clinical, Health and Neuro Psychology, Leiden University, Leiden, Netherlands

Synonyms

Intrusive thoughts; Perseverative cognition; Repetitive thinking; Rumination

Definition

Worry is defined as "*a chain of thoughts and images, negatively affect-laden and relatively uncontrollable. The worry process represents an attempt to engage in mental problem-solving on an issue whose outcome is uncertain but contains the possibility of one or more negative outcomes. Consequently, worry relates closely to fear process*" (Borkovec, Robinson, Pruzinsky, & DePree, 1983). Worry can impact health in several ways. First, it is a form of the so-called perseverative cognition (see term), which is defined as "the ongoing cognitive representation of psychological stressors (threat)" (Brosschot, Gerin, & Thayer, 2006). Perseverative cognition is believed to be responsible for a large part of the health impact of psychological stressors, because it prolongs the physiological responses to these

stressors. Second, disease-specific worry can lead to maladaptive outcomes in the long or short term, for example, in the aftermath of surgery or other intrusive medical treatments (Verkuil, Brosschot, Gebhardt, & Thayer, 2010). Third, severe worry about illness can take the form of the anxiety disorder hypochondriasis, or disorders such as somatization or somatoform disorders. In a milder form of illness, worry can increase the number and severity of medically unexplained symptoms, presumably via the excessive activation of illness-related memory networks, that bias perception and behavior in the direction of experiencing and reporting symptoms (Brosschot, 2002; Brown, 2004). Fourth, a symptom-specific, catastrophizing form, for example "pain catastrophizing," appears to play a role in the maintenance and exacerbation of symptoms. Catastrophizing thoughts about a symptom such as pain may drive the vicious circle that leads from pain to catastrophizing to immobility to more pain, etc. (Vlaeyen & Linton, 2000). Last but not least worry and related perseverative thinking styles, such as rumination, play a causal or maintaining role in several forms of psychopathology (Watkins, 2008).

Wound Healing

Christopher G. Engeland
Center for Wound Healing and Tissue Regeneration, University of Illinois, Chicago, IL, USA

Synonyms

Tissue repair

Definition

Wound healing pertains to the repair and regeneration of damaged tissue.

Stages of Wound Healing

Tissue repair involves three interdependent and overlapping phases: (1) the inflammatory phase (hours to days) in which blood flow to the injured area is decreased, a blood clot forms, inflammatory cells (e.g., neutrophils, monocytes) are recruited to the site of injury, and bacterial clearance occurs; (2) the proliferative phase

(days to weeks) in which fibroblasts, epithelial cells, and endothelial cells are recruited and proliferate for the rebuilding process which involves wound contraction, reepithelialization, and angiogenesis; and (3) the remodeling phase (weeks to months) in which the connective tissue matrix begun in the previous phase is fully formed and restructured (for review, see Engeland & Marucha, 2009). Psychological stress can impair healing through its effects on each of these phases.

Description

Overview

It is generally accepted that a patient's state of mind can modulate immune responses (for reviews, see Christian et al., 2009; Hawkley, Bosch, Engeland, Cacioppo, & Marucha, 2007), affecting factors such as healing rates and surgical outcomes. Numerous psychological factors such as stress, anxiety, depression, hostility, and anger can relate to poor healing, such as slowed wound closure which increases the risk of infection and other complications. Conversely, factors such as positive mood, optimism, and positive social interactions can improve healing outcomes.

Stress Pathways

The primary effects of stress on wound healing occur through central activation of the hypothalamic pituitary adrenal (HPA) axis and the sympathetic nervous system (SNS). HPA activation promotes the systemic release of glucocorticoids (GCs) (e.g., cortisol in humans) from the adrenal glands. GCs are potently anti-inflammatory and immunosuppressant and act as the main brake on inflammation. By dysregulating the release and function of GCs, chronic stress can result in higher inflammatory reactions following immune activation (e.g., response to injury). Activation of the SNS by stress results in vasoconstriction (caused by norepinephrine), which limits blood flow to injury sites resulting in hypoxia and lowering available nutrient supplies to tissues. Vasoconstriction may also delay the arrival of immune cells, such as neutrophils and monocytes, to the site of injury, further impeding the healing process. Through these two pathways, stress dysregulates immune functions and alters early wound repair. The end result is impaired bacterial clearance, prolonged inflammation, higher risk of infection, and greater postsurgical (or post-injury) complications (for reviews see Marucha & Engeland, 2007; Engeland & Marucha, 2009).

