All of the patients had normal numbers of the earliest B cell precursors, pro-B cells that express both CD34 and CD19. However, cells at the next stage of differentiation, cells that express CD19 but are negative for CD34, were markedly decreased in number in the patients with mutations in Btk,  $\lambda_{5/14.1}$ , and BLNK, and were completely missing in patients with mutations in the  $\mu$  heavy-chain gene or Ig $\alpha$  (Yel et al., 1996; Minegishi et al., 1998, 1999a, 1999c) (Fig. 22.3). The patients with mutations in Btk (seven patients) or BLNK had an unusual population of B lineage cells that expressed cytoplasmic  $\mu$  heavy chain but still expressed CD34 and TdT, which suggests incomplete but not absent signaling through the pre-B cell receptor complex. It is not surprising that mutations in  $\mu$  heavy chain,  $\lambda_{5/14.1}$ , and Ig $\alpha$  all resulted in a block in B cell development at the same point in differentiation as all three proteins are required to form the normal pre-B cell receptor complex. The results also demonstrate that the earliest point in B cell differentiation at which defects in Btk and BLNK impair B cell development coincides with expression of the pre-B cell receptor complex, suggesting that these two proteins are required for normal signaling through this complex.

### Clinical Characteristics in Patients with Autosomal Recessive Agammaglobulinemia

It is the impression of many physicians who provide care for patients with hypogammaglobulinemia that girls with an XLA phenotype have a more severe disease than males. The 21 affected patients from 14 families with known mutations in the  $\mu$  heavy-chain gene represent a small sample size. However, if we exclude the youngest affected child in family 2, who was evaluated in the first month of life because of the family history of immunodeficiency, the patients with mutations in this gene were recognized to have an immune deficiency at an earlier age than patients with mutations in Btk (mean of 11 months vs. 32 months) (Lederman and Winkelstein, 1985; Farrar et al., 1996; Meffre et al., 1996; Yel

et al., 1996; Lopez et al., 2002) and the majority experienced a life-threatening infection. Seven of the patients developed chronic enteroviral encephalitis, a complication seen in less than 10% of patients with XLA (Lederman and Winkelstein, 1985). Three of the patients died of chronic enteroviral encephalitis at 3 to 9 years of age. One of the remaining patients continues to have significant infections despite intravenous  $\gamma$ -globulin therapy. However, there is clear variability in the clinical course; two of the patients have survived more than 40 years.

The patient with mutations in  $\lambda_{5/14.1}$  had recurrent otitis as an infant and was recognized to have immunodeficiency at 3 years of age, when he developed hemophilus influenza meningitis despite previous immunization with the conjugated vaccine. The Ig $\alpha$ -deficient patients have had a clinical course similar to that of patients with defects in  $\mu$  heavy chain. Two were recognized as having immunodeficiency at about 1 year of age and one died at 8 years of age of probable chronic enteroviral infection (Minegishi et al., 1999a; Milili et al., 2002). The patient with BLNK deficiency had the onset of recurrent otitis at 8 months of age and was diagnosed as having XLA at 16 months of age, after his second episode of pneumonia. He has done moderately well after  $\gamma$ -globulin therapy was started; however, he has had chronic otitis and sinusitis, hepatitis C acquired from intravenous  $\gamma$ -globulin, and an episode of protein-losing enteropathy in adolescence. It is noteworthy that this patient had an older brother who died of pseudomonas sepsis and neutropenia at 16 months of age, probably due to BLNK deficiency.

If patients with complete blocks in B cell differentiation, like the patients with mutations in  $\mu$  heavy-chain gene or Ig $\alpha$ , have a more severe clinical disease than patients with mutations in Btk, then the small amount of immunoglobulin found in patients with XLA may play a protective role, perhaps through complement activation or FcR binding.

The treatment for patients with autosomal recessive agammaglobulinemia is currently the same as that for other patients with hypogammaglobulinemia, including patients with XLA. Immunoglobulin replacement and aggressive use of antibiotics provide excellent but not perfect protection from infection. Consideration of gene therapy to treat mutations in  $\mu$  heavy-chain gene presents unusual problems because of the size and complexity of the immunoglobulin heavy-chain locus. In patients with single base pair substitutions, correction by homologous recombination (Rice et al., 2001) or by ribozyme-mediated repair of a defective transcript (Lan et al., 1998) might be successful.

### Defects in B Cell Development Associated with Morphologic Abnormalities

Several reports have described patients with markedly reduced numbers of peripheral blood B cells and morphologic defects (Adderson et al., 2000; Revy et al., 2000; Hoffman et al., 2001; Verloes et al., 2001). All of these patients have had microcephaly and some are described as having dysmorphic facial features and abnormalities of the hands (Hoffman et al., 2001; Verloes et al., 2001). Progressive pancytopenia has been reported in others (Adderson et al., 2000; Revy et al., 2000). It is not clear whether these patients represent a single gene defect or several different disorders. In at least one case, the parents were consanguineous, increasing the probability that the child had a single gene defect. Most of these patients have been analyzed for defects in the gene for PAX5, a transcription factor that is essential for normal central nervous system and B cell development (Urbanek et al., 1994); however, no abnormalities have been found.

## Conclusions

Although a larger sample size could permit a more accurate estimate, we calculate that mutations in  $\mu$  heavy-chain gene,  $\lambda_{5/14.1}$ ,  $Ig\alpha$ , or  $BLNK$  account for approximately half of all patients with defects in early B cell development who do not have abnormalities in the gene for  $Btk$ . It is not clear at this point whether the remaining half represent one or a small number of genetic defects or whether they are a heterogeneous group in which almost every patient may be unique.

Over the next few years it is likely that additional gene defects responsible for abnormal B cell development will be elucidated. Identification of these genes is of obvious importance to the families of affected patients. However, it also provides new perspectives on normal B cell development and the functional relationship between the various genes required for normal B cell development. For example, a comparison of B cell development in patients with mutations in  $\mu$  heavy-chain gene with that seen in patients with XLA supports the hypothesis that  $Btk$ , the defective protein in XLA, plays a major role in signal transduction through the pre-B cell receptor complex. Comparison of human disorders in B cell development with murine models of immunodeficiency also highlights the aspects of B cell signaling that are invariant and those that may be influenced by other genetic or environmental factors.

## Genetic Approach to Common Variable Immunodeficiency and IgA Deficiency

LENNART HAMMARSTRÖM and C. I. EDVARD SMITH

Common variable immunodeficiency (CVID), Mendelian Inheritance in Man (MIM) number 240500, affects approximately 1 in 10,000–100,000 individuals. The patients display a marked reduction in serum levels of both immunoglobulin G (IgG) and IgA. In half of the patients, IgM is also reduced. The onset of disease shows two peaks, around 1–5 and 16–20 years of age (Hermaszewski and Webster, 1993) and is equally distributed between the two sexes. The disorder may appear in previously immunologically normal individuals, although the induction phase has been documented only in a few cases (Smith et al., 1985). Usually the patients present with clinical symptoms due to the hypogammaglobulinemia, as they suffer from frequent respiratory and gastrointestinal tract infections (see Table 23.2). In addition to the B cell defect, variable degrees of T cell dysfunction have frequently been noted in CVID patients. Low or normal proportions of CD19-positive cells are also often observed, a finding that distinguishes “classical” CVID patients from those with a concomitant thymoma.

With 0.05 g/l of serum IgAD as the upper limit for diagnosis, selective IgA deficiency (IgAD), MIM number 137100, is the most common form of immunodeficiency in the Western world and affects approximately 1 in 600 individuals. Great variability in the prevalence can, however, be found in different ethnic groups, and a markedly lower frequency has been reported in mongoloid populations (Table 23.1), suggesting a genetic influence. In about two-thirds of cases, the deficiency does not lead to an increased occurrence of infections, whereas the remaining patients suffer from bacterial infections in both the upper and lower respiratory tract (Table 23.2). The defect is manifested already at the stem cell level, and transfer of bone marrow from an IgA-deficient donor to a normal recipient results in IgA deficiency in the recipient (Hammarstrom et al., 1985c) whereas transfer of bone marrow from a normal individual to an

IgA-deficient patient will correct the defect (Kurobane et al., 1991).

The genes for  $\alpha 1$  and  $\alpha 2$  can readily be demonstrated in the genome of both CVID (Smith and Hammarstrom, 1984) and IgAD patients (Hammarstrom et al., 1985a), and the silent genes can be re-expressed in the children of IgA-deficient parents (Hammarstrom et al., 1987). These findings strongly suggest that the defect is due to dysregulation of the expression of the Ig genes. In a few selected cases, the defect is restricted to one of the two subclasses, and these cases are most often although not invariably due to deletions of the corresponding  $\alpha$  chain gene (Migone et al., 1984; Lefranc et al., 1991). Some of these mutations have been identified by screening of healthy blood donors (Lefranc et al., 1982, 1991; Rabbani et al., 1996), whereas a few have been found in patients prone to infections. Thus, selective IgG1 and IgG2 deficiency caused by homozygous gene deletions have both been reported in patients with an increased susceptibility to infections (Smith et al., 1989; Tashita et al., 1998).

By definition, IgAD is expected to be selective and confined to the IgA class. In many cases, however, a simultaneous change in the IgG subclass pattern is seen with a lack of specific antipolysaccharide antibodies of the IgG2 subclass (Hammarstrom et al., 1985d) or a total lack of serum IgG2 (Oxelius et al., 1981), IgG4, and IgE (Hammarstrom et al., 1986), reflecting a relative or absolute block in switching to genes downstream of the  $\gamma 1$ . Progression from IgAD to CVID has been observed in a number of cases, suggesting that the two diseases are related and may represent faults of the same underlying defect.

During the past few years, mutations in a number of genes associated with B cell differentiation, including *ICOS*, *TACI*, *BAFF-R*, and *CD19*, have been found in patients with CVID and IgAD. However, the molecular basis still remains unknown in the vast majority of patients.

## Historical Overview

In 1952 the first report of Ig deficiency appeared (Bruton, 1952). This report inspired a large number of investigators to analyze Ig levels in patients prone to infections (reviewed in Good et al., 1962; Sideras and Smith, 1995; Smith and Notarangelo, 1997). At the time, knowledge on lymphocyte subsets was lacking, and patients with autosomal recessive severe combined immunodeficiency were sometimes referred to as having agammaglobulinemia (Keidan et al., 1953). Females with CVID had already been reported the year after Bruton's original description (Olhagen, 1953). Both adult-onset (Olhagen, 1953; Grant and Wallace, 1954; Jacobsen, 1954; Lang et al., 1954; Prasad and Koza, 1954; Saslaw and Wall 1954) and congenital agammaglobulinemia in females (Pearce and Perinpanayagam, 1957) were described. Adult onset in male patients with a CVID phenotype was also reported (Olhagen, 1953), as reviewed in Citron (1957), who described additional patients suffering from agammaglobulinemia with concomitant splenomegaly.

The first study on selective Ig deficiency reported the absence of IgG in the hyper-IgM syndrome (Israel-Asselain et al., 1960; Rosen et al., 1961). In 1964, IgA deficiency was observed in two healthy laboratory workers, clearly demonstrating that IgA may be dispensable in certain individuals (Rockey et al., 1964). However, on the basis of a review of 30 cases, it was later determined that this defect frequently results in a propensity for infections (Ammann and Hong, 1971).

The classification of Ig deficiencies was often complicated by the lack of suitable techniques. In the mid-1960s Rosen and Janeway subdivided the antibody deficiency syndromes into six forms. Among these were congenital forms, including sex-linked and sporadic/autosomal recessive inheritance; acquired agammaglobulinemia; and a third subgroup, congenital and acquired dysgammaglobulinemia, which included IgAD and the hyper-IgM syndrome (Rosen and Janeway, 1966). The present classification of Ig deficiency dates back to 1973 (Cooper et al., 1973).

### Mode of Inheritance

Familial inheritance of the deficiency is observed in approximately 20% of cases, and CVID and IgAD may both be present in the same family. In rare instances, patients with IgAD may progress to CVID, a phenomenon suggesting that the disorders reflect facets of the same underlying disease (Schaffer et al., 1989). These data therefore strongly argue that the two disorders represent an allelic condition with a variable expression of a common defect, and there is substantial evidence supporting a common genetic susceptibility. The finding of Ig deficiency in only one of two monozygotic twins (Huntley and Stephenson, 1968; Lewkonja et al., 1976; Ulfarsson et al., 1982) suggests an environmental, possibly infectious, agent as a triggering factor.

### Clinical and Pathological Manifestations

#### Infections

Patients with IgAD and CVID suffer from a variety of respiratory and gastrointestinal tract infections (Table 23.2). The severity of infections reflects the degree of immune dysfunction and is thus more pronounced in patients with hypogammaglobulinemia. Enlarged lymph nodes and spleen are noted in up to half of patients with CVID, but not in patients with X-linked agammaglobulinemia (XLA) (Curtin et al., 1995), and may reflect persistence of low-grade infections. The lymph nodes may show a striking reactive follicular hyperplasia, and non-caseating granulomas in the liver (Color Plate 23.I) and skin (Color Plate 23.II) occur. The gastrointestinal tract may also be involved in this process with a characteristic nodular lymphoid hyperplasia. The spectrum of infections in IgAD and CVID patients is, however, usually rather limited. Some of these are highlighted below.

*Hemophilus influenzae* is a common pathogen in the human respiratory tract. The majority of isolates are non-encapsulated and fall into the category of serologically nontypable strains, which often cause acute otitis media, acute sinusitis, conjunctivitis, pneumonia, and bronchitis in immunocompetent patients. These bacteria also constitute the major pathogen in CVID patients who suffer from frequent upper respiratory tract infections. Patients may remain colonized for years with the same strain in spite of "adequate"  $\gamma$ -globulin therapy and antibiotics (Samuelson et al., 1995) and may develop multiple bouts of symptoms. It is still unclear why the bacteria are poorly cleared by antimicrobial therapy but intracellular growth may occur in crypt cells in the adenoid and tonsils.

*Moraxella catharralis* and *Streptococcus pneumoniae* are the second and third most common pathogens in patients with CVID; both organisms give rise to upper respiratory tract infections. In earlier published series of patients, serious pulmonary manifestations such as bronchiectasis, pulmonary fibrosis, and respiratory failure were not uncommon (Dukes et al., 1978; Hausser et al., 1983; Bjorkander et al., 1984). However, increasing awareness of immunodeficiency disorders, early diagnosis, and prompt institution of antibiotic therapy and  $\gamma$ -globulin substitution have resulted in far lower frequency of severe respiratory tract complications (Sweinberg et al., 1991; Hermaszewski and Webster, 1993).

Mycoplasmas have been increasingly recognized as pathogens in humans. *Mycoplasma pneumoniae* is a common cause of pneumonia in both normal and immunodeficient individuals. Two additional species, *Mycoplasma hominis* and *Ureaplasma urealyticum*, have also been implicated in a variety of infections, particularly in the urogenital tract. Each of these species has also

been isolated from synovial fluid of patients with acute arthritis (Color Plate 23.III), and a role for these organisms in chronic arthritis has therefore been suggested.

Hypogammaglobulinemic patients appear to be highly susceptible to systemic mycoplasma infections, but the diagnosis may be delayed because of the insidious onset of symptoms. As antibodies are of major importance to combat these infections, CVID patients may suffer a protracted clinical course, and severe sequelae have been reported (Webster et al., 1978; Taylor-Robinson et al., 1985; Vogler et al., 1985; Roifman et al., 1986; Kraus et al., 1988; Jorup-Ronstrom et al., 1989; Mohiuddin et al., 1991) with extensive joint destruction (Fig. 23.I).

The use of contaminated  $\gamma$ -globulin preparations has been responsible for several outbreaks of hepatitis C infections in CVID patients. The long-term prognosis for these patients is poor, with about one-third developing cirrhosis within 10 years and ultimately dying of liver failure. In the latest outbreak, identical sequences for the envelope protein genes could be identified in the incriminated batch of  $\gamma$ -globulin and in the sera from infected patients (Widell et al., 1997).

Transient recovery of the ability to produce immunoglobulins at the time of hepatitis C infection has been reported in a few patients (Hammarstrom and Smith, 1986; Osur et al., 1987) and has also been demonstrated in patients infected with HIV (Morell et al., 1986; Webster et al., 1986; Wright et al., 1987). These findings strongly suggest an immunoregulatory dysfunction as a cause of CVID.

Lack of immunoglobulins might affect the acquisition and persistence of hepatitis C infections, and an increased prevalence of hepatitis C in IgAD patients has previously been suggested (Benbassat et al., 1973; Ilan et al., 1993). However, because IgAD may develop during the course of the hepatitis infection (Hishitani et al., 1980), the association of hepatitis C and IgAD probably reflects an effect rather than a cause.

#### Inflammatory Bowel Disease

An infectious etiology of inflammatory bowel diseases (IBD) has previously been strongly suspected but no microorganism has been etiologically linked to these disorders. Mice in which the genes for interleukin (IL)-2 or IL-10 or the T cell receptor (Mombaerts et al., 1993) genes have been inactivated (knockout mice) exhibit an inflammatory reaction in the gastrointestinal tract, which both histologically and "clinically" resembles human IBD. An infectious origin of the intestinal symptoms in these mice is likely, since the animals do not suffer from IBD if kept under germ-free conditions (Kuhn et al., 1993; Sadlack et al., 1993). These observations support the involvement of a microbial agent in the pathogenetic process.

A few IgAD and CVID patients have previously been described who suffer from Crohn's disease (Eggert et al., 1969; Douglas et al., 1971; Soltoft et al., 1972; Hodgson and Jewell, 1977; Saxon et al., 1977; Elson et al., 1984; Abramowsky and Sorensen, 1988; Teahon et al., 1994) or ulcerative colitis (Hollinger, 1967; Kaplinsky et al., 1973; Matuchansky et al., 1977; Curzio et al., 1985), but an association has not been ascertained because of the lack of a sufficiently large patient population.

#### Cancer Incidence

A high frequency of cancer, especially malignant lymphomas, has been described among patients with primary immunodeficiencies, but there are few investigations following patients over time and comparing cancer incidence with a background population for

**Figure 23.1.** Destruction of carpal bones and subluxation of the wrist joint in a 42-year-old patient with common variable immunodeficiency and *M. hominis* infection.

estimation of a relative risk. A British prospective study from 1985 (Kinlen et al.) reported a 23-fold increased risk for malignant lymphoma and 50-fold increase for gastric cancer among 377 patients with hypogammaglobulinemia, primarily CVID. Patients were followed for an average of 10 years. In another study, 98 patients with CVID were followed for up to 13 years, and the risk for lymphomas was estimated to be more than 100-fold increased (Cunningham-Rundles et al., 1987). This is comparable to the relative risk for non-Hodgkin's lymphoma found among 301 patients with combined immunodeficiencies such as the Wiskott-Aldrich syndrome (Perry et al., 1980). However, in a recent study on a large number of IgA-deficient individuals, followed for 20 years, no increased risk for malignancy could be observed (Mellekjaer et al., 2002), although a slightly increased incidence in malignant lymphoma and stomach cancer was noted in CVID patients followed for a similar time. The etiology of lymphoproliferative malignancy in primary immunodeficiency may involve infection with Epstein-Barr virus (EBV), defects in immunoregulations, and/or genetic instability, and previous experiments in  $\gamma$ -globulin-treated SCID mice repopulated with human peripheral blood lymphocytes from EBV-positive donors show a strong inhibitory effect of this therapy on tumor formation (Abedi et al., 1993). The excess of gastric cancer in immunodeficient patients may be related to a reduced immune response against *Helicobacter pylori*. However, we did not ob-

serve an increased prevalence in IgAD patients or healthy IgAD blood donors, nor was there any evidence for a higher titer of IgG antibodies against the microorganism in carriers. These findings argue against a pivotal role for IgA in the protection against infection (Bogstedt et al., 1996). Long-term studies are, however, not available to answer the question of whether the risk for ulcer development or gastric cancer is greater in IgAD-seropositive individuals than in a control population.

### Autoimmunity

The list of autoimmune disorders associated with IgAD and CVID has grown to include systemic lupus erythematosus, rheumatoid arthritis, Sjögren syndrome, dermatomyositis, thyroiditis, celiac disease, insulin-dependent diabetes mellitus, pernicious anemia, Addison disease, idiopathic thrombocytopenic purpura (ITP), and autoimmune hemolytic anemia. This is in stark contrast to XLA, in which autoimmunity is rare (see Chapter 21). In an early survey of IgAD patients, 37% were in fact found to have autoimmune disease or autoimmune phenomena (Amman and Hong, 1971). Similar data on the prevalence of autoantibodies in IgAD patients have been obtained through use of a panel of antinuclear antibody-related antigens (Goshen et al., 1989) and may suggest a predisposition to autoimmune symptoms in antibody-deficient individuals. Whether this is related to genetic factors (see below) or

caused by increased exposure to putatively cross-reactive antigens through an increased permeability of the respiratory and gastrointestinal mucosa remains unknown.

### Anti-IgA Antibodies

Antibodies against IgA are a common finding in patients with IgAD or CVID and up to 60% show demonstrable titers. The etiology of this immune response is unknown; it could be due to an autoimmune reaction against autologous IgA (Mochizuki et al., 1993) or occur through immunization via exposure to blood products containing IgA (Cunningham-Rundles et al., 1986; Frankel et al., 1986) or induced by IgA epitope-mimicking food products. Approximately 20–40% of the patients with IgAD have developed anti-IgA antibodies at the time of diagnosis without being exposed to IgA-containing blood products. Antibodies against IgA are usually of the IgG class, mainly IgG1 and IgG4 (Hammarstrom et al., 1983), but IgM anti-IgA antibodies may also be present (Bjorkander et al., 1987). In exceptional cases, the antibodies have been suggested to be of the IgE class (Burks et al., 1986; Ferreira et al., 1988), which may give rise to serious anaphylactic phenomena upon injection of IgA-containing blood products. Several severe reactions have indeed been reported after infusion of IgA-containing preparations (Vyas et al., 1968; Schmidt et al., 1969), and different methods have been tried to reduce or eliminate the concentration of anti-IgA antibodies in selected patients. Development of antibodies of differing specificities is genetically determined, and the induction of anti-IgA antibodies has also been suggested to be associated both with major histocompatibility complex (MHC) alleles (Strothman et al., 1989; Olerup et al., 1990) and Gm allotypes (Hammarstrom et al., 1985b).

Maternal transmission of IgAD, mediated by placentally transferred anti-IgA antibodies, could theoretically contribute to induction of the deficiency in selected cases of IgAD (Petty et al., 1985; de Laat et al., 1991). Human anti-IgA antibodies are transferred to the fetus and have been shown to inhibit IgA production in human cells in vitro (Warrington et al., 1982; Hammarstrom et al., 1983).

### Laboratory Findings

The pathognomonic hallmark of IgAD is a low level of serum IgA with normal levels of IgM and IgG (Table 23.3). However, raised levels of IgG, mainly IgG1 and IgG3, may be seen in up to a third of the patients. In most instances IgAD is defined as <0.05 g/l of serum IgA in adults. Almost invariably, there is a concomitant lack of secretory IgA, although a dichotomy has been documented in exceptional cases, and in small children, a saliva sample may suffice for determination of IgA status, thus avoiding blood sampling.

In CVID, IgA is usually absent and IgG levels are decreased, whereas IgM is low or absent in only half of the cases (Table 23.3). There is currently no recognized diagnostic level of IgG in CVID, although our working definition would suggest <3 g/l in adults.

Surface IgA-expressing B cells are usually low in patients with IgAD, and most cells express an immature phenotype with most IgA-positive cells simultaneously expressing IgD (Conley and Cooper, 1981). In contrast, the proportion of surface Ig-positive cells remains unaffected in most CVID patients. However the B cells do not mature properly, and plasma cell numbers are low in the bone marrow. A large number of additional cell surface CD markers have been analyzed in IgAD and CVID, but their diagnostic value is limited, although fluorescence-activated cell sorter (FACS) profiles have been suggested for subclassification of CVID patients (Warnatz et al., 2002). Similar restrictions

**Table 23.3.** Characteristic Laboratory Findings in IgA Deficiency and Common Variable Immunodeficiency

<i>Parameter</i>	<i>CVID</i>	<i>IgAD</i>
Serum IgM levels	Low/normal	Normal
Serum IgG levels	Low	Normal/high
Serum IgA levels	Low	Low
Secretory IgA	Low	Low
Surface IgM <sup>+</sup> cells	Normal	Normal
Surface IgG <sup>+</sup> cells	Normal	Normal
Surface IgA <sup>+</sup> cells	Normal	Low/normal
Autoantibodies (anti-IgA)	20%–30%	40%–60%
Lymphocyte CD markers	(Normal)	Normal
Mitogen responsiveness	Low/normal	Normal
Plasma cells (bone marrow)	Low	Normal

apply to in vitro testing with a panel of mitogens such as phytohemagglutinin (PHA), although it may aid in determining the extent of the T cell defect seen in a proportion of CVID patients.

The age at which the disease manifests itself may vary. In IgAD, most cases are probably manifest at birth, although formal studies on this point are lacking. Induction of “idiopathic” IgAD has actually been described in a few children.

CVID may develop in children, although most patients present with symptoms as adults. A biphasic distribution, with incidence peaks at 1–5 and 16–20 years of age, has been suggested (Hermaszewski and Webster, 1993).

Antibodies against IgA are also typical markers of IgAD and CVID. These autoantibodies are not seen in individuals with normal levels of IgA.

### Genetic Component of IgA Deficiency and Common Variable Immunodeficiency

#### Heritability of IgA Deficiency and Common Variable Immunodeficiency

Most cases of IgAD and CVID described to date have been sporadic, but familial cases have been observed, and a susceptibility trait can occasionally be traced back for many generations (Wollheim et al., 1964). Thus far, more than 100 families with multiple cases of IgAD have been reported in the literature (for references see Vorechovsky et al., 1995; Kralovicova et al., 2003). The mode of inheritance of the deficiency has been suggested to be either recessive or dominant. In 20% of the published cases, both IgAD and CVID occurred in the same family, usually presenting with CVID in the parental generation and IgAD in the children.

On the basis of extensive segregation analysis in hundreds of families, it was recently shown that a single gene is likely responsible for the regulation of serum levels of IgA (Borecki et al., 1994). Since no skewed sex ratio has been found in IgAD patients, it is possible that a single, autosomally inherited gene with a limited penetrance is responsible for the development of the defect. This hypothesis has prompted a search for the implicated gene.

#### Chromosome 6

The human leukocyte antigens (HLA) are implicated in the genetic susceptibility to a large number of diseases. Some of the diseases associated with HLA class II are related to specific amino acids or epitopes on the domain of the DR or DQ molecules.

As early as the late 1970s, an association between IgAD and certain HLA types was suggested. However, because these investigations were carried out on groups of patients with a variety of

diseases, the findings may have been secondary and due to an association with the primary diseases. In the early 1980s, it was shown for the first time that there was an association between isolated IgA deficiency and the MHC region (Oen et al., 1982), in particular the HLA class II region (Hammarstrom and Smith, 1983). A genetic predisposition similar to that found in IgA deficiency has also been observed in patients with CVID (Schaffer et al., 1989; Olerup et al., 1992), although the gene(s) implicated varies.

A report by Wilton et al. (1985) provided the first suggestion that genes within the MHC class III region are associated with IgA deficiency, as they found that deletions, duplications, or defects at the C4A or 21-hydroxylase (CYP21) loci were present on the majority of independent MHC haplotypes in the studied IgAD subjects. It was later reported that IgAD and CVID share polymorphisms of MHC class III complement genes (Schaffer et al., 1989). In a subsequent study by Volanakis and coworkers (1992), 12 IgAD and 19 CVID individuals from 21 families and their relatives were investigated. They found that a small number of MHC haplotypes were shared between most of the immunodeficient individuals and that at least one of two of these haplotypes was present in 77% of these individuals. These authors later confirmed their findings in a report on a family with two IgAD and three CVID members (Ashman et al., 1992). Similar results have been reported by Howe and coworkers (1991), who found a striking increase of C4A gene deletions in CVID patients, which were associated with specific HLA or tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ) gene polymorphisms.

We have previously investigated 110 Swedish IgAD subjects by C4 and factor B typing (Bucin et al., 1991). Of these individuals, 18% were C4A deficient compared to 5.8% of the controls ( $p < 0.01$ ). No significant deviations in the distribution of factor B variants were observed. Results from C4 typing in CVID patients showed a similar change to that in the IgAD patients compared to controls (Truedsson et al., 1995). Because of the strong linkage disequilibrium within the MHC, most haplotypes with C4A gene deletion are examples of an extended haplotype (Schneider et al., 1986).

The strong linkage disequilibrium of the MHC region makes the location of the locus associated with IgAD and CVID difficult to determine, and this question is still not answered. On the basis of data on MHC class III variants in these immunodeficiencies, a possible location in the class III region between the C4B and the C2 genes has been suggested (Volanakis et al., 1992).

Our own work suggests instead that the class II region, and in particular the DQ locus, is involved in mediating both susceptibility and resistance to development of IgAD (Olerup et al., 1990, 1991; Kralovicova et al., 2003) and CVID (Olerup et al., 1992; Kralovicova et al., 2003). A comparison of the sequences of the polymorphic amino-terminal domain of the DQ chain showed that the three susceptibility haplotypes all had a neutral alanine or valine at position 57, whereas the protective allele carried the negatively charged aspartic acid at this position. Recently, independent reports have suggested that two distinct loci, one in the class II region and one in the class III region, located on different MHC haplotypes, confer susceptibility to development of IgAD and CVID (de la Concha et al., 2002; Gual et al., 2004; Schroeder et al., 2004).

#### Chromosome 18

IgAD in patients with aberrations of chromosome 18 was first recognized in the mid-1960s. Deletions of the short arm, long arm, or ring chromosome 18 all result in Ig deficiency in approximately

half of the reported cases (for references see Hammarstrom and Smith, 1999). Because the exact breakpoint has not been delineated in most of these patients, it is possible that the extent of the deletion determines whether a deficient state will ensue or not. However, the results achieved to date suggest that the size of the lost fragment does not correlate directly to the immunoglobulin phenotype. Since one of the chromosomes is structurally normal, the deficiency must result from a hemizygous deletion or malfunction of the gene in question, and similar gene dose effects have been noted in other diseases. Li et al. (1995) have previously suggested an involvement of NFATc, a transcription factor in activated T cells that is involved in the expression of cytokines and surface molecules required for an immune response, in 18q patients lacking IgA. Because the defective gene in the immunodeficient wst/wst mouse resides in the corresponding syntenic region, a relationship could be possible. However, the mouse model does not clinically resemble IgAD or CVID (Kaiserlian et al., 1985), arguing in favor of the involvement of a different gene in the human disease. Furthermore, extensive analysis of a large number of families with IgAD/CVID shows no association with chromosome 18 markers in "idiopathic" IgAD (Vorechovsky et al., 1999).

An analysis of serum levels in our own patients with chromosome 18p deletions showed that one of them also lacked IgG2 and IgG4, giving rise to a CVID phenotype (Truedsson et al., 1995). This finding suggests a relation between the two different forms of defect in Ig production also in this category of patients.

### Functional Aspects

#### Defective Immunoglobulin Class Switch in IgA Deficiency and Common Variable Immunodeficiency

Switching is preceded by transcription of the I and switch regions upstream of the Ig heavy-chain constant-region gene, giving rise to germ-line transcripts. These transcripts are also referred to as *sterile transcripts* as they do not contain V region sequences. The I region is thought to play an important although not crucial role in the induction of switch, as mice with a targeted deletion of this genetic element still produce normal levels of IgA (Harriman et al., 1996). Germ-line I transcripts are easily detected in unstimulated peripheral blood mononuclear cells from normal donors whereas they are absent in cells from IgAD individuals (Islam et al., 1994). However, they can be readily induced by the addition of transforming growth factor- $\beta$  (TGF- $\beta$ ), demonstrating that the locus is accessible for transcription provided that additional signals are supplied. These transcripts, which are generated early after activation of the cells, also include  $\alpha$ . However, all subsequent stages of IgA production, including the switch at the genomic level, appear to be impaired (Islam et al., 1994). Although TGF- $\beta$  has been suggested as a switch factor for IgA, we could not find any difference in the steady-state production of this cytokine in cells from IgAD individuals. Still, a dysregulation of TGF- $\beta$  was suggested to be involved in the pathogenesis of IgAD because serum levels of the cytokine were markedly lower in patients than in controls (Müller et al., 1995).

IL-5 is a pleiotropic molecule with effects on both granulocytes and lymphocytes. In the mouse, this cytokine has been demonstrated to be of major importance for IgA production (Harriman et al., 1988; Stavnezer et al., 1988). Expression of IL-5 in the mouse appears to be regulated by genes within the MHC complex (Dieli et al., 1993), and in vivo administration of

the cytokine to low-responder mice results in an enhanced IgA response (Dieli et al., 1995). Human B cells also produce IgA when stimulated with IL-5 (Yokota et al., 1987), and in view of the association between genes within the HLA complex and IgAD and CVID, an involvement in the etiology may be envisaged. However, we have failed to demonstrate any decrease in the frequency of IL-5-producing cells or in the level of mRNA in individual cells from IgA-deficient individuals (Smith et al., 1990), thus diminished production of IL-5 may not be part of the pathophysiological process.

A cultivation system that allows the expression of immunoglobulins of both cells from IgA-deficient (Briere et al., 1994) and CVID (Zielen et al., 1993) patients has been previously described. In this system anti-CD40 antibodies are used in conjunction with IL-10. Although the physiology of this in vitro system—i.e., the induction of switching at the molecular level—still remains to be proven, it clearly demonstrates that secretion of IgG1, IgG3, IgG4 (Fujieda et al., 1995), and IgA (Zielen et al., 1993; Briere et al., 1994), with a biased expression of IgA1 (Friman et al., 1996), can indeed be achieved if the appropriate stimuli are added. Again, however, the basis of the inability to switch in vivo remains elusive as the gp39 (CD40 ligand) is expressed on T cells from CVID patients (Farrington et al., 1994), although at a slightly lower level in a subgroup of patients. This expression may be the cause of their long-recognized ability to support IgA synthesis in normal B cells (Smith and Hammarstrom, 1987). Thus, although the timing and concentration of cytokines may play a crucial role in the switching process, there is no strong evidence to implicate any cytokine or cytokine receptor in the disease process.

### Drug-Induced Immunoglobulin Deficiencies

IgA deficiency is infrequently seen in patients treated with a variety of antirheumatic and antiepileptic drugs (Table 23.4) (for references see Truedsson et al., 1995; Zhou et al., 2006). In approximately half of the reported patients the deficiency is reversible after cessation of treatment, although full recovery requires months or even years. The deficient state can be induced by multiple drugs in a given patient (Farr et al., 1991), thus selected individuals may be predisposed to develop drug-induced Ig deficiency. Recent findings clearly suggest that selected drugs

such as hydantoin act late in B cell differentiation through a mechanism distinct from the idiopathic form of IgAD (Zhou et al., 2006).

CVID and IgG2-IgA deficiency have also been shown to be induced by some of the above drugs (for references see Truedsson et al., 1995), and the recent identification of unifying links between drug-induced CVID and IgAD suggests that the iatrogenic form may be similar to the idiopathic form of Ig deficiency and that the etiological process involves common steps.

The mechanism underlying the drug-induced form of IgAD and CVID has not been determined. There is as yet no common molecular denominator in the drugs used, and identification of novel drugs, or category of drugs, would therefore be of marked benefit for our understanding of the phenomenon. Some of them contain a highly reactive sulfhydryl group. It is therefore possible that the immunological dysregulation induced by these agents, including the formation of immune complexes and induction of autoimmune disorders such as systemic lupus and pemphigus (for references see Smith and Hammarstrom, 1985), plays a role in development of the deficiency in genetically susceptible patients.

### Strategies for Diagnosis

Selective IgAD hardly presents any diagnostic problems in adults. But because serum IgA levels may remain low for a protracted time period in children (Plebani et al., 1986), a diagnosis of IgAD cannot be made before the teens, using <0.05 g/l as a cutoff. A simultaneous absence of IgG2 and IgG4, even in early childhood, is a strong indicator of persistent IgAD.

CVID probably represents a mixture of diseases with different etiologies. Recently, a deletion in the *ICOS* gene, encoding the inducible costimulator expressed on T cells and required for late B cell differentiation, class switching, and memory B cell generation, was shown to result in a disorder resembling adult-onset CVID (Grimbacher et al., 2003). However, only a minority of CVID patients is affected by mutations of *ICOS*, and all patients described to date show the same genetic alteration.

Genes on chromosome 5 have also been suggested to be involved in the pathophysiological process in selected CVID patients (Braig et al., 2003), as have mutations in the *LRRC8* gene on chromosome 9 (Sawada et al., 2003).

Surface Ig-positive cells remain unaffected in the blood of most patients with CVID. However, in patients with XLA, these cells are low or absent, which may aid in the differential diagnosis in young boys. The cloning of the *BTK* gene (see Chapter 21) enables the differential diagnosis in a vast majority of XLA patients by mutation screening. The spectrum of infections also differs slightly, and patients with CVID are prone to nonbacterial infections, as a proportion of patients show a concomitant T cell defect.

A distinction between CVID and hyper-IgM syndrome can be made on the basis of gender, as most patients show an X-linked inheritance pattern, and through levels of immunoglobulins where IgM levels are elevated in typical cases. Again, the spectrum of infections appears slightly different, and since most genes involved have been cloned (see Chapter 19), a correct diagnosis is possible by mutation screening.

X-linked lymphoproliferative disease (XLP) is a primary immunodeficiency caused by a defect in the *SH2D1A* gene. The disease is characterized by severe, often fatal infectious mononucleosis, lymphomas, and Ig deficiencies. Although typical cases (see Chapter 32) are easily distinguishable from CVID patients,

**Table 23.4.** Pattern of Drug-Induced Immunoglobulin Deficiencies

Drug	CVID	IgG2-IgAD	IgAD
Sulfasalazine	X	X	X

\*Requires independent confirmation.

problems in the differential diagnosis may occur (Morra et al., 2001; Soresina et al., 2002), and sequencing of the *SH2D1A* gene may therefore be warranted.

The warts, hypogammaglobulinemia, immunodeficiency, myelokathexis (WHIM) syndrome represents yet another potential differential diagnosis to CVID. The genetic defect of the WHIM syndrome was recently identified as truncating mutations in the cytoplasmic portion of the G protein-coupled, chemokine receptor *CXCR4* gene, which is located on chromosome 2q21 (Hernandez et al., 2003). *CXCR4* is the receptor for CXCL12, also known as stromal-derived factor 1 (SDF-1). Coined by Wetzler et al. (1990), this autosomal dominant disease is characterized by recurrent bacterial infections and extensive human papillomavirus infections, whereas infection with cytomegalovirus or *Toxoplasma gondii* runs a normal course (Diaz, 2005). The phenotype is not identical among affected individuals, because warts are not seen in all patients and the hypogammaglobulinemia may be variable. Nonimmunological phenotypes may also exist, since at least one patient and deficient mice have cardiac abnormalities. In terms of the immunological phenotype, both mice (Ma et al., 1998; Zou et al., 1998) lacking the protein and humans with truncating mutations show B cell lymphopenia. There is a special lack of memory B cells and a restricted T cell repertoire (Gulino et al., 2004) in the mouse, and myeloid progenitors fail to migrate to the bone marrow. In affected humans, myeloid cells fail to exit the bone marrow (myelokathexis) in the absence of inflammation, resulting in neutropenia. Treatment consists of granulocyte colony-stimulating factor (G-CSF) (not used by all centers) and intravenous immunoglobulin (IVIG). Lymphoid tumors have been reported, which suggests the importance of intact CXCL12–*CXCR4* signaling for proper regulation of lymphocyte proliferation (Chae et al., 2001; Imashuku et al., 2002). Certain patients have abnormalities in the CXCL12–*CXCR4* pathway that are not caused by *CXCR4* mutations, thus the genetic basis may be diverse (Balabanian et al., 2005).

TACI and BAFF-R are TNF-like receptors, responding to a number of ligands (BAFF, BCMA, and APRIL) involved in maturation and differentiation of B cells. In view of the impaired Ig class switching recently described in APRIL- (Castigli et al., 2004) and BAFF-deficient mice (Schiemann et al., 2001), it seems likely that similar defects involving this family of receptors and ligands will also be involved in the pathogenesis of selected cases of CVID in humans. Indeed, truncating and mismatch mutations have been described in both TACI (Salzer et al., 2004b; Castigli et al., 2005, Salzer et al., 2005) and BAFF-R (Salzer et al., 2004a) and shown to be associated with a CVID phenotype. The former may account for up to 10% of all patients, whereas the latter seems much more rare.

The CD19 molecule is expressed by B lymphocytes and follicular dendritic cells of the hematopoietic system and it is the earliest of the B lineage-restricted antigens. It is present on the cell surface associated with CD21, CD81, CD225, and the B cell receptor (BCR) complex, and acts to lower the threshold for antigen-mediated signaling. In mice, the CD19 molecule is involved in development of B1 and marginal-zone B cells and, when lacking, antibody responses and B cell memory are strongly affected. The first mutations in CD19 in patients with CVID were recently described in two separate families (van Zelm et al., 2006). It is likely, however, that this is a rare cause of CVID.

In patients with hypogammaglobulinemia due to thymoma, B cells are lacking altogether in both peripheral blood and the bone marrow, and a scan of the thymus may indicate presence of a tumor. Age at onset may also be of some help in the differential

diagnosis of hypogammaglobulinemia. Adult onset of infections clearly suggests CVID rather than XLA, and thymomatous patients are usually although not invariably older than the average CVID patient.

## Treatment Options

The foundation of therapy for CVID and IgAD patients is antibiotics and Ig replacement. Gammaglobulin infusions have been used for decades in patients with CVID, but only recently have infectious-prone patients with IgAD received  $\gamma$ -globulin therapy (Gustafson et al., 1997). The doses employed have gradually risen, and today a weekly dose of 100–150 mg/kg body weight is recommended (Rosen et al., 1995).

Prior to the introduction of  $\gamma$ -globulin replacement therapy in XLA patients,  $\gamma$ -globulin had been given intramuscularly primarily as prophylaxis against various viral diseases. Bruton (1952) however, started his patients on prophylactic treatment using subcutaneous injections of  $\gamma$ -globulin, a treatment regimen that was later altered to intramuscular administration. The intramuscular injections remained the mode of therapy for immunodeficiency patients for almost two decades. However, because of the limited amount that could be given, IVIG preparations were developed.

Treatment with slow, subcutaneous infusions of  $\gamma$ -globulin was reintroduced by Berger et al. (1980), and a number of reports on the treatment of hypogammaglobulinemic patients followed (for references, see Gardulf et al., 1991). However, because of the slow rate of infusion, this form of treatment did not meet with widespread appreciation.

Home treatment of hypogammaglobulinemia in patients with primary immunodeficiency disorders with  $\gamma$ -globulin for intravenous use (IVIG) was introduced in 1986 (Ochs et al., 1986) and represented a significant step forward in the prophylactic use of  $\gamma$ -globulin. This initial report was soon followed by additional reports (Ashida and Saxon, 1986; Chapel et al., 1988; Ryan et al., 1988) showing the effectiveness of the method. This form of treatment is limited, however, to patients with no prior history of adverse reactions to  $\gamma$ -globulin treatment, requires the training and continuous presence of a partner during infusions, and is dependent on easy access to suitable blood vessels.

Rapid subcutaneous infusion of  $\gamma$ -globulin preparations intended for intramuscular administration was first described by Gardulf et al. (1991) and can be used in patients with a previous history of adverse reactions even in a home setting, requires no presence of a trained partner, results in a very low incidence of adverse reactions (Gardulf et al., 1995), and is markedly cheaper than home treatment with IVIG. This treatment therefore represents a preferred form of prophylaxis in patients with CVID (Gardulf and Hammarstrom, 1996).

In spite of replacement therapy with intravenous or subcutaneously administered  $\gamma$ -globulin, some patients still suffer from respiratory and gastrointestinal tract infections. Topical application of  $\gamma$ -globulin preparations might therefore be of benefit, as it provides a high local concentration of specific antibodies at the site of infection. In five patients with CVID who were chronic nasopharyngeal carriers of non-encapsulated *Hemophilus influenzae*, nose drops containing human immunoglobulins were provided as treatment. The preparation of IgA and IgG was given as nose drops and the results showed that two of the five patients cleared their infection and remained culture negative for a prolonged period of time (Lindberg et al., 1993). Coughing was also alleviated in all patients, thus nasally administered Ig may be of potential use in treating immunodeficient patients.

Oral administration of polyclonal human Ig has also been shown to be therapeutically effective against intestinal infections in immunodeficient patients (Melamed et al., 1991; Hammarstrom et al., 1993; Tjellstrom et al., 1993). Although this form of therapy remains experimental, it may constitute a valuable therapeutic option in selected cases.

During the past few years, we have witnessed a remarkable increase in our knowledge of the molecular basis of a variety of immunodeficiency disorders in humans. As a result of these efforts, novel findings on point mutations, deletions, and splicing abnormalities have been described in a number of diseases, including XLA, hyper-IgM syndrome, Wiskott-Aldrich syndrome, and ataxia-telangiectasia (AT). It is clear from the published studies not only that different mutations may give rise to varying phenotypical appearances, but the very same mutation can be associated with quite diverse clinical pictures, depending on the presence of modifying "background" genes.

Diseases such as IgAD, IgAD combined with IgG2 and IgG4 deficiency, and CVID all seem to share a common genetic background and may therefore be related diseases, expressing different facets of the same underlying defect. This finding is important not only for a conceptual understanding of these disorders and the development of a correct nomenclature but also for mapping of disease genes. Induction of IgAD and CVID probably requires the presence of a predisposing gene and a triggering factor, the nature of which is still unknown. In most of the multicase families, affected family members are found in more than one generation, a pattern compatible with an autosomal dominant inheritance with a limited penetrance. It is not clear whether a predisposing gene would have to be present in a heterozygous or a homozygous state. If disease symptoms occur from a heterozygous state, the immunoglobulin deficiency-associated protein could be part of a multimer complex—perhaps a receptor involved in cell proliferation, differentiation, and class switching, where an improper balance in concentrations of the subcomponents may perturb its function. It is thus likely that the key to understanding the true basis of IgAD and CVID is the identification of the gene(s) involved in their pathogenesis. A genome-wide search for susceptibility genes in a large cohort of multiplex families is required to solve the questions of etiology and pathogenesis of these forms of immunological defects.

### Animal Models

Although there are a number of reports on IgA-deficient dogs (Felsburg et al., 1985; Moroff et al., 1986; Glickman et al., 1988) and chickens (Luster et al., 1976), the molecular basis of these deficiencies has not been elucidated.

There is as yet no rodent model available that resembles the human disease, although knockout mice with a deleted J chain (Hendrickson et al., 1995), I $\alpha$  region (Harriman et al., 1996), or C $\alpha$  region (Harriman et al., 1999) have been described. In J chain-deficient mice, only secretion of IgA is impaired, and serum levels of IgA are up to 30-fold higher than in normal wild-type mice. Interestingly, there seems to be a J chain-independent IgA transport in the intestinal, mammary, and respiratory epithelial cells of these mice (Hendrickson et al., 1996), adding to the complexity of the secretory IgA machinery. Contrary to what might have been expected from mice with deleted I regions or I region promoters for  $\gamma$ 1,  $\gamma$ 2b, and  $\epsilon$ , mice with an I region deletion produced normal levels of IgA. This observation suggests that the I region as such is redundant and can be replaced by other gene sequences (Lorenz et al., 1995). Thus splicing of germ-line

transcripts rather than transcription per se may control DNA rearrangement leading to class switch.

Mice with a targeted inactivation of the  $\alpha$  heavy-chain constant-region gene and part of the S $\alpha$  region have also been produced (Harriman et al., 1999). These mice are profoundly deficient in both systemic and secretory IgA and show a perturbed pattern of expression of immunoglobulins, manifested as an increased level of IgM and IgG (primarily IgG2b) and decreased levels of IgG3 and IgE in both serum and secretions. These mice are, however, largely normal in development of their lymphoid tissues and proliferative responses. Cytokine profiles in response to antigenic challenge (influenza virus) are altered with a down-regulation of Th1-mediated immune responses (Zhang et al., 2002).

### Acknowledgments

This work was supported by the Swedish Research Council and EU grant QLGI-CT-2001-01536. We are indebted to Dr. David Webster at the Royal Free and University College Medical School, London, for kindly providing the figures presented in this chapter.

## Autoimmune Lymphoproliferative Syndrome

JENNIFER M. PUCK, FREDERIC RIEUX-LAUCAT, FRANÇOISE LE DEIST,  
and STEPHEN E. STRAUS

Immunodeficiency disorders have traditionally been thought of as conditions resulting from the inability to mount effective host responses to infectious agents. However, immune dysregulation and autoimmune phenomena are seen in many inherited and acquired immunodeficiency disorders. Particular alleles of the major histocompatibility (MHC) locus have long been associated with increased susceptibility to a variety of diseases with an autoimmune basis, for example, insulin-dependent diabetes mellitus and celiac disease (Bodmer, 1996; Hammer et al., 1997; Thorsby, 1997). The detailed mechanisms that allow tolerance to be broken so that immune reactions can be directed against one's own tissues are becoming better understood. The composition of the lymphocyte antigen recognition repertoire and the potential for cross-reactivity between self-antigens in one's tissues and foreign antigens from the environment is defined in part by an individual's MHC haplotypes. With improved understanding of the processes directing selection, expansion, and control of an appropriate lymphocyte repertoire, several non-MHC-linked heritable immune disorders are now recognized in which disruption of regulatory functions is a predominant feature. For example, autoimmune polyendocrinopathy with candidiasis and ectodermal dystrophy, or APECED (see Chapter 25), is due to defects in an inducer of presentation of self-antigens in the thymus to provide for central tolerization (Anderson et al., 2002; Liston et al., 2003). Autoimmunity is also a hallmark of interleukin (IL)-2 receptor  $\alpha$ -chain deficiency (Chapter 15), common variable immunodeficiency (Chapter 23), Wiskott-Aldrich syndrome (Chapter 31), and X-linked immunodysregulation–polyendocrinopathy–enteropathy (IPEX, Chapter 26). The present chapter concentrates on a discrete class of inherited autoimmune disorders due to impaired apoptosis of activated peripheral lymphocytes.

After leaving the thymus, mature T cells normally undergo a life cycle of activation and effector responses followed by

apoptosis, or programmed cell death. Apoptosis maintains immune homeostasis and minimizes potential reactions against self-antigens by limiting lymphocyte accumulation after appropriate expansion in response to antigenic challenge. It is not surprising that a process as important as apoptosis is tightly regulated by interactions among multiple components. Two major mechanisms for the death of lymphocytes after their stimulation are recognized (Lenardo et al., 1999). Passive apoptosis mediated by mitochondrial mechanisms follows withdrawal of IL-2 after clearance of antigen, whereas active apoptosis requires the engagement of specific cell surface molecules, principally the Fas receptor, a member of the tumor necrosis factor receptor (TNFR) gene superfamily also known as CD95 or APO-1.

After lymphocytes have been stimulated and are proliferating, a second encounter with antigen induces expression of both the transmembrane receptor Fas and its ligand, Fas ligand (FasL). Extracellular engagement of a trimer of FasL chains with homotrimeric Fas triggers a cascade of intracellular molecular events leading to alterations in the cell membrane, DNA fragmentation, and ultimately the death of the cell. Two animal models that reveal the *in vivo* importance of this pathway in maintaining lymphocyte homeostasis are mice with *lpr* and *gld* mutations, genetic defects in Fas and FasL expression, respectively (Nagata and Goldstein, 1995). These mice develop lymphoproliferation, autoantibody formation, and autoimmune nephritis. The relevance of the Fas apoptotic pathway to human disease was postulated in 1992 with a description of two children with massive, nonmalignant lymphoid hyperplasia and autoimmune disease (Sneller et al., 1992). Subsequently, Rieux-Laucat et al. (1995) from INSERM, in Paris, and Fisher et al. (1995) from the U.S. National Institutes of Health (NIH) documented that this disorder, now called *autoimmune lymphoproliferative syndrome* (ALPS), is associated with inherited mutations in the

gene encoding Fas, *FAS* or *TNFRSF6* (for tumor necrosis factor receptor superfamily member 6, MIM #601859, \*134637). The condition has also been called *lymphoproliferative syndrome with autoimmunity* and *Canale-Smith syndrome*, named for the authors of an early clinical description of the condition (Canale and Smith, 1967). Further reports by these and other teams of investigators have enlarged the number of known patients with ALPS to well over 200 and documented that the syndrome can be associated with defects in apoptosis pathway members other than the transmembrane Fas receptor. While the series of patients followed at the NIH is currently the largest (Sneller et al., 1997, 2003; Jackson et al., 1999; Bleesing et al., 2001), patients have been reported worldwide (Drappa et al., 1996; Bettinardi et al., 1997; Le Diest et al., 2003; Rieux-Laucat et al., 2003), providing an increasingly comprehensive picture of the clinical, genetic, and immunologic features of ALPS and its consequences for a patient bearing this defect in lymphocyte apoptosis over a period of decades.

Even among the cohorts of ALPS patients bearing Fas mutations, the story is a complex one. The majority of patients with ALPS have heterozygous *TNFRSF6* mutations, but compound heterozygous or homozygous mutations have been found in a few severely affected patients with early-onset disease in infancy. Most of the mutant Fas alleles from patients with ALPS have a dominant negative effect on apoptosis by normal alleles coexpressed in the same cell. The relatives of ALPS patients who share the same Fas defects may have mild or undetectable lymphoproliferation and autoimmunity, or may be severely affected. These considerations suggest that factors in addition to heterozygous defects of Fas are required for the full clinical expression of ALPS. In addition, individuals with inherited Fas defects are at increased risk of lymphoma and possibly other malignancies. Thus, as the first human immune disorder to be associated with defective lymphocyte apoptosis, ALPS illuminates the critical role of cell death in health and disease.

### Diagnostic Criteria and Classification by Genotype

Autoimmune lymphoproliferative syndrome is defined as an impairment of lymphocyte apoptosis that includes chronic, nonmalignant lymphadenopathy and/or splenomegaly, plus expansion of a normally rare subset of lymphocytes in the peripheral blood and tissues—T cells that express  $\alpha/\beta$  T cell receptors (TCR $\alpha/\beta^+$ ) but express neither CD4 nor CD8 coreceptors (CD4 $^-$  CD8 $^-$ ), cells that are referred to as *double-negative T* (DNT) cells. The

**Table 24.1.** Defining Features of Autoimmune Lymphoproliferative Syndrome

#### I Required

Chronic (>6 months duration) accumulation of nonmalignant lymphocytes  
Splenomegaly  
Noninfectious lymphadenopathy  
Elevated numbers of CD4 $^-$  CD8 $^-$  T cells expressing  $\alpha/\beta$  T cell receptors (DNT cells)  
>1% of T cells in peripheral blood  
Demonstrated in histological specimens such as spleen or lymph nodes  
Defective lymphocyte apoptosis by in vitro assay

#### II Nearly Universal

Autoimmunity, including one or more of the following:  
Autoimmune hemolytic anemia  
Autoimmune thrombocytopenia  
Autoimmune neutropenia  
Other autoimmune manifestations  
Autoantibodies, especially positive direct Coombs test

#### III Supporting

Positive family history of  
Lymphoproliferation, with or without documented autoimmunity  
Lymphoma  
Deleterious mutation of *TNFRSF6* or other gene encoding apoptosis mediator proteins

DNT, double-negative T (cells).

strict case definition of ALPS (Table 24.1) requires lymphocyte accumulation, DNT expansion, and defective lymphocyte apoptosis as assayed in vitro. Autoimmune phenomena occur at some time in many individuals manifesting these required elements. Subjects in whom all ALPS criteria cannot be met because of the nonavailability of suitable specimens for analysis can be considered to have a presumptive diagnosis of ALPS. Both the definitive and presumptive diagnoses are further supported by a family history consistent with an autosomal dominant disorder, by occurrence of lymphoma in the patient or his or her relatives, and by molecular diagnostic studies discussed below.

A classification system for genotypes of ALPS has been established by the NIH group (Puck and Straus, 2004), with variations suggested by others (Rieux-Laucat et al., 2003; Holzelova et al., 2004). As shown in Table 24.2, *ALPS Ia* includes the originally reported patients, in whom germ-line *TNFRSF6* mutations produce deleterious consequences for the expression or function of the Fas protein. This type accounts for two-thirds to three-quarters of all

**Table 24.2.** Genotypic Classification of Autoimmune Lymphoproliferative Syndrome in Unrelated Probands

ALPS Type	Defective Gene	Protein	Percent of ALPS Cases*
Ia	<i>TNFRSF6</i>	Fas, major apoptosis receptor in lymphocytes	79
Ia (somatic mutant)	<i>TNFRSF6</i>	Same as type Ia	Unknown
Ib	<i>TNFSF6</i>	Fas ligand	<1
II	<i>CASP10</i> , <i>CASP8</i>	Caspase-10 or caspase-8, intracellular protease in apoptosis cascade	3
III <sup>†</sup>	Unknown	Unknown	17

\*NIH cohort (Zhu et al., 2006, and unpublished data).

<sup>†</sup>May include individuals with ALPS Ia, somatic mutant.

ALPS cases in various series. The majority of ALPS Ia patients have dominant, heterozygous *TNFRSF6* mutations, but two patients with compound heterozygous mutations and a patient with homozygous null mutation of Fas have been reported (Rieux-Laucat et al., 1995; Jackson et al., 1999; van der Burg et al., 2000). A few patients reported more recently have had somatic changes in Fas without germ-line mutations (Holzelova et al., 2004), and these are designated *ALPS Ia, somatic*.

Patients who meet the defining criteria for ALPS but lack Fas defects may have deleterious mutations in genes encoding other components of apoptosis pathways. A defect in FasL in an adult patient with atypical lupus defined *ALPS Ib* (Wu et al., 1996). Patients with ALPS and defects in caspase-10 are known as having *ALPS II* (Wang et al., 1999; Zhu et al., 2006). Two siblings with defects in caspase-8 and a phenotype including mild ALPS features plus immunodeficiency can also be considered to have ALPS II (Chun et al., 2002). Patients who meet all the clinical and laboratory criteria for ALPS but in whom mutations in apoptosis pathway genes have not been identified are termed *ALPS III*. Additional patients have been described who have some features of ALPS, but no demonstrable defects of in vitro apoptosis; these are not included in the strictly defined syndrome (Dianzani et al., 1997; unpublished data).

### Epidemiology

Autoimmune lymphoproliferative syndrome occurs in both sexes and in persons of diverse racial backgrounds. Because it is a rare condition that has been defined only within the past few years, no figures estimating incidence have yet been generated. However, patients with idiopathic lymphoproliferation and autoimmune phenomena, sometimes inherited as autosomal dominant

traits, have appeared in multiple literature reports and clinical series from the 1960s onward (Randall et al., 1965; Canale and Smith, 1967; Holimon and Madge, 1971; Rao et al., 1974; Cheng et al., 1980). Some of these individuals are likely to have been suffering from ALPS, and in at least three cases ALPS has been proven in follow-up by detection of mutations in *TNFRSF6* (Drappa et al., 1996). Patients with medical findings consistent with ALPS have been under the care of physicians in many specialties: hematologists, called upon to manage the thrombocytopenia and hemolytic anemia; oncologists, who have biopsied the enlarged lymph nodes and sometimes felt compelled to treat patients with persistent adenopathy as if they had lymphoma; and rheumatologists, who have evaluated and managed some of their autoimmune phenomena.

In patients with defined mutations of *TNFRSF6* it has been possible to recognize multiple relatives bearing identical mutations, but with highly variable clinical penetrance. However, similar mutations have not been detected in large numbers of healthy individuals screened at random. In some ALPS families most or all individuals with Fas mutations meet strict criteria for ALPS, as listed in Table 24.1, whereas in other genetically affected persons few or no clinical, immunological, or hematological manifestations can be found.

### Clinical Manifestations

Clinical features of ALPS Ia due to mutations in *TNFRSF6* are listed in Table 24.3. The frequencies of each feature are given for probands, defined as unrelated individuals who were the first in their kindred to be referred to the NIH, and their relatives who carry the same *TNFRSF6* mutations as the probands (Sneller et al., 2003, unpublished data). Other series are similar in overall

**Table 24.3.** Clinical Findings in Probands with ALPS Ia and Their *TNFRSF6* mutation–Positive Relatives (NIH Cohort)

<i>Clinical Finding</i>	<i>Probands*</i> (n = 79)	<i>Relatives†</i> (n = 164)
Age of diagnosis	Birth to 15 years (mean, 2 years)	NA
Gender	36 males, 43 females	
Lymphoproliferation	100%	44%
Lymphadenopathy	92%	30%
Splenomegaly	88%	23%
Splenectomy	51%	17%
Hepatomegaly	72%	NA
Autoantibodies in significant titer	69%	24%
Overt autoimmune disease	70%	24%
Hemolytic anemia, Coombs positive	51%	12%
Idiopathic thrombocytopenic purpura	47%	12%
Neutropenia	23%	2%
Hepatitis, biliary cirrhosis	2–3%	1%–2%
Optic neuritis, uveitis, episcleritis	2–3%	0%
Thyroiditis, hypothyroidism	1–2%	2%
Glomerulonephritis	1–2%	0%
Polyneuroradiculitis (Guillain-Barré)	1%	1%–2%
Encephalomyelitis	1%–2%	0%
Skin rashes, including urticaria, vasculitis	common	NA
Malignancy		
Lymphoma	9%	4%

NA, not available.

\*Proband, the first member of each family referred to the NIH.

†While some relatives with *TNFRSF6* mutations meet the criteria for the full definition of ALPS, others do not, because of reduced penetrance and variable expressivity.

range and frequency of clinical features (Le Deist et al., 1996; Vaishnav et al., 1999b). The presentation of probands with splenomegaly and adenopathy is most often in infancy or early childhood, with a mean age of 2 years; only rarely do patients present with adenopathy as late as 15 years. At least three children were clinically affected at birth (Le Deist et al., 1996, 2003; Bettinardi et al., 1997).

### Lymphoproliferation

Lymphoproliferation is the most dramatic and consistent physical feature of ALPS (Table 24.3). In addition, patients almost always develop splenomegaly of moderate to massive proportions before age 5. Although the dimensions of the spleen may fluctuate over time in a given patient, palpable splenomegaly almost always persists. The spleen may extend only 2 to 4 cm below the left costal margin or past the umbilicus and into the pelvis with commensurate degrees of abdominal distention. Splenectomy, originally performed in most patients to manage blood cytopenias, is now discouraged unless severe hypersplenism is refractory to other measures. Splenectomy has been necessitated in ALPS patients by traumatic rupture of their enlarged spleens.

Mild to moderate hepatomegaly is observed in most patients at some point in time. However, clinical signs of liver dysfunction are uncommon in the absence of hepatitis C virus infection, which has complicated the course of some patients who have received blood transfusions for management of severe hemolytic anemia.

Lymphadenopathy is a consistent feature of ALPS. Virtually all patients have experienced protracted periods of palpable, nontender lymph node enlargement, but the dimensions of the nodes can fluctuate, tending to become relatively less impressive through adolescence and adulthood. On the other hand, lymphadenopathy may be massive, distorting anatomical landmarks, as seen in the 5-year-old child depicted in Color Plate 24.I, in whom the lymphoid mass varied but did not abate through 10 years of serial clinical observations. The anterior, posterior cervical, and axillary chains in this patient were the primary sites of enlarged lymph nodes, but as seen in the rear view, there was also enlargement of posterior nodes. Some patients have had enlargement of preauricular and submental nodes as well as nodes in the axillary, epitrochlear, and inguinal chains. Mediastinal and retroperitoneal adenopathy can be detected on imaging studies (Avila et al., 1999; Rao et al., 2006). Canale and Smith (1967) observed that intercurrent infections were associated with reductions in lymph node size, and patients followed at the NIH have had similar paradoxical decreases in lymph nodes in a few, but not most, instances of documented infections.

### Autoimmunity

Autoimmunity in ALPS is largely directed against blood cells. Direct Coombs-positive autoimmune hemolytic anemia (AIHA) is the most common autoimmune complication (Table 24.3), immune-mediated thrombocytopenia (ITP) second, while autoimmune neutropenia has been proven less frequently, possibly because of a lack of sensitive standardized tests for antineutrophil antibodies. Episodes of hemolysis may be severe; many patients have experienced at least one occasion on which hemoglobin levels fell below 7 mg/dl. Similarly, platelet counts below 10,000/ $\mu$ l have been seen one or more times in almost half of the patients followed at the NIH (Sneller et al., 1997, unpublished results).

Glomerulonephritis with renal compromise has been severe enough to require dialysis, and Guillain-Barré polyneuroradiculi-

tis has occurred without any recognized predisposing infectious illness (Sneller et al., 1997; Rieux-Laucat et al., 2003). In addition, many patients suffer from recurring rashes, including urticaria and nonspecific cutaneous vasculitis. Other infrequently reported findings of unclear, but presumably immune-mediated pathogenesis in ALPS patients have immune-mediated included arthralgia, arthritis, hepatitis, biliary cirrhosis, iridocyclitis or uveitis, mucosal ulcers, panniculitis, pulmonary infiltrates, seizures, and vasculitis (Rieux-Laucat et al., 2003; Sneller et al., 2003).

Autoimmunity is a hallmark in ALPS. However, it can be difficult to document for three reasons. First, not all patients are tested for many recognized types of autoantibodies. Second, some patients manifest overt autoimmune phenomena only after many years of lymph node and spleen enlargement. For example, one patient seen at the NIH first developed ITP at age 31, while another first manifested AIHA at age 54. Finally, in the absence of demonstrable antiplatelet, antineutrophil, or anti-red cell antibodies, one cannot diagnose with certainty an immune basis for blood cytopenias in a setting of ongoing hypersplenism. Additional patients such as those in reports of Le Deist et al. (1996) and Bettinardi et al. (1997), who were recognized because of their more severely affected siblings, are so far without overt autoimmune disease but do have circulating autoantibodies.

### Malignancy

In some patients who later proved to have ALPS a lymphoreticular malignancy had been diagnosed and even treated with multidrug chemotherapy, but this diagnosis was later reversed upon review of the histology in lymph node biopsies. However, in one of the earliest reports of ALPS, Hodgkin disease (HD) and non-Hodgkin lymphoma (NHL) were confirmed in two young adult brothers with ALPS, one of whom died (Fisher et al., 1995). An unrelated ALPS patient treated for confirmed NHL has had an affected cousin who developed HD at age 7, and another unrelated woman and her son with ALPS both had HD (Infante et al., 1998; NIH, unpublished data). A multicenter study determined that in patients with ALPS Ia, the risk of NHL was 14-fold and that of HD was 51-fold above that of the general population (Straus et al., 2001). Lymphomas are almost exclusively B cell derived and include various subtypes of HD, Burkitt lymphoma, follicular B lymphoma, and T cell-rich B cell lymphoma. The overall rate of lymphoma among ALPS Ia patients followed at the NIH is 9% (Table 24.3) (Sneller et al., 2003). Lymphoma has been diagnosed in patients up to 51 years of age; as young patients are followed for increasing durations of time, the overall rate of lymphoma may increase.

Two older ALPS patients reported by Drappa et al. (1996) had malignancy. One, who died of hepatocellular carcinoma at age 43, had risk factors including hepatitis C and a history of prior cytotoxic chemotherapy for his adenopathy. The other had multiple thyroid and breast adenomas and two basal cell carcinomas, all between the ages of 15 and 41. Other solid-organ malignancies have occurred in some of the older relatives of ALPS patients, but neither their frequency nor any other features recognized to date clearly distinguish them from malignancies in the general population.

### Overlap Between Autoimmune Lymphoproliferative Syndrome and Other Syndromes

With increased awareness in the medical community, patients previously diagnosed with other conditions have been recognized

to have ALPS. Evans syndrome is a hematologic disorder of unknown etiology consisting of multiple autoimmune blood cytopenias, most commonly hemolytic anemia and thrombocytopenia. Enlargement of lymph nodes, spleen, and liver occurs in over half of the cases. First described by Evans et al. (1951), this syndrome is clinically similar to ALPS. A recent examination of 12 patients with Evans syndrome confirmed ALPS in half of them (Teachey et al., 2005). The authors of this study suggested enumeration of  $\alpha\beta$  DNT cells in all cases of Evans syndrome as an initial screening test for ALPS.

Children with sinus histiocytosis with massive lymphadenopathy (SHML), also known as Rosai-Dorfman disease, share some clinical features with ALPS, including prominent adenopathy, hypergammaglobulinemia, and autoimmune phenomena in 10%–15% of cases (Rosai and Dorfman, 1969, 1972; Grabczynska et al., 2001). Histological examination of tissues from 44 patients with confirmed ALPS Ia revealed in 18 cases the characteristic SHML histiocytic proliferation with emperipolesis (enlarged histiocytes that have engulfed other blood cells) and prominent expression of the S-100 antigen that typifies Rosai-Dorfman syndrome (Maric et al., 2005). A preliminary report has also noted *TNFRSF6* mutations in DNA isolated from tissues of SHML patients (George et al., 2004).

Although the original mouse with Fas deficiency was developed as a model for human systemic lupus erythematosus (SLE), *TNFRSF6* mutations have not been found commonly in patients with SLE. Nonetheless, at least one patient each with ALPS Ia, Ib, and II confirmed by mutation analysis has fulfilled the diagnostic criteria for SLE (Wu et al., 1996; Vaishnav et al., 1999b; Gill et al., 2003; Zhu et al., 2006).

Finally, the recognition of increased risk of lymphoma in ALPS Ia suggests that with other forms of ALPS, inherited mutations in the receptor-mediated apoptosis pathway may underlie a proportion of sporadic occurrences of this malignancy, and possibly a considerable proportion of familial lymphomas. Somatic mutations in Fas are already well known to occur in some 10% of cases of B cell lymphomas and leukemias. The recent demonstration of somatic mutations in ALPS (Holzelova et al., 2004) indicates that clinical features of autoimmunity and lymphoproliferation can long predate the actual emergence of clonal lymphoproliferation.

### Pathological Features

Histopathological analysis of lymph nodes of patients affected with ALPS shows characteristic pathologic changes (Sneller et al., 1992; Lim et al., 1998), as seen in Color Plate 24.II. There is architectural preservation, but with a florid reactive follicular hyperplasia and marked paracortical expansion with immunoblasts and plasma cells. The features resemble those of viral lymphadenitis except for the conspicuous absence of histiocytes normally seen to contain apoptotic debris. The paracortical expansion in ALPS is in some cases extensive enough to consider a differential diagnosis of immunoblastic lymphoma, with many cells expressing the Ki-67 antigen indicative of active proliferation (Gerdes et al., 1984).

Analysis of splenic tissue from patients demonstrates lymphoid hyperplasia of the white pulp with histological features similar to those of the lymph nodes. B cells expand the lymphoid follicles while DNT cells accumulate in the paracortical areas. Bone marrow aspirates are generally unremarkable, although trilineage hematopoiesis is seen in patients with autoimmune cytopenias.

Although many of the T cells in both spleen and lymph nodes are CD4<sup>+</sup> or CD8<sup>+</sup>, the remarkable and most characteristic feature of the lymphoid histology in ALPS is the large proportion of TCR  $\alpha\beta$  CD4<sup>+</sup> CD8<sup>+</sup> cells in the paracortical areas. Given the underlying defects in apoptosis in ALPS, it was surprising when histological analyses showed many splenic lymphocytes undergoing apoptosis (Le Deist et al., 1996). It is presumed that alternative pathways of lymphocyte apoptosis may be up-regulated in an attempt to compensate for a defect in the Fas-mediated apoptosis pathway. As discussed above, histiocytic infiltrates and emperipolesis of lymphocytes and plasma cells, as seen in SHML, are found in biopsied lymph nodes of about 40% of ALPS cases. The enlarged histiocytes, located in paracortical areas and sinusoids, are strongly positive for the S-100 antigen (Maric et al., 2005).

In ALPS II associated with defects in caspase-10, impairment of dendritic cell apoptosis was noted and associated in one patient with expansion of dendritic cells in a lymph node biopsy (Wang et al., 1999).

## Laboratory Findings

### Immunologic Findings

Lymphocyte phenotyping provided the first clues as to the unique nature of ALPS. There is an increase of peripheral blood CD3<sup>+</sup> T cells that exceeds the sum of CD4<sup>+</sup> plus CD8<sup>+</sup> cells, indicating expansion of a normally minor DNT cell subset. Such cells can be found in the blood of some patients with malignancy, HIV infection, acute viral infections, and certain other inflammatory states. However, in these disorders, the expanded cell subpopulation bears TCR  $\gamma\delta$  T cell receptors. In contrast, the subpopulation that is increased in virtually all patients with ALPS on virtually every occasion includes  $\alpha\beta$  CD4<sup>+</sup> CD8<sup>+</sup> T cells. This population is less than 1% of CD3<sup>+</sup> T cells in normal controls and Fas-normal relatives of ALPS patients, whereas ALPS patients typically have 5% to 20% DNT cells, with a range from 1% to 68% (Bleesing et al., 2001). These cells are also generally CD45RA<sup>+</sup>, CD45RO<sup>+</sup>, CD57<sup>+</sup>, and many of them express DR, or HLA class II, antigens (Sneller et al., 1997). Unlike CD4<sup>+</sup> CD8<sup>+</sup> thymocytes, the DNT cells of ALPS, when isolated and studied in vitro, are poorly responsive to mitogens and antigens and fail to produce cytokines such as IL-2 upon activation (Sneller et al., 1992). Rather than immature cells, they appear to be a population of aged T cells that have escaped elimination by apoptosis. Thus they are a marker for the ALPS disease state, but are probably not themselves a primary cause of autoimmunity.