Stress and Anxiety

Since 1995, numerous studies have demonstrated that stress negatively affects healing and this notion is now widely accepted. Stressors such as caregiving for an Alzheimer's patient and university examinations, along with preoperative and perceived stress, have each been shown to slow dermal healing (for reviews, see Devries et al., 2007; Engeland & Graham, 2011). For instance, stress associated with caregiving slowed the healing of skin wounds by 24%. Such delays are typically accompanied by elevated cortisol levels and reduced inflammation, and similar stress-induced changes are mirrored in animal research (Engeland & Marucha, 2009). Aside from skin, stress affects mucosal inflammation and is a known risk factor for periodontal disease. Stress from university examinations in American dental students slowed the healing of experimental oral mucosal wounds by 40%. It is of note that a stressor as predictable and transient as examinations should delay healing to such a degree in professional students. Interestingly, stress appears to delay healing in mucosal tissues by increasing early inflammation, rather than by inhibiting inflammation as has been shown in skin wounds (Engeland & Graham, 2011). Clinically, efforts should be made to reduce both pre- and postsurgical stress and to avoid scheduling elective surgery during or shortly after a period of stress (e.g., university examinations).

Depression and Other Behavioral Constructs

Psychosocial factors other than stress and anxiety also affect immunity. Higher depressive symptoms, marital disagreements, lower levels of anger control, and higher levels of hostility have

all been related to slowed healing in skin. Similarly, subclinical depression (dysphoria) relates to slower healing of mucosal wounds. Conversely, positive mood, optimism, and positive social communications relate to faster healing times in skin (for review, see Engeland & Graham, 2011), suggesting a positive role for behavioral interventions on wound healing (see below).

Pain

Pain usually accompanies healing and can be viewed as a unique stressor with both physiological and psychological components. Pain can alter immunity directly by promoting cytokine release and indirectly through activation of stress pathways and changes in behavior. Through these different mechanisms, pain exacerbates the negative effects of stress on healing. Greater pain from elective gastric bypass surgery has been related to slower healing of an experimental skin wound placed on the day of surgery. Importantly, pain and stress are not additive but synergistic in their effects. Not only does each negatively affect healing, but each promotes the other through physiological and immune responses and through changes in mood and behavior. For instance, pain can lead to maladaptive health behaviors such as loss of sleep, inactivity, and alcohol use, each of which has been linked with poorer healing. Not only pain, but also its anticipation, can be a tangible source of anxiety for surgical patients, as well as concerns about the healing process. Efforts to minimize not only pain, but also these sources of anxiety, are encouraged (for review, see Engeland & Graham, 2011).

Ageing

It is well accepted that ageing alters skin morphology. Aged skin undergoes reductions in vascularization, granulation tissue, collagen, elastin, mast cells, fibroblasts, and epidermal turnover (reduced ~50% as one ages from 20 to 70 years). In general, the elderly have slower healing times, increased rates of infection and wound dehiscence, and reduced wound strength. This is primarily caused by reductions in reepithelialization, angiogenesis, macrophage infiltration, and collagen deposition. In women, menopause exacerbates these effects. It is important to note that wound healing is slowed but not impaired in the elderly and the eventual healing outcome is similar to that of young adults. This appears to hold true for mucosal healing as well. Also, for reasons unknown, wounds in the aged heal better aesthetically with less scarring. However, risk factors for impaired healing occur more commonly in the elderly, such as comorbidity, malnutrition, immobility, and obesity. Stress is also more common in the aged and negatively impacts tissue healing to a greater degree than in young adults. Prior to surgery, each of these risk factors for impaired healing should be tested for, monitored and treated vigorously to ensure maximal healing outcomes. In the elderly, the presence of any of these risk factors should serve as a red flag to the clinician (for review, see Engeland & Gajendrareddy, 2011).