Patients with ALPS also show other abnormalities in their immunological profiles (Bleesing et al., 2001, 2002) (Table 24.4). In addition to CD4<sup>+</sup> and CD8<sup>+</sup> T cells displaying DR and CD57, ALPS patients average a five-fold or greater expansion of B cell numbers relative to normal subjects. Natural killer (NK) cell numbers are normal. ALPS patients have a characteristic TH2 T helper cell-oriented cytokine profile, with reduced in vitro release of the TH1 cytokines IL-12, IL-2, and interferon- $\gamma$  (IFN- $\gamma$ ) and increased TH2 cytokines IL-4, IL-5, and IL-10. Levels of IL-10 in serum are profoundly elevated in some patients with ALPS, especially those with Fas mutations, whereas they are usually undetectable in normal subjects and patients without ALPS, even those who have a variety of autoimmune disorders characterized by autoantibodies, such as SLE (Fuss et al., 1997). The TH2 cytokine profile is thought to promote the development of autoimmune features of ALPS.

**Table 24.4.** Laboratory Findings in Autoimmune Lymphoproliferative Syndrome*Immunology*

## Lymphocytes

Relative, if not absolute lymphocytosis involving both B and T cells

Excess of CD4<sup>+</sup> CD8<sup>-</sup> T cells, specifically >1%  $\alpha/\beta$  TCR

CD4<sup>+</sup> CD8<sup>-</sup> cells

Increased proportions of HLA DR<sup>+</sup> and CD57<sup>+</sup> T cells

Decreased CD4<sup>+</sup> CD25<sup>+</sup> regulatory cells

Decreased CD27 expression on B cells (with increased soluble CD27 in serum)

Decreased delayed-type hypersensitivity to skin test antigens

## Granulocytes

Neutropenia

Eosinophilia

## Immunoglobulins

Elevated levels of IgG, IgA, and/or IgM

Monoclonal IgG1 spike in one severely affected patient with homozygous Fas deficiency

Poor and/or unsustained specific antibody responses to polysaccharide antigens

## Autoantibodies to the following:

Erythrocytes (direct Coombs)

Platelets

Neutrophils

Phospholipids

Smooth muscle

Rheumatoid factor

Antinuclear antigens

## Cytokines

Elevated serum IL-10

*Hematology*

## Anemia

Hypersplenism

Autoimmune hemolysis

Iron deficiency

Elevated vitamin B<sub>12</sub> levels

*Chemistry*

Elevated aminotransferases (in cases of hepatitis)

Proteinuria (in cases of glomerulonephritis)

Despite a dramatic and at times alarming degree of lymphoid organ enlargement, immunity in ALPS is surprisingly intact unless disease complications are being treated with immunosuppressive medications. Except for frequent pneumococcal sepsis following splenectomy and a distinctive immunodeficient profile in the two siblings reported with caspase-8 defects, ALPS patients have rarely experienced unusual or severe opportunistic infections. Nonetheless, abnormalities in both humoral and cellular immunity can be demonstrated. Of eight NIH patients tested, four failed to respond to a panel of three delayed-type hypersensitivity skin test antigens. Although antibody responses to T-dependent antigens appear to be intact, patients with ALPS respond poorly to polysaccharide antigens, such as those in the pneumococcal polysaccharide vaccines. Moreover, several patients have failed to sustain initially protective antibody levels to pneumococcal polysaccharides, a concern in asplenic individuals who are susceptible to bacterial sepsis. Antibodies to the T-dependent antigen tetanus toxoid have also been noted to be poorly sustained. Immunoglobulin levels are usually elevated, with IgG concentrations as high as 8 g/dl. IgA or other isotypes may be elevated. The immunoglobulin is almost invariably polyclonal, but Rieux-Laucat et al. (1995) reported one child with a monoclonal IgG-1 spike.

Autoantibody production is very common in ALPS, with most antibodies directed against red cells or platelets. Anti-neutrophil antibodies and low titers of anti-smooth muscle, antiphospholipid, antinuclear antibodies, and rheumatoid factor can also be seen.

*Hematology*

Most ALPS patients are anemic on the basis of one or more of three mechanisms: hypersplenism, Coombs-positive hemolysis, and iron deficiency. Prior to splenectomy it is not uncommon for hemoglobin levels to average 7–8 mg/dl. Hemoglobin concentrations below 3 mg/dl can be seen in acute hemolytic crises. Red cell indices are mostly normocytic, but microcytosis is common, and red cell survival is short.

Platelet counts can be normal, but in the presence of hypersplenism are typically low, and they are elevated post-splenectomy. Thrombocytopenic crises with bruising and epistaxis are frequent immune-mediated events.

Nearly all patients with ALPS sustain an absolute lymphocytosis ranging from 8000 to 90,000 cells/ $\mu$ l or even higher, but averaging about 14,000 cells/ $\mu$ l after splenectomy. Granulocytosis can occur, although an absolute neutropenia is common prior to splenectomy. Post-splenectomy immune-mediated neutropenia is well documented (Kwon et al., 2003). Most patients also exhibit a relative, if not absolute, eosinophilia ranging from 3% to 32% and averaging about 7%.

For unknown reasons, vitamin B<sub>12</sub> levels are modestly to markedly elevated in subjects with ALPS.

*Chemistry*

The blood chemistry profile in ALPS is largely normal, but occasional patients have persistently elevated aminotransferases in the 100–300 IU/ml range. One individual in the NIH series had hypercholesterolemia associated with lymphocytic infiltration into the hepatic sinusoids and portal triads; liver transplantation was eventually required (S.E. Straus, unpublished). While this patient did not have any evidence of viral hepatitis, a patient with ALPS and hepatitis C has been reported to develop hepatocellular carcinoma (Drappa et al., 1996).

**Molecular Basis**

The similarity between humans with ALPS and mice with *lpr* and *gld* mutations was postulated in 1992 in a report from the NIH of two children with massive, nonmalignant lymphoid hyperplasia, autoimmune disease, and markedly elevated numbers of DNT cells (Sneller et al., 1992). The *lpr* mouse had been studied for many years as a model for immune complex diseases, particularly lupus, and was known to have lymphoid hyperplasia and expanded DNT cells as well as nephritis due to renal deposition of autoantibodies (Theofilopoulos et al., 1981; Cohen and Eisenberg, 1991). Shortly after the NIH patients were reported in 1992, the genetic cause of the murine *lpr* phenotype was discovered to be a homozygous autosomal recessive mutation causing extremely reduced levels of the protein designated Fas (for FS-7 cell line-associated surface antigen) (Yonehara et al., 1989; Watanabe-Fukunaga et al., 1992). The same protein was independently identified and named APO-1 (Trauth et al., 1989; Dhein et al., 1992; Oehm et al., 1992), and a third name, CD95, was subsequently assigned.

In both the Japanese group led by S. Yonehara and S. Nagata and the German group led by P.H. Krammer, monoclonal antibodies were developed that induced apoptosis upon binding to the surface of cells. In addition to their effect of cross-linking a cell surface apoptosis receptor, these antibodies were used to purify the Fas/APO-1/CD95 protein, which in turn was partially sequenced, leading to isolation of the human cDNA for the apoptosis gene *TNFRSF6* (previously called *APT1*). Furthermore, the same antibodies were used to demonstrate the absence of Fas on lymphocytes of the *lpr* mouse, indicating that defective lymphocyte apoptosis was the basis of the autoimmune phenotype of this mouse. In related studies, the defect in *gld* mice proved to be in FasL, which cross-links Fas under physiological conditions to induce apoptosis (Fig. 24.1) (Takahashi et al., 1994). Both Rieux-Laucat et al. (1995) and Fisher et al. (1995) described defects in the human *TNFRSF6* gene in patients with autoimmunity, lymphoproliferation, and excess CD4<sup>+</sup> CD8<sup>-</sup> T cells, including one of the original NIH patients described by Sneller et al. (1992).

Fas and FasL are members of two superfamilies of receptors and ligands that are important in immune regulation (reviewed in Nagata and Goldstein, 1995; Lenardo et al., 1999). Fas is a member of the tumor necrosis factor receptor superfamily, which includes TNFRSF1A (p55) (see Chapter 27) and TNFRSF1B (p75); CD40, important in B cell activation (see Chapter 19); CD30, found on Reed-Sternberg cells in Hodgkin lymphoma; and several other receptors. These type 1 membrane-spanning proteins share up to 25% amino acid identity and contain variable numbers of conserved extracellular cysteine-rich domains (CRDs). Fas and TNFRSF1A share an intracellular region of homology as well, a 70-amino acid “death domain,” around which is assembled a death-inducing signal complex (DISC) that propagates intracellular signals for apoptosis.

Protein structural studies indicate that FasL, which occurs in membrane-bound and secreted forms, self-associates into homotrimers with a conical configuration to become functionally active (Fig. 24.1). The FasL trimer engages a trimeric complex of Fas chains displayed on the surface of lymphocytes. Fas chains self-assemble at the cell surface by means of their preligand association domains in the first CRD of the Fas molecules (Siegel et al., 2000). Upon ligand engagement, the extracellular projections of the Fas trimeric complex extend and embrace the FasL trimer. Disulfide bonds between the cysteine residues of the CRDs stabilize the conformation of the extracellular portion of Fas.

Extracellular binding of a FasL trimer to a Fas trimer results in the formation at the intracellular side of the cell membrane a DISC that consists of the trimeric Fas death domains, the Fas-associated death domain protein FADD (also called *MORT1*), TRADD, RIP, and associated partners that possess proteolytic ICE-like domains (named for their homology to interleukin-1 $\beta$  converting enzyme) (Enari et al., 1995; Hsu et al., 1995, 1996; Los et al., 1995). These ICE-like proteases, now collectively referred to as *caspases*, cleave proteins at specific amino acid recognition sites. Procaspase-8 (originally called FLICE and MACH by different independent groups of discoverers) and procaspase-10 can be cleaved by the proteolytic domain of FADD. After cleavage, caspase-8 and caspase-10 themselves become active proteases that cleave further protease precursors in a cascade, eventually leading to activation of effectors caspase-3 and caspase-9, which in turn bring about the cellular

**Figure 24.1.** Lymphocyte apoptosis pathways (Nagata, 1997). After Fas is linked by trimeric Fas ligand, its intracellular death domain transduces signals to cytoplasmic death domain-containing protein FADD. Caspase protease domains of FADD cleave downstream proteases caspase -8 and -10, which in turn signal the activation of proteolytic enzymes and DNases.

events that constitute the apoptosis program. Characteristic lethal cellular events collectively known as *apoptosis* include early membrane permeabilization and exposure of proteins not normally detectable at the cell surface; DNA cleavage between nucleosome units into fragments of incremental sizes, visible on electrophoresis gels as “ladders”; condensation and segmentation of nuclei; and shedding of “apoptotic bodies,” nuclear particles encased in membrane that are rapidly phagocytosed by macrophages (Nagata and Goldstein, 1995; Lenardo, 1996). Apoptosis, in contrast to necrosis, the other major physiologic mechanism for removal of cells in the body, does not incite local inflammation.

Figure 24.2 shows the organization of the *TNFRSF6* gene encoding Fas; the gene has nine exons within a genomic span of about 25 kb on human chromosome 10q23 (Behrmann et al., 1994). The open reading frame, beginning in exon 2, encodes a signal peptide of 16 amino acids. After directing transmembrane expression this peptide is cleaved off of the mature protein. Exons 2 through 5 encode the three extracellular CRDs of Fas; the sequences encoding the transmembrane domain lie within exon 6. The intracellular domain of *TNFRSF6* includes in exon 9 a death domain with homology to the intracellular portion of *TNFRSF1A*. A number of single nucleotide polymorphisms (SNPs) that do not alter amino acid sequence have been defined within the *TNFRSF6* gene (Neimela et al., 2005). Particularly common SNPs in exon 3 and exon 7 (Fiucci and Ruberti, 1994) make possible allotype assignment for family genetic studies. The Fas protein is expressed in heart and liver as well as in lymphocytes. Particularly high amounts are found in T cells activated by T cell receptor (TCR) engagement and IL-2.

**Figure 24.2.** Diagram of the structure of the human *TNFRSF6* gene encoding the protein CD95/Fas/APO-1, showing mutations in patients with ALPS. Asterisks above gene, single nucleotide polymorphisms; symbols below, disease-causing mutations. Symbols containing numbers indicate multiple independent mutations at the same site. Genbank accession number M67454.

### Mutation Analysis and Genotype-Phenotype Correlations in ALPS Ia

To date, well over 200 patients with ALPS have been identified (Kasahara et al., 1998; Jackson et al., 1999; Vaishnav et al., 1999a, 1999b; Le Deist et al., 2003; Puck, 2005). Among these, *TNFRSF6* gene mutations causing ALPS Ia have been found in over 136 families, and several families have more than one affected member (Drappa et al., 1996; Le Deist et al., 1996; Bettinardi et al., 1997; Sneller et al., 1997; Infante et al., 1998; Puck, 2005). There are 107 unique mutations and a minority of recurrent mutations, as indicated in Figure 24.2, which depicts the sites and types of mutations in *TNFRSF6* in patients with ALPS Ia. These mutations, other than the polymorphisms mentioned above and other SNPs that do not alter the predicted amino acid sequence of the Fas protein, have not been detected upon screening over 200 alleles of chromosome 10 from unrelated healthy individuals.

All of the mutations causing ALPS Ia to date are changes of a single nucleotide or a few nucleotides in *TNFRSF6*, except for one 331 bp insertion 5' of exon 8 that disrupts splicing and one 290 bp terminal deletion in exon 9 (Fig. 24.2). The latter deletion was found in homozygosity in a very severely affected daughter of consanguineous parents (Rieux-Laucat et al., 1995; Le Deist et al., 1996). The infant had massive lymphoproliferation at birth, evidenced by hydrops fetalis with massive hepatosplenomegaly. The spleen had to be removed at the age of 2 months, at which time it weighed 1.8 kg. Other findings were pulmonary infiltrates, intra-abdominal lymph node enlargement as shown by

computed tomographic scanning, and lymphocytosis up to 150,000/ $\mu$ l. Although a *TNFRSF6* mRNA signal of reduced length was detected by Northern analysis in this patient, consistent with deletion of the 3' end of the gene, Fas protein was not detectable by cell surface staining with anti-Fas antibody, a finding suggesting a defect either in protein synthesis or in stability or transport to the cell membrane. The heterozygous parents of this patient were healthy, and their lymphocytes had normal Fas-mediated apoptosis according to the in vitro testing method employed (Le Deist et al., 1996). Thus, this human null mutation was most reminiscent of the *lpr* mouse mutation in that it resulted in nonexpression of Fas and a recessive, severe disease phenotype.

The three brothers with striking lymphoproliferation characteristic of ALPS reported by Bettinardi et al. (1997) were compound heterozygotes for two missense mutations, one in the extracellular CRD2 domain and the other at the proximal end of the intracellular death domain. One brother had autoimmune thrombocytopenia and hemolytic anemia, while the others had no overt autoimmune disease but did have autoantibodies. Interestingly, their parents, each a heterozygous carrier with one wild-type Fas allele, were reported to be healthy and without elevated DNT cells or defective apoptosis. The mechanism by which the two mutations in these brothers might combine to produce ALPS with recessive phenotype is not clear.

By far the most common form of type Ia ALPS is that associated with heterozygous Fas mutations; ALPS is inherited in an autosomal dominant fashion along with Fas defects in most

kindreds, although de novo mutations in probands have been documented. Patients with this form of ALPS have one mutant and one normal, functional Fas allele. As shown in Figure 24.2, the most common region of the *TNFRSF6* gene to be mutated in ALPS Ia is the intracellular death domain in exon 9, expanded in the figure to show the large number of mutations clustered within it. The heterozygous death domain mutations occur in and around the six  $\alpha$ -helical regions of the peptide structure (Huang et al., 1996). These mutations are predicted to result in either early termination of protein synthesis (frameshifting insertions and deletions; amino acids changed to stop codons) or single amino acid substitutions (missense mutations) as shown in Figure 24.2. They occur in portions of the death domain that are highly conserved in other death domain proteins and in other species such as the mouse. For example, a point mutation in murine Fas in the *lpr<sup>cg</sup>* mouse strain has been identified and found to predispose to lymphoproliferation and autoimmune disease similar to that in mice with the *lpr* and *gld* mutations (Watanabe-Fukunaga et al., 1992; Kimura and Matsuzawa, 1994). This missense point mutation in the *lpr<sup>cg</sup>* mouse introduces a nonconserved asparagine residue corresponding to human Fas amino acid 238, between the second and third  $\alpha$  helices. Immediately adjacent to the position of this mouse mutation, three human missense mutations—G237V, G237S, and G237D—have been identified in patients with ALPS. The heterozygous death domain substitution mutations are compatible with expression of mRNA and protein, which suggests that mutant protein molecules may inhibit apoptosis by normal Fas expressed concurrently. Ultrastructural studies have indicated disruption of the death domain architecture by some mutations, whereas others appear to affect contact points between Fas and FADD (Huang et al., 1996).

Many other mutations in the extracellular domains of *TNFRSF6* as well as in the more proximal intracellular regions result in clinical and immunological presentations similar to those of ALPS patients with death domain mutations, but often of milder clinical severity. As an example, one patient with a splice mutation immediately following exon 3 was shown to make in-frame abnormal mRNA and protein that skipped exon 3 (Fisher et al., 1995; this individual is pictured in Color Plate 24.I). Two other patients had mutations within exon 3, a nonsense mutation, and a single base deletion with a frameshift. Curiously, unlike the splice mutation described above, analysis of cDNA clones showed that these mutant alleles were not associated with exon 3 skipping (Jackson et al., 1999; J.M. Puck, unpublished results). If translated, they would produce truncated proteins corresponding only to the first CRD. Splice mutations of exons encoding intracellular domains have also been found, in some cases producing a shortened mRNA and protein terminating immediately after the transmembrane region, but without intracellular charged amino acids to anchor it (Fisher et al., 1995). The possibility that some mutations encode shortened Fas proteins that are secreted from the cell needs to be explored. These mutations may cause disease through the mechanism of haploinsufficiency. Expression and function of mutant alleles must be addressed experimentally to determine whether and by what mechanism they are deleterious.

Satisfactory correlations between the Fas genotype and the clinical presentation or phenotype of each individual are complicated by several factors. First, as indicated above, ALPS may be recessive, but it is more often a dominant disorder associated with heterozygous mutations; the mode of inheritance is at least in part dependent on the type of mutation itself, with homozygous or compound heterozygous mutations expected to produce

more severe, recessive disease. Second, penetrance and expressivity of phenotypes associated with heterozygous Fas mutations are also variable, in that mutation-bearing relatives of ALPS probands may have all of the defining criteria for ALPS or may instead have milder or even completely undetectable clinical and immunological abnormalities (Infante et al., 1998; Jackson et al., 1999; Vaishnaw et al., 1999a).

### Functional Aspects: In Vitro Assay of Apoptosis

Defective apoptosis is the hallmark of peripheral blood lymphocytes of patients with ALPS. Activated, cultured T cells from ALPS patients exhibit reduced rates of apoptotic death when stimulated through the TCR CD3 or through the Fas pathway (Fig. 24.3A). To assay apoptosis, peripheral blood mononuclear cells in vitro are initially exposed to a strong activating stimulus such as phytohemagglutinin (PHA). Then the activated T cells from these cultures are maintained and expanded in IL-2, and after 1 to 3 weeks the cells are subjected to cross-linking with an

**Figure 24.3.** Fas-mediated apoptosis. (A) Fas-mediated killing of activated, interleukin-2-dependent T cells derived from ALPS patients vs. normal controls. The percent cell loss reflects the difference between cells exposed to an anti-CD3 monoclonal antibody and cells not exposed to the antibody (Fisher et al., 1995). (B) Expression (open bars) and apoptosis (black bars) in cells transfected in vitro with mixtures of plasmids expressing *TNFRSF6* cDNA constructs, followed by exposure to anti-Fas antibody to induce cell loss. Transfection with normal Fas leads to killing of all cells expressing Fas, whereas essentially no cell loss occurs with mutant Fas. Mixtures of normal and mutant Fas show the dominant negative inhibition of apoptosis by mutated Fas (\*) despite the presence of normal Fas.

anti-CD3 antibody, Fas ligand, or an anti-Fas monoclonal antibody, such as CH11 or Apo-1 (Fisher et al., 1995). Apoptosis can be quantitated by a variety of means, perhaps most directly by measuring loss of viable cells in culture wells exposed to antibody vs. no antibody for 24 hours. As shown in Figure 24.3A, after anti-CD3 cross-linking, activated cultures of lymphocytes from four ALPS patients exhibited rates of cell loss averaging only 7% compared to an average of 50% for cultures from three healthy control subjects. Other methods of demonstrating apoptosis include staining free DNA ends that result from DNA fragmentation and demonstrating characteristic membrane changes. Assay conditions and normal ranges for all apoptosis tests must be established and monitored in each laboratory.

By definition, lymphocytes from all ALPS patients with deleterious Fas mutations have defective Fas-specific apoptosis. ALPS patient B cell lines transformed with Epstein Barr virus likewise show defective apoptosis after anti-Fas exposure, indicating that both B and T lymphocytes express the defect in Fas-mediated programmed cell death (Sneller et al., 1997). In addition, mutation-bearing family members, even those with no clinical abnormalities and no elevations of CD4<sup>+</sup> CD8<sup>+</sup> T cells, demonstrate defective apoptosis in vitro. Thus the impairment in cellular apoptosis associated with Fas mutation is inherited as a dominant trait.

The NIH group (Fisher et al., 1995) studied the mechanism by which a heterozygous mutant Fas allele can exert a dominant inhibition of apoptosis by using an in vitro transfection system (Fig. 24.3B). *TNFRSF6* cDNA in an expression plasmid introduced into a Fas-negative mouse thymoma cell line by electroporation achieved measurable cell surface expression of mutant or normal Fas in about 50% of the target cells (Fig. 24.3B, open bars). When the human-specific CH11 anti-Fas monoclonal antibody was added (black bars), 50% of cells treated with 10 µg of normal Fas plasmid were killed; thus virtually all of the Fas-expressing cells died. When thymoma cells were transfected with *TNFRSF6* cDNA bearing the death domain mutation T225P found in an ALPS patient, protein was expressed at the cells surface, but there was no apoptotic cell loss after treatment with CH11. As shown on the right of the figure, when mixtures of normal and mutant *TNFRSF6* cDNA were transfected together, the mutant allele inhibited transmission of a death signal by the normal, wild-type allele (Fig. 24.3B, asterisks). With equal amounts of wild-type and mutated Fas cDNA, apoptosis was almost completely interrupted; this dominant inhibitory effect was still seen with a 3:1 wild type-to-mutant ratio.

The dominant interfering effect on apoptosis of Fas proteins with a death domain mutation is consistent with the model of Fas as a functional trimer (Fisher et al., 1995). Three Fas molecules form a trimeric complex to interact with a FasL trimer at the cell surface, and the intracellular death domains of the Fas molecules must interact properly with downstream mediators in the DISC to accomplish cell killing. If there is equal expression of normal and mutant Fas mRNA, normal and defective protein chains are expected to be synthesized and expressed equally at the cell surface. Assembly of these Fas monomer chains into trimers at random will yield only one out of every eight trimer complexes with three normal Fas subunits. Following this model, the presence of one, two, or three defective Fas molecules in a complex is predicted to render that complex nonfunctional. Thus, heterozygous interfering mutations are expected to have a profound inhibitory effect on apoptosis, as is actually observed.

Some Fas proteins with mutations outside of the death domain may also have a dominant inhibitory effect (Fisher et al., 1995;

Jackson et al., 1999). Similarly, truncated Fas protein terminating before or within the death domain may impair apoptosis in a dominant negative fashion (Jackson et al., 1999; Rieux-Laucat et al., 1999; Vaishnaw et al., 1999a). On the other hand, certain mutations, and indeed some splice variants of normal Fas, produce a protein that lacks the transmembrane region and thus may be secreted rather than membrane bound (Cheng et al., 1994; Papoff et al., 1996; Ruberti et al., 1996). In vitro studies by some investigators indicate that peptides containing the first 49 amino acids of Fas are sufficient to inhibit apoptosis in cultured cells (Papoff et al., 1996). However, the pathophysiologic role of secreted Fas in ALPS or in other autoimmune disorders, whether produced by mutant alleles or splice variants, remains unclear. Furthermore, some *TNFRSF6* mutations, such as termination codons at the far 5' end of the gene are null, resulting in loss of function rather than dominant interference (Jackson et al., 1999; Vaishnaw et al., 1999a). These mutations appear to cause ALPS by producing haploinsufficiency, implying that the amount of Fas at the cell surface is a critical parameter for induction of apoptosis in physiologic conditions.

### Autoimmune Lymphoproliferative Syndrome Due to Somatic Mutations of Fas

Holzelova et al. (2004) studied a group of six children presenting by 2 years of age with typical clinical features of ALPS, including lymphadenopathy, splenomegaly, elevated DNT cells, hypergammaglobulinemia, and, in four of six cases, autoimmune disease. Interestingly, none of the patients had affected relatives; moreover, they lacked demonstrable defects in lymphocyte Fas-mediated apoptosis and did not have germ-line mutations of *TNFRSF6*. The DNT cells of these patients were isolated by flow-cytometric sorting, and DNA prepared from this cell subset was subjected to *TNFRSF6* sequence analysis. In all six DNT samples, deleterious Fas mutations either identical to or having the same effects as previously known dominant interfering mutations were found. T cells from these patients that had been activated in vitro and cultured in IL-2 did not harbor the mutations, nor did the patients' buccal mucosal cells, indicating that the Fas defects had arisen by somatic mutation and were subject to positive selective pressure because of their resistance to physiologic apoptosis signals in vivo. ALPS due to Fas defects arising by somatic mutation in T cell precursors, common lymphoid progenitors, or hematopoietic progenitors is designated *ALPS Ia (somatic mutant)* (Table 24.2). It is not yet clear what proportion of patients currently diagnosed as ALPS III may actually have somatic defects in Fas.

### ALPS-Like Illnesses Without Fas Defects

Both children and adults who have autoimmune lymphoproliferation but no mutations in *TNFRSF6* have been observed. Some of these individuals have modestly expanded numbers of DNT cells. Among this group are patients with impaired in vitro apoptosis via the Fas pathway, those with normal apoptosis after anti-Fas antibody exposure but impairment of apoptosis by TCR restimulation, and patients with no demonstrable apoptosis defects (Dianzani et al., 1997; Sneller et al., 1997; S.E. Straus and J.M. Puck, unpublished observations; J.P. Villartay, unpublished observations). Additional patients with clinical findings similar to those of ALPS patients have failed to show elevations of DNT cells, although not all have been studied over long time periods with consistent staining protocols. A variety of patients with

autoimmune blood cytopenias have splenomegaly with or without adenopathy; they are not considered to have ALPS unless the required features in Table 24.1 are fully met.

Of probands (the first subject enrolled in each kindred) in the NIH cohort who met the criteria for ALPS in Table 24.1, 79% had specific Fas defects (ALPS Ia), as shown in Table 24.2. The remaining patients, however, had normal *TNFRSF6* gene sequences, and were thus investigated for mutations in other components of lymphocyte apoptosis pathways, many of which are depicted in Figure 24.1. A single patient had a mutation in FasL, similar to the patient reported by Wu et al. (1996), and was designated as having ALPS Ib (Bi et al., 2001). No humans to date have been found with mutations in FADD, consistent with the finding that mice with targeted disruptions of this gene are nonviable. However, patients with either caspase-10 or caspase-8 defects have been recognized, and are designated as ALPS II (Table 24.2).

Two heterozygous, dominant-interfering caspase-10 mutations have been found to cause ALPS II in three families (Wang et al., 1999; Zhu et al., 2006). The missense mutations are L285F, located in the proximal portion of the p17 protease domain, and I406L, very near the active site made up of conserved amino acids QACQG at 399–403. An additional mutation V410I was initially noted in homozygosity in a subject with recurrent fevers, noninfectious lymphocytic meningitis, optic neuritis, and no Fas defect (Wang et al., 1999). However, the patient's disease may have been caused in part by a subsequently identified TNF receptor-associated periodic fever mutation (see Chapter 27). Furthermore, the V410I variant of caspase-10 is now known to be a polymorphism in healthy populations, with an allele frequency of 6.8% in Danish, 3.4% in U.S. Caucasian, and 0.5% in African American unrelated individuals (Gronbaek et al., 2000; Zhu et al., 2006). Zhu et al. also confirmed that individuals with caspase-10 V410I, including homozygotes, are healthy, and even found statistical evidence that caspase-10 V410I may have a protective effect against severe disease in subjects with Fas mutations that can cause ALPS Ia. Zhu et al. further reported another caspase-10 population variant, Y446C, present in 1.6% of Caucasian alleles, for which no functional role has yet been demonstrated.

A single family has been found in which a son and daughter of a consanguineous marriage were homozygous for the caspase-8 mutation R248W, a nonconserved amino acid substitution in the proximal p18 protease subunit. Both children had features of ALPS, including adenopathy, mildly increased DNTs, autoantibodies, and impaired lymphocyte apoptosis, whereas heterozygous relatives were unaffected. Moreover, unlike other ALPS cases, these children also manifested T and B cell immunodeficiency with growth retardation, recurrent sinopulmonary and herpes simplex virus infections, eczema, and poor responses to immunizations. The caspase-8 mutation not only abrogated the cleavage activity of experimental protease substrates and failed to mediate apoptosis when transfected into epithelial cell lines, it also rendered the patients' lymphocytes refractory to stimulation in vitro (Chun et al., 2002). Further studies confirmed a requirement for full-length caspase-8 in the NF- $\kappa$ B activation phase of normal T, B, and NK cell responses (Su et al., 2005). Thus caspase-8 has dual functions, in both apoptotic and cell activation pathways.

Patients with ALPS type III are those who meet the criteria for ALPS but have no defined molecular defect. Whereas some have defective Fas-mediated apoptosis, others have been studied whose lymphocytes demonstrate reduced TCR-mediated killing, while Fas-mediated apoptosis is intact by in vitro assay (Sneller et al., 1997). Although some of these individuals may belong to

the ALPS Ia somatic mutant group of patients, lymphocyte apoptosis pathways other than the Fas pathway but still activated by TCR restimulation could be the site of a genetic defect in some of these individuals. It is possible that the majority of such patients described by Dianzani et al. (1997), who had ALPS with Fas pathway apoptosis defects but normal Fas gene sequences, also carry as-yet unidentified mutations in other apoptosis pathway genes.

## Strategies for Diagnosis

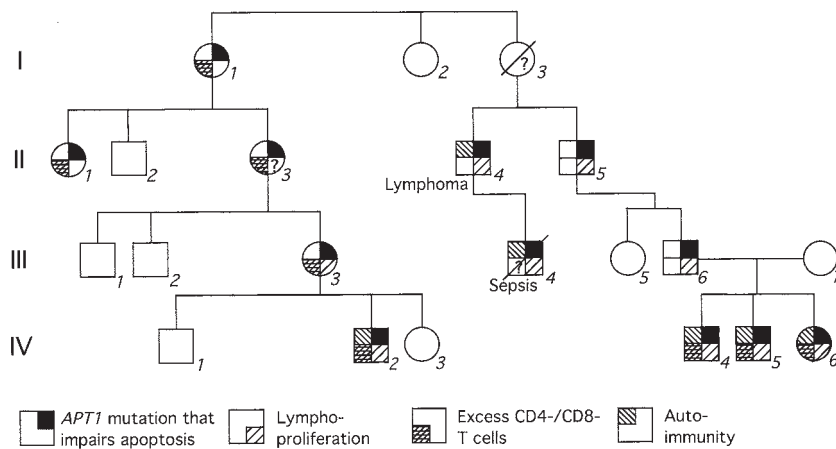

Unexplained splenomegaly and lymphadenopathy of early onset, particularly when accompanied by overt autoimmune disease and/or a positive family history, are the clinical features that lead to a suspicion of ALPS. More than 1% of  $\alpha/\beta$  CD4<sup>+</sup> CD8<sup>+</sup> T cells are a defining characteristic of ALPS, but may not be counted correctly if only CD4, CD8, and CD3 are quantified because several more common conditions are associated with increased  $\gamma/\delta$  T cells lacking CD4 and CD8. Hypergammaglobulinemia and elevated numbers of B cells and autoantibodies are further important clues and are more widely assayed. Since Fas membrane expression is absent only in rare patients with null mutations in both alleles, its assessment is of little help in diagnosis. Histological examination of enlarged lymph node biopsies yields a fairly characteristic appearance in ALPS, especially in cases associated with Fas mutations, and special stains revealing DNT cells can be diagnostic even in subjects who are not available to provide fresh blood samples (Lim et al., 1998). In vitro evaluation of lymphocyte apoptosis as triggered by agonistic Fas-specific or anti-CD3-specific antibodies can help establish the diagnosis.

Abnormal Fas-mediated apoptosis should lead first to investigation for causative mutations in the *TNFRSF6* gene transcript and sequence. Single-strand confirmation polymorphism (SSCP) analysis or dideoxy fingerprinting can be used to screen the nine *TNFRSF6* exons (Hyashi, 1992; Sarkar et al., 1992; Fisher et al., 1995). DNA sequencing can be performed on segments of the gene that exhibit abnormal migration in screening assays, characteristic of altered primary sequence. Alternatively, exon 9, the most frequently mutated portion of the gene, can be sequenced first, with subsequent attention to the remaining eight exons if no deleterious mutation is found. Special attention should be given to establishing the significance of missense mutations. SNPs in *TNFRSF6* have been delineated that are not associated with ALPS (Niemela et al., 2006). For previously unreported changes a panel of 100 chromosomes from 50 unrelated, healthy individuals helps to suggest that a missense mutation is not merely a polymorphism without functional consequences. However, functional assays of apoptosis must be combined with sequence abnormalities to prove the deleterious nature of any Fas mutation.

In a patient with clinical and immunologic features of ALPS, a constitutional *TNFRSF6* mutation associated with defective Fas and impaired lymphocyte apoptosis would confirm the diagnosis of ALPS Ia. Patients with Fas defects only in a sublineage of their hematopoietic cells, designated ALPS Ia (somatic mutant), can be diagnosed on the basis of deleterious *TNFRSF6* mutations in isolated DNT cells (Holtzelova et al., 2004). If the sequence of both *TNFRSF6* alleles is normal, deleterious mutations in the genes encoding caspase-10 and caspase-8 (ALPS II) can be sought, as well as FasL (ALPS Ib) if apoptosis in response to anti-Fas stimulation is intact. Remaining patients without defined defects receive a diagnosis of ALPS III.

It is not yet clear to what extent defects in Fas or other lymphocyte apoptosis mediators, particularly caspase-8, contribute to

**Figure 24.4.** Dominant inheritance of *TNFRSF6* mutation and features of ALPS in a large kindred (adapted from Infante et al., 1998). Squares, males; circles females; slash, deceased; ?, could not be ascertained.

common variable immunodeficiency (CVID) (see Chapter 23) or autosomal hyper-IgM syndrome (see Chapter 20), both syndromes representing collections of defects with diverse genetic etiologies. Up to one-third of CVID and autosomal hyper-IgM patients may experience chronic lymphadenopathy and/or splenomegaly, and autoimmune features are commonly present in both conditions. However, it is not common for CVID to be diagnosed as early in life as ALPS, and CVID frequently becomes more severe in the teen years to adulthood, when the findings of ALPS, if anything, tend to regress. Nonetheless, potential overlap between several features of ALPS and other primary immunodeficiency syndromes is an area for further investigation.

The differential diagnosis of ALPS vs. malignancy and the apparent increased risk of lymphomas in ALPS remain major concerns for patients presenting with enlarged lymphoid organs or those who exhibit significant new lymph node enlargement. A biopsy of consistently large or rapidly growing nodes should reveal the characteristic histological features of ALPS (Color Plate 24.II), whereas in lymphoma a homogenous monoclonal cell population disrupts the normal architecture. Study of clonality of immunoglobulin or TCR gene rearrangements and cytogenetic investigation for chromosomal translocations must be done to identify true lymphomas in patients with a history of prolonged adenopathy.

### Findings in Relatives of ALPS Probands

Studies of family members of ALPS Ia probands have been undertaken to find additional individuals who might carry the same mutations as ALPS probands (Fisher et al., 1995; Rieux-Laucat et al., 1995, 1999; Drappa et al., 1996; Bettinardi et al., 1997; Sneller et al., 1997; Infante et al., 1998; Jackson et al., 1999; Vaishnav et al., 1999a). In some instances newly occurring *TNFRSF6* germ-line mutations have been found in probands whose healthy parents had normal *TNFRSF6* gene sequences (Sneller et al., 1997). In the rest of the families, regardless of whether the mode of inheritance was recessive or dominant, relatives with a mutated Fas allele have been identified. Some of these relatives proved completely free of symptoms and signs of ALPS, whereas others met the diagnostic criteria for ALPS (Table 24.1). Still other mutation-bearing relatives had some but not all of the features of ALPS, such as episodes of significant adenopathy or an enlarged spleen without autoimmune disease. For example, in the family of one ALPS patient followed by the NIH group, four relatives in addition to the patient were found to

share the same mutation on one *TNFRSF6* allele. All had defective in vitro lymphocyte apoptosis. However, none of the relatives experienced any clinical manifestations of ALPS and none had autoantibodies or any other laboratory abnormalities except for one individual with mildly increased (1.7%) DNT cells.

In contrast, a large kindred was studied in which 12 individuals in four generations were followed for over 30 years with a variety of findings including splenomegaly, adenopathy, and Coombs-positive anemia; affected subjects were recently proven to have a heterozygous mutation changing an aspartic acid to valine at position 244 (D244V) in the death domain of Fas (Fig. 24.4) (Infante et al., 1998). The diagnosis of ALPS was first confirmed in individual IV-5, who at age 2 was in general good health but had adenopathy and splenomegaly, Coombs-positive anemia, 2.1% DNT cells, and a plasma IgG of 2355 mg/dl. All of the surviving mutation-bearing members of this kindred (black upper right quadrants of pedigree symbols in Fig. 24.4) had impaired lymphocyte apoptosis. Furthermore, as shown in Figure 24.4 each of these individuals had features of ALPS in at least one category—lymphoproliferation, evidenced by splenomegaly and/or adenopathy (lower right quadrant),  $\geq 1\%$  DNT cells (lower left quadrant), and autoimmunity, with either overt manifestations such as hemolytic anemia or ITP or significant titers of autoantibodies (upper left quadrant). By late adolescence or adulthood, lymphoproliferation and autoimmune manifestations tended to abate, and the only premature death in the family has been due to post-splenectomy sepsis at age 9 in individual III-4. However, the occurrence of NHL in individual II-4 at age 50 and his development of ITP at age 23 and hemolytic anemia at age 54 demonstrate the lifelong risk of malignancy and the unpredictable course in this and many other families with Fas defects. Since this kindred was reported, Hodgkin lymphoma was diagnosed in individual IV-4 at age 7 years.

Only limited family studies have been conducted in ALPS II, which, seems to have variable penetrance and severity similar to ALPS Ia (Zhu et al., 2006). Prenatal diagnosis has not been published by either mutational analysis of *TNFRSF6* or assessment of lymphocyte surface markers in fetal blood. The prenatal hydrops of the severely affected recessive case reported by Le Deist et al. (1996) indicates that, at least in this patient, lymphoproliferation was ongoing before birth.

### Prognosis and Treatment

Growing experience with ALPS indicates that patients can achieve a normal life span. Patient histories suggest that adenopathy may

diminish with age; but while the most severe autoimmune disease appears to occur in early childhood, as indicated above, episodes can recur or, in fact, arise unpredictably at any age. In older individuals now recognized to have a longstanding history of ALPS, splenectomy was common, but recognition of the risks of infection in asplenic subjects has made this a procedure of last resort in current practice. Nonetheless, splenectomy has been required in about half of all of our patients with ALPS to manage their severe hypersplenism, severe hemolysis, or refractory thrombocytopenia without resorting to chronic use of steroids at doses that impair growth and development. Splenectomy has also been performed following splenic rupture and in some cases when lymphoma was suspected. Fatal post-splenectomy sepsis has been documented in multiple patients despite prior administration of polysaccharide vaccines and prescription of prophylactic antibiotics.

On the basis of studies suggesting efficacy in *lpr* mice with an ALPS-like phenotype (Mountz et al., 1987), one patient received sequential therapeutic trials of prednisone, IFN- $\alpha$ , IL-2, and cyclosporine-A for treatment of her disease (Sneller et al., 1997). Therapy with high-dose prednisone resulted in a transient decrease of lymphadenopathy, but the lymph nodes returned to their original size following reduction of the dose. None of the other treatments resulted in a change in the degree of lymphadenopathy or clinical status. In view of the substantial toxicity and lack of efficacy of the various agents used to treat this patient and the fact that the lymphoproliferative disease was not threatening any vital organ function, no attempt has been made to specifically treat lymphoproliferation in other patients seen by the NIH group.

However, many patients with ALPS, even after splenectomy, suffer severe episodes of AIHA, thrombocytopenia, and neutropenia requiring immunosuppressive therapy. Most episodes of ITP and some hemolytic crises respond to short courses of high-dose steroids, such as 1 mg/kg of prednisone daily. In these patients, like the one described above, lymph node size transiently decreases to some degree during treatment. In several patients, multiple courses of high-dose steroid pulses, or prolonged daily steroid plus intravenous immunoglobulin therapy may be required for control of autoimmune disease. At various times in patients with refractory autoimmunity, vincristine, azathioprine, methotrexate, and cyclophosphamide have been used.

Of 87 splenectomized patients followed at the NIH 5 have died. Two children had fatal sepsis due to *Streptococcus pneumoniae*, while three other patients developed opportunistic infections associated with multidrug immunosuppressive therapy for aggressive, infiltrative polyclonal lymphoproliferation (Rao et al., 2005). Efforts to avoid the complications of chronic steroids and immunosuppressive regimens in children with ALPS have led to investigation of alternative agents. The antimalarial drug combination of pyrimethamine and sulphadoxine (Fansidar) was suggested to be effective in a preliminary study of seven ALPS patients, two with ALPS Ia and five with ALPS III (van der Werff Ten Bosch et al., 2002). However, experience with Fansidar among NIH patients has not been as encouraging as suggested by this report. More recently, mycophenolate mofetil (MMF) was evaluated in NIH patients as a potential steroid-sparing immunosuppressive agent. MMF is a prodrug of mycophenolic acid, which inhibits a key enzyme in the purine synthetic pathway, an especially active pathway in T and B lymphocytes. MMF, previously shown to be effective in immune-mediated cytopenias (Howard et al., 2002; Hou et al., 2003), was used to treat cytopenias in 13 ALPS patients who were steroid-dependent (Rao et al., 2005). Twelve of 13 responded, making

possible a reduction or termination of steroid treatment and, in some cases, avoidance of splenectomy.

Most ALPS patients can be successfully weaned from treatment after an acute episode of an autoimmune cytopenia, and the rate of occurrence of episodes and their severity may diminish as patients enter adolescence. Adults with ALPS may cease to experience autoimmune complications, but conversely, new onset of ITP has occurred in adulthood (Drappa et al., 1996; Infante et al., 1998).

In a patient with complete Fas deficiency, ALPS manifestations were so severe that several courses of antithymocyte globulin and then chemotherapy were given to reduce the lymphocyte burden (Le Deist et al., 1996). This treatment proved to be only transiently beneficial, so T cell-depleted, parental haploidentical bone marrow transplantation (BMT) was undertaken. A first attempt of marrow transplantation led to early rejection. However, a second transplant with T cell-depleted marrow from the second HLA haploidentical parent was successful. There was no recurrence of lymphoproliferation or of autoimmunity, although DNT cells continued to be detected in the child's blood for over 2 years. This child was well 3 years after the second BMT attempt (Benkerrou et al., 1997). Clearly, the role of BMT is not well defined in ALPS, and this treatment should be considered only for the rare patient in whom life-threatening complications prove refractory to more conservative measures.

### Animal Models

The MRL *lpr* mouse pointed the way to the discovery of Fas defects in humans. This spontaneous mouse mutant strain has increased autoimmunity compared to the MRL parent strain; it was discovered to have high numbers of CD4<sup>+</sup> CD8<sup>+</sup> lymphocytes and defective apoptosis and was subsequently demonstrated to be Fas deficient (Watanabe-Fukunaga et al., 1992; Nagata and Goldstein, 1995). Originally described as having a lupus phenotype, the MRL *lpr* mouse actually lacks some of the more typical features of human lupus such as anti-DNA antibodies and frequent arthritis. However, these mice regularly develop antinuclear antibodies, hypergammaglobulinemia, adenopathy, and nephritis. Additional spontaneous mutant mouse strains with a similar phenotype are *gld*, found to have recessive defect of Fas ligand, and *lpr<sup>cs</sup>*, a strain with a death domain point mutation causing a change in a conserved amino acid of Fas. Transgenic mice expressing dominant negative mutations in Fas corresponding to the mutations found in humans with ALPS had apoptosis defects and developed hepatosplenomegaly and lymphocytic liver infiltration (Choi et al., 1999).

Like the human, the phenotype in mice with *lpr* mutation is highly strain-dependent. For example, C57BL/6 mice with the *lpr* mutation have much less severe disease than that of MRL *lpr* mice. Furthermore, the MRL strain is autoimmune-prone, even without defective apoptosis conferred by the *lpr* Fas defect, in part because it expresses a hypoactive variant of IL-2 (Choi et al., 2002). Both class I and class II MHC determinants are important in development of autoimmunity in Fas-deficient mice (Creech et al., 1996; Christianson et al., 1996).

The range of autoimmune findings in *lpr*, *gld*, and *lpr<sup>cs</sup>* mice is not identical to that seen in humans with ALPS; for example, nephritis is uncommon in patients. While FasL defects are not a frequent cause of ALPS, an adult male with atypical lupus and adenopathy was reported to have a dominant heterozygous FasL mutation (Wu et al., 1996); one additional ALPS patient in the NIH series has a FasL defect (Bi et al., 2001).

Although the mouse is an excellent model system in which to evaluate relationships between Fas apoptosis and other modulators of immune responses, differences between species need to be recognized. For example, the mouse lacks caspase-10, which in humans is located adjacent to caspase-8 and probably arose by gene duplication. Thus the relative roles of these caspases in the Fas apoptosis pathway cannot readily be dissected in mice. Mice with targeted disruptions of caspase-8 have cardiac and hematopoietic defects and do not survive (Varfolomeev et al., 1998), whereas humans lacking caspase-8 activity have features of both ALPS and combined immunodeficiency.

## Future Directions and Challenges

### Molecular Events Controlling Apoptosis

The importance of programmed cell death in diverse physiologic processes involving dividing cells is widely recognized. We now understand that apoptosis is critical for maintenance of immune cell homeostasis, both by terminating an appropriate immune response and by preventing runaway responses by mature lymphocytes with cross-reactivity to self-antigens. However, all of the molecular events that deliver an apoptotic signal, the process of cell death itself, and the regulation of every step of the process are not yet fully understood (Chinnaiyan and Dixit, 1997; Nagata, 1997). Added insights into these processes have been garnered with extensive studies driven by the availability of cells with Fas defects and of increasingly sophisticated *in vitro* technologies. For example, the redistribution of Fas into lipid rafts at the cell surface has been highlighted as an important mechanism for making lymphocytes more sensitive to apoptosis (Muppidi and Siegel, 2004). The transmembrane molecules TNFR1 and Fas interact with their ligands as trimers and share intracellular death domain regions. Both the TNFR1 pathway and the Fas pathway are expressed in mature lymphocytes (Zheng et al., 1995). The TNFR1 pathway involves some genes with restricted specificity, such as TNFR1 itself, TRADD, and TRAF-2, but some of the other death domain interacting genes, and perhaps certain caspases and final nuclear effectors of apoptosis, may be shared with the Fas pathway. An additional apoptosis pathway through a distinct receptor DR3 (death receptor 3) has been identified in lymphocytes and additional receptors DR4 and DR5 have been isolated (Chinnaiyan et al., 1996). Other intracellular signal transducers are also involved. The pivotal molecule NF- $\kappa$ B can be activated and appears to have an antiapoptotic effect by up-regulating cellular survival factors, but its relationship with caspase-8 in cell activation is also essential. It is not entirely clear how mitochondrial apoptosis pathways interact with pathways of apoptosis involving TNFR family members, and defects in these pathways may underlie some cases of ALPS III as well as other clinical syndromes involving inflammation, lymphoproliferation, and immune dysregulation.

### Modifiers of the ALPS Phenotype

Even among ALPS patients with a well-defined Fas defect, the clinical phenotype can be highly variable, as appreciated early in the course of work in the field. This variation suggests that additional genetic and/or environmental factors must be required to interact with Fas defects to produce overt lymphoproliferation and autoimmunity. These putative ALPS-modifying factors might include other members of the Fas apoptosis pathway or related pathways, many of which are still being identified. An existing

model for severe disease produced by complementation between two apoptosis pathway mutations is the mouse doubly heterozygous for *gld* and *lpr<sup>cs</sup>* defects of FasL and Fas, respectively. Identification of critical intracellular signaling mediators in the caspase protease cascade provides additional candidate genes for modifiers of the ALPS phenotype. Moreover, a large number of gene products regulating lymphocyte signaling networks have been implicated in lymphoproliferation and autoimmunity in mice; many of these could be exacerbated by further impairment of apoptosis and therefore may also be candidates for second mutations in ALPS.

The MHC locus is a major modifier of risk for many autoimmune conditions, and HLA B44 appears to be protective against severe disease in individuals with ALPS Ia (Vacek et al., 2006). The caspase-10 variant V410I is also protective (Zhu et al., 2006). In contrast to many autoimmune diseases, ALPS appears to affect males somewhat more severely than females. Identification and an understanding of the mechanisms whereby these and other factors modify risk promise to clarify the genetic etiologies of further autoimmune syndromes, and perhaps provide new therapeutic approaches for autoimmune disorders.

## Acknowledgments

We thank members of ALPS research teams at the NIH: Michael Lenardo, Koneti Rao, Janet Dale, Faith Dugan, Joie Davis, Roxanne Fischer, Thomas Fleisher, Amy Hsu, and Elaine Jaffe; and at INSERM and Hôpital Necker: Alain Fischer, J.P. de Villartay, J.F. Emiel, and N. Brousse. We also thank the families and their referring physicians who have participated in our studies.

## Autoimmune Polyendocrinopathy, Candidiasis, Ectodermal Dystrophy

LEENA PELTONEN-PALOTIE, MARIA HALONEN, and JAAKKO PERHEENTUPA

Autoimmune polyendocrinopathy–candidiasis–ectodermal dystrophy (APECED; OMIM 240300), an autosomal recessive disease, provides a unique model for molecular studies of autoimmunity because of the monogenic inheritance of this disorder, characterized by multiple features of abnormal immunological tolerance. APECED was first mentioned in the literature by Thorpe and Handley in 1929, and since then it has been given several names, such as APS1 or Whitaker's syndrome (Leonard, 1946; Whitaker et al., 1956; Neufeld et al., 1981; Ahonen, 1985). Patients with APECED have been identified in numerous populations and among multiple ethnicities. The disease occurs more frequently in isolated populations, the lifetime prevalence being rather high among the Finns, Iranian Jews, and Sardinians (1/25,000, 1/9000, and 1/14,500, respectively) (Zlotogora and Schapiro, 1992; Rosatelli et al., 1998).

The APECED locus was mapped in the Finnish families to 21q22.3 (Aaltonen et al., 1994). The locus homogeneity was confirmed in a multinational group of patients, although the mutations in patients with distinct origins are expected to be different because of different haplotypes of disease alleles (Björnses et al., 1996). A novel gene, *AIRE* (for AutoImmune REgulator), which causes APECED, was positionally cloned in 1997 (Finnish-German APECED Consortium, 1997; Nagamine et al., 1997). *AIRE* contains 11.9 kb of genomic DNA and 14 exons with boundaries that follow the GT-AG rule (Mount, 1982). The last exon of the gene seems to overlap with the promoter region of the *PFKL* gene, transcribed from the same strand of DNA as *AIRE* (Levanon et al., 1995). Close to 50 mutations have been identified in APECED patients. The distribution of these mutations has guided analyses of the functional domains of the 545–amino acid–long Aire protein. This protein is targeted to both the nucleus and cytoplasm and its role as a transcription activator has been demonstrated in vitro. Analysis of the first knockout mouse mod-

els suggests a role for Aire in the development of both central and peripheral tolerance (Anderson et al., 2002; Ramsey et al., 2002b). Several excellent reviews on APECED and AIRE have been published (Anderson, 2002; Björnses et al., 1998; Peterson et al., 1998a, 1998b; Aaltonen and Björnses, 1999; Meriluoto et al., 2001).

### Clinical and Pathological Manifestations

The clinical picture of APECED is highly variable (Ahonen et al., 1990; Betterle et al., 1998; Perheentupa and Miettinen, 1999; Myhre et al., 2001; Perheentupa, 2002) (Table 25.1) and the frequencies of the phenotype components vary from one population to another. Symptoms include components of three biological pathways: (1) autoaggressive destruction of tissues, predominantly endocrine glands; (2) consequences of a partial defect of cell-mediated immunity, most commonly superficial candidiasis; and (3) ectodermal dystrophies. Factors contributing to the complexity of the disease are not yet understood, but variation in symptoms among siblings suggests that factors other than the *AIRE* mutations play an important role. Unlike other APECED patients, Iranian Jewish patients (Zlotogora and Schapiro, 1992) have no keratopathy and have a lower prevalence of candidiasis and hypoadrenocorticism. Italian patients differ from Finnish patients in having less frequent keratoconjunctivitis (12% vs. 21%) and diabetes (2% vs. 18%) (Betterle et al., 1998).

A so-called Whitaker's triad of symptoms—hypoparathyroidism, adrenocortical failure (Addison's disease), and chronic mucocutaneous candidal infections—is pathognomonic for APECED (Ahonen et al., 1990). Other endocrinopathies include gonadal atrophy, type 1 diabetes, gastric parietal cell atrophy, and hypothyroidism (Ahonen et al., 1990; Betterle et al., 1993). The mucocutaneous candidiasis can affect the oral, ungual, esophageal,

**Table 25.1.** Frequency of Clinical Features of APECED

<i>Disease Component</i>	<i>Prevalence (%)</i>
<i>Endocrine Components</i>	
Hypoparathyroidism	79
Addison disease	72
Ovarian failure	60*
Hypothyroidism	4
Type 1 diabetes	12
Pernicious anemia	13
<i>Nonendocrine Components</i>	
Mucocutaneous candidiasis	100
Enamel hypoplasia	77
Vitiligo	13
Alopecia	72
Nail dystrophy	52
Malabsorption	18
Autoimmune hepatitis	12
Keratopathy	35
<i>Rare Disease Components</i>	
	<i>No. of cases</i>
Central diabetes insipidus	6

Gonadotropin deficiency	2
Hyperthyroidism	3
Autoimmune hemolytic anemia	3
IgA deficiency	>18
Asplenia	18
Cholelithiasis	7
Periodic fever with rash	11
Sjögren syndrome	20
Oral squamous cell carcinoma	8

\*Calculated for postpubertal females.

and vaginal mucosa and nails. Autoimmune hepatitis, enamel hypoplasia, nail dystrophies, keratoconjunctivitis, vitiligo, and alopecia are other typical manifestations of APECED (Wagman et al., 1987; Lukinmaa et al., 1996; Perniola et al., 1998) (Table 25.1 and Color Plates 25.I to 25.VI). Candidiasis, hypoparathyroidism, and hypoadrenocorticism were found in 50% of Finnish patients at the age of 20 years, 55% at age 30, and 40% at age 40. It should be emphasized that the diagnostic criterion of having at least two elements of this triad would leave many cases missed. In some cases the rare components dominate with none of the triad present.

### Candidiasis

Oral candidiasis usually appears first in the mildest cases as angular cheilosis (Color Plate 25.V). Presentations include acute inflammation of all oral mucosa, hyperplastic chronic candidiasis with thick, white tongue coating, and atrophic disease characterized by scant coatings and scarred thin mucosa with leukoplakia-like areas (Myllärniemi and Perheentupa, 1978). This chronic condition is carcinogenic. Candidal esophagitis is also common; it causes substernal pain and odynophagia and may lead to stricture with dysphagia. Perianal candidal eczema is common, and intestinal mucosal candidiasis may cause abdominal pain, meteorism, and diarrhea. The infection may spread to the skin of the hands and face and the nails. Candidal vulvovaginitis is also common after puberty. Humoral immunity against *Candida*

develops normally. Generalized candidiasis has only been reported in patients on immunosuppressive medication (Betterle et al., 1998). Serious lung disease may be more common (Brun, 1982). Extensive bilateral pneumonia was reported in one patient (Arvanitakis and Knouss, 1973). In a 30-year-old patient of ours who died of septicemia after hip joint replacement, the autopsy revealed *Candida* abscesses in the pericardium and small intestine, along with necrotizing inflammation of the large intestine and mesenterium.

### Endocrinopathies and Associated Clinical Features

In some patients, hypoparathyroidism can be latent for years before a distinct manifestation occurs. In the Finnish series of 90 APECED patients, it remained the only endocrinopathy in 27% of patients at age 20 and in 18% at age 30. Adrenocortical insufficiency remained the only endocrinopathy in 15% of our patients at age 20 and in 14% at age 30. Hypogonadism manifested as primary gonadal failure in our patients. Half of the affected females had primary amenorrhea, many with partial pubertal development. All females with hypogonadism also had hypoadrenocorticism, and 92% of females over 15 years of age who had hypoadrenocorticism also had hypogonadism. Of 7 males who had hypogonadism, 5 had hypoadrenocorticism, whereas only 5 of 27 males with hypoadrenocorticism had hypogonadism.

Diabetes mellitus (DM) affected 12% of our APECED patients—4.5- to 9-fold more patients than in other large series (Neufeld et al., 1981; Betterle et al., 1998). This rate reflects the prevalence of type I DM in the general population. Hypothyroidism is relatively uncommon, but was the first endocrinopathy in one of our patients. Hyperthyroidism is rare. Hashimoto's thyroiditis may occur at the same frequency as that of hypothyroidism (Brun, 1982). Pernicious anemia (autoimmune gastritis) is the most common gastrointestinal problem, with a peak incidence at 10 to 20 years of age.

Periodic or chronic diarrhea, usually with steatorrhea, and severe obstipation (often alternating with diarrhea) are equally prevalent. In most cases the diarrhea is secondary to hypoparathyroidism and depends on the presence of hypocalcemia (Peracchi et al., 1998). However, most patients having equally severe hypocalcemia never develop diarrhea. Also, some patients develop hypoparathyroidism years after the onset of diarrhea, and some not at all. The diarrhea may become severely incapacitating through a vicious cycle with hypocalcemia: diarrhea impairs the ability to absorb calcium and the calciferol drugs, making the hypocalcemia difficult to control by oral medication. Apparently, hypocalcemia prevents secretion of cholecystokinin by the duodenal mucosa in response to a meal, leading to failure of the physiologic stimulus for normal gall bladder contraction and pancreatic enzyme secretion (Miettinen and Perheentupa, 1971; Heubi et al., 1983; Högenauer et al., 2001). In three cases secretory failure of the exocrine pancreas appeared to be the predominant mechanism, thus enzyme replacement was necessary (Scirè et al., 1991; Ward et al., 1999, 2001; J. Perheentupa, unpublished observations). The autoimmune destruction of enterochromaffin cells (EC) of duodenal mucosa, which produce cholecystokinin and serotonin, has been demonstrated (Ekwall et al., 1998; Ward et al., 1999). This condition has been treated with success using immunosuppressive medication (Padeh et al., 1997; Ward et al., 1999, 2001).

Autoimmune hepatitis may be the first manifestation of APECED. In most cases chronic and without symptoms, it may

lead to cirrhosis or be fulminant and lethal. Three of our 15 patients died within 2 months of the diagnosis, despite intensive immunosuppressive therapy.

Keratoconjunctivitis is relatively common, seemingly independent of hypoparathyroidism, and typically develops before the age of 17. In some Finnish cases this was the first symptom or part of the initial manifestation, or it occurred after candidiasis. Initial symptoms are intense photophobia, blepharospasm, and lacrimation.

Skin Symptoms and Ectodermal Dystrophies

The most frequent manifestation of ectodermal dystrophy is enamel hypoplasia of permanent teeth (Color Plate 25.1) (Myl  rniemi and Perheentupa, 1978; Lukinmaa et al., 1996). Alopecia was the first manifestation or among the initial symptoms in 4% of Finnish patients. Appearing as patchy loss of hair, in 21 of 28 of our patients it became universal, being transient in some cases. Vitiligo is highly variable. In a few patients initial spots fade, but in most patients they grow larger (Color Plate 25.VI). Urticaria-like erythema with fever recurred frequently over 2 months to 11 years in 8 of our 89 patients. In three cases, biopsy revealed lymphoplasmacytic vasculitis. Serum IgG levels were supranormal, and circulating immune complexes were detected in one patient. Hepatitis was 3.5-fold and iridocyclitis 30-fold more prevalent in these patients than in the others.

Pathological Manifestations

The autoimmune tissue destruction in APECED appears similar to that observed in the same tissues in non-APECED autoimmunity. Initial features include tissue infiltration by lymphocytes, plasma cells, and macrophages. The tissue structure is then gradually destroyed, resulting in atrophy or hyalinization. In some cases parenchymal cells are replaced by fat cells or fibrotic tissue. The atrophy may be focal (Williams and Wood, 1959) and its timing may differ among the three layers of the adrenal cortex (Craig et al., 1955). The parathyroid and adrenal glands often become undetectable and the adrenal medulla, initially unaffected, may dramatically atrophy (Gass, 1962). Early in the course of hepatitis, lymphocytic infiltration is confined to portal tracts and immediate periportal areas. With periportal lymphoplasmacytic infiltration necrosis of periportal hepatocytes may appear. At later stages, heavy infiltration of lymphocytes, macrophages, and polymorphonuclear leukocytes results in the widening of portal tracts and in a fibrotic process dominated by collagen fibers and lobular necroinflammation. Cirrhosis is followed by canalicular and intracellular cholestasis, ballooning degeneration of hepatocytes, and lobular disarray (Craig et al., 1955; Goldstein et al., 1996).

The keratitic corneas show irregular, initially slightly raised, confluent and grayish opacities, with mild bulbar injection of the conjunctiva, and subsequent superficial corneal neovascularization (Gass, 1962). In advanced cases, the corneal epithelium becomes severely atrophic with areas of incipient epidermalization. Bowman’s membrane is destroyed and the anterior corneal stroma can be replaced by vascularized scar tissue and areas of chronic lymphoplasmacytic infiltration (Tarkkanen and Merenmies, 2001).

There are also reports of nontypical pathological tissue changes in APECED. In a patient with microscopic hematuria and significant proteinuria, a biopsy revealed focal segmental proliferative glomerulonephritis with crescentic glomeruli, and

Table 25.2. Autoantigens Characterized in Patients with APECED

Disease Component	Autoantigen
Endocrine	
Addison’s disease	P450c21 P450c17 P450scc
Gonadal failure	P450scc
Hypoparathyroidism	Calcium sensing receptor
Hypothyroidism	TPO TG
IDDM	ICA GAD65, GAD67 IA-2
Nonendocrine	
Alopecia	TH
Autoimmune hepatitis	P4501A2 P4502A6 AADC
Autoimmune gastritis	H+K+-ATPase intrinsic factor
Malabsorption	TPH
Vitiligo	Transcription factors SOX9 and SOX10

Abbreviations: AADC, aromatic L-amino acid decarboxylase; GAD, glutamic acid decarboxylase; H+K+ATPase, proton pump of the gastric mucosa; IA-2, tyrosine phosphatase; ICA, islet cell antigen; scc, side chain-cleaving enzyme; TG, thyroglobulin; TH, tyrosine hydroxylase; TPH, tryptophan hydroxylase; TPO, thyroid peroxidase.

irregular granular deposits of IgG and C3 on the basement membrane (Berberoglu et al., 2000). One patient with emotional lability associated with retrograde amnesia had patchy demyelination lesions in deep white matter, characteristic of progressive multifocal leukoencephalopathy (Parker et al., 1990). At the autopsy of a 6-year old patient with no apparent neurological clinical abnormalities, isolated focal perivascular collections of lymphocytes and large mononuclear cells were observed in the hippocampal gyrus and medulla. The olivary nucleus showed degeneration, neurophagia, loss of nerve cells, and accumulation of glial elements (Craig et al., 1955). Not surprisingly, this would imply a general autoimmune reaction manifesting in multiple tissues and showing wide individual variation.

Laboratory Findings

The autoimmune manifestations of APECED include not only infiltration of lymphocytes in affected organs but also the presence of various circulating, antigen-specific autoantibodies (Table 25.2) (Ahonen, 1993; Song et al., 1996; Perniola et al., 2000). The autoantibodies facilitate the clinical diagnosis and to some degree predict the course of the disease. The sensitivity of an APECED diagnosis obtained by detection of autoantibodies (P450c21, P450scc and AADC) is 89%. One group of autoantibodies is targeted against hydroxylases P450c17 (Krohn et al. 1992), P450c21 (Winqvist et al., 1992; Uiibo et al., 1994b) and P450scc (Uiibo et al., 1994a; Winqvist et al., 1995), which catalyse those chemical reactions required for the production of steroid hormones such as aldosterone, progesterone, and cortisol (Chen et al., 1996). The presence of P450c21 precedes the development of both adrenal and ovarian failure (Ahonen et al., 1987). Another group of enzymatic autoantigens is pteridine-dependent hydroxylases, and tryptophan, tyrosine, and phenylalanine hydroxylases (TPH, TH, and PAH respectively).

All enzymes of this group are involved in the catalysis of serotonin and dopamine, as is the aromatic L-amino acid decarboxylase (AADC), also a target autoantigen in APECED patients (Husebye et al., 1997; Ekwall et al., 1998, 2000; Hedstrand et al., 2000). The gastrointestinal dysfunction in APECED patients has been shown to be associated with the presence of TPH autoantibodies. The role of TH autoantibodies is linked to the development of alopecia areata. Various other autoantibodies have also been found. These are targeted against GAD65 and GAD67 (Bjork et al., 1994; Velloso et al., 1994), tyrosine phosphatase IA-2 (Gylling et al., 2000), CYP1A2 (Clemente et al., 1997; Gebre-Medhin et al., 1997), CYP2A6 (Clemente et al., 1998), thyroid peroxidase (Betterle et al., 1998), thyroglobulin (Betterle et al., 1998), the proton pump of the gastric mucosa H+K+AT-Pase (Karlsson et al., 1988), intrinsic factor (Mirakian and Bottazzo, 1994), and the calcium-sensing receptor (Li et al., 1996). Recently, two transcription factors, SOX9 and SOX10, were found to be targets for autoantibodies in APECED patients (Hedstrand et al., 2001). The autoantibodies against P4501A2 and P4502A6 associate weakly with active hepatitis and those against SOX9 and 10 with vitiligo in patients with APECED.

### Molecular Basis of APECED

To date, 48 different mutations have been characterized in the *AIRE* gene of patients with APECED (Table 25.3). The mutations vary from single nucleotide substitutions, small insertions and deletions, splice-site donor or acceptor mutations, to gross deletions. Most APECED mutations lead to a premature termination codon and are predicted to delete the carboxy terminus of the AIRE protein. Another significant group is missense mutations, found in all functional domains of AIRE; the homogeneous staining region (HSR) domain (discussed below) shows a distinct clustering of disease mutations.

### Functional Aspects of the AIRE Protein

#### Domains of the AIRE Polypeptide

The *AIRE* gene encodes a 545-amino acid protein, AIRE, with a molecular weight of 57.5 kDa and a calculated pI of 7.53. The AIRE protein consists of multiple functional domains suggested to be involved in nuclear import, transcriptional activity, DNA binding, and homomultimerization (reviewed in Kumar et al., 2002) (Fig. 25.1). The first 100 amino acids form the HSR, which is predicted to form a four-helix bundle structure (Pitkänen et al., 2000). The HSR defines a protein family including Sp100, Sp140 (the speckled proteins 100 and 140 kDa, respectively), and a putative human protein, AA431918 (Sternsdorf et al., 1999). Interestingly, the homomultimerization capacity of AIRE (Pitkänen et al., 2000) resides on the HSR domain (Sternsdorf et al., 1999). In the nucleus, AIRE is associated with dots that resemble promyelotic leukemia (PML) bodies (Zhong et al., 2000), whereas in the cytoplasm, it is attached to intermediate filaments that colocalize with vimentin and  $\alpha$ -tubulin representing microtubules, and to aggregates of varying size (Björnses et al., 1999; Heino et al., 1999a; Rinderle et al., 1999). The HSR domain of AIRE has been suggested to be responsible for the attachment of AIRE with cytoplasmic filaments (Pitkänen et al., 2001; Ramsey et al., 2002a), whereas the HSR of Sp100 is responsible for the targeting of Sp100 to the PML bodies (Sternsdorf et al., 1999).

The amino acids 189–290 of AIRE represent a SAND domain (amino acids 189–290), recently characterized as a novel DNA-

binding structure (Gibson et al., 1998; Bottomley et al., 2001). The SAND domain is present in a family of proteins including members such as Sp 100, AIRE, NucP41/75, and deformed epidermal autoregulatory factor-1 (DEAF-1) of *Drosophila melanogaster* (Gibson et al., 1998). The structure of the SAND domain of Sp100b contains a fold with five-stranded, twisted antiparallel  $\beta$  sheets that pack against four  $\alpha$  helices (Bottomley et al., 2001). SAND is suggested to represent a DNA-binding domain particularly characteristic for chromatin-dependent transcriptional regulation, as it is often found in proteins carrying putative modules for association with chromatin—for example, plant homeodomain type (PHD) zinc fingers. Interestingly, the AIRE protein seems to bind to zinc finger consensus DNA sequence EGR as a homomultimer, and to oligo-TGG with high affinity when part of a large complex (Kumar et al., 2001). Nevertheless, the specific DNA-binding capacity of the SAND domain of AIRE has not yet been shown. In addition to DNA binding, the SAND domain of AIRE may be necessary for the nuclear localization (Ramsey et al., 2002a).

Two regions of AIRE (amino acids 296–343 and 434–475) contain PHD zinc fingers, predominantly found in proteins that regulate transcription at the chromatin level (Aasland et al., 1995). The PHD fingers are found in proteins that function in the regulation of transcription at the chromatin level (Aasland et al., 1995) and at present, one or more PHD fingers have been described in >400 proteins (Capili et al., 2001). The characteristic motif for PHD fingers consists of seven cysteines and a histidine arranged in a C4HC3 consensus (Aasland et al., 1995; Pascual et al., 2000). The presence of two PHD zinc finger domains in the carboxy-terminal half of AIRE suggests a role for AIRE in the regulation of gene expression. Indeed, AIRE has been characterized as a powerful transactivator of transcription (Björnses et al., 2000; Pitkänen et al., 2000) and the PHD zinc fingers have been mapped as the transactivation domains of AIRE (Pitkänen et al., 2001; Halonen et al., 2002). The three-dimensional structure of the PHD zinc fingers supports their suggested role as mediators of protein–protein interactions (Capili et al., 2001). However, this function of PHD domains of the AIRE protein has not yet been demonstrated.

In addition to the HSR, SAND, and PHD domains, the AIRE protein harbors a leucine zipper motif within the first PHD domain (amino acids 319–341), a putative nuclear localization signal (NLS) (amino acids 113–133), and four LXXLL motifs (amino acids 7–11, 63–67, 414–418, 518–524). The leucine zipper motif characterizes a major class of eukaryotic transcriptional regulators. The leucine zipper motif of AIRE has been proposed to be involved in the homomultimerization of AIRE (Kumar et al., 2001), but this remains to be shown. The NLS of AIRE has been shown to be functional (Pitkänen et al., 2001), but so far, the nuclear import mechanisms have not been characterized. Our recent unpublished data suggest that the NLS of AIRE functions via the importin  $\alpha$ -mediated mechanism. The LXXLL domains are found in a family of nuclear proteins. In addition, they have been shown to be necessary and sufficient for the binding of proteins to ligated nuclear receptors (Heery et al., 1997). As a result of this protein–protein interaction, the proteins containing LXXLL motifs mediate the transcriptional activity of nuclear receptors. No experimental data on the function of the LXXLL motifs of the AIRE protein have been presented thus far.