Chronic Wounds

Most wound healing studies have been conducted in a controlled laboratory setting on acute wounds which heal relatively quickly (for a review of wound healing models, see Bosch, Engeland, & Burns, 2011). Clinical studies, which involve more naturally occurring wounds (e.g., diabetic foot ulcers, surgical wounds, accidents), provide valuable information about how such factors affect larger and more chronic wounds where poor outcomes may have more serious implications. Higher levels of depression and anxiety have been related to slower healing of chronic leg ulcers, with patients who scored in the top 50% of these measures being four times more likely to be categorized as slow healers. Thus, psychological stress has been shown to exert negative effects on the healing of both acute and chronic wounds.

Skin Barrier Recovery

The skin is an essential barrier for providing pathogen resistance and limiting water loss. This barrier plays an important factor in numerous skin diseases (e.g., psoriasis, atopic

dermatitis) and in dermal healing. Repair to this barrier can be evaluated through tape stripping, in which cellophane tape is repeatedly applied to and removed from a dermal area (e.g., forearm). An evaporimeter is then used to assess transepidermal water loss (TEWL) over time. Stress from public speaking (i.e., Trier Social Stress Test) slows barrier recovery times and is associated with increased levels of cortisol and inflammation. Similar delays in barrier recovery times have been demonstrated with stress stemming from marital dissolution, university examinations, and sleep deprivation. Higher positive mood relates to faster recovery times, indicating the negative effect of stress on skin barrier repair is buffered by positive emotion. Skin barrier function, which is an important factor in numerous skin diseases (e.g., psoriasis, atopic dermatitis) and in dermal healing, undergoes slower recovery/repair during stress (for review, see Engeland & Graham, 2011).

Health Behaviors

Stress and pain can affect wound healing indirectly through behavioral alterations such as poor sleep and nutrition, reduced exercise, increased consumption of alcohol or nicotine, and self-neglect. For example, sleep deprivation can disrupt macrophage/lymphocyte functions and alter inflammation, thereby hindering immunity. Such changes can themselves promote stress, often in the form of anxiety or depression, which further impact on health creating a downward spiral effect. Smoking, which often increases during times of stress, reduces vitamin C and oxygen levels in blood, impairs collagen deposition and macrophage function, and alters turnover of the extracellular matrix during healing. It has been shown that smoking intervention 6–8 weeks before surgery reduces postoperative morbidity including wound-related complications. In addition, interventions aimed at lowering stress prior to surgeries such as patient education, massage therapy, and relaxation with guided imagery can have positive effects on postsurgical outcomes. Similarly, a 4-week exercise regimen was shown to speed healing rates by 25% in experimental skin wounds, independent of perceived stress. Emotional disclosure interventions, which involve participants writing about traumatic personal events, have been shown to positively affect immunity and speed up the healing of experimental wounds in skin. Wounds were 11% smaller compared to control subjects that wrote about time management (for reviews, see Engeland & Marucha, 2009; Engeland & Graham, 2011). Given the impact that such behaviors and interventions have on health, reducing negative behaviors and facilitating positive behaviors will help to optimize immune responses, wound healing, and postsurgical outcomes.

Yoga

Melissa M. A. Buttner
Department of Psychology, University of Iowa, Iowa City, IA, USA

Definition

Yoga is an ancient tradition originating in India and is derived from a Sanskrit word meaning "to yoke" or "to unite" (Desikachar, 1999). In Western culture, yoga is considered a form of physical activity and, more recently, a mind-body intervention designed to support overall health and well-being. In its full expression, yoga integrates three basic components: breath (*pranayama*), physical poses (*asanas*), and meditation (*dhyana*).

Description

Origins

Yogic philosophy traces back to 3000 BCE, with roots spanning four periods known as the Vedic (2000–600 BC), Preclassical (600–200 BC), Classical (200 BC), and Postclassical periods (Feuerstein, 2001). The Preclassical period is associated with the emergence of the *Upanishads* (200 texts influencing Hindu philosophy) and the creation of the *Bhagavad Gita*, considered to be among yoga's oldest written texts. It was during this time that the foundations of meditation and the concept of *samadhi* (a path to enlightenment) surfaced (Feuerstein, 2001). Patanjali's *Yoga Sutras* was compiled during the Classical period (Iyengar, 1993) and contains 196 sutras describing raja yoga and its underlying eight-limbed path, or *ashtanga* yoga: *yama* (ethical guidelines), *niyama* (spiritual observances), *asana* (physical poses), *pranayama* (breathing exercises), *pratyahara* (control of the senses), *dharana* (concentration), *dhyana* (meditation), and *samadhi* (state of bliss) (Iyengar, 2001). During the Postclassical period, *Hatha* yoga emerged, the most common form of yoga practiced in Western culture today (Feuerstein, 2001).