Several predicted domains of AIRE, together with its localization in nuclear dots, imply its role in the regulation of transcription, and it has been shown that AIRE acts as powerful transcriptional transactivators in vitro (Björnses et al., 2000;

LZ, leucine zipper; ORF, open reading frame.

Pitkänen et al., 2001). Further, it seems that the carboxy-terminal part of AIRE, containing the PHD finger and leucine zipper domains, is important for the transactivation capacity. Homomultimerization may be required for specific molecular interactions; in the case of AIRE it may be required for DNA binding. A phosphorylated form of the AIRE protein has been found in mono-, di-, and tetrameric forms in vivo and in vitro

and the amino-terminal HSR domain has been shown to be required for the homomultimerization of AIRE in vitro (Pitkänen et al., 2000; Kumar et al., 2001). So far, the only specific protein–protein interaction characterized for AIRE is that with CREB binding protein (CBP). However, the specific AIRE domain(s) responsible for this interaction has not been mapped (Pitkänen et al., 2000).

**Figure 25.1.** Domains of the AIRE protein. HSR, homogeneous staining region; LZ, leucine zipper; NLS, nuclear localization signal.

### Subcellular Localization of the AIRE Protein

Characteristically, the *in vitro*-expressed AIRE polypeptides show two types of distribution in cells: (1) nuclear dot-like staining excluding the nucleoli, and (2) cytoplasmic filamentous or microtubular staining (Finnish-German APECED Consortium, 1997). Immunostaining of cells in tissue sections reveals mostly nuclear staining, although some cell types, including the interstitial cells of the testis and neurons in the trigeminal ganglions, exhibit specific smooth cytoplasmic staining. Both human and mouse cells show similar dual nuclear and cytoplasmic subcellular distribution.

### Tissue Expression of AIRE

Human AIRE protein expression was initially found in the thymus and lymph node (Björnses et al., 1999; Heino et al., 1999a), as well as in the spleen and peripheral blood cells (Björnses et al., 1999). The mRNA expression pattern was similar, and appendix and fetal liver were found to express AIRE (Nagamine et al., 1997; Heino et al., 1999a).

By use of sensitive reverse transcription polymerase chain reaction (RT-PCR) techniques, low level of transcripts can be identified in most human and mouse tissues (Table 25.4). In the thymus, AIRE/Aire protein expression seems to be restricted to the medulla. Studies on expression of the mouse *Aire* gene indicate a wider tissue expression pattern than that detected in human tissue studies (Heino et al., 2001; Kogawa et al., 2002b). Most probably the mouse findings better reflect the real distribution of Aire expression because of multiple complications associated with accessing and handling human tissue samples. At the cellular level, Aire protein expression has been observed in thymic corpuscles, reticular epithelial cells, and a small subpopulation of medullary thymocytes. Consistent results show that in the mouse Aire is mainly expressed in the thymic epithelial cells (TEC) (Zuklys et al., 2000; Heino et al., 2001) and particularly in a subpopulation of corticomedullary and medullary 29<sup>+</sup> epithelial cells in the adult tissue (Zuklys et al., 2000).

### Consequences of APECED Mutations

Several of the studied mutations change the distribution of the AIRE protein between the nucleus and cytoplasm. In particular, mutations of the predicted surface area of the HSR domain block the cytoplasmic localization of AIRE. Instead, the mutant proteins accumulate in the nucleus. This finding suggests that the mutations either enhance nuclear import or inhibit nuclear export (Björnses et al., 2000). Since the NLS of the AIRE protein seems to be sufficient for nuclear import (Pitkänen et al., 2001), inhibition of nuclear export by these mutations seems more likely. AIRE seems to be exported from the nucleus by specific nuclear

export signal (NES)-dependent export, and the export signal is suggested to lie within the amino terminus of AIRE (Pitkänen et al., 2001). Mutations of the SAND domain appear to disturb the distribution of AIRE between the nucleus and cytoplasm and, when expressed *in vitro*, reveal excessive staining in the perinuclear region (Björnses et al., 2000; Ramsey et al., 2002a). This finding suggests a role for the SAND domain in nuclear transport mechanisms. The most common APECED mutation, R257X, is a nonsense mutation that severely disturbs subcellular localization of the mutant protein, inhibits the transactivation function, and complex formation of AIRE, but exerts almost no effect on the homomultimerization capacity of the mutant protein.

### AIRE Genotype–APECED Phenotype Associations

In a series of over 100 patients from Finland, Sweden, Norway, and Italy, an association between the absence of R257X mutation in *AIRE* and decreased frequency of mucocutaneous candidiasis was established (Halonen et al., 2002). Compared to the consequences of many other mutations, the R257X mutation results in a total loss of function, whereas the less dramatic truncations of the AIRE protein and many missense mutations, especially the predicted surface mutations of the HSR domain and the mutations in the leucine zipper domain, seem to have less severe effects on the function of the AIRE protein. Since a large proportion of patients from nonfounder populations represent compound heterozygotes, the genotype–phenotype associations may be difficult to assess. In addition, the effects of the mutations *in vivo* may be complicated to predict because of the multimer structure of AIRE.

The wide variation in phenotype of patients with APECED suggests that factors other than the diversity of mutations in the *AIRE* gene affect the phenotype. The linkage and association between the human leukocyte antigen (HLA) genes and the APECED phenotype were studied earlier, but no significant associations have been established (Maclaren and Riley, 1986; Ahonen et al., 1988; Aaltonen et al., 1993; Huang et al., 1996; Betterle et al., 1998). Many of the disease components of APECED are associated with specific HLA alleles when these appear as isolated diseases or as a part of polyglandular syndrome type II, and HLA class II alleles seem to modify the APECED phenotype. Associations with specific HLA haplotypes have been found for alopecia, Addison disease, and type 1 diabetes. These same associations have been established for non-APECED patients, indicating a significant dependence of these disease components on the HLA type (Maclaren and Riley, 1986; Weetman et al., 1991; Colombe et al., 1999; Yu et al., 1999) (Table 25.5). Alopecia is associated strongly with the DRB1\*04 allele, which is also associated with severe forms of idiopathic alopecia. Increased risk for Addison disease is associated with the DRB1\*03 allele, which together with the DRB1\*04 allele has repeatedly been found associated with Addison disease in non-APECED patients. The haplotype DRB1\*1501-DQB1\*0602 is associated with protection from type 1 diabetes. Interestingly, this is the major protective haplotype for type 1 diabetes in non-APECED patients as well.

Only weak associations have been observed between HLA type and autoantibodies in APECED patients. Thus in APECED, the HLA alleles may not have a strong influence on autoantibody formation. This finding contrasts with those made in APECED trait components, isolated autoimmune diseases in which HLA alleles are often associated with the presence of autoantibodies.

**Table 25.4.** Expression of Aire Protein in Different Tissues as Detected by Immunohistochemistry

<i>Organ System</i>	<i>Tissue</i>	<i>Cellular Level</i>

Keratopathy	11	0.037		
Vitiligo			0301	0.032

<sup>†</sup>Data from non-APECED patients supports the association (Halonen et al., 2002).

### Mouse Models of APECED

Recently, two different *Aire*-deficient mouse models have been developed (Ramsey et al., 2002a; Anderson et al., 2002). In both models, the mice were kept in sterile conditions, they developed normally, and were clinically healthy. However, autoimmune features of APECED in *Aire*<sup>-/-</sup> mice were evident, including multi-organ lymphocytic infiltration, circulating autoantibodies, and infertility.

The first *Aire*-deficient mouse model was constructed through the targeted disruption of exon 6 of the mouse *Aire* gene (Ramsey et al., 2002b). Exon 6 was chosen, as the major Finnish mutation R257X leads to a premature stop codon in exon 6 of the human *AIRE* gene. Reproduction in the *Aire*-deficient mice was abnormal, and 85% of the males and females were found to be infertile. This is in concordance with findings in APECED patients, who develop ovarian failure in 39% of the cases at the age of 15 years; the incidence is estimated to increase up to 72% by the age of 36 years (Perheentupa, 2002). Histologic analyses in 2- to 3-month-old *Aire*-deficient mice revealed atrophy of the thymus, lymphocyte infiltrations in liver and in a single atrophied ovary, and atrophy of adrenal glands. The liver findings are consistent with the incidence of autoimmune hepatitis in 12% of patients with APECED. The variation in lymphocyte infiltrates and atrophy of the organs varied among mice, a result concordant with the highly variable phenotype of APECED patients.

The presence of autoantibodies was observed in liver, spermatogonia/spermatids, exocrine pancreas, adrenal cortex, and, in a single case, the  $\beta$  cells of the islets of Langerhans. These findings are consistent with the presence of various circulating autoantibodies in patients with APECED. The distribution of B and T lymphocytes in both thymus and periphery were normal. A normal number of apoptotic thymocytes and proliferating T and B cells in the *Aire*<sup>-/-</sup> mice was seen, whereas hyperproliferation of *Aire*-deficient T cells was detected after immunization.

Further, an alteration in spectra of the complementary determining region 3 (CD3) of the T cell receptor (TCR)  $\nu\beta$  chain in *Aire*-deficient T cells after immunization was observed in splenic but not in thymic T cells; a clear alteration was found in 3 of the 24  $\nu\beta$  families (MuBV18, MuBV19, and MuBV20). The overrepresentation of certain TCRs may cause imbalance in T cell homeostasis and trigger autoimmunity. The findings in this model suggest that the autoimmunity in *Aire*-deficient mice may at least partially be caused by defects in the peripheral regulation mechanisms of tolerance.

A second knockout mouse model for APECED was produced through conditional targeted disruption of exon 2, including parts of the surrounding intronic sequences (Anderson et al.,

2002). Thus, the defect differs from that induced by Ramsey and colleagues in that (1) the deletion of exon 2 affects a different functional part of the Aire protein, the HSR domain, than that affected by the deletion of exon 6, and (2) recombination was induced by lox/cre-mediated recombination. However, the first difference may not have relevance, as the truncated Aire mRNA may not be translated to a protein or this protein may be unstable.

Also observed in this *Aire*-deficient mouse were lymphocyte infiltrations in particular structures of several organs, including the perivascular region of the salivary gland, ovarian follicles, and retina of the eye. Serum autoantibodies against particular structures of multiple organs were also observed, such as oocytes of the ovary, parietal cells in the stomach, and the outer layer of the retina of the eye. These findings suggest that the organs of the *Aire*-deficient mice are selectively attacked by autoimmune inflammation, and the defect in tolerance is broad, yet specific. The findings in the ovary are consistent with those in patients with APECED, but no defects in the retina or in the salivary glands have been reported in patients with APECED. Compared to the findings in the first mouse model, different organs or parts of organs were the targets of autoimmune attack; thus the phenotype of the two models may differ to some degree. Concerning the immune cells, the number of mTECs was twice as high as in controls and the number of activated memory T cells was doubled in the *Aire*-deficient mice. Four types of radiation bone marrow chimeras were produced: those that expressed Aire (1) only in radioresistant cells (i.e., nonhematopoietic), (2) only in radiosensitive cells (i.e., hematopoietic cells), (3) in neither cell type, or (4) in both cell types. Only type 2 and 3 chimeras exhibited autoimmune features, which suggests that Aire functions in nonhematopoietic cells (Anderson et al., 2002).

Thymus graft experiments were performed to explore whether Aire functions in the thymus or in the periphery. After 6 weeks, signs of autoimmunity similar to those in *Aire*-deficient mice were seen in those recipient mice transplanted by *Aire*-deficient thymus, whereas no signs of autoimmunity were present in the control mice (Anderson et al., 2000). These findings suggest that Aire would function in the radioresistant stromal cells of the thymus.

Anderson et al. (2000) also isolated *Aire*-deficient naive lymphocytes from the spleen and lymph nodes of *Aire*-deficient and control mice and transferred them into alymphoid recipients. After 12 weeks, autoimmunity similar to that in *Aire*-deficient mice was detected in the recipient mice of *Aire*-deficient lymphocytes. This result suggests that *Aire*-deficient lymphocytes educated in *Aire*-deficient thymus are sufficient to provoke autoimmunity. The authors concluded that Aire expression in peripheral parenchymal tissue is not the factor controlling autoimmune attack.

On the basis of the expression pattern of Aire in the epithelial cells of thymus, together with its probable role as a transcriptional regulator, an intriguing hypothesis was tested: Aire may control autoimmunity by regulating the expression of ectopic antigens in thymic medullary epithelial cells. Analysis of the transcriptional profiles of thymic epithelial cells from *Aire*-deficient mice revealed down-regulation of numerous genes, implying that Aire is a transcriptional activator of 100–300 genes represented on the array. Specifically, some previously established ectopically expressed genes (Derbinski et al., 2001) were found to be silenced or repressed. The 30 most strongly down-regulated genes were analyzed further, and all of these except for one were found to be genes encoding for tissue-restricted antigens expressed ectopically. Interestingly, the analysis of all the down-regulated

genes showed that a significant number of the genes encoding for tissue-restricted antigens were from the target tissues of autoimmune attack in *Aire*-deficient mice.

Both mouse models for APECED seem to provide good murine models for organ-specific autoimmunity, although none of the most common phenotype components of APECED—i.e., mucocutaneous candidiasis, adrenocortical failure, and hypoparathyroidism—were manifested in these mice, and the mice did not have any symptoms of disease, except for infertility. However, future studies will show whether the APECED mice develop a more severe phenotype after being exposed to different pathogens and to specific environmental stimuli.

### Diagnosis

Diagnostic DNA analysis of mutations in the *AIRE* gene should be considered in patients under 30 years of age with two of the typical disease components (or even one if additional features exist). All patients and their families should be provided with information on APECED and the possible development of new components. Certain autoantibodies help in predicting the development of new disease components (Perheentupa, 2002). Candidiasis of the mouth is diagnosed by findings of typical white coatings and abundant growth of *Candida albicans* on culture. Usually the determination of plasma parathyroid hormone is not necessary, and a diagnosis of hypoparathyroidism can be made by the presence of simultaneous hypocalcemia and hyperphosphatemia, if renal insufficiency is excluded. Addison disease is usually indicated by high serum titers of P450c21 antibodies. The inability of the zona fasciculata of the adrenal cortex to produce cortisol can be tested at an early stage with a short adrenocorticotrophic hormone test, and later on the inability is indicated by low plasma cortisol levels. The inability of the zona glomerulosa to produce renin is indicated at early stages by supranormal plasma renin activity and at later stages by salt craving, hyponatremia, and hyperkalemia (Perheentupa, 2002). If the patient's serum contains antiadrenocortical or CYP450c21 antibodies, progress to adrenal insufficiency is almost certain. In females, circulating antibodies to CYP450csc or CYP450c17 predict ovarian atrophy. Gonadotropin deficiency and primary gonadal failure can be confirmed with the gonadotropin-releasing hormone test. To predict DM, GAD autoantibodies are of value, although a patient with high levels may never develop the disease. Patients with these antibodies should be followed by monitoring blood glycohemoglobin levels. These will probably be supranormal before the onset of clinical diabetes.

Mutation diagnosis is available from several specialized laboratories internationally. The relatively large number of mutations creates the challenge for DNA-based diagnostics. APECED cannot be excluded even when *AIRE* mutation remains unidentified. This is probably a passing phase, until the sequencing methods and their full coverage of the gene become more efficient.

### Treatment and Prognosis

Patients usually require continuous hormone replacement therapy, calcium and vitamin D supplements, and systemic antibiotics for candidal infections. Immunosuppressive therapy is used for treatment of autoimmune hepatitis. With careful treatment, patients can usually cope with the disease and their life expectancy is only slightly decreased. However, oral squamous cell carcinoma or a sudden onset of the disease by hypocalcemic or Addisonian crisis or acute hepatitis can sometimes be of a fulminant nature (Ahonen et al., 1990).

Management of patients for several diseases, particularly hypoparathyroidism, hypoadrenocorticism, diabetes, and chronic diarrhea, is more demanding than the sum of efforts for the isolated diseases. They and their therapies interfere with each other. Because of the basic immunodeficiency, live virus vaccines must be avoided. To identify persons with partial destruction of the parathyroids and risk of hypocalcemia during periods of hypocalcemic stress such as fasting, exceptionally low calcium intake, or high Pi intake or diuretics, the reserve capacity of the parathyroid glands can be evaluated with an EDTA infusion test.

Regular follow-up must include determination of serum alanine aminotransferase (ALT) activity to monitor liver function. Even slightly supranormal levels call for frequent follow-up, and very high levels justify needle biopsy. If a patient with chronic or recurrent diarrhea of steatorrhea has hypoparathyroidism, calcemia should be brought to a normal range to find out whether the disorder is simply secondary to hypocalcemia. If not, gastroenterological expertise is needed for duodenoscopy, cholecystokinin test of exocrine pancreatic function, bile concentration, and mucosal biopsy. Since asplenic patients need appropriate immunization and antibiotic coverage, patients with signs of splenic insufficiency on blood smear need an abdominal ultrasound for assessment of the spleen and detection of gallstones.

A systematic survival study has been carried out in 89 Finnish patients; 20 died of nonaccidental causes at 6–60 (median, 35.5) years of age. Three patients died of oral cancer at age 34–45 years and three died of fulminant hepatitis at 10–15 years of age. Six patients living alone were unexpectedly found dead at home, having died of unknown causes at ages 26–63 years. They all had hypoadrenocorticism and hypoparathyroidism, three had diabetes, and two were alcoholics. Six patients died of various APECED-related causes at 6–60 years of age. Three of them died before APECED was recognized, two had diabetes and hypoparathyroidism at age 6–60 years, and one had hypoparathyroidism at age 13. In retrospect, Addisonian crisis was possible. At autopsy, the 13-year-old had lymphocytic myocarditis. A 60-year-old man with hypoadrenocorticism, hypoparathyroidism, and Parkinson disease died after several months with high fever and unconsciousness. A 32-year-old woman with hypoadrenocorticism, diabetes, and hypoparathyroidism died of a pulmonary embolism after a 4.5-hour vacation flight. A 29-year-old woman with hypoadrenocorticism, hypoparathyroidism, renal insufficiency, and fulminant rheumatoid arthritis died of septicemia after replacement of necrotic hip joints. A 44-year-old man with hypoparathyroidism, hypoadrenocorticism, and tapetoretinal degeneration died of alcoholism.

Of the living Finnish patients, 44 are older than 20 (20–54, median 35) years of age. Of them, 38 have an approximately normal working capacity; two others work at a capacity limited by poor vision. One man retired after a career as a businessman at the age of 50 because he felt incapacitated. Two patients retired because of blindness, at ages 32 and 36 years. Of our 22 patients older than 20, 3 are partially incapacitated from APECED-related problems. Of our nine nonhypogonadal male patients older than 25 living in a steady heterosexual relationship, six had fathered children. Of the 10 nonhypogonadal female patients over 20 years of age, 5 had lived in a similar relationship. Four had given birth to a child—two in the natural way, and two through embryo transfer.

### Conclusions And Future Challenges

APECED is one of the rare autoimmune diseases with monogenic inheritance. It provides a unique model for studies of more

common autoimmune diseases. Furthermore, the sequence alterations in the *AIRE* gene may contribute to the pathogenesis of other, more common autoimmune diseases such as type 1 diabetes and Addison disease. In the future, the genetic association between the mutations and polymorphisms in the *AIRE* gene and the incidence of common autoimmune diseases should be analyzed.

Defective function of the *AIRE* gene may cause defects in the effector cells of the immune system and alter immune reactivity in general. Another level of disease phenotype modification is the presentation and recognition of self-antigens, which is affected by certain HLA alleles that either favor or disfavor the presentation of certain disease-associated self-antigens. Interestingly, new data indicate that *AIRE* may also function by regulating the expression of ectopic antigens in thymic medullar cells and, thus, by regulating efficient antigen presentation during negative selection in the thymus (Anderson et al., 2005; Kuroda et al., 2005).

The tissue expression pattern of *Aire* suggests that it functions in the regulation of central tolerance, but it may also function in the secondary lymphoid organs as well as in nonlymphoid peripheral tissues. *AIRE* acts as a powerful transactivator in vitro and the regions that regulate the transactivation function of *AIRE* have been initially identified in SAND and PHD finger domains. *AIRE* has been found to be present in a soluble form in large complexes of molecular weight over 670 kDa. One possibility is that *AIRE* functions as a co-activator in a large transcriptional complex. In general, transcriptional regulation may occur at the DNA, histone, nucleosome, or chromatin level. Identification of other protein-protein interactions is important; so far only one protein that interacts with *AIRE*, CBP, has been identified.

The *Aire*-deficient mouse models provide us with the possibility of introducing the deficiency of *Aire* to different genetic backgrounds and thus explore the genetic modifying factors of the APECED phenotype. In addition, these mice can be exposed to different environmental stimuli to identify the phenotype-modifying environmental factors. An understanding of the factors that modify the phenotype will provide clues to the pathogenesis of APECED and better tools to predict the disease course of an individual.

The recent findings concerning function of the *AIRE* protein in vitro and in vivo strongly support the idea that it provides a good model for general studies of immunological tolerance and its breakdown. The autoimmune reactions in patients with APECED are mostly targeted against endocrine glands, which have highly specialized functions and express a number of proteins that are unique for these organs. The mechanism of ectopic expression of rare tissue antigens may have evolved to protect the highly specialized organs with specific antigens from autoimmunity. A more detailed understanding of these features will increase our capacity to treat patients and control their tissue-specific symptoms.

## Immune Dysregulation, Polyendocrinopathy, Enteropathy, and X-Linked Inheritance

TROY R. TORGERSON, ELEONORA GAMBINERI, STEVEN F. ZIEGLER,  
and HANS D. OCHS

In 1982, Powell and colleagues reported on a large family with multiple affected males in a five-generation pedigree (Fig. 26.1). Affected males presented early in life with multiple endocrinopathies, severe chronic enteropathy, dermatitis, autoimmune hemolytic anemia, and antibody-induced neutropenia and thrombocytopenia. Most of the affected boys died before the age of 3 years of malabsorption, failure to thrive, infections, or other complications. Characteristic findings at autopsy of these and subsequently identified patients included lymphocytic infiltrates affecting the lungs and endocrine organs such as pancreas and thyroid, and increased lymphoid elements in lymph nodes and spleen (Powell et al., 1982; Wildin et al., 2002). Symptomatic therapy with immunosuppressive drugs provided some beneficial effects (Seidman et al., 1990).

More than 20 years before the initial description of this syndrome of immune dysregulation, polyendocrinopathy, enteropathy, with X-linked inheritance (IPEX), a spontaneously occurring mutant mouse strain called *scurfy* was identified at the Oakridge National Laboratory (Russell et al., 1959). Affected male mice have many phenotypic similarities to IPEX, including X-linked inheritance, polyendocrinopathy, enteropathy resulting in failure to thrive, and dermatitis. Death occurs invariably during the first 3–4 weeks of life.

The gene responsible for IPEX was mapped to Xp11.23–Xq13.3 by linkage analysis (Bennett et al., 2000; Ferguson et al., 2000). Using positional cloning, the gene responsible for the scurfy syndrome was identified and found to be a transcription factor, *Foxp3*, belonging to the forkhead/winged helix family (Brunkow et al., 2001). The human orthologue, *FOXP3*, was subsequently recognized as the causative gene for IPEX (Chatila et al., 2000; Bennett et al., 2001b; Wildin et al., 2001). Following this discovery, additional families with mutations of *FOXP3* were identified and the phenotype was characterized (Kobayashi

et al., 2001; Wildin et al., 2002; Gambineri et al., 2003; Owen et al., 2003).

Finally, using the scurfy mouse model, three independent groups have demonstrated that *Foxp3* plays an essential role in generating CD4<sup>+</sup> CD25<sup>+</sup> regulatory T cells (Fontenot et al., 2003; Hori et al., 2003; Khattri et al., 2003), providing convincing evidence that the lack of regulatory T cells is the direct cause of the early onset of multiple autoimmune disorders in scurfy mice and patients with the IPEX phenotype.

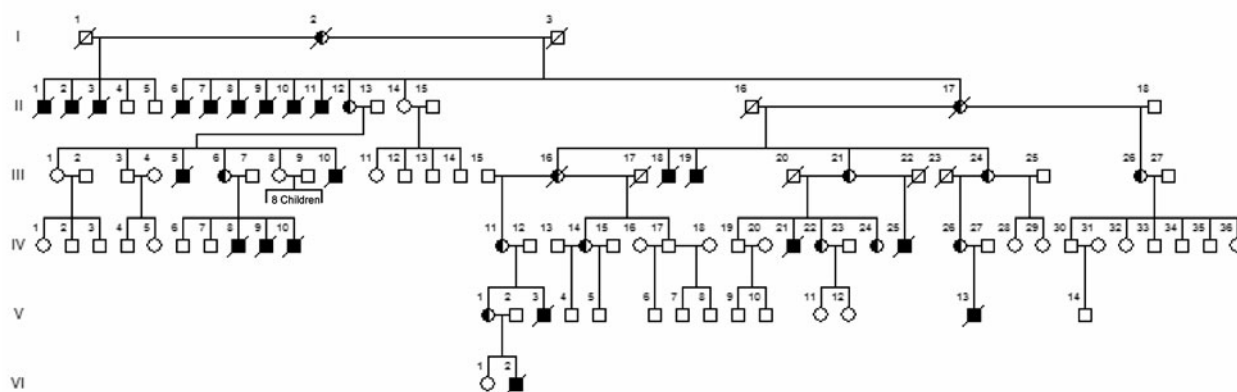

### Clinical and Pathologic Manifestations

#### Incidence, Onset of Symptoms, and Age at Diagnosis

Because of underreporting, the true incidence of IPEX is unknown. Following the discovery of the genetic defect in IPEX, more than 50 unrelated families with *FOXP3* mutations have been identified (Gambineri et al., submitted). A positive family history leads to an early diagnosis, based on the triad of severe diarrhea and failure to thrive due to villous atrophy, an eczema-like skin disease, and early-onset diabetes. As one would expect, there are milder, less characteristic phenotypes not readily recognized as IPEX. The oldest boy in our series was 11 years of age when the diagnosis of IPEX was considered and confirmed by mutation analysis.

#### Gastrointestinal Symptoms and Failure to Thrive

Early-onset diarrhea associated with villous atrophy and lymphocytic infiltrates in the small bowel mucosa are the most prominent clinical findings in patients with the IPEX phenotype (Meyer et al., 1970; Ellis et al., 1982; Hattevig et al., 1982;

**Figure 26.1.** Updated pedigree of the IPEX kindred originally described by Powell et al. (1982), demonstrating X-linked inheritance and high mortality (half-filled circle, carrier female; filled square with slash, affected deceased male).

Powell et al., 1982; Savage et al., 1982; Walker-Smith et al., 1982; Seidman et al., 1990; Jonas et al., 1991; Satake et al., 1993; Zeller et al., 1994; Roberts and Searle, 1995; Finel et al., 1996; Di Rocco and Marta, 1996; Peake et al., 1996; Kobayashi et al., 1998; Chatila et al., 2000; Cilio et al., 2000; Ferguson et al., 2000; Baud et al., 2001; Bennett et al., 2001b; Levy-Lahad and Wildin, 2001; Wildin et al., 2002; Gambineri et al., 2003, submitted). Every patient in our series of 50 families with IPEX or IPEX-like phenotype presented with gastrointestinal symptoms of watery or mucoid-bloody diarrhea that does not respond to dietary manipulation. In many instances, total parenteral nutrition (TPN) is required to prevent severe failure to thrive. Severe villous atrophy and mucosal erosion with lymphocytic infiltrates of the submucosa or lamina propria are frequently observed in small-bowel biopsies, often leading to the diagnosis of Crohn disease or, if present in the colon, ulcerative colitis. In rare cases, gastrointestinal symptoms may occur at a later age, possibly resulting from a less severe mutation of *FOXP3* or, in some cases, non-*FOXP3*-related mechanisms. Treatment with immunosuppressive drugs may improve gastrointestinal symptoms in some patients.

### Autoimmune Endocrinopathy

Early-onset (sometimes neonatal) insulin-dependent type 1 diabetes is a frequent initial finding (Meyer et al., 1970; Dodge and Lawrence, 1977; Hattevig et al., 1982; Powell et al., 1982; Jonas et al., 1991; Satake et al., 1993; Zeller et al., 1994; Roberts and Searle, 1995; Finel et al., 1996; Di Rocco and Marta, 1996; Peake et al., 1996; Bennett et al., 2000; Cilio et al., 2000; Ferguson et al., 2000; Levy-Lahad and Wildin, 2001; Wildin et al., 2002; Nieves et al., 2004; Gambineri et al., submitted). On appropriate evaluation, patients lack detectable insulin in the serum and often have anti-islet cell antibodies. At autopsy, chronic interstitial inflammation with lymphocytic infiltrates and absence of islet cells is a characteristic finding. Thyroid disease, initially presenting as either hypo- or hyperthyroidism, is a common complication (Powell et al., 1982; Satake et al., 1993; Wildin et al., 2001, 2002; Nieves et al., 2004) and may be associated with elevated thyrotropin levels or anti-thyroid microsomal antibodies (Savage et al., 1982; Kobayashi et al., 1998; Wildin et al., 2002).

In our own clinical survey of IPEX patients, type 1 diabetes was present in 78% and thyroid disease in 39% of patients with a

*FOXP3* mutation. Interestingly, only 1 of 50 IPEX patients had adrenal insufficiency.

### Autoimmune Hematologic Disorders

Coombs-positive hemolytic anemia, autoimmune thrombocytopenia, or neutropenia with early or late onset is a frequent complication (Powell et al., 1982; Satake et al., 1993; Roberts and Searle, 1995; Di Rocco and Marta, 1996; Baud et al., 2001; Levy-Lahad and Wildin, 2001; Wildin et al., 2002; Gambineri et al., 2003, submitted; Nieves et al., 2004). Specific autoantibodies (anti-red blood cell, antiplatelet, or antineutrophil antibodies) are frequently present in the circulation.

### Dermatologic Abnormalities

Some of the most common clinical findings are lesions of the skin (Powell et al., 1982; Ellis et al., 1982; Zeller et al., 1994; Roberts and Searle, 1995; Di Rocco and Marta, 1996; Peake et al., 1996; Ferguson et al., 2000; Baud et al., 2001; Chatila et al., 2001; Levy-Lahad and Wildin, 2001; Nieves et al., 2004; Gambineri et al., submitted). Newborns may present with erythematous lesions involving the entire body; older patients may develop eczema (Color Plate 26.I) or localized psoriasiform dermatitis (Color Plate 26.IIA). Histologically, the psoriasiform lesions show irregular hyperplasia of the epidermis with overlying parakeratosis and lymphocytic infiltrates (Color Plate 26.IIB). Two patients have developed *alopecia universalis*, accompanied by longitudinal ridging of the nails (Nieves et al., 2004). Treatment with steroid ointment may improve the skin lesions.

### Infections

It is unclear whether IPEX patients have a significantly increased susceptibility to infections as a function of their genetic defect as was suspected by Powell et al. (1982), or whether this susceptibility is secondary to other clinical features, such as decreased barrier function of the skin and gut, or to immunosuppressive therapy. In a large group of patients with the IPEX phenotype, half had serious infection including sepsis, meningitis, pneumonia, and osteomyelitis, many of these infections occurring prior to the initiation of immunosuppressive therapy (Gambineri et al., submitted). Sepsis due to line infections is a common complication. It is likely that autoimmune neutropenia, if present,

contributes to the susceptibility to infections. The most common pathogens identified were *Enterococcus* and *Staphylococcus* species, cytomegalovirus, and *Candida* (Jonas et al., 1991; Roberts and Searle, 1995; Peake et al., 1996; Kobayashi et al., 1998; Ferguson et al., 2000; Levy-Lahad and Wildin, 2001; Gambineri et al., 2003).

### Other Clinical Manifestations

Severe, acute reactions to routine immunizations have been reported (Powell et al., 1982). Such reactions suggest that FOXP3 and regulatory T cells are necessary to keep immune responses to foreign antigens under control and prevent the potential of "horror autotoxicus" or autoimmunity predicted by Paul Ehrlich (1910) more than 100 years ago.

Renal disease, described as glomerulonephropathy or interstitial nephritis, has been reported early on (Powell et al., 1982; Ellis et al., 1982; Zeller et al., 1994; Kobayashi et al., 1998). In our own IPEX series, more than 50% of the patients with *FOXP3* mutation had renal abnormalities (Gambineri et al., submitted). In some instances, renal disease may be directly caused or worsened by treatment with cyclosporin A, FK506, or sirolimus; however, renal disease has been described in patients not receiving any immunosuppressive drugs.

Hepatosplenomegaly and lymphadenopathy due to extensive lymphocytic infiltrates have been reported in patients at autopsy (Roberts and Searle, 1995; Peake et al., 1996; Levy-Lahad and Wildin, 2001; Wildin et al., 2002). Unexpectedly, almost half of the IPEX patients in our own series had neurologic problems including seizures and mental retardation (Gambineri et al., submitted).

### Histopathology

Histologic evaluation of the intestinal tract is characterized by a striking loss of villi in the small bowel, associated with mucosal erosions and lymphocytic infiltrates in the lamina propria and submucosa. The large bowel may also be involved, demonstrating lymphocytic infiltrates. The pancreas of infants with insulin-dependent diabetes shows lymphocytic infiltrates and loss of Langerhans cells; the thyroid, if affected, is invaded by lymphocytes (Levy-Lehad and Wildin, 2001; Wildin et al., 2002).

Microscopic evaluations of skin biopsies are consistent with eczema. Some lesions resemble psoriasiform dermatitis showing hyperplasia of the epidermis with overlying confluent parakeratosis (Color Plate 26.IIB). The epidermis may contain large numbers of infiltrating lymphocytes that consist predominantly of CD4<sup>+</sup> and CD8<sup>+</sup> T cells (Nieves et al., 2004).

The liver is frequently enlarged with fatty changes, cholestasis, and lymphocytic infiltrates that suggest "autoimmune hepatitis." Some of these changes may be due to long-term hyperalimentation. The enlarged spleen and lymph nodes represent hyperplasia caused by infiltrating lymphocytes (Levy-Lehad and Wildin, 2001; Wildin et al., 2002). A hypoplastic thymus, often observed at autopsy, may be the result of chronic illness or prolonged immunosuppressive therapy. Sections of the lung often reveal lymphocytic infiltrates and hemorrhagic changes. Renal abnormalities include interstitial nephritis, focal tubular atrophy, membranous glomerulopathy, and lymphocytic infiltrates.

### Laboratory Findings

The immunologic evaluation of IPEX patients is unremarkable except for elevated serum levels of IgE and IgA and marked

eosinophilia. IgG and IgM levels, absolute lymphocyte counts, and subset numbers are within normal range, and in vitro lymphocyte proliferations are normal. In our series, 90% of IPEX patients had elevated IgE and 67% had elevated IgA (Gambineri et al., submitted).

Following immunization with protein and polysaccharide antigens, most patients, with a few exceptions, respond with normal antibody titers (for review, see Wildin et al., 2002). These evaluations are difficult since most patients are on systemic immunosuppressive therapy at the time of testing.

The presence of autoantibodies is a hallmark of this syndrome. Most patients with insulin-dependent diabetes have autoantibodies against pancreatic islet cells (Jonas et al., 1991; Roberts and Searle, 1995; Finel et al., 1996; Peake et al., 1996; Ferguson et al., 2000; Baud et al., 2001; Wildin et al., 2002). Anti-insulin and anti-glutamic acid decarboxylase (GAD) antibodies have also been reported (Cilio et al., 2000; Baud et al., 2001). In addition, antimicrosomal/antithyroglobulin antibodies and antibodies against smooth muscles have been demonstrated (Powell et al., 1982; Savage et al., 1982; Seidman et al., 1990; Satake et al., 1993; Di Rocco and Marta, 1996; Finel et al., 1996; Ferguson et al., 2000; Baud et al., 2001). Antibodies against human intestinal tissue and a circulating antibody specific for a 75 kDa gut- and kidney-specific antigen (AIE-75) have been observed (Walker-Smith et al., 1982; Satake et al., 1993; Kobayashi et al., 1998, 1999).

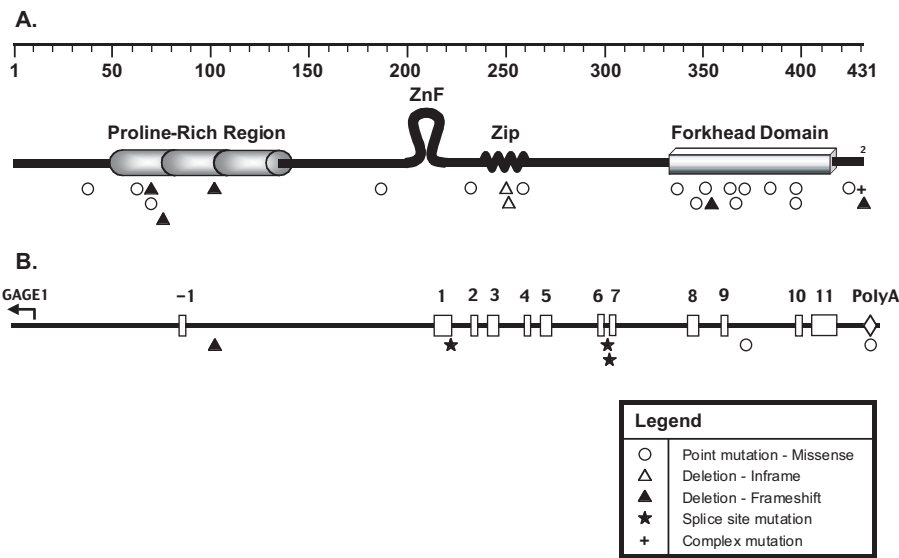

Peripheral blood lymphocytes expressing the CD4 and CD25 markers are present in IPEX patients with mutations of *FOXP3*. However, based on flow cytometric analysis, patients with mutations of *FOXP3* (even if the missense mutation allows expression of the mutated protein) completely lack CD4<sup>+</sup> CD25<sup>+</sup> cells expressing FOXP3 (Gavin et al., in press).

### Molecular Basis of IPEX

Following the identification of a 2 bp insertion in the *Foxp3* gene of mice with the scurfy phenotype (Brunkow et al., 2001), several laboratories reported that symptomatic males of families with X-linked IPEX had mutations of the human *FOXP3* gene (Chatila et al., 2000; Bennett et al., 2001b; Wildin et al., 2001). The human *FOXP3* gene is located at the short arm of the X chromosome (Xp11.23) and consists of 11 translated exons that encode a protein of 431 amino acids (429 amino acids for the murine Foxp3). The two proteins, human and murine, have 86% sequence identity. The gene is expressed predominantly in lymphoid tissues (thymus, spleen, and lymph nodes), particularly in CD4<sup>+</sup> CD25<sup>+</sup>(bright) T cells (Roncador et al., 2005). In mice, Foxp3 is expressed at low levels in CD4<sup>+</sup> CD25<sup>-</sup> cells but not or at very low levels in CD8<sup>+</sup> cells (Brunkow et al., 2001; Hori et al., 2003; Fontenot et al., 2005). Human CD8<sup>+</sup> cells can express FOXP3, although typically at lower levels (Cosmi et al., 2003; Walker et al., 2003; Xystrakis et al., 2004; Roncador et al., 2005).

The Forkhead (FKH) BOX protein FOXP3 is a member of the P subfamily of Fox transcription factors, which, as a group, are characterized by the presence of a highly conserved winged helix/forkhead DNA binding domain. Proteins bearing a forkhead DNA-binding motif comprise a large family of related molecules that play diverse roles in enhancing or suppressing transcription. Studies in model organisms such as *Caenorhabditis elegans*, *Drosophila melanogaster*, and *Mus musculus* have demonstrated a pivotal role for Fox family transcription factors in embryonic patterning, development, and metabolism (Gajiwala and Burley,

**Figure 26.2.** FOXP3 structure. (A) Schematic representation of FOXP3 protein, highlighting the proline-rich region at the N terminus, followed by a C2H2 zinc finger domain (ZnF), a leucine zipper (Zip), and the DNA-binding forkhead domain at the C terminus. (B) Genomic organization of the *FOXP3* gene. There are 11 coding exons, a Poly A region located 878–883 bp downstream of the FOXP3 stop codon, and the adjacent (upstream) gene (*GAGE1*). The location and type of *FOXP3* mutations identified to date are indicated by specific symbols. Nucleotide 1 is the first nucleotide of exon 1.

2000; Carlsson and Mahlapuu, 2002). A subset of these transcription factor family members was shown to play a role in the development and maintenance of normal immune responses and thymic development (Foxn1), in lineage commitment (Foxp3, e.g., CD4<sup>+</sup> CD25<sup>+</sup> regulatory T cells), and in the function of lymphocytes (Foxj1 and Foxo3).

The FOXP3 protein has a number of characteristic structural features including a proline-rich domain at the N terminus, a C2H2 zinc finger and a leucine zipper (both conserved structural motifs involved in protein-protein interaction) in the central portion, and a forkhead DNA-binding domain at the C terminus (Fig. 26.2). There is a putative nuclear localization signal at the C-terminal portion of the forkhead domain.

Function of FOXP3

The most essential functions of a transcription factor are nuclear import and binding to DNA. Transcription factors often interact with partners to form either homo- or heterodimers. Using N-terminal green fluorescent protein (GFP)-tagged c-DNA constructs, it is possible to transfect HEK293 cells and analyze the transfectants for the ability of the encoded FOXP3 protein fragments to enter the nucleus and bind to DNA. The intact forkhead domain is required for this process. If the forkhead domain is

deleted or mutated—for example, by point mutation that results in an amino acid substitution that leads to the IPEX phenotype—nuclear import and DNA binding are abolished (Fig. 26.3) (Lopes et al., submitted). To be functionally active, FOXP3 has to be in the homodimer formation, which depends on the intact leucine zipper sequence; naturally occurring mutations in this region interfere with this homodimerization. A novel functional domain within the amino-terminal region of FOXP3 seems to be required for FOXP3-mediated repression of nuclear factor of activated T cells (NFAT)-controlled gene transcription (Lopes et al., submitted).

FOXP3 Acts as a Transcriptional Repressor of Cytokine Promoters

Foxp3 was shown to localize to the nucleus in a forkhead domain-dependent manner. Overexpression of full-length Foxp3 was capable of suppressing transcription from a promoter construct consisting of multimers of either a consensus forkhead DNA-binding site or of a DNA-binding site for NFAT. Jurkat T cells overexpressing human FOXP3 produced less interleukin-2 (IL-2) in response to cross-linking of CD3 than did wild-type cells (Schubert et al., 2001). A recent study suggests that Foxp3, but not Foxp1 or Foxp2, physically associates and functionally interacts with NF-κB and NFAT protein, and as a result inhibits

**Figure 26.3.** Nuclear import of FOXP3. The Forkhead (FKH) domain of FOXP3 is required for nuclear import. Constructs encoding N-terminal green fluorescent protein (GFP), GFP-FOXP3 (WT), or GFP-FOXP3 lacking the forkhead (ΔFKH) domain were transiently transfected into HEK 293 cells and evaluated by standard fluorescence microscopy for

the ability to translocate to the nucleus. GFP by itself is below the size-exclusion limit for the nuclear pore complex and therefore is present throughout the cell. WT FOXP3 is located entirely in the nucleus; if the forkhead domain is deleted (ΔFKH-FOXP3) the protein is excluded from the nucleus (N). C, cytoplasm.

IL-2, IL-4, and interferon- $\gamma$  (IFN- $\gamma$ ) production by CD4<sup>+</sup> effector cells (Bettelli et al., 2005). Scurfy mice T cells have a substantial increase in NFAT and NF- $\kappa$ B transcriptional activity compared with T cells derived from wild-type mice. This overexpression of NFAT and NF- $\kappa$ B is reduced to normal levels by complementation of Foxp3 in scurfy-derived T cells (Bettelli et al., 2005). Thus Foxp3 functions as a specific transcription corepressor for the two pivotal transcription factors, NFAT and NF- $\kappa$ B, which play a key role in the expression of multiple cytokine genes.

### FOXP3 as a Rheostat of the Immune Response

The generation of transgenic mice expressing multiple copies of the *Foxp3* gene results in a dramatic suppression of immune responses. Transgenic mice have markedly decreased numbers of CD4<sup>+</sup> T cells in the peripheral blood, and decreased cellularity in lymph nodes and the spleen. In contrast to the scurfy T cells, those derived from Foxp3 transgenic mice were hyporesponsive to stimulation both in vivo and in vitro. The suppressive effect was shown to be entirely dependent on peripheral T cells, as overexpression of wild-type Foxp3 in the thymus did not affect peripheral blood T cell numbers or functions (Khattari et al., 2001). In this model, Foxp3 functions as a rheostat of the immune system, with activation responses being inversely proportional to the amount of Foxp3 protein expressed by CD4<sup>+</sup> T cells. Combined with the findings reported by Bettelli et al. (2005, *vide supra*), this hypothesis postulates that Foxp3 has an important function in peripheral CD4<sup>+</sup> T cells, in addition to its role in generating regulatory T cells in the thymus. If Foxp3 directly interacts with NFAT and NF- $\kappa$ B, it is possible that this physical association recruits Foxp3 to the promoters of cytokine genes. Being a potent transcriptional repressor, the recruitment of Foxp3 to these promoters would turn off any transcriptional activity. Such a mechanism would explain the fact that scurfy T cells are hyperresponsive to T cell receptor (TCR) stimulators with anti-CD3 (Clark et al., 1999). The observation that myelin proteolipid protein-specific autoreactive T cells transduced with Foxp3 are no longer able to mediate experimental autoimmune encephalomyelitis supports the notion that Foxp3 suppresses the effector function of autoreactive T cells (Bettelli et al., 2005). A similar suppression of experimental allergic encephalomyelitis by Foxp3 positive regulatory T cells was reported by Yu et al. (2005).

### FOXP3 and CD4<sup>+</sup> CD25<sup>+</sup> Regulatory T Cells

A small subset of CD4<sup>+</sup> T cells expressing the low-affinity IL-2 receptor  $\alpha$ -chain (CD25) have been associated with antigen-specific suppression of T cell responses (Sakaguchi et al., 2001). CD4<sup>+</sup> CD25<sup>+</sup> regulatory T cells (Tregs) are anergic, but upon activation suppress the proliferation and IL-2 production of naive and memory CD4<sup>+</sup> T cells through a contact-dependent, cytokine-independent mechanism (Itoh et al., 1999; Shevach, 2002).

Regulatory T cells have been recognized as leading factors in the control of chronic human diseases. They play a major role in transplantation tolerance (reviewed by Wood and Sakaguchi, 2003) and seem to be low in numbers (and expression of FOXP3) in patients with chronic graft-versus-host disease (following bone marrow transplantation) (Zorn et al., 2005). Similarly, a lack of regulatory T cells has been associated with autoimmune diseases in both human and mice (Wei et al., 2004; Loser et al., 2005; Marinaki et al., 2005; Yu et al., 2005), and, as expected, treatment strategies to increase Treg function have improved transplantation tolerance and autoimmune symptoms (Bettelli et al., 2005; Loser et al., 2005). Protocols to expand human CD4<sup>+</sup> CD25<sup>+</sup> regulatory

T cells while maintaining their suppressive activity to inhibit effector T cell proliferation have been established. CD4<sup>+</sup> CD25<sup>+</sup> T cells, isolated from human peripheral blood, can be expanded up to 200-fold in vitro in the presence of anti-CD3 and anti-CD28 coated Dynabeads and high concentrations of exogenous IL-2 (Earle et al., 2005). These cells maintain markers of Tregs, including expression of CD25 and FOXP3, and maintain suppressor activity in regard to proliferation and cytokine secretion by effector T cells. Increased numbers and activities of Tregs have been associated with tumor progression (Karube et al., 2004; Viguier et al., 2004; Berger et al., 2005; Ormandy et al., 2005; Unitt et al., 2005), and therapies are being explored to reduce Treg activity (Wei et al., 2004; Beyer et al., 2005; Sharma et al., 2005).

Although the precise molecular events that lead to the production and regulation of these regulatory T cells are unknown, recently it was shown that Foxp3 plays a crucial role in the generation of Tregs in mice (Fontenot et al., 2003; Hori et al., 2003; Khattari et al., 2003). Foxp3 is preferentially expressed in the CD4<sup>+</sup> CD25<sup>+</sup> pool of cells, and mice that lack Foxp3 (scurfy or Foxp3 knockout mice) lack functional Tregs. Expression of FOXP3 in human or murine CD4<sup>+</sup> CD25<sup>+</sup> T cells, achieved by a transgene, is sufficient to convert these cells to a Treg-like phenotype regardless of CD25 expression (Hori et al., 2003; Khattari et al., 2003; Yagi et al., 2004). Murine CD4<sup>+</sup> CD25<sup>+</sup> cells, if activated in vitro by cross-linking CD3, do not express Foxp3 and do not acquire suppressor activity, despite strong expression of CD25 on the cell surface (Fontenot et al., 2003; Khattari et al., 2003). In contrast to the finding in mice, at least one group has reported that human CD4<sup>+</sup> CD25<sup>+</sup> cells can be activated in vitro to express FOXP3 and to suppress T cell proliferation (Walker et al., 2003); this finding could not be confirmed by a second group of investigators (Yagi et al., 2004), and the issue needs to be clarified.

Thus, Foxp3 is both required and sufficient to generate a population of Tregs, at least in mice. It is unknown at this time how this population of CD4<sup>+</sup> CD25<sup>+</sup> regulatory T cells exerts its potent suppressive effect on the immune response and how regulatory T cells themselves are generated and modulated. Using a sophisticated staining technique, it was recently shown that IPEX patients with known FOXP3 mutations, including missense mutations that allow expression of mutated FOXP3 protein with a single amino acid substitution, lack CD4<sup>+</sup> CD25<sup>+</sup> T cells expressing FOXP3 (Color Plate 26-III and Fig. 26.4) (Gavin et al., 2006).

On the basis of available experimental data, Tregs can be defined as a subset of CD4<sup>+</sup> CD25<sup>+</sup> T cells that express Foxp3, are anergic, and suppress the proliferation and IL-2 production of naive and memory CD4<sup>+</sup> T cells through a contact-dependent, cytokine-independent mechanism (Itoh et al., 1994; Shevach, 2002). Tregs function in a dominant, *trans*-acting way to actively suppress immune activation. Tregs, therefore, play a critical role in establishing and maintaining self-tolerance and immune homeostasis (Fontenot and Rudensky, 2005).

In contrast to this "dominant tolerance" created by dedicated regulatory T cells, "recessive tolerance" refers to the passive mechanism of "negative selection" that leads to deletion or functional inactivation of autoreactive T and B cell clones in the thymus, bone marrow, and peripheral lymphoid organs, respectively, without affecting other self-reactive lymphocyte clones (see Chapters 24 and 25).

Although the Treg story is still in flux, several key facts are generally accepted. CD4<sup>+</sup> CD25<sup>+</sup> regulatory T cells have been demonstrated in the thymus of both mice and humans (Papiernik et al., 1998; Itoh et al., 1999; Stephens and Mason, 2000; Roncador

et al., 2005). These CD4<sup>+</sup> CD25<sup>+</sup> thymocytes are capable of suppression in adoptive transfer models and in in vitro suppression assays (Itoh et al., 1999). Furthermore, the generation of Tregs in the thymus requires TCR signaling during thymocyte development (Hsieh and Rudensky, 2005). In this model of regulatory T cell lineage commitment, high-avidity TCR–self-peptide–MHC interactions take place in the thymus, augmented by CD28 signaling and perhaps additional, unidentified signals to induce Foxp3 expression. The human FOXP3 promoter was recently shown to be T cell specific and to exhibit a TATA and CAAT box approximately 6000 bp upstream of the translation start site. The basal promoter contains 3 NFAT and 3 AP-1 sites, which positively regulate the trans activation of the FOXP3 promoter in response to TCR engagement. This event is suppressed by cyclosporine A (Mantel et al., 2006). Such regulatory mechanisms ensures that Tregs represent a dedicated T cell lineage capable of controlling T cell self-reactivity and autoimmune disorders. The role of Foxp3, therefore, is that of being the single-most important Treg lineage specification factor (Fontenot and Rudensky, 2005). The lymphoproliferative autoimmune syndrome of scurfy and IPEX resulting from Foxp3 and FOXP3 deficiency, respectively, identifies Treg cells as guarantors of immunologic tolerance to self, and FOXP3 as the mediator of the genetic mechanism of dominant tolerance.

### Mutation Analysis

In an effort to define the clinical and immunologic phenotype and to explore a possible genotype–phenotype correlation, we evaluated more than 70 patients from 50 families living in North or South America, Europe, or Asia with a clinical phenotype compatible with IPEX for mutations of *FOXP3* (Gambineri et al., submitted). To date, we have identified over 25 novel mutations (Fig. 26.2), in addition to 6 mutations reported previously by others (Chatila et al., 2000; Wildin et al., 2001, 2002; Owen et al., 2003). These naturally occurring mutations have been invaluable for understanding the relative importance of the structural domains of FOXP3. The missense mutations identified thus far cluster in three specific functional domains: the proline-rich domain, the leucine zipper, and the forkhead domain (Fig. 26.2). No missense mutations have been discovered in the zinc finger domain, which suggests that it may not play a critical role in FOXP3 function. Other mutations identified include missense mutations, deletions, and splice site mutations. In one family with multiple

affected members, we found a large deletion upstream of exon 1 resulting in failure to initiate splicing. The family initially described by Powell in 1982 has a point mutation affecting the first canonical polyadenylation region (AAUAAA → AAUGAA) which resides 878–883 bp downstream of the FOXP3 stop codon (Bennett et al., 2001a). This mutation seems to result in a milder phenotype, sometimes with onset of symptoms at school age. Nevertheless, all affected members of that family eventually succumbed to this disease (Fig. 26.1). Not all patients who present with the IPEX phenotype have detectable mutations of *FOXP3*. Of 50 unrelated families with symptoms compatible with IPEX referred to our laboratory for sequencing of *FOXP3*, only 60% had identifiable mutations of *FOXP3* (Gambineri et al., submitted). Through use of real-time polymerase chain reaction (PCR), half of these “IPEX-like” patients were shown to have low levels of mRNA, whereas the others had normal concentrations of FOXP3 mRNA, findings suggesting that at least some IPEX-like patients may have mutations involving regulatory sequences of the *FOXP3* gene such as promoter or enhancer regions. Alternatively, there may be other genes or gene products that are directly or indirectly involved in the activation of FOXP3 itself.

### Strategies for Diagnosis

Because of the wide spectrum of clinical findings, the diagnosis of IPEX should be considered in any young male patient presenting with intractable diarrhea, villous atrophy, and failure to thrive. The presence of an erythematous/eczematoid rash or a psoriasiform dermatitis supports the diagnosis (Color Plates 26.I and 26.II). Early onset of insulin-dependent diabetes and/or hypothyroidism in a patient with gastrointestinal symptoms and eczema is almost pathognomonic for IPEX. Autoimmune hemolytic anemia, neutropenia, or thrombocytopenia are not always present. The diagnosis of IPEX is confirmed by demonstrating the absence of CD4<sup>+</sup> CD25<sup>+</sup> FOXP3<sup>+</sup> regulatory T cells (Fig. 26.4 and Color Plate 26.III) (Gavin et al., 2006) or by mutation analysis of *FOXP3*.

### Differential Diagnosis

Other single-gene defects have been identified as cause of a clinical phenotype involving immune dysregulation in either humans or mice (Table 26.1). FAS/APO-1 (CD95) is a transmembrane receptor belonging to the tumor necrosis factor (TNF) receptor superfamily. Engagement of FAS/APO-1 by its ligand, FASL,

**Figure 26.4.** Identification of regulatory T cells in peripheral blood. A proportion of CD4<sup>+</sup> CD25<sup>+</sup>(bright) T cells express FOXP3. The cells were stained for CD4 and CD25, permeabilized, and stained with anti-FOXP3 monoclonal antibody and submitted to flow cytometry.

induces programmed cell death in a variety of cell lines including lymphocytes (Nagata, 1997). Programmed cell death is an important mechanism of regulating the immune response by deleting autoreactive lymphocyte clones from the peripheral lymphocyte pool ("recessive tolerance"). Mice with inactivating mutations in either Fas or FasL show dramatic lymphocytic proliferation and infiltration of multiple organs. Unlike scurfy mice, whose infiltrating lymphocytes have an activated phenotype, the majority of lymphocytes in the infiltrates of Fas/FasL mutant mice are immature, nonactivated double-negative T cells (Watanabe-Fukunaga et al., 1992; Takahashi et al., 1994). Fas/FasL mutants develop autoantibodies, including IgM rheumatoid factor and antichromatin antibodies (Weintraub et al., 1998). These mutant mice survive for prolonged periods of time, in contrast to mice with mutations of *Foxp3*. In humans, mutations in FAS or FASL cause a rare autosomal-dominant syndrome known as autoimmune lymphoproliferative syndrome (ALPS) or Canale-Smith syndrome, which presents in the first 1–2 years of life and is characterized by massive lymphadenopathy and splenomegaly caused by nonmalignant lymphocytic infiltrates and a variety of autoimmune phenomena (Fisher et al., 1995; Rieux-Laucat et al., 1995; Drappa et al., 1996) (see Chapter 24). The most frequent autoimmune disorders associated with ALPS are episodic hemolytic anemia, thrombocytopenia, or neutropenia. Patients with ALPS survive well into adulthood and, as they age, they continue to have autoimmune manifestations. Although the lymphoproliferative component of the syndrome often resolves with age, ALPS patients have a high incidence of B cell lymphoma.

Autoimmune regulator (AIRE) is a DNA-binding protein encoded by a single gene on chromosome 21 (Bjorses et al., 1998). The *Aire* gene is expressed in lymph nodes, spleen, testis, and thymus, particularly in the dendritic cell population of the murine thymus (Heino et al., 2000). Mutations in this gene cause the rare autosomal recessive human syndrome of autoimmune polyendocrinopathy, candidiasis, ectodermal dysplasia (APECED) (see Chapter 25). The three most common characteristics of this disease are mucocutaneous candidiasis, hypoparathyroidism, and adrenocortical insufficiency. Patients may develop a variety of other symptoms, including type 1 diabetes, Hashimoto's thyroiditis, vitiligo, and hemolytic anemia. The onset of APECED is less fulminant than that of IPEX, typically starting with candidiasis by age 5, hypoparathyroidism by age 10, and Addison disease by age 15 (Vogel et al., 2002). *Aire*-deficient mice, generated by targeted gene disruption, develop many of the typical APECED features (Anderson et al., 2002; Ramsey et al., 2002). Affected mice are born and develop normally but have lymphocytic infiltrates in liver and atrophy of adrenals and gonadal tissue. *Aire*-deficient mice often develop autoantibodies to liver, exocrine pancreas, testis, and adrenal glands. Recently it was demonstrated in mice that Aire expression by thymic dendritic cells is required for the expression of self-antigens by these antigen presenting cells (Anderson et al., 2002). Following presentation of self-antigens to autoreactive T cell clones, they are eliminated by negative selection (reviewed by Su and Anderson, 2004). Thus, Aire provides a mechanism for deletion of functional autoreactive T cells in the thymus, contributing substantially to "recessive tolerance."

Omenn syndrome is a clinically defined disorder characterized by early onset, a generalized erythematous rash, combined immune deficiency, elevated serum IgE, and eosinophilia (see Chapter 9). Most patients with Omenn syndrome have normal numbers of (oligoclonal) T cells and low numbers or absent circulating B cells. Because of severe gastrointestinal symptoms

and failure to thrive, TPN is often required and line infection is a frequent complication. Hypomorphic mutations of *Rag1* and *Rag2* are frequently associated with Omenn syndrome, but mutations of Artemis or IL-7R have been reported.

Patients with the Wiskott-Aldrich syndrome (WAS), caused by mutations of WASP, frequently present during early infancy with bloody diarrhea, bacterial and viral infections, eczema, and bleeding due to congenital thrombocytopenia. Patients with WAS may develop autoimmune hemolytic anemia or thrombocytopenia, and neutropenia. As in IPEX, the inheritance is X-linked (see Chapter 31).

### Carrier Detection and Prenatal Diagnosis

If the mutation in a given family is known, a suspected carrier female can be identified by mutation analysis. Similarly, prenatal diagnosis of a male fetus at risk can be determined by DNA analysis with chorionic villous biopsy or cultured amniocytes as DNA source. It is unclear if fetal blood contains regulatory T cells that express CD4, CD25, and FOXP3.

### Treatment and Prognosis

Early, aggressive therapy is of utmost importance in treating IPEX patients. Often TPN is necessary to ensure adequate nutrition. This type of treatment requires placement of a central catheter, which may cause problems with line infection and septicemia. Red blood cell and platelet transfusions may be necessary. It is unclear if early immunosuppressive therapy can prevent the onset of type 1 diabetes. Long-term immunosuppression has proven effective in some patients, but usually only partially and for a limited period of time. Cyclosporin A or tacrolimus (FK506), often in combination with steroids, has been used with some success (Seidmann et al., 1990; Satake et al., 1993; Kobayashi et al., 1995; Di Rocco and Marta, 1996; Finel et al., 1996; Ferguson et al., 2000; Baud et al., 2001; Levy-Lahad and Wildin, 2001; Wildin et al., 2002). Sirolimus (rapamycin) is better tolerated and seems to be less nephrotoxic (Bindl et al., 2005). The combinations of a long list of immunosuppressive medications, including methotrexate, corticosteroids, infliximab and rituximab, have been tried but not with convincing success. Chronic immunosuppressive therapy may facilitate opportunistic infections.

Hematopoietic stem cell transplantation is currently the only effective cure for IPEX, and some patients have achieved complete remission of symptoms following bone marrow transplantation (Baud et al., 2001; Mazzolari et al., 2005), despite the fact that at least in one case only 20%–30% of the T cells were of donor origin (Baud et al., 2001). However, the long-term outcome of stem cell transplantation is often unfavorable (Baud et al., 2001; Wilden et al., 2002), although the number of reported transplants is small. The degree of symptomatic remission following stem cell transplantation depends on the transplant being initiated prior to irreversible damage that may have occurred to target organs such as the pancreas and thyroid. Interestingly, the patients reported by Baud et al. (2001) had complete symptomatic remission, including reversion of type 1 diabetes, during the conditioning regimen that consisted of anti-T lymphocyte globulin, busulfan, and cyclophosphamide. This result raises the possibility that cytotoxic or biologic agents that target T cells may be an effective treatment in patients who have failed other therapies. In general, the prognosis of IPEX is poor. Untreated, most patients die at an early age. Patients with unusual muta-

tions, such as those affecting mRNA splicing or polyadenylation, may benefit from the generation of a small amount of normal mRNA, and present with a relatively mild clinical phenotype. However, even these patients do poorly in the long run, with most dying before 10 years of age, and a few surviving to the third decade of life (Powell et al., 1982; Bennett et al., 2001b) (Fig. 26.1). Treatment with potent immunosuppressive agents that target T cells in particular can make a difference, but because of toxicity and increased susceptibility to infection, these agents do not guarantee long-term amelioration of symptoms. Although bone marrow transplantation does provide hope for a cure, the risks are substantial. Stem cell transplantation has to be performed early in the course of the disease, before the pancreatic islet cells and other target organs have been irreversibly damaged. At this time, it is unclear how regulatory T cells are generated and maintained following stem cell transplantation.

### Animal Models

#### The *Scurfy* (*sf*) Mutation, a Mouse Model for IPEX

The original *sf* mutation, a fatal X-linked condition, has occurred spontaneously in a partially in-bred strain of mice at the Oakridge National Laboratory (Russell et al., 1959). Shortly after birth, affected male mice present with a scaly skin rash and severe runting secondary to chronic diarrhea and malabsorption. They have scaling of the ears (Color Plate 26.IV), eyelids, feet, and tail, which is short, and are born with thickened ears. Characteristically, the mice exhibit lymph adenopathy, splenomegaly, massive lymphocytic infiltrates in the skin, liver, and lungs, and develop hemolytic anemia associated with a positive Coomb test (Godfrey et al., 1991b) suggesting that the *sf* mutation causes a “generalized autoimmune-like syndrome.”

#### Immunologic Findings

After a systematic study of these mice, Godfrey and colleagues suggested that “the scurfy disease may be the result of immune dysfunction rather than being a classic immune deficiency” (Godfrey et al., 1991b). The thymus of young *sf* mice, although small in size, is densely populated with lymphocytes and has a distinct cortex and medulla. As the disease progresses, the thymic cortex is rapidly depleted of lymphocytes, and in mice older than 25 days, the thymus is a “shrunken stromal remnant lacking any corticomedullary distinction” (Godfrey et al., 1991b). Lymph nodes, spleen, and liver, however, are markedly enlarged from extramedullary hematopoiesis and cellular infiltrates. This lymphoproliferative disease is mediated by CD4<sup>+</sup> CD8<sup>-</sup> T lymphocytes (Godfrey et al., 1994). Serum IgG and IgM are markedly elevated; IgA, which is absent in young normal mice, is demonstrable in male pups with the *sf* mutation (Godfrey et al., 1991a). Flow-cytometric analysis of cell suspensions from spleen or lymph nodes of *sf* mice reveal a characteristic increase in Mac-1<sup>+</sup> monocytic cells and a decrease in B220<sup>+</sup> cells; the latter population shows an increased expression of B7.1 and B7.2 costimulatory molecules, suggesting a state of activation (Clark et al., 1999). The activity of *sf* T cells appears up-regulated in vivo, as suggested by the spontaneous expression of CD69, CD25, CD80 (B7.1), and CD86 (B7.2). Although *sf* T cells are hyperresponsive to TCR ligation, they still require costimulation through CD28, albeit at decreased intensity (Clark et al., 1999).

Following successful activation, they produce large amounts of granulocyte-macrophage colony-stimulating factor (>1000-fold higher than wild-type CD4<sup>+</sup>) as well as a number of other cytokines, including IL-2, IL-5, IL-6, IL-7, IL10, IFN- $\gamma$ , and TNF- $\alpha$  (Blair et al., 1994; Kanangat et al., 1996; Clark et al., 1999). Interestingly, this hyperresponsiveness is resistant to suppression by inhibitors of tyrosine kinases, such as genistein and herbimycin A, and cyclosporin A (Clark et al., 1999). These observations suggest that the *sf* mutation interferes with a physiologic down-regulation of T cell activation and may have implications for the immunosuppressive therapy of IPEX patients.

#### Transfer Experiments in *sf* Mice

The effect of transplantation of lymphoid organs and cell suspensions from *sf* (or wild-type) mice into athymic nude or severe combined immunodeficiency disease (SCID) mice (Godfrey et al., 1994) can be summarized as follows. First, transplanted *sf* thymus transfers the *sf* phenotype to nude and SCID mice. Second, euthymic (immunologic competent) recipients of congenic *sf* thymus grafts remain clinically normal, as do all SCID and nude recipients of normal thymic transplants. Third, single-cell suspensions of thymus, lymph node, or spleen from *sf* mice transferred into histocompatible nude or SCID mice by intraperitoneal injection result in an *sf* phenotype in all recipients. Additional transfer experiments have demonstrated that the primary cause of the *sf* phenotype is the CD4<sup>+</sup> CD8<sup>-</sup> T cell population; CD4<sup>+</sup> but not CD8<sup>+</sup> lymph node T cells from *sf* mice transfer the disease to syngenic host nude mice (Blair et al., 1994). Finally, if normal CD4<sup>+</sup> T cells are added to the CD4<sup>+</sup> *sf* T cells, the host nude mice do not develop the *sf* phenotype. These in vivo experiments suggest that *sf* is the result of dysregulated CD4<sup>+</sup> T cells, which express activation markers, excrete large quantities of cytokines, and are capable of inducing autoimmune disorders. Thus, *sf* is most consistent with an autoimmune lymphoproliferative disease due to an inability to down-regulate antigen-driven T cell activation.

#### Mutation of *Foxp3* as the Cause of *sf*

The *sf* locus was originally mapped to a 1.7 Cm interval between *DXWas70* and *Otc* in the proximal region of the mouse X chromosome (Lyon et al., 1990; Kanangat et al., 1996). Through combining high-resolution genetic and physical mapping with large-scale sequence analysis, the gene responsible for the *sf* mutation was identified and designated as *Foxp3* (Brunkow et al., 2001). The protein encoded by *Foxp3* is a new member of the forkhead winged-helix family of transcriptional regulators and is highly conserved in different mammalian species. The spontaneous mutation of *Foxp3* in *sf* mice is a 2 bp insertion in exon 8, resulting in a frameshift that leads to a truncated protein product lacking the carboxy-terminal forkhead domain (Brunkow et al., 2001).

#### *Foxp3* Transgenic Mice

To examine the in vivo consequences of *Foxp3* overexpression, several different *Foxp3*-transgenic mouse lines were established, each with differing levels of transgene expression (Brunkow et al., 2001; Khattry et al., 2001). Each of these lines, when bred into an otherwise wild-type background, resulted in a reduction of lymph node size and cellularity. The extent of this reduction

correlated with transgene copy number and expression, with higher Foxp3 levels resulting in a greater reduction in lymph node and splenic cellularity. Both CD4<sup>+</sup> and CD8<sup>+</sup> lymphocytes were reduced in number; thymic cellularity was unaffected. A transgenic line with 16 copies of the transgene had an expression level of Foxp3 that was approximately threefold higher than that in normal controls. This transgenic line had a 50% reduction in the number of peripheral blood CD4<sup>+</sup> T cells and a 75% reduction in CD8<sup>+</sup> T cells. Histologically, peripheral lymphoid organs lacked follicular structure and were without margins between follicular and interfollicular regions. To explore the effect of increased Foxp3 expression, mice from this transgenic line were studied for T cell function. Purified CD4<sup>+</sup> T cells displayed reduced proliferative responses when activated in vitro and lacked IL-2 production. Thus, Foxp3 is capable of regulating the ability of CD4<sup>+</sup> T cells to respond to TCR-mediated signals. As a direct consequence, T helper function is severely impaired in *Foxp3* transgenic mice that fail to respond to T-dependent antigen (Kasprowicz et al., 2003).

Finally, the *sf* mouse model was instrumental in the discovery of regulatory T cells (Fontenot et al., 2003; Hori et al., 2003; Khattri et al., 2003) (see FOXP3 and CD4<sup>+</sup> CD25<sup>+</sup> Regulatory T cells, above) and thus played a major role in understanding the molecular basis of IPEX. Using Foxp3 negative gene-targeted mice and a GFP-Foxp3 fusion-protein-reporter knock-in allele, it could be shown that expression of Foxp3 was highly restricted to  $\alpha\beta$  CD4<sup>+</sup> T cells and, irrespectively of CD25 expression, correlated with suppressor activity (Fontenot et al., 2005).

### CTla-4- and Tgf- $\beta$ 1-Deficient Mice

Two mouse models, both without a human counterpart, show many similarities to the scurfy mouse. *CTla-4*-deficient mice develop a lymphoproliferative syndrome similar to that of scurfy mice; however, the lymphocytic infiltrates tend to be more widespread, with accumulation of activated T cells in heart, lungs, lymph nodes, thymus, spleen, liver, bone marrow, and pancreas. Mice are well until 2 weeks of age, then become ill and die by 3 to 4 weeks of age, probably of myocardial infarction due to massive lymphocytic infiltrates in the heart muscle (Waterhouse et al., 1995; Tivol et al., 1995). *CTla-4* is a cell surface molecule that is expressed in activated T cells. When engaged by its ligand B7.1 or B7.2, *CTla-4* has an inhibitory effect on T cell activation responses including proliferation, cytokine secretion, and cell surface protein expression (Chambers and Allison, 1999). Although there is no human syndrome caused by mutations of *CTla-4*, it has been suggested that specific polymorphisms may increase the risk of developing Graves disease or autoimmune diabetes (Cosentino et al., 2002; Yung et al., 2002). Transforming growth factor  $\beta$ 1 (TGF- $\beta$ 1) belongs to a family of related growth factors that play diverse roles in cellular processes including wound healing, hematopoiesis, and immune regulation. Tgf $\beta$ 1-deficient mice develop normally until 2 weeks of age, when they begin to waste, and die by 3 to 4 weeks of age. Deficient mice also develop lymphocytic infiltrates into major organs, particularly heart, lungs, and salivary glands, and die of cardiopulmonary symptoms secondary to massive lymphocytic infiltrates (Shull et al., 1992; Christ et al., 1994; Kulkarni et al., 1995). Tgf $\beta$ 1 knockout mice develop high autoantibody titers to several nuclear antigens, including single and double-stranded DNA (Yaswen et al., 1996). Mice conditionally lacking the transforming growth factor beta type II receptor (T $\beta$ RII), one of the two cell surface receptors for the TGF- $\beta$  family of growth factors, have a phenotype of lym-

phocytic infiltration and autoimmunity but with a less fulminant course (Leveen et al., 2002). No human syndromes with mutations of *CTla-4*, Tgf $\beta$ 1, and T $\beta$ RII have been described.