Complementary and Alternative Medicine (CAM)

Complementary and alternative medicine (CAM) is a form of medicine consisting of systems, practices, and consumer products that are outside the realm of traditional or conventional forms of medicine (Barnes, Bloom, & Nahin, 2008). Acceptance of this nontraditional form of medicine is growing. Findings from a 2008 survey on Americans' use of CAM published by the National Center for Complementary and Alternative Medicine (NCCAM) showed that *yoga* was one of the top ten most commonly used CAM therapies among adults, with 6.1% indicating use

of yoga in the past year (Barnes et al., 2008). Preference for yoga as a CAM option over that of conventional forms of medicine may be associated with characteristics including decreased stigma, a more gentle form of treatment with minimal side effects, and flexibility in personalizing treatment (Uebelacker et al., 2010).

Yoga's Role in Behavioral Medicine

The past few decades have witnessed a confluence of Western medical science and psychological theories with ideas from Eastern practices such as yoga, which has led to the recent emergence of yoga as a mind-body intervention. In contrast with traditional forms of medicine, yoga offers a holistic approach to treating physical and mental health issues (Hayes & Chase, 2010) and is currently being used to address various health conditions (see Table 1 for a detailed list). Recent reviews of the yoga literature suggest that yoga has beneficial effects on pain syndromes, cardiovascular, autoimmune and immune conditions, and on pregnancy (Field, 2011). Further, there is evidence to suggest that yoga yields physiological benefits as evidenced in studies showing links between yoga and decreased heart rate and blood pressure, as well as physical effects, such as weight loss and increased muscle tone (Field, 2011). More well-established physiological effects of yoga include stress reduction (Ross & Thomas, 2010), with psychological effects evidenced by increased mindfulness and reduced symptoms of depression and anxiety (Field, 2011; Uebelacker et al., 2010) (see Figs. 1 and 2 for illustrations of yoga poses).

Stress

Stress has adverse effects as evidenced in many health conditions. Empirical evidence for yoga in combating these adverse effects suggests that controlled breathing helps to focus and relax the mind through activation of the autonomic nervous system (ANS), which may work to counteract stress (Harinath et al., 2004). To understand the role of stress in disease and the effects of relaxation associated with a yoga practice in prevention and recovery, it is important to understand the function of the ANS. The ANS is responsible for regulating the heart, intestines, and other internal organs through a synergistic relationship between the sympathetic nervous system (SNS) and the parasympathetic nervous system (PNS) (McCall, 2007). In general, when activity is high in the SNS, it will be low in the PNS, and vice versa. The SNS, along with the

Yoga, Fig. 1 *Warrior II Pose* (*Virabhadrasana II*) requires weight bearing and helps to strengthen and stretch the legs and ankles, stimulates abdominal organs, and increases stamina. This pose is recommended for carpal tunnel syndrome, flat feet, osteoporosis, and sciatica (McCall, 2007)

Yoga, Fig. 2 *Cobra Pose* (*Bhujangasana*) helps to strengthen the spine, stretch the chest and lungs, shoulders, and abdomen. It is recommended for stress, fatigue, and sciatica (McCall, 2007)

stress hormones cortisol and andrenaline, is responsible for generating a response to stressful situations, leading to physiological changes such as increased heart rate and blood pressure (McCall, 2007). Increased mobilization of energy and additional blood and oxygen flowing to the body will enable a person to respond to the stressor, otherwise known as the classic "fight or flight" response (McCall, 2007). Conversely, the PNS slows the heart rate and lowers blood pressure to support recovery from a stressful situation, thereby functioning as a restorative mechanism that is often referred to as the "relaxation response" (Benson, 2000).