### Conclusion and Future Directions

FOXP3 is the key mediator of regulatory T cell development in the thymus. Naturally occurring mutations of *FOXP3* interfere with this process, resulting in the generation of autoaggressive T lymphocyte clones that are directly responsible for IPEX in humans and scurfy in mice; both are lethal diseases. Bone marrow transplantation is the only cure for patients with IPEX. It is anticipated that exploitation of the scurfy mouse model and further evaluation of patients with IPEX will lead to a better understanding of the function of FOXP3 as a transcription factor and will facilitate the identification of genes that are regulated by FOXP3. Finally, we need an answer to the question of what regulates the regulator. Investigations along these lines will provide important insight into the mechanisms of immunosuppression, autoimmunity, and tolerance, and may lead to novel strategies to treat not only patients with IPEX but also those suffering from autoimmune diseases, graft versus host disease, or cancer.

## Periodic Fever Syndromes

DANIEL L. KASTNER, SUSANNAH BRYDGES, and KEITH M. HULL

The periodic fever syndromes are a heterogeneous group of inherited disorders characterized by recurrent episodes of fever and localized inflammation, most commonly affecting the serosal membranes, joints, and skin (Table 27.1). A significant minority of patients develop systemic deposition of amyloid A protein (AA amyloidosis) as a longer-term consequence of their inflammatory episodes. While at first glance these disorders appear to be similar to the more commonly recognized autoimmune disorders (e.g., systemic lupus erythematosus), they differ in several important respects, including the lack of high-titer autoantibodies or antigen-specific T cells, and the predominance of monocytes and neutrophils rather than lymphocytes as effector cells. Hence, the term *autoinflammatory disorders* has been proposed to describe the periodic fevers and related conditions (McDermott et al., 1999; Galon et al., 2000; Hull et al., 2003).

Advances in the past several years have significantly increased our understanding of these disorders, with four genes underlying six clinically distinct periodic fever syndromes having been identified. In 1997 a novel gene causing perhaps the most common of these illnesses, the recessively inherited familial Mediterranean fever (FMF; Mendelian Inheritance in Man [MIM] 249100), was identified by positional cloning (French FMF Consortium, 1997; International FMF Consortium, 1997). Within 2 years, mutations in the 55 kDa tumor necrosis factor (TNF) receptor were found in a group of patients with dominantly inherited periodic fever (the TNF receptor–associated periodic syndrome [TRAPS; MIM 142680] (McDermott et al., 1999), and mutations in the mevalonate kinase gene (*MVK*) were identified in the recessively inherited hyperimmunoglobulinemia-D with periodic fever syndrome (HIDS; MIM 260920) (Drenth et al., 1999; Houten et al., 1999). A fourth periodic fever gene, which shares a functional domain with the FMF gene, was discovered by positional cloning in 2001 (Hoffman et al., 2001a). Mutations in this gene

were first shown to cause two dominantly inherited conditions, Muckle-Wells syndrome (MWS; MIM 191100) and familial cold autoinflammatory syndrome (FCAS; MIM 120100). The following year mutations in the same gene were discovered in patients with yet another recurrent fever disorder, neonatal-onset multisystem inflammatory disease (NOMID, also called chronic infantile neurologic cutaneous articular [CINCA] syndrome; MIM 607115) (Aksentijevich et al., 2002; Feldmann et al., 2002).

Although the precise mechanism by which mutations in each of these genes causes recurrent fever and inflammation is still under investigation, the available molecular genetic data suggest that the recurrent fever syndromes represent deficiencies in the regulation of innate immunity. There is an emerging body of data indicating that both pyrin, the FMF protein, and cryopyrin, the protein mutated in FCAS, MWS, and NOMID/CINCA, are regulators of interleukin (IL)-1 $\beta$  production, nuclear factor (NF)- $\kappa$ B activation, and leukocyte apoptosis, all critical components of innate immunity. Similarly, the mutations in the extracellular domain of the p55 TNF receptor lead to increased TNF signaling, due in part to a failure in TNF receptor ectodomain cleavage. And although mutations in mevalonate kinase, a key enzyme in cholesterol biosynthesis, were quite unexpected in HIDS, new data suggest a nexus between the mevalonate pathway and IL-1 $\beta$  regulation. The periodic fever syndromes thus represent yet another example of how Mendelian disorders can inform our understanding of normal immune function.

### Familial Mediterranean Fever

Although molecular genetic data suggest that founder mutations causing FMF (MIM 249100) arose many centuries ago (International FMF Consortium, 1997), the first recognizable report of

**Table 27.1.** Characteristics of Periodic Fever Syndromes

	<i>FMF</i>	<i>TRAPS</i>	<i>HIDS</i>	<i>FCAS</i>	<i>MWS</i>	<i>NOMID</i>
Inheritance	Recessive	Dominant	Recessive	Dominant	Dominant	Dominant, de novo
Ethnicity	Turkish, Armenian, Arab, Jewish, Italian, Greek, other	Any ethnicity	Dutch, French, other European	Mostly European	Mostly European	Any ethnicity
Duration of attacks	12–72 hours	>7 days	3–7 days	12–24 hours	2–3 days	Continuous
Cutaneous	Erysipeloid erythematous rash on lower leg, ankle, foot	Migratory rash, often associated with underlying myalgia	Maculopapular rash on trunk and limbs, urticaria	Urticaria-like rash induced by cold temperatures	Urticaria-like rash	Urticaria-like rash
Abdominal	Sterile peritonitis, constipation	Peritonitis, diarrhea or constipation	Severe pain, vomiting, diarrhea, rarely peritonitis	Nausea	Abdominal pain	Not common
Pleural	Common	Common	Rare	Not seen	Rare	Rare
Arthropathy	Monoarthritis, occasionally protracted arthritis in knee or hip	Arthritis in large joints, arthralgia	Arthralgia, symmetric polyarthritis	Polyarthralgia	Polyarthralgia, oligoarthritis	Epiphyseal overgrowth, contractures, intermittent or chronic arthritis
Ocular	Rare	Conjunctivitis, periorbital edema	Uncommon	Conjunctivitis	Conjunctivitis, episcleritis	Uveitis, conjunctivitis, progressive vision loss
Neurologic	Rare	Rare	Headache	Headache	Sensorineural deafness	Sensorineural deafness, chronic aseptic meningitis, mental retardation, headache
Lymph/spleen	Splenomegaly more common than lymphadenopathy	Splenomegaly more common than adenopathy	Cervical adenopathy	Not seen	Rare	Hepatosplenomegaly, adenopathy
Vasculitis	Henoch-Schönlein purpura, polyarteritis nodosa	Henoch-Schönlein purpura, lymphocytic vasculitis	Cutaneous vasculitis common, rarely Henoch-Schönlein purpura	Not seen	Not seen	Occasional
Amyloidosis	Risk depends on <i>MEFV</i> and <i>SAA</i> genotypes, other factors	Occurs in ~10%	Case reports	Rare	Occurs in ~25%	May develop in a portion of patients reaching adulthood
Treatment	Colchicine	Etanercept, NSAIDs, steroids	Etanercept investigational, NSAIDs, steroids	Anakinra investigational, NSAIDs	Anakinra investigational, NSAIDs, prednisone	Anakinra investigational

FCAS, familial cold autoinflammatory syndrome; FMF, familial Mediterranean fever; HIDS, hyperimmunoglobulinemia-D with periodic fever syndrome; MWS, Muckle-Wells syndrome; NOMID, neonatal-onset multisystem inflammatory disease; NSAIDs, nonsteroidal anti-inflammatory drugs; TRAPS, TNF receptor–associated periodic syndrome.

a case of FMF was published in 1908 (Janeway and Mosenthal, 1908), and the first series of 10 cases of "benign paroxysmal peritonitis" was published in 1945 (Siegal, 1945). Subsequent descriptions of large numbers of North African and Iraqi Jewish cases in the newly formed state of Israel led to the proposal of the now widely accepted *familial Mediterranean fever* nomenclature (Heller et al., 1958; Sohar et al., 1967), although it should be noted that other names, such as *recurrent polyserositis*, *recurrent hereditary polyserositis*, and *periodic disease*, are sometimes used.

During the 1960s and 1970s, studies of FMF focused on the clinical phenotype, mode of inheritance, ethnic distribution, and treatment. Several large series, particularly from Israel (Sohar et al., 1967), described in detail the serosal, synovial, and cutaneous manifestations of FMF, and elucidated the connection between FMF and systemic AA amyloidosis. Although high carrier frequencies gave rise to pseudodominance, careful segregation analysis indicated that FMF is recessively inherited, with incomplete penetrance (Sohar et al., 1962, 1967). The preponderance of cases reported were of non-Ashkenazi Jewish, Armenian, Arab, and Turkish origin. Later epidemiologic and family-based studies among non-Ashkenazi Jews and Armenians demonstrated extremely high frequencies of FMF (Rogers et al., 1989; Yuval et al., 1995), suggesting a possible heterozygote advantage, and identified ethnic differences in the susceptibility to amyloidosis (Meyerhoff, 1980; Pras et al., 1982). Finally, the early 1970s saw the serendipitous discovery of colchicine as an effective prophylaxis for the inflammatory attacks of FMF (Goldfinger, 1972; Dinarello et al., 1974; Goldstein and Schwabe, 1974; Zemer et al., 1974). Ten years later colchicine was also established as effective in preventing the amyloidosis of FMF (Zemer et al., 1986).

Further advances in the understanding of FMF awaited the development of positional cloning techniques and the infrastructure of the Human Genome Project. In 1992 the FMF locus, *MEFV*, was mapped to chromosome 16p13 (Pras et al., 1992), and 5 years later two groups independently identified disease-associated missense mutations in a novel positional candidate gene (French FMF Consortium, 1997; International FMF Consortium, 1997), the protein product of which was termed *pyrin* or *marenostin* by the respective consortia (and for simplicity will be denoted as *pyrin* in these pages). Availability of genetic testing has broadened the clinical and ethnic/geographic spectrum of FMF, while studies of pyrin have shed new light on the regulation of cytokine production, NF- $\kappa$ B activation, and apoptosis, and have defined a functional domain present in over 20 human proteins involved in the regulation of inflammation.

### Clinical and Pathological Manifestations

This disorder is characterized by relatively discrete, usually 1- to 3-day episodes of fever with serositis, synovitis, or skin rash. In some patients attacks begin in infancy or very early childhood, and 80%–90% of patients experience their first episode by age 20. Young children sometimes present with fever alone. The frequency of FMF attacks is highly variable, both among patients and for any given patient, with the interval between attacks ranging from days to years. Moreover, the type of attack (abdominal, pleural, arthritic) may also vary over time. Some patients relate attacks to physical or emotional stress, although in many cases there is no obvious provocative event. There is a slight predominance of males in most series, possibly the result of underreport-

ing in women for social reasons or underrecognition because of confounding gynecologic diagnoses. In some women attacks may occur at a specific point in the menstrual cycle (Ben-Chetrit and Ben-Chetrit, 2001) and sometimes remit during pregnancy (Sohar et al., 1967; Schwabe and Peters, 1974).

Attacks of fever and abdominal pain occur at some time in nearly all FMF patients, and range from a dull, aching pain to full-blown peritonitis. Constipation is usual during the attacks, sometimes with a diarrheal stool at the very end of the episode. Plain films may demonstrate air-fluid levels, and computed tomography (CT) may show thickened mesenteric folds, lymphadenopathy, splenomegaly, or mild ascites (Zissin et al., 2003). On laparoscopy there may be a neutrophil-rich exudate. Repeated episodes may lead to peritoneal adhesions.

Pleurisy may occur alone with fever or concurrently with abdominal pain. Pleuritic episodes are usually unilateral, with sharp, stabbing chest pain and, in some cases, diaphragmatic pain referred to the ipsilateral shoulder. Radiographic findings may include atelectasis (Brauman and Gilboa, 1987) due to splinting and, in a minority of cases, pleural effusion. Thoracentesis, when performed, yields a neutrophil-laden exudate. Pleural thickening sometimes develops after multiple attacks (Livneh et al., 1999).

Other forms of serosal inflammation may also be seen in FMF. Nonuremic pericarditis is much less common than peritoneal or pleural involvement (Kees et al., 1997; Tutar et al., 2003; Turkish FMF Study Group, 2005). Although small subclinical effusions are more frequent than symptomatic pericarditis, there have been rare reports of tamponade (Zimand et al., 1994). Unilateral acute scrotum occurs in about 5% of prepubertal boys with FMF (Livneh et al., 1994a; Majeed et al., 2000b), resulting from inflammation of the tunica vaginalis, an embryologic remnant of the peritoneal membrane.

Joint involvement in FMF is particularly common among North African Jews (Pras et al., 1998; Brik et al., 2001), and has been related to the M694V homozygous genotype (Brik et al., 1999; Cazeneuve et al., 1999; Gershoni-Baruch et al., 2002), which is very frequent in this population. Acute monoarticular arthritis is most characteristic in FMF (Heller et al., 1966), often affecting the knee, ankle, or hip. Such attacks tend to last somewhat longer than serosal episodes (often about 1 week), sometimes with large effusions, extreme pain, and inability to bear weight. Synovial fluid often appears septic, with as many as 100,000 polymorphonuclear leukocytes/mm<sup>3</sup>, but cultures are sterile. Soft tissue swelling may be apparent on X-rays taken during attacks, but erosive changes do not develop. A number of other less common oligo- or polyarticular patterns of arthritis may occur, especially in children (Majeed and Rawashdeh, 1997; Ince et al., 2002). Arthralgia is also very common in FMF.

In the precolchicine era, about 5% of patients with acute monoarticular arthritis went on to develop protracted arthritis, usually affecting the hip (Sneh et al., 1977). In such cases, symptoms could last for several months, sometimes leading to secondary osteoarthritic radiographic changes and/or osteonecrosis, and requiring total hip replacement surgery. Chronic sacroiliitis may also occur in FMF, regardless of the HLA-B27 status or colchicine therapy (Brodey and Wolff, 1975; Lehman et al., 1978; Langevitz et al., 1997).

The most characteristic cutaneous lesion of FMF is erysipeloid erythema (Color Plate 27.I), a sharply demarcated, erythematous, warm, tender, swollen area 10–15 cm in diameter occurring unilaterally or bilaterally, usually on the dorsum of the foot, ankle,

or lower leg (Azizi and Fisher, 1976; Barzilay et al., 2000). On skin biopsy, there is a mixed perivascular infiltrate of polymorphonuclear leukocytes, histiocytes, and lymphocytes. As is the case for arthritis, the frequency of erysipeloid erythema may be increased among M694V homozygotes (Koné Paut et al., 2000).

Children with FMF frequently develop myalgia of the legs related to vigorous exertion (Majeed et al., 2000a). Much less commonly, FMF patients may experience attacks of febrile myalgia, with excruciating muscle pain unrelated to exertion, that can last from a few days to several weeks (Langevitz et al., 1994; Sidi et al., 2000). During these episodes the creatine kinase is normal, the erythrocyte sedimentation rate (ESR) is prolonged, and the electromyogram shows nonspecific myopathic changes. Histologic data suggest that febrile myalgia is a form of vasculitis. Other forms of vasculitis, including Henoch-Schönlein purpura and polyarteritis nodosum, are also seen at increased frequency in FMF (Gedalia et al., 1992; Rawashdeh and Majeed, 1996; Özdogan et al., 1997; Tinaztepe et al., 1997; Ozen, 1999; Tekin et al., 1999; Ozen et al., 2001; Turkish FMF Study Group, 2005).

Systemic amyloidosis develops in a subset of FMF patients, as a result of deposition of a fragment of serum amyloid A (SAA) in the kidneys, adrenals, intestine, spleen, lung, and testes (Sohar et al., 1967). SAA is an acute-phase reactant produced by the liver and found at high levels in the serum during FMF attacks. Patients with amyloid deposition in the kidneys progress from albuminuria to the nephrotic syndrome to renal failure, usually over the course of 3 to 5 years. Amyloid deposits in the gastrointestinal tract may cause malabsorption (Mor et al., 2003), and deposits in the testis may cause azoospermia and infertility (Ben-Chetrit et al., 1998). Cardiac involvement, neuropathy, and arthropathy are very uncommon with the amyloidosis of FMF. The diagnosis is usually established by renal or rectal biopsy.

The amyloidosis of FMF usually occurs after the onset of inflammatory attacks (phenotype I), but rarely can occur as the first manifestation of FMF (phenotype II) (Sohar et al., 1967; Turkish FMF Study Group, 2005), perhaps from subclinical elevations in the SAA. The overall risk of amyloidosis in FMF is the product of a complex interaction of factors. Prior to the cloning of *MEFV*, epidemiologic data indicated that among Jewish subpopulations, the risk was highest for North African Jews, intermediate for Iraqi Jews, and very low for Ashkenazi Jews (Pras et al., 1982). This gradient has subsequently been found to parallel the frequency of the M694V/M694V genotype, which in most studies is associated with an increased risk of amyloidosis (Brik et al., 1999; Cazeneuve et al., 1999; Mansour et al., 2001; Gershoni-Baruch et al., 2002, 2003; Majeed et al., 2002), although not in a large recent series from Turkey (Turkish FMF Study Group, 2005). Other risk factors for amyloidosis include male gender, the SAA1  $\alpha/\alpha$  genotype, a positive family history for amyloidosis, and colchicine noncompliance (Cazeneuve et al., 2000; Akar et al., 2003; Gershoni-Baruch et al., 2003; Turkish FMF Study Group, 2005). There are also geographic and secular effects on amyloid susceptibility, perhaps reflecting improvements in general medical care that may modify the SAA load from intercurrent illness.

### Laboratory Findings

During acute attacks of FMF, there is a leukocytosis, often with a left shift, an accelerated ESR, and increases in several serum acute-phase proteins, including SAA, C-reactive protein

(CRP), fibrinogen, haptoglobin, and the C3 and C4 complement components. Urinalysis may demonstrate albuminuria and microscopic hematuria during attacks.

During the intercritical period, the white count and acute-phase reactants may normalize, but in some patients there is biochemical evidence of persistent subclinical inflammation, including abnormalities of the ESR, SAA, CRP, and fibrinogen (Tunca et al., 1999; Korkmaz et al., 2002; Duzova et al., 2003). Patients may also have a mild anemia of chronic disease and modest elevations in the serum immunoglobulins between attacks (Eliakim et al., 1981). A minority of patients have an increased serum IgD, although usually not to the level seen in HIDS (Medlej-Hashim et al., 2001).

A number of laboratory abnormalities are associated with the amyloidosis of FMF. The earliest finding is isolated albuminuria, without hematuria, with a normal or only slightly depressed serum albumin and normal renal function. As proteinuria increases, the serum albumin begins to fall, and renal function deteriorates over approximately 3 to 5 years to the point of renal failure. During this period laboratory findings of uremia evolve, including hyperphosphatemia, acidosis, hyperkalemia, and anemia.

### Molecular Basis of Familial Mediterranean Fever: The Disease Gene, *MEFV*

The gene mutated in FMF, *MEFV*, is comprised of 10 exons, oriented 5' → 3' centromere to telomere over an approximately 15 kb genomic interval on chromosome 16p13.3 (International FMF Consortium, 1997). *MEFV* encodes an ~3.7 kb transcript with a 781-amino acid open reading frame that is expressed in granulocytes, cytokine-activated monocytes, and synovial and peritoneal fibroblasts (Centola et al., 2000; Matzner et al., 2000; Papin et al., 2003; Diaz et al., 2004). Initial computational analysis of the conceptual protein identified a cassette comprising a B-box zinc finger (residues 375–407), an  $\alpha$ -helical coiled-coil domain (residues 408–594), and a B30.2 domain (residues 598–774), all of which have been implicated in protein–protein interactions. Although not apparent at the time the gene was cloned, exon 1 encodes a 92-amino acid motif now called the *PYRIN domain* that facilitates homotypic interactions among proteins involved in the regulation of inflammation and apoptosis (Bertin and DiStefano, 2000; Inohara and Nuñez, 2000; Martinon et al., 2001; Pawlowski et al., 2001; Richards et al., 2001; Staub et al., 2001; Girardin et al., 2003).

Four single nucleotide substitutions in FMF patients were initially identified in exon 10, resulting in conservative missense mutations clustered in a 47-amino acid interval in the C-terminal B30.2 domain (French FMF Consortium, 1997; International FMF Consortium, 1997). One leads to the substitution of isoleucine for methionine at residue 680 (M680I), two others lead to the substitution of valine or isoleucine for methionine at residue 694 (M694V, M694I), and the fourth causes the substitution of alanine for valine at residue 726 (V726A). For each of the M680I, M694V, and V726A mutations, microsatellite and single nucleotide polymorphism haplotype analysis disclosed ancestral relationships among carrier chromosomes in populations that have been separated for centuries.

At the time of this writing, a total of 35 disease-associated *MEFV* mutations have been published (Fig. 27.1), and a substantial number of others have been directly communicated to a database available on the World Wide Web at <http://fmf.igh.cnrs.fr/infervers/>. Of the 35 published mutations, 30 are missense single amino acid substitutions, 2 are in-frame deletions, and 1 is an

**Figure 27.1.** Schematic of *MEFV* gene and the encoded protein, pyrin (marenostrin). The number of published mutations for each exon is indicated in parentheses above the schematic. Protein domains are indicated: PYD, PYRIN domain; BB, B-box zinc finger. The amino acid residue range for each domain is indicated below the schematic. Mutational hot spots and mutations noted in the text are also shown.

in-frame insertion. Only 2 of the 35 mutations, a frameshift in exon 2 and a nonsense mutation in exon 10, would truncate the pyrin protein. Nineteen of the mutations (54%) are in exon 10, encoding the B30.2 domain, and there are two “hot spots” (M680 and M694) in exon 10 with more than one known mutation. The second major cluster of mutations is in exon 2, where there are nine mutations (26% of the total), and there is a mutational hot spot at E148.

### Function of Pyrin, the *MEFV* Gene Product

Recent work on the function of pyrin, the *MEFV* gene product, has focused on interactions mediated by the N-terminal 92–amino acid domain encoded by exon 1. This motif, which has variously been denoted the *PYRIN domain* (Bertin and DiStefano, 2000), *PYD* (Martinon et al., 2001), *PAAD* (Pawlowski et al., 2001), or *DAPIN* (Staub et al., 2001), has now been recognized in a total of over 20 human proteins involved in the regulation of inflammation and apoptosis (Harton et al., 2002; Tschopp et al., 2003). Computational modeling and subsequent NMR spectroscopy have demonstrated that the PYRIN domain is the fourth member of the death domain–fold superfamily (Fairbrother et al., 2001; Richards et al., 2001; Eliezer, 2003; Hiller et al., 2003; Liepinsh et al., 2003; Liu et al., 2003), which also includes death domains, death effector domains, and caspase-recruitment domains (CARDs). All four assume a six  $\alpha$ -helix three-dimensional structure that facilitates homotypic interactions through electrostatic charge interactions. Thus, the PYRIN domain of pyrin is a docking motif that facilitates cognate interactions with other PYRIN domain proteins.

The PYRIN domain of pyrin interacts specifically with the homologous domain of a protein called ASC (apoptosis-associated specklike protein with a CARD), a bipartite adaptor consisting solely of an N-terminal PYRIN domain and a C-terminal CARD in tandem (Masumoto et al., 1999, 2003; Richards et al., 2001; Chae et al., 2003; Dowds et al., 2003). Through its CARD, ASC binds caspase-1 (also known as *IL-1 $\beta$  converting enzyme* [ICE]) and other adaptor proteins, leading to the cleavage of caspase-1 into enzymatically active p20 and p10 subunits (Martinon et al., 2002; Srinivasula et al., 2002; Wang et al., 2002; Chae et al., 2003; Stehlik et al., 2003; Agostini et al., 2004; Martinon and Tschopp, 2004). Activated caspase-1, in turn, cleaves IL-1 $\beta$  from its 31 kDa precursor form to its 17 kDa biologically active fragment, which is a potent mediator of fever and inflammation. Data from mice expressing a hypomorphic pyrin mutant indicate that wild-type pyrin plays an important role in regulating the ASC-ICE-IL-1 $\beta$  cascade (Chae et al., 2003).

Although less completely understood, the interaction of pyrin with ASC also appears to regulate leukocyte apoptosis. Peritoneal macrophages from the pyrin-deficient mice exhibit a defect in apoptosis through a caspase-8-dependent, IL-1 $\beta$ -independent pathway, suggesting a role for wild-type pyrin in limiting the duration of the innate immune response through cell death (Chae et al., 2003). Nevertheless, underscoring the complexity of the process, in certain transfection systems wild-type pyrin exerts an antiapoptotic effect (Richards et al., 2001; Dowds et al., 2003; Masumoto et al., 2003).

Finally, again mediated through its interactions with ASC, pyrin modulates NF- $\kappa$ B activation, another important component of the innate immune response. ASC has been shown to bind to components of the I $\kappa$ B kinase complex, which regulates NF- $\kappa$ B through the phosphorylation of I $\kappa$ B (Stehlik et al., 2002). Depending on the cellular context, cotransfection of wild-type pyrin with ASC may potentiate or suppress NF- $\kappa$ B activation (Stehlik et al., 2002; Dowds et al., 2003; Masumoto et al., 2003).

While the interaction of the N-terminal domain of pyrin with ASC sheds new light on the regulation of inflammation, it does not yet explain the molecular mechanism by which missense mutations in pyrin, many of which are at the C-terminal end of the protein, lead to autoinflammatory disease. Possibly, these mutations indirectly influence the effect of pyrin on IL-1 $\beta$  processing, apoptosis, and/or NF- $\kappa$ B activation, perhaps conferring a selective advantage by pushing the balance, under some circumstances, toward heightened innate immunity.

### Mutation Analysis

Prior to the identification of *MEFV*, FMF was thought to be primarily a disease of non-Ashkenazi Jews, Armenians, Arabs, and Turks. Availability of genetic testing has allowed unequivocal identification of numerous cases among several additional populations with Mediterranean roots, including Ashkenazi Jews (Samuels et al., 1998; Aksentijevich et al., 1999; Stoffman et al., 2000; Gershoni-Baruch et al., 2001; Kogan et al., 2001), Italians (Samuels et al., 1998; Aksentijevich et al., 1999; La Regina et al., 2003), Greeks (Konstantopoulos et al., 2003), Spaniards (Touitou, 2001), and Cypriots (Deltas et al., 2002), and of occasional cases in a broad range of other ethnicities (Dodé et al., 2000b; Touitou, 2001). In some of these newly recognized patients, the clinical phenotype is milder than that usually seen in the classically affected ethnic groups, perhaps owing to documented differences in the population distribution of specific *MEFV* mutations.

Direct screening for mutations has confirmed previous estimates of extraordinarily high carrier frequencies in several ethnic groups. Carrier frequencies of at least 20% have now been established among North African, Iraqi, and Ashkenazi Jews, Arabs, Turks, and Armenians (Stoffman et al., 2000; Gershoni-Baruch et al., 2001; Kogan et al., 2001; Yilmaz et al., 2001). Assuming complete penetrance, these data would predict a disease frequency of at least 1% among these populations. Since these figures overestimate the disease frequencies, where they are known, by at least a factor of 2 (Yuval et al., 1995; Ozen et al., 1998), it is likely that there are substantial numbers of individuals with two *MEFV* mutations but minimal symptoms. Recent family studies support this assertion (Tunca et al., 2002), but contrast with the almost absolute association of *MEFV* genotype with disease in the families analyzed in positional cloning studies. This discrepancy is most likely explained by the fact that the earlier families were chosen for disease severity and for sibships with

multiple affected individuals, both factors that would favor the cosegregation of modifier alleles tending to increase the penetrance of *MEFV* mutations.

As noted above, over half of the known mutations in *MEFV* are located in exon 10, which encodes the C-terminal B30.2 domain of pyrin. When the frequencies of the various mutations among patients are taken into account, the bias toward exon 10 becomes much stronger (Touitou, 2001). Among certain populations, such as Ashkenazi Jews, E148Q (exon 2) and P369S (exon 3) are also observed at a relatively high frequency (Aksentijevich et al., 1999). For this reason, many commercial and academic laboratories screen for FMF by sequencing exon 10 and performing mutation-specific tests, such as restriction endonuclease assays, for E148Q and P369S. The diagnostic yield of this approach is comparable to that obtained with a more systematic mutational screen of the entire coding region by denaturing gradient gel electrophoresis (Cazeneuve et al., 2003).

FMF patients homozygous for the E148Q mutation alone are much less common than would be predicted on the basis of the observed frequency of this mutation (Ben-Chetrit et al., 2000; Ozen et al., 2002; Tchernitchko et al., 2003). Nevertheless, E148Q is frequently the only identifiable mutation in *trans* with an exon 10 mutation in patients with moderate to severe disease, indicating that this variant is more than a benign polymorphism (Samuels et al., 1998; Aksentijevich et al., 1999; Akar et al., 2001; Ben-Chetrit and Backenroth, 2001). At the other end of the genotype–phenotype spectrum is M694V. Studies of Jewish, Arab, and Armenian patients indicate that M694V homozygotes are at increased risk of amyloidosis (Brik et al., 1999; Cazeneuve et al., 1999; Mansour et al., 2001; Gershoni-Baruch et al., 2002, 2003; Majeed et al., 2002), although this appears not to be the case among Turks (Turkish FMF Study Group, 2005). As noted previously, M694V homozygotes may also be at increased risk for arthritis and erysipeloid erythema, as well as for an early age of onset and frequent attacks (Dewalle et al., 1998; Brik et al., 1999; Cazeneuve et al., 1999; Koné Paut et al., 2000; Gershoni-Baruch et al., 2002). Although the data are less extensive, the M694I mutation may also confer increased risk of amyloidosis (Ben-Chetrit and Backenroth, 2001; Mansour et al., 2001).

At least two additional factors complicate the interpretation of mutational studies in FMF. First, the E148Q mutation can be seen in *cis* with several exon 10 mutations, most commonly V726A. The V726A-E148Q complex allele is relatively common in the Ashkenazi Jewish population, and haplotype analysis suggests that it arose by recombination between FMF chromosomes carrying the respective individual mutations (Aksentijevich et al., 1999). There is also evidence that V726A-E148Q is a high-risk allele for amyloidosis (Gershoni-Baruch et al., 2002). From a practical standpoint, family studies would be required to determine phase in patients heterozygous for these two mutations and with no other demonstrable sequence changes.

A second problem is that up to 30% of patients with typical clinical findings of FMF, including a therapeutic response to colchicine, have only one demonstrable *MEFV* mutation (Aksentijevich et al., 1999; Cazeneuve et al., 1999; Akar et al., 2000; Medlej-Hashim et al., 2000; Mansour et al., 2001; Padeh et al., 2003), even when the entire coding region is screened (Cazeneuve et al., 2003). Noncoding mutations offer one possible explanation, but would not explain the divergence from Hardy-Weinberg equilibrium that has recently been described in Armenians from the Karabakh (Cazeneuve et al., 2003). Alternatively, it is possible that, at least on certain genetic backgrounds, a single

*MEFV* mutation is sufficient to manifest symptoms. Consistent with this view, it is now well established that FMF carriers often exhibit biochemical evidence of intermittent inflammation, and there are at least two rare *MEFV* mutations ( $\Delta$ M694 and the M694I-E148Q complex allele) that transmit clinically typical FMF in a dominant fashion (Booth et al., 2000). Finally, on the basis of the findings of Turkish FMF families unlinked to chromosome 16 (Akarsu et al., 1997) and FMF patients from Palma de Mallorca having no demonstrable *MEFV* mutations (Domingo et al., 2000), some investigators have posited the existence of additional FMF genes besides *MEFV*, accounting for the “mutation deficit” in symptomatic heterozygotes.

### Strategies for Diagnosis

In many instances, the possibility of FMF is first considered in a child with recurrent, unexplained episodes of fever, with or without localized inflammatory manifestations. In Western countries, patients often experience multiple episodes over a period of several months before the diagnosis is entertained, and it is not unusual for such patients to have already undergone extensive evaluations for infection, malignancy, and, in some cases, inflammatory bowel disease. In considering the diagnosis of FMF, it is important to recall that there are occasional FMF patients without known Mediterranean heritage, and because of the recessive mode of inheritance of FMF and the small family size and increased mobility of Western society, about half of the patients in most series have a negative family history.

A number of sets of clinical criteria were proposed prior to the identification of *MEFV*; the most widely quoted one was developed at a large center in Tel-Hashomer, Israel (Livneh et al., 1997b). The various sets of criteria agree that the cardinal features of FMF are short (12 hours to 3 days), recurrent (3 or more) episodes of fever (rectal temperature  $>38^{\circ}\text{C}$ ) with painful manifestations in the abdomen, chest, joints, or skin in the absence of any other demonstrable causative factors. The Tel-Hashomer criteria enumerate milder attacks, exertional leg pain, and a favorable response to colchicine as minor criteria, and a positive family history, age of onset  $<20$  years, appropriate ethnicity, parental consanguinity, an acute-phase response during attacks, episodic proteinuria/hematuria, and an unproductive laparotomy as supportive criteria. The diagnosis is then established with appropriate combinations of major, minor, and supportive criteria.

Although the Tel-Hashomer criteria perform extremely well in high-risk populations, they probably do not work as well in Western nations, where the Bayesian pretest probabilities are much lower, the disease is milder (due to a different spectrum of mutations), physicians have had much less clinical experience with FMF, and the frequency of other hereditary periodic fevers may be higher than the frequency of FMF. These criteria nevertheless provide important guidance for physicians in the United States and Europe. Clinical features that may help differentiate FMF from the other hereditary periodic fevers include ethnicity, duration of attacks, type of skin rash, and responsiveness to colchicine (Table 27.1).

Genetic testing has assumed a major adjunctive role in the diagnosis of FMF, and, as previously noted, has extended both the clinical and the ethnic spectrum of FMF. Nevertheless, the previously issues of sensitivity (the “mutation deficit”) and penetrance underscore the need to consider clinical information in the interpretation of *MEFV* genetic test results.

To date there are no protein-based tests or assays for pyrin expression or function that would aid in the diagnosis of FMF,

although this goal now seems within reach. Twenty years ago a metaraminol infusion to provoke an attack was proposed as a diagnostic test (Barakat et al., 1984), but it is not generally used because of safety concerns (Cattan et al., 1984; Buades et al., 1989).

### Mode of Inheritance, Carrier Detection, and Prenatal Diagnosis

Standard teaching is that FMF is inherited as an autosomal recessive disorder with reduced penetrance in females (M:F ratios are generally around 1.5 to 1). Hence, in a family with two unaffected parents whose first child is diagnosed with FMF, the recurrence risk to each subsequent male child would be 25%. For families in which one parent is affected and the other is not, if one child is affected the recurrence risk is 50%. In cases where an affected individual marries an unaffected individual of unknown carrier status from a high-risk ethnic group, the risk of having an affected child is one-half the carrier frequency for that ethnic group. Since the measured carrier frequencies for Jewish, Arab, Armenian, and Turkish populations are often >20%, in many cases this translates into a risk of 10% or more.

Because molecular diagnosis has broadened the FMF phenotype and ethnic distribution, the foregoing analysis may be oversimplified. We now know that some mutations, such as M694V, have greater penetrance than others, such as E148Q; that a few *MEFV* mutations truly show a dominant mode of inheritance; that there is a biochemical inflammatory phenotype associated with the FMF carrier state; and that a substantial number of patients (often with relatively mild symptoms) have only one demonstrable mutation. Such information complicates genetic counseling.

Given the rare occurrence of FMF phenotype II, in which patients present with amyloidosis as the first manifestation of the disease, the question may be raised whether asymptomatic relatives of FMF patients should be screened for *MEFV* mutations, perhaps with the intention of initiating prophylactic colchicine in those individuals who test positive for two mutations. In Western nations in which phenotype II is exceedingly rare, where the M694V frequency is low and amyloidosis is uncommon even in patients with FMF, screening of asymptomatic family members is generally not performed, since the discovery of "genetic FMF" may adversely affect the insurability of individuals who may never develop symptoms. There is still no consensus on presymptomatic screening in families with a strong history of amyloidosis, and some physicians would advocate careful follow-up rather than colchicine prophylaxis in asymptomatic family members with two mutations.

Prenatal diagnosis of FMF is feasible but requires careful genetic counseling to appropriately explain decreased penetrance and interpretation of heterozygous genotypes. In addition, given the relative effectiveness of colchicine therapy, prenatal diagnosis raises significant moral and ethical issues regarding the possible termination of pregnancy for what many regard to be a treatable disease.

### Treatment and Prognosis

Daily oral colchicine therapy has been established as effective in preventing both the acute attacks of FMF and systemic amyloidosis. About three-fourths of adult FMF patients taking 1.2 to 1.8 mg of colchicine per day experience a near-complete remis-

sion of their attacks, and over 90% demonstrate a marked improvement. Colchicine may cause diarrhea or gastrointestinal upset, but this side effect can be minimized by starting at a low dose and gradually titrating upward, and by dividing the daily dose. In some patients the gastrointestinal effects of colchicine are aggravated by lactose intolerance (Fradkin et al., 1995), in which case a lactose-free diet may be helpful. Colchicine is safe in children but must be carefully titrated to efficacy and toxicity (Zemer et al., 1991; Özkaya and Yalçinkaya, 2003).