The three basic components of yoga – physical postures, breathing, and meditation – interact

with the PNS and SNS as potential mechanisms by which yoga has a calming effect on the nervous system, potentially leading to decreased stress reactivity (Ross & Thomas, 2010). For example, ujjayi breathing (a form of slow yoga breathing characterized by an oceanic sound) is hypothesized to increase activation of the PNS, leading to a calm but alert state while simultaneously having a restorative effect on the body (McCall, 2007). Practicing more rigorous forms of breathing (e.g., *kapalabhati* breathing) and poses (e.g., sun salutations) triggers a sympathetic response similar to that found in traditional forms of aerobic activity. In contrast to a typical aerobic workout, however, a more invigorating yoga practice followed by a sequence of relaxing poses will stimulate the PNS and restore energy (McCall, 2007).

Mindfulness

The most commonly used definition of *mindfulness* is that of Jon Kabat-Zinn's, who defined it as "paying attention in a particular way: on purpose, in the present moment and nonjudgmentally" (Kabat-Zinn, 1994, p. 4). Support for mindfulness as an agent of change comes by way of its role as an active component of evidence-based psychotherapies (e.g., acceptance and commitment therapy and mindfulness-based cognitive therapy). The practice of mindfulness allows one to experience disengaging from evaluative thinking in the presence of negative stimuli through cultivation of an attitude of curiosity and attention to ongoing reactions to emotions, thoughts, and feelings (Shapiro et al., 2008). In depressed patients, for example, a repetitive focus on negative feelings (rumination) is a typical way of responding and is implicated in the onset and maintenance of depression. *Mindfulness* cultivated in a yoga practice may counteract ruminative thinking by offering participants an alternative focus, such as the breath and physical sensations experienced in the body (Uebelacker et al., 2010). Through a regular yoga practice, yoga practitioners naturally begin to adopt a lifestyle guided by yogic philosophies such as self-acceptance, compassion, and spirituality. In general, the more one commits to the practice, the greater the benefits tend to be, and healthier habits begin to form (McCall, 2007).

Yoga Styles

There is a preponderance of *Hatha* yoga styles practiced in the West today, with popular forms including *Anusara, Ashtanga, Bikram, Iyengar, Power, Vinyasa flow*, and *Viniyoga*. Most styles generally incorporate mindfulness with physical activity. Yoga, however, is distinct from traditional forms of physical activity with its focus on breath, and the intentional linking of breath with movement of the body through a sequence of postures (McCall, 2007). In addition, there are some forms of *Hatha* yoga that focus on the therapeutic application of poses for various medical conditions, including *Anusara*, *Iyengar*, and *Viniyoga*.

Anusara yoga was developed by John Friend who integrated his Iyengar background with a "heart-centered" approach to teaching (Friend, 2006). The focus in this style of yoga is on the physical poses and precision of alignment; however, chanting, pranayama, and meditation are also woven into many classes (Friend, 2006). Although the application of Anusara yoga is not well established in the empirical literature, characteristics such as a focus on alignment may support its use as a therapeutic tool (McCall, 2007).

Iyengar yoga, developed by B.K.S. Iyengar, is rooted in Patanjali's *Yoga Sutras* and is known for its therapeutic application based on a large body of literature supporting the benefits of Iyengar yoga and its emphasis on precision and alignment (Iyengar, 1995). Iyengar yoga is often employed in research trials examining the effectiveness of yoga for treating mood disorders such as depression and anxiety. This particular style of yoga incorporates the use of props (bolsters, blankets, blocks) to make yoga accessible to beginners, despite limited experience and flexibility, and to help assist in guiding the student into the posture (Iyengar, 2001). In this style of yoga, the poses are typically held for a longer duration of time relative to other forms of yoga such as Vinyasa flow. It is thought that holding the poses allows for proper alignment that is the hallmark

of Iyengar yoga (Iyengar, 2001). Yoga therapy performed according to this lineage of yoga can only be performed by instructors certified at a Junior Intermediate II level or above (see IYNAUS website for instructors and their level of certification). Iyengar yoga is known to have the highest standards in terms of teacher training and certification. Benefits of Iyengar yoga can be seen with many health conditions, ranging from depression to stress-related illnesses (Shapiro et al., 2007).

Viniyoga is a highly therapeutic and gentle style of yoga founded by T.K.V. Desikachar, in which poses and sequences are modified according to the needs of the student (Desikachar, 1999). Students practicing this style of yoga will flow from one pose to the next, holding the poses for a brief period of time, minimizing the risk of injury and making this style of yoga suitable for students with chronic diseases (McCall, 2007). In addition, pranayama breathing and chanting are integrated into a typical class.

Application of Yoga

Currently, there is no reliable system for identifying the most effective style of yoga for any one individual. Despite the number of studies examining the beneficial effects of yoga, most studies do not compare different styles of yoga or the mechanisms of action by which one particular style of yoga is effective (Uebelacker et al., 2010). In general, it is recommended that the elements of a yoga class (e.g., relaxation, rigorous flow with challenging poses), in addition to the quality of instruction, be considered when starting a yoga practice (McCall, 2007). The length of a yoga class may range from 60 to 90 minute, with each posture being held for a few seconds to 1 minute, depending on the style of yoga.

For physically fit individuals with no serious medical conditions contraindicated with yoga, most yoga classes are appropriate. For beginning students, learning yoga in a group environment or through private instruction with a certified instructor is preferable; however, individuals may also learn using audiotapes or DVDs. Individuals presenting with serious medical conditions seeking yoga as a form of therapy should consult with a certified yoga instructor specializing in the medical issue being treated (Shapiro et al., 2008). An increasing number of classes are now being offered that are tailored to the needs of specific populations, such as pregnant and postpartum women. Women practicing yoga during and after pregnancy are advised to attend classes with an instructor knowledgeable in providing modifications specific to the perinatal population. If a woman established a rigorous yoga practice prior to conceiving, it is recommended that she transition to a gentler style of yoga until after childbirth (McCall, 2007).

Definition

The Zung Depression Inventory (SDS) is a 20-item self-rating scale concerning affective, cognitive, behavioral, and somatic symptoms of depression (Zung, 1965). Half of the items are worded positively, half are phrased negatively. The scale was developed on the basis of the most commonly found diagnostic criteria of depression and patient interviews. Subjects rate each item according to how they felt during the preceding week. The response categories range from (1) "none or a little of the time" to (4) "most or all of the time." The scale takes on average 5 min to complete. An index for the SDS is derived by summing the item scores. This summary score is then divided by a maximum possible score of 80. The SDS index ranges from 0.25 to 1. The following cutoffs are recommended by the author of the scale: Individuals with an index below 0.62 are considered normal, with an index of 0.62–0.74 are considered to suffer from a mild depression, and with an index of 0.75–0.86 are considered to suffer from a moderate to marked depression. Indices of 0.87 and above indicate severe depression. The SDS is available in about 30 languages.

The little available data examining the reliability of the SDS reveals satisfactory *split-half reliability* ($r = 0.73$) and *internal consistency* (Cronbach's alpha = 0.79). *Concurrent validity* of the scale could be demonstrated by correlating the SDS with other standardized self-rating scales of depression like the Beck Depression Inventory

M.D. Gellman & J.R. Turner (eds.), *Encyclopedia of Behavioral Medicine*,
DOI 10.1007/978-1-4419-1005-9,

and the Depression Scale of the Minnesota Multiphasic Personality Inventory. Results of correlations between the SDS and clinician-rated instruments like the Hamilton Rating Scale for Depression are less consistent. *Factor analyses* of the SDS revealed three main factors: positive symptoms/well-being, negative effect, and somatic symptoms. Sensitivity of the SDS in differentiating between depressed and nondepressed subjects was found to be adequate. The influence of different demographical variables on the SDS index was also examined. There seem to be higher SDS scores for individuals being older than 64 or younger than 20 years in non-patient groups. Associations between SDS score and age in psychiatric populations could not be demonstrated clearly. Women in patient as well as non-patient groups seem to have slightly higher scores than males. Furthermore, SDS scores are slightly negatively correlated with education (range: $r = -.08$ to $-.28$).

The SDS has not only been used in psychiatric settings and in clinical research to monitor for treatment effectiveness but also in behavioral medical settings. Specific difficulties have to be considered when the SDS is used for screening depressive symptoms in medically ill patients. For example, somatic symptoms of depression can be confounded with symptoms of the organic illness or side effects of medication. This can lead to an overestimation of depression (e.g., fatigue or insomnia can also be a symptom of cancer or can be a side effect of pain medication). Especially in diseases influencing cognitive functions, the use of reverse coding introduces complexity. In summary, evidence of validity supports the use of the SDS as screening tool but not as a diagnostic measure of depressive disorder.