Oral colchicine may also prevent amyloid progression in FMF patients who already have proteinuria due to amyloidosis (Livneh et al., 1994b; Simsek et al., 2000; Öner et al., 2003). The prognosis is best if the serum creatinine is <1.5 mg/dl, and is adversely affected by tubulointerstitial disease at diagnosis and by noncompliance. Doses of 1.5 mg/day or more are most effective in these patients, as well as in patients who have already undergone renal transplantation (Livneh et al., 1992). The combination of colchicine and cyclosporine should be avoided when possible in transplant patients, since cyclosporine inhibits the MDR1 transport system required for hepatic and renal colchicine excretion (Speeg et al., 1992; Gruberg et al., 1999; Simkin and Gardner, 2000; Minetti and Minetti, 2003).

Agents that inhibit or compete for the hepatic cytochrome P450 system component CYP 3A4, such as cimetidine, erythromycin, lovastatin, and grapefruit juice, may also increase colchicine blood levels (Ben-Chetrit and Levy, 1998a). Colchicine toxicity other than diarrhea is rare in patients taking standard doses, but can occur in the presence of inhibitors of clearance in elderly patients with renal insufficiency (Kuncl et al., 1987; Altıparmak et al., 2002) or if colchicine is given intravenously to abort an attack in patients already receiving oral colchicine (Wallace and Singer, 1988; Putterman et al., 1991; Bonnel et al., 2002). Most experts advise continuing colchicine in female FMF patients during conception and pregnancy and performing an amniocentesis to screen for the slightly increased risk of trisomy 21 (Ben-Chetrit and Levy, 2003). Although small concentrations are present in the breast milk of women taking colchicine, breast-feeding is considered safe (Ben-Chetrit et al., 1996).

Colchicine may prevent the attacks of FMF through multiple mechanisms. Colchicine is concentrated in granulocytes, the major effector in FMF attacks, perhaps because these cells express only low levels of the *MDR1*-encoded P-glycoprotein pump (Ben-Chetrit and Levy, 1998b; c). Through its interaction with microtubules or other less well-defined mechanisms, colchicine inhibits L-selectin expression on neutrophils (Cronstein et al., 1995) and inhibits neutrophil chemotaxis (Dinarello et al., 1976; Bar-Eli et al., 1981). It is also of interest but of unknown significance that pyrin itself is expressed predominantly in neutrophils and associates with microtubules (Mansfield et al., 2001).

When FMF presents with polyarteritis nodosum, Henoch-Schönlein purpura, or febrile myalgia, additional therapy with high-dose corticosteroids, and sometimes cyclophosphamide, may be necessary (Langevitz et al., 1994; Tinaztepe et al., 1997; Majeed et al., 2000a; Ozen et al., 2001). For the subset of patients with FMF whose more typical attacks do not respond well to colchicine, several adjunctive approaches are under investigation, including subcutaneous interferon- $\alpha$  (Tunca et al., 1997; Calguneri et al., 2004a, 2004b; Tunca et al., 2004), weekly low-dose intravenous colchicine (Lidar et al., 2003), and biologic therapies targeted at TNF or IL-1 $\beta$ . Allogeneic bone marrow transplantation has recently been proposed as a treatment for refractory FMF (Milledge et al., 2002), but many experts regard the risk-benefit ratio as unacceptable (Touitou et al., 2003).

In a large majority of patients with FMF, the prognosis on standard colchicine therapy is excellent, allowing for a full range of activities and a normal life span. Amyloidosis is the major life-limiting manifestation of FMF, but fortunately the incidence is much reduced with colchicine prophylaxis. Renal transplantation has proven to be effective in patients who take adequate doses of colchicine in the post-transplant period. Patients who respond poorly to colchicine are often very impaired functionally and are a major therapeutic priority.

### Animal Models

Chae and colleagues (2003) recently reported the development of a mouse line expressing a truncated, hypomorphic form of pyrin. Consistent with the previous discussion of the role of pyrin in IL-1 $\beta$  maturation, peritoneal macrophages from these mice exhibited increased caspase-1 activation, increased IL-1 $\beta$  processing and secretion and a defect in apoptosis that was independent of IL-1 $\beta$  but associated with impaired caspase-8 cleavage. Overall, the mice exhibited an inflammatory phenotype. Low doses of bacterial lipopolysaccharide (LPS) induced an accentuated body temperature response in homozygous mutant mice, and higher doses induced increased lethality in the homozygous mutants, relative to wild type. Moreover, the induction of inflammatory peritoneal exudates by thioglycollate was increased in homozygous mutants relative to heterozygotes or wild-type mice.

Thus murine pyrin plays an important role in the regulation of the innate immune response; mutants with diminished function may confer heightened inflammatory responses that could be beneficial in the heterozygous state. Additional studies with pyrin-null mice and knock-ins of FMF-associated mutants may further delineate these pathways.

### TNF Receptor–Associated Periodic Fever Syndrome

The term *familial Hibernian fever* (FHF; MIM142680) was first proposed to describe a large family of Irish/Scottish ancestry afflicted with recurrent episodes of fever, abdominal pain, myalgia, and erythematous rash that responded to corticosteroid but not colchicine treatment (Williamson et al., 1982). Fifteen years later, a follow-up report confirmed a dominant mode of inheritance in this family, extended the clinical phenotype to include conjunctivitis and periorbital edema, and documented systemic AA amyloidosis in 1 of 16 living affected family members (McDermott et al., 1997). Several other reports described families with similar, although not completely identical, dominantly inherited inflammatory symptoms from several different ethnic backgrounds (Bergman and Warmenius, 1968; Gertz et al., 1987; Hawle et al., 1989; Karenko et al., 1992; Zweers and Erkelens, 1993; Gadallah et al., 1995; Mache et al., 1996; Zaks and Kastner, 1997), making it difficult to be certain whether these syndromes arose from distinct mutations at a common locus or occurred as a result of mutations in different genes.

In 1998, two independent groups mapped the susceptibility loci for FHF and an Australian (Scottish) variant denoted *familial periodic fever syndrome* to chromosome 12p13 (McDermott et al., 1998; Mulley et al., 1998), suggesting that the same locus was responsible for both syndromes. Plausible functional candidates in the linkage interval included *CD27*, *LAG-3*, *CD4*, *C1R*, *C1S*, and *TNFRSF1A*. *TNFRSF1A* encodes the 55 kDa receptor for TNF (also known as TNFR1, TNFRSF1A, p55, p60, and

CD120a). Given the central role of TNF signaling in inflammation and the observation of reduced levels of the soluble p55 receptor in the serum of several patients with FHF, a collaborative effort was undertaken to sequence *TNFRSF1A* among affected and nonaffected members from seven families of various ethnicities with autosomal dominant recurrent fever syndromes.

Sequence analysis demonstrated six distinct *TNFRSF1A* missense mutations, five of which resulted in substitutions at highly conserved cysteine residues (McDermott et al., 1999). The discovery of mutations in *TNFRSF1A* consolidated these clinical variants into a single nosologic entity denoted the TNF receptor–associated periodic syndrome (TRAPS), a name chosen to reflect the involvement of the p55 TNF receptor in the pathogenesis of the disease while avoiding the suggestion of a specific ethnic bias. Over 30 *TNFRSF1A* mutations have now been reported in patients with recurrent fever (McDermott et al., 1999; Dodé et al., 2000a, 2002a; Aganna et al., 2001, 2002b, 2003; Ak-sentijevich et al., 2001; Jadoul et al., 2001; Simon et al., 2001b, 2001c; Nevala et al., 2002; Kriegel et al., 2003; Weyhreter et al., 2003; Horiuchi et al., 2004), subsuming a wide range of ethnic groups, including African Americans, East Asians, and populations in which FMF and HIDS are common.

### Clinical and Pathological Manifestations

In the largest single group of TRAPS patients reported to date (Hull et al., 2002b), the median age of onset was 3 years, ranging from 2 weeks to 53 years of age. Males and females are equally affected. In contrast with FMF, the duration of TRAPS attacks is quite variable (Dodé et al., 2002a), ranging from short episodes of 1 to 2 days to month-long flares, and in rare cases, patients experience nearly continuous, fluctuating symptoms (McDermott et al., 1997). At the onset of an attack, inflammatory symptoms, such as muscle cramping, abdominal pain, or pleuritic chest pain, may be relatively subtle, gradually increasing over the course of 1 to 3 days. Pain often persists at its maximum intensity for several days before gradual resolution. Some patients associate the onset of attacks with physical or emotional stress, menses, or local trauma, but in many cases there does not appear to be a definite stimulus that provokes an attack. In women, pregnancy is sometimes associated with remission (McDermott et al., 1997; Kriegel et al., 2003), with possible exacerbation during the postpartum period (Rösen-Wolff et al., 2001).

Nearly all patients develop fever in association with at least some of their attacks. Temperature  $>38^{\circ}\text{C}$  (maximally  $41^{\circ}\text{C}$ ) usually lasts for more than 3 days, often heralding the onset of other inflammatory symptoms. Young children invariably experience fever with their attacks, but fever may be absent during some attacks in adults.

Serosal involvement is a prominent feature of TRAPS (Hull et al., 2002b). Attacks consisting solely of fever and abdominal pain occur in over 90% of patients with TRAPS, and can be the result of inflammation of the peritoneum or of the abdominal musculature or both. Serosal inflammation often produces the physical findings of an acute abdomen, and approximately half of the patients in one series had undergone at least one laparoscopy or exploratory laparotomy. Findings frequently include mononuclear infiltrates in the bowel wall or peritoneal adhesions, which eventually can cause bowel necrosis. Pleuritic attacks, with or without radiographic evidence of effusion, occur in about 50% of TRAPS patients. Less common serosal manifestations include pericarditis and episodes of scrotal pain.

Localized myalgia is extremely common during TRAPS attacks. The myalgia of TRAPS manifests as cramp-like discomfort, fluctuating in severity but disabling at its worst. Affected areas are warm, tender to palpation, and often associated with an erythematous patch. When found on an extremity, the myalgia and rash of TRAPS characteristically migrate centrifugally (as opposed to spreading) from proximal to distal limb over several days. As the region of inflammation passes over a joint (e.g., knee or elbow), there is often evidence of synovitis and effusion, with transient contracture. Although most commonly affecting the limbs and torso, myalgia and rash can also occur on the face and neck. During the episodes of myalgia, serum creatine kinase and aldolase concentrations remain normal. Magnetic resonance imaging demonstrates focal areas of edema in the affected muscular compartments and intramuscular septa (Hull et al., 2002d). Biopsies in TRAPS patients with active myalgia have demonstrated monocytic fasciitis or lymphocytic vasculitis but not myositis (Hull et al., 2002d; Drewe et al., 2003a).

TRAPS attacks frequently lead to arthralgia or arthritis, either as a part of the migratory myalgia picture or independently. Polyarticular arthralgia is by far the most common rheumatic manifestation of TRAPS. The arthritis of TRAPS tends to be nonerosive and either monoarticular or pauciarticular and asymmetric, most commonly affecting the hips, knees, and ankles.

The most distinctive of the cutaneous manifestations of TRAPS is the centrifugally migratory erythematous rash (Color Plate 27.II) (Toro et al., 2000). Such lesions are warm, tender, and blanch on palpation and are sometimes as much as 30 cm in diameter. Histologically, there is a superficial and deep perivascular and interstitial mononuclear cell infiltrate, sometimes with a low-grade lymphocytic vasculitis (Toro et al., 2000). Other less unique rashes are also commonly observed in TRAPS. They include urticaria-like plaques and serpiginous erythematous patches and plaques (Toro et al., 2000). These variants often involve several different areas of the body simultaneously and are neither migratory nor associated with concurrent myalgia. Relapsing episodes of panniculitis have also been reported (Lamprecht et al., 2004).

Eye involvement is much more common in TRAPS than in FMF, occurring in over 75% of patients (Hull et al., 2002b). The most frequent ocular findings are conjunctivitis and periorbital edema. Uveitis is relatively rare, but should be considered in patients experiencing blurred vision or eye pain.

As in FMF, systemic amyloidosis is the most serious complication of TRAPS and is due to the deposition of an insoluble fragment of SAA (Jadoul et al., 2001; Simon et al., 2001b; Dodé et al., 2002b), as in other forms of secondary amyloidosis. As the clinical spectrum of mutation-positive TRAPS expands, the frequency of amyloidosis among reported cases has diminished and is currently about 10%. Nephrotic syndrome and renal failure are the most common consequences; there is also one case of hepatic transplantation due to TRAPS amyloidosis reported in the literature (Hull et al., 2002b).

### Laboratory Findings

The attacks of TRAPS are nearly always associated with a vigorous acute-phase response (Hull et al., 2002b), including an accelerated ESR and increased CRP, haptoglobin, fibrinogen, C3 and C4 complement, and ferritin. Although not widely available, the SAA level represents the most sensitive and rapid measure of the acute-phase response and may be an important determinant to monitor in patients with systemic amyloidosis (Gillmore et al.,

2001). During attacks patients may have prominent leukocytosis and neutrophilia, sometimes with white counts  $>20,000/\text{mm}^3$ , and children often have thrombocytosis.

Patients with TRAPS frequently manifest biochemical evidence of ongoing inflammation even between their acute episodes, although the magnitude of laboratory abnormalities may be diminished. The anemia of chronic disease is common among patients with frequent attacks, and a moderate polyclonal gammopathy is often seen. Modest elevations in the serum IgD have been reported (Simon et al., 2001c; Dodé et al., 2002a). Low-titer anticardiolipin antibodies and antinuclear antibodies are seen in a minority of patients.

As in FMF, albuminuria, usually without significant hematuria, is the most common manifestation of systemic amyloidosis in TRAPS. Initially, renal function is normal, although TRAPS amyloidosis may progress to renal failure within 1 to 2 years. Hepatic involvement usually causes an elevated alkaline phosphatase with normal transaminases. The diagnosis of amyloidosis should be confirmed with appropriate tissue specimens.

### Molecular Basis of TRAPS: The Disease Gene, *TNFRSF1A*

*TNFRSF1A* is a 10-exon gene with a 455-codon open reading frame (Loetscher et al., 1990; Fuchs et al., 1992). The encoded protein has a 29-amino acid leader, a 182-amino acid extracellular domain, a 21-amino acid transmembrane domain, and a 223-residue intracellular domain. At the time of this writing, 39 mutations in *TNFRSF1A* have been reported in patients with recurrent episodes of fever and inflammation, and an updated database of mutations is available on the World Wide Web at <http://fmf.igh.cnrs.fr/infevers/>. All of the known mutations affect the extracellular cysteine-rich domains of the p55 TNF receptor (Fig. 27.2). Nineteen cause missense substitutions at cysteine residues, 18 cause missense substitutions at noncysteine residues, 1 causes an in-frame single amino acid deletion, and one is a splice mutation that causes a 4-amino acid insertion. There are also several mutational hot spots, including five at cysteine residues (C30, C33, C52, C70, and C88, numbered relative to the leucine immediately following the cleavage of the signal peptide) and four noncysteine residues (Y20, H22, T50, and R92). To date, no patients have been identified with mutations in either the transmembrane or intracellular domains of the *TNFRSF1A* protein, null mutations, or mutations in the p75 TNF receptor (*TNFRSF1B*), which is encoded on chromosome 1p36. Several reports have described families or individuals with TRAPS-like clinical findings but no demonstrable mutations in *TNFRSF1A*, raising the possibility of locus heterogeneity (Aksentijevich et al., 2001; Dodé et al., 2002a; Aganna et al., 2003).

### Function of the p55 TNF Receptor, the *TNFRSF1A* Gene Product

TNF is a proinflammatory cytokine with pleiotropic biologic effects (Vassalli, 1992). At a cellular level, TNF stimulation can lead either to NF- $\kappa$ B activation or apoptosis, depending on a number of contextual factors that have still not been completely defined. Administration of TNF to experimental animals can cause leukocyte activation, cytokine secretion, increased expression of adhesion molecules on leukocytes and endothelial cell surfaces, host resistance to intracellular pathogens, angiogenesis, pyrexia, anemia, and cachexia.

**Figure 27.2.** Structures of the first two cysteine-rich domains (CRDs) of the 55 kDa TNF receptor, TNFRSF1A. Loops (L1–L3) are indicated. Thick lines represent well-conserved regions, dotted lines depict disulfide bonds. Eighteen cysteine mutations causing the TNF receptor–associated periodic syndrome (TRAPS) are shown. A 19th cysteine mutation is in CRD 3 (C98Y). Several other noncysteine mutations are also shown. At the time of this writing a total of 39 TRAPS mutations have been published or presented in abstracts. All are in the extracellular domains of TNFRSF1A. To date, none are frameshift or nonsense mutations.

As noted above, there are two cellular receptors for TNF, a 55 kDa protein encoded on chromosome 12p13 (TNFRSF1A) and a 75 kDa receptor encoded on chromosome 1p36 (TNFRSF1B) (Smith et al., 1990). Both are members of a family of cell-surface receptors with repeating cysteine-rich extracellular domains (CRDs) (Bazzoni and Beutler, 1996). Both receptors have four extracellular CRDs comprising about 40 residues, with three intrachain disulfide bonds stabilizing the structure of each CRD. The intracellular segment of the p55 receptor also includes a death domain of around 70 residues that is involved in signal transduction (Hsu et al., 1995). The p55 receptor is expressed widely, whereas the p75 receptor is expressed predominantly on leukocytes and endothelial cells.

TNF forms homotrimers that in turn aggregate homotrimers of either p55 or p75 receptors on the cell surface (Engelmann et al., 1990). All of the cysteine mutations in the p55 receptor are predicted to have a major effect on its three-dimensional structure, since they would prevent the formation of highly conserved disulfide bonds important to maintaining proper folding of the molecule. In addition, noncysteine mutations, such as those at T50, may prevent the formation of hydrogen bonds (Aksentijevich et al., 2001). Because TNF signaling requires homotrimerization of receptors, the dominant inheritance of TRAPS may be explained by the fact that structural modifications of even one of the three molecules in the complex may disrupt necessary interactions. If equimolar amounts of wild-type and mutant receptor were present on the cell surface, only one of eight homotrimers would be expected to be composed solely of normal chains.

Nevertheless, it was somewhat surprising that mutations in the p55 TNF receptor caused autoinflammatory disease rather than a more conventional immunodeficiency phenotype. In the initial report describing TRAPS (McDermott et al., 1999), leukocytes from three patients with the C52F mutation were studied for in-

creased TNF binding or constitutive activation through the mutant receptors (possibly by the formation of interchain disulfide bonds). The data supported neither possibility.

Instead, evidence was presented that mutant p55 receptors are refractory to activation-induced cleavage of the ectodomain, a homeostatic process that normally limits repeated signaling at the cell surface and creates a pool of potentially antagonistic soluble receptors. Four lines of evidence were adduced: (1) patients with four different *TNFRSF1A* mutations had diminished levels of soluble p55 in the serum, relative to healthy controls or patients with other inflammatory disorders; (2) membrane p55 was increased on peripheral blood leukocytes from C52F patients; (3) activation-induced clearance of cell surface p55 was reduced in leukocytes from C52F patients; and (4) activation-induced soluble p55 in leukocyte culture supernatants was less for C52F patients than for normal controls. The mechanism by which disease-associated mutations impair cleavage most likely represents an indirect structural effect, since all but 1 of the 39 known mutations are remote from the Asn<sub>172</sub>–Val<sub>173</sub> site where metalloprotease-induced cleavage actually occurs (Gullberg et al., 1992).

Current evidence suggests that impaired ectodomain cleavage is unlikely to be the whole explanation for the TRAPS phenotype. Impaired receptor shedding has been observed by flow cytometry in leukocytes from patients with nine mutations (H22Y, C30S, C33G, P46L, T50M, T50K, C52F, F112I, and I170N) (McDermott et al., 1999; Aksentijevich et al., 2001; Nevala et al., 2002; Aganna et al., 2003), but not in patients with six other disease-associated variants (T37I,  $\Delta$ D42, C52R, the splice mutation, N65I, and R92Q) (Aksentijevich et al., 2001; Aganna et al., 2003). The issue is further complicated by the observation that receptor shedding defects are in some cases cell type-dependent (Huggins et al., 2004). Although inappropriately low levels of soluble p55 are seen in a substantial subset of patients, this is also not a universal finding in mutation-proven TRAPS (Aganna et al., 2003). Other possible mechanisms of disease include effects on ligand-independent receptor self-association (Chan et al., 2000), effects on ligand-binding (Todd et al., 2004), abnormal intracellular trafficking of mutant receptors (Todd et al., 2004), and the relative balance of signaling through p55 and p75 receptors.

### Mutation Analysis

Most specialty laboratories use automated DNA sequencing, with or without a screening step such as denaturing high-performance liquid chromatography, for mutation detection. Thirty-seven of the 39 mutations are in exons 2 to 4 of the 10 exon gene, and 37 of the 39 are in the first two CRDs. Mutational screening therefore usually focuses on these high-probability regions of the gene. The conventional system for numbering mutations in TRAPS found in this chapter and most published reports denotes the leucine that immediately follows the cleavage of the signal peptide as residue 1. Inclusion of the signal peptide would increase these numbers by 29.

In general, the penetrance of noncysteine mutations appears lower than that of cysteine substitutions (Aksentijevich et al., 2001). Moreover, cysteine mutations have been associated with a higher risk of amyloidosis.

Two specific noncysteine *TNFRSF1A* mutations are sufficiently common to be considered polymorphisms in some populations (Aksentijevich et al., 2001). R92Q, which is present in almost half of the independent TRAPS chromosomes identified

in a large cohort followed at the U.S. National Institutes of Health, is also present in approximately 1% of Caucasian control chromosomes. Since the population frequency of TRAPS is far less than 1%, the penetrance of this variant must be low. However, data are accumulating that the TRAPS phenotype is but one end of a spectrum of inflammatory conditions associated with R92Q. Recent reports demonstrate an increased frequency of this *TNFRSF1A* variant in an early arthritis clinic (Aksentjevich et al., 2001), in association with atherosclerosis (Poirier et al., 2004), and in patients with systemic amyloidosis complicating juvenile idiopathic arthritis (Aganna et al., 2004). Similarly, the P46L variant is found in approximately 2% of African-American control chromosomes (Aksentjevich et al., 2001) and at an even higher frequency among some sub-Saharan African populations (Tchernitchko et al., 2005).

### Strategies for Diagnosis

Clinical suspicion is the cornerstone of the diagnosis of TRAPS. Among the clinical features of TRAPS that help distinguish it from the other periodic fever syndromes are the duration of attacks (episodes lasting more than 1 week suggest TRAPS, although shorter attacks can be seen), the migratory myalgia and overlying erythematous rash, presence of periorbital edema during attacks, a dominant pattern of inheritance, and the differential response to corticosteroids over colchicine. Also in the differential diagnosis are systemic-onset juvenile chronic arthritis (SOJCA) and adult-onset Still's disease. Distinguishing features include fever pattern (temperatures usually return to normal or below normal each day in SOJCA and adult Still's, rather than remaining elevated around the clock in TRAPS), clinical course of the arthritis (progressive, erosive polyarticular arthritis are common in SOJCA and adult Still's), and cutaneous manifestations (evanescent salmon-colored macular or maculopapular rash in SOJCA and adult Still's).

Once clinical suspicion has been established, the diagnosis of TRAPS is confirmed or refuted by *TNFRSF1A* sequence analysis. More complete sequencing may be entertained if the clinical suspicion is high but the yield is relatively low. There are numerous sporadic and some familial cases that clinically resemble TRAPS but do not have *TNFRSF1A* mutations, and it is probably best to reserve a term such as *idiopathic autoinflammatory disease* for such cases.

Serum levels of soluble p55 receptor, while of theoretical interest, have not proven to be an adequate substitute for genetic testing. Soluble p55 levels can be low, normal, or high among patients who are suspected of having TRAPS but are found to be mutation negative (Aganna et al., 2003). Moreover, although most mutation-positive TRAPS patients do have low levels of soluble p55, inflammatory attacks or renal insufficiency can spuriously normalize soluble p55 measurements.

### Mode of Inheritance, Carrier Detection, and Prenatal Diagnosis

Although TRAPS is inherited in an autosomal dominant fashion, penetrance is not 100%, even for substitutions at cysteine residues. Further complicating the issue are reports of several cases of de novo *TNFRSF1A* mutations (Aganna et al., 2002b, 2003). Careful history-taking can sometimes identify unsuspected cases among the allegedly unaffected relatives of TRAPS patients, and genetic testing is of benefit in establishing the correct diagnosis in these individuals. Genetic testing may also be warranted for asymp-

tomatic relatives in families with a strong history of TRAPS-associated amyloidosis. However, in cases where the risk of amyloidosis is low, the possible benefits of identifying other mutation-positive asymptomatic relatives should be weighed against the potential impact of such information on insurability, especially for children. Similarly, the use of molecular techniques for prenatal diagnosis should be approached with great caution, since there are still insufficient data to make reliable estimates of penetrance, and since the field of targeted cytokine-inhibitory therapies is rapidly evolving.

### Treatment and Prognosis

In contrast to FMF, colchicine prevents neither the acute attacks nor the amyloidosis of TRAPS (Dodé et al., 2002b; Hull et al., 2002b). The efficacy of nonsteroidal anti-inflammatory drugs is limited to mild attacks. Short courses of oral or parenteral corticosteroids may be effective in more severe episodes, but escalating doses are often required, with the attendant toxicities. There is a growing body of evidence that twice- or thrice-weekly administration of etanercept, the p75 TNFR:Fc fusion protein, is effective in reducing, although usually not eliminating, the clinical and laboratory manifestations of TRAPS (Kastner et al., 1999; Galon et al., 2000; Nigrovic and Sundel, 2001; Simon et al., 2001c; Hull et al., 2002a, 2002b; Drewe et al., 2003b; Weyhreter et al., 2003; Lamprecht et al., 2004). Etanercept also appears to have a role in preventing amyloid deposition, although monitoring of SAA levels may be necessary to titrate the dosage (Drewe et al., 2000, 2004; Hull et al., 2002c).

The prognosis of TRAPS is largely related to development of systemic amyloidosis, which is more frequent among patients with cysteine substitutions or a positive family history of amyloidosis (Aksentjevich et al., 2001; Kallinich et al., 2004). Infrequently, TRAPS patients develop life-threatening abdominal complications, such as bowel obstruction or necrosis.

### Animal Models

Kollias and colleagues recently reported knock-in mice that express a nonshedtable p55 TNF receptor with a mutation at the cleavage site (Xanthoulea et al., 2004). These mice exhibited a dominantly inherited autoinflammatory phenotype that supports the hypothesis that TNF receptor shedding is an important negative homeostatic mechanism. Mutant mice developed chronic active hepatitis, were more susceptible to the toxic effects of bacterial LPS and TNF than wild-type animals, and exhibited increased susceptibility to experimental autoimmune encephalomyelitis and TNF-induced arthritis. Moreover, macrophages from these mice exhibited increased innate immune responses to Toll-like receptor stimulation. Nevertheless, differences between the phenotype of these mice and the clinical picture in TRAPS suggest that additional mechanisms are probably operative in the human disease. Development of mouse lines that are knock-ins for specific TRAPS-associated mutations may shed light on this issue.

### Hyperimmunoglobulinemia D with Periodic Fever Syndrome

Among the currently recognized hereditary periodic fever syndromes, HIDS (MIM 260920) was the most recently described, with the initial study proposing a unique disorder in six Dutch patients in 1984 (van der Meer et al., 1984). Although these pa-

tients had a clinical picture similar to that of FMF, there were distinguishing features, including prominent lymphadenopathy, and less severe abdominal symptoms than usually seen with FMF. Moreover, all six Dutch patients were found to have polyclonal elevations in their serum IgD levels, and all five of the Dutch patients who underwent bone marrow aspiration and biopsy had markedly increased numbers of  $\delta^+$  plasma cells in the marrow. In contrast, only one of eight patients with FMF had an increased serum IgD, and the one FMF patient who underwent a bone marrow examination had normal numbers of  $\delta^+$  plasma cells. The HIDS nomenclature was proposed to describe this apparently new periodic fever syndrome.

Three of the initial patients had a positive family history, but it was only after additional patients and families were identified that a clear autosomal recessive mode of inheritance was apparent (Drenth et al., 1994c; Livneh et al., 1997a). Ten years after the first description of HIDS, a report of 50 cases with this disorder, most of them from the Netherlands and France, established HIDS as a clinical entity distinct from FMF (Drenth et al., 1994b). Two other studies demonstrated that the susceptibility locus for HIDS is not linked to the FMF locus on the short arm of chromosome 16 or to the immunoglobulin heavy-chain region on the long arm of chromosome 14 (Drenth et al., 1994c; Livneh et al., 1997a).

In 1999, 15 years after its initial description, two groups from the Netherlands independently discovered HIDS-associated mutations in *MVK*, the gene encoding mevalonate kinase, an enzyme involved in cholesterol and nonsterol isoprene biosynthesis (Fig. 27.3) (Drenth et al., 1999; Houten et al., 1999). Although not well understood, this surprising conclusion was strengthened by the complementary functional and positional cloning approaches employed by the competing groups, and *MVK* mutations still account for most patients with clinical HIDS (Simon et al., 2001a). Nevertheless, as is the case for both FMF and TRAPS, elucidation of the underlying gene has led to recognition of additional complexity. Thus, it is now clear that some patients with periodic fever have raised serum IgD levels without *MVK* mutations (Simon et al., 2001a), whereas others with *MVK* mutations have normal IgD levels (Houten et al., 1999; Frenkel et al., 2000; Saulsbury, 2003; Takada et al., 2003). Moreover, as we gain further insight into the role of the mevalonate pathway in regulating inflammation, the study of HIDS promises dividends that will extend far beyond these fascinating but relatively uncommon patients.

### Clinical and Pathological Manifestations

HIDS was first recognized in the Netherlands, and even 20 years later the majority of reported cases are of Dutch or neighboring northern European ancestry (Drenth and van der Meer, 2001; Simon et al., 2003). Typically febrile attacks begin within the first year of life, often precipitated by childhood immunizations, and there is no gender bias (Drenth et al., 1994b). The duration of attacks, 3 to 7 days, is somewhat longer than the duration of FMF attacks, but shorter than the episodes sometimes seen in TRAPS. In addition to immunizations, minor infections, trauma, surgery, and menses may trigger attacks. On average, attacks occur about once or twice a month but usually without true periodicity in childhood and adolescence; attacks may become less frequent or severe in adults.

The attacks of HIDS often begin with chills and headache. In children, diffuse tender lymphadenopathy, particularly in the cervical chains, is common and is much more frequent than in FMF or TRAPS. As in the latter two disorders, abdominal pain is often

**Figure 27.3.** The mevalonate pathway. The hyperimmunoglobulinemia D with periodic fever syndrome (HIDS) is caused by recessively inherited mutations in the mevalonate kinase enzyme. HIDS-associated mevalonate kinase mutations typically leave 1%–3% residual enzymatic activity. More severe mutations in this enzyme cause mevalonic aciduria, a condition characterized by severe developmental delay as well as episodic inflammatory attacks.

present during attacks, although the incidence of peritoneal signs in HIDS is much lower than in FMF or TRAPS (Drenth et al., 1994b; Livneh et al., 1997a). Moreover, whereas the abdominal attacks of FMF and TRAPS are frequently associated with constipation, because of decreased peristalsis, the abdominal attacks of HIDS are often accompanied by diarrhea and vomiting. Nevertheless, some patients with HIDS do develop adhesions, probably from recurrent peritoneal inflammation. Scrotal pain, presumably due to inflammation of the tunica vaginalis, has been reported in HIDS (Saulsbury, 2003), but pleurisy and pericarditis have not been observed.

HIDS can present with a number of different mucocutaneous findings, including diffuse, painful, erythematous macules, a diffuse, erythematous macular and papular rash (Color Plate 27.III), erythematous papules and nodules, urticaria, and a morbilliform rash (Drenth et al., 1994a, 1994b). Unlike FMF, there is no predilection for the feet, ankles, or lower legs, and, unlike TRAPS, the rash of HIDS is not migratory. Histologically,

cutaneous vasculitis, perivascular inflammatory cells, and deposits of IgD, IgM, or C3 may be present. Other forms of cutaneous vasculitis reported in HIDS include Henoch-Schönlein purpura (Haraldsson et al., 1992) and erythema elevatum diutinum (Miyagawa et al., 1993). Aphthous ulcers of the mouth and vagina may also be seen in HIDS, which, in combination with fever and cervical lymphadenopathy, may be confused with the syndrome of periodic fever, aphthous stomatitis, pharyngitis, and adenopathy (PFAPA), a common nongenetic cause of recurrent fever in children (Marshall et al., 1987, 1989; Thomas et al., 1999).

HIDS can also affect the joints (Haraldsson et al., 1992; Drenth and Prieur, 1993; Loeliger et al., 1993; Drenth et al., 1994b), most frequently with polyarthralgia. HIDS may also present with intermittent episodes of polyarticular arthritis of the large joints, usually but not always with fever, and sometimes coinciding with abdominal attacks. Arthritic attacks are more common in children and are usually nondestructive; synovial fluid is rich in granulocytes.

Systemic amyloidosis is uncommon in HIDS but has been reported (Obici et al., 2004; D'Osualdo et al., 2005). There is currently no explanation for the relative infrequency of amyloidosis in HIDS.

### Laboratory Findings

Prior to the identification of the underlying gene, HIDS was defined by the polyclonal elevation of the serum IgD (>100 IU/ml or >14.1 mg/dl) on two occasions at least 1 month apart (Drenth et al., 1994b). While the vast majority of *MVK* mutation-positive patients with recurrent fevers meet this criterion, a small percentage of these patients do not. Serum IgD levels do not correlate with the severity of HIDS, either when following an individual patient or when comparing patients, and do not predictably fluctuate with attacks (Hiemstra et al., 1989; Drenth et al., 1994b). Over 80% of HIDS patients also have persistent polyclonal increases in serum IgA levels (Hiemstra et al., 1989; Haraldsson et al., 1992; Klasen et al., 2001).

As in FMF and TRAPS, during their inflammatory attacks HIDS patients present with leukocytosis and a left shift, an accelerated ESR, elevated acute-phase reactants (including CRP and SAA), and sometimes transient hematuria (Drenth et al., 1994b; Frenkel et al., 2000; Drenth and van der Meer, 2001). Serum levels of several proinflammatory cytokines may be increased during attacks, as is the urinary excretion of neopterin and leukotriene E<sub>4</sub> (Drenth et al., 1995; Frenkel et al., 2001b). Urinary levels of mevalonic acid are also markedly increased during attacks (Drenth et al., 1999; Houten et al., 1999; Frenkel et al., 2001a; Kelley and Takada, 2002).

### Molecular Basis of HIDS: The Disease Gene, *MVK*

HIDS is caused by recessively inherited mutations in *MVK*, encoded on the long arm of human chromosome 12 (Drenth et al., 1999; Houten et al., 1999). HIDS-associated mutations lead to a marked reduction in mevalonate kinase enzymatic activity (vide infra), but fibroblasts from patients nevertheless typically demonstrate 1% to 3% of the activity seen in fibroblasts from healthy controls. *MVK* mutations leading to the complete loss of enzymatic activity cause mevalonic aciduria, an extremely rare condition that manifests not only the periodic fevers, lymphadenopathy,

abdominal pain, rash, and arthralgia seen in HIDS, but also hypotonia, mental retardation, cataracts, and failure to thrive (Hoffmann et al., 1986, 1993; Kelley, 2000).

*MVK* spans a genomic region of 22 kb, and is comprised of 11 exons, the first of which encodes most of the 5' untranslated region in the cDNA (Cuisset et al., 2001; Houten et al., 2001). The gene encodes a 396-amino acid protein (Schafer et al., 1992). At the time of this writing over 30 HIDS-associated mutations have been published, and an updated database of mutations (some of which have not yet been published) is available on the World Wide Web at [fmf.igh.cnrs.fr/infervers/](http://fmf.igh.cnrs.fr/infervers/). HIDS-associated *MVK* mutations are distributed throughout the coding sequence, whereas mutations causing mevalonic aciduria are concentrated around sequences encoding the active sites of the mevalonate kinase enzyme (Cuisset et al., 2001; Houten et al., 2001).

### Function of Mevalonate Kinase, the *MVK* Gene Product

Mevalonate kinase catalyzes the conversion of mevalonic acid to 5-phosphomevalonic acid in the synthesis of the sterols, which include cholesterol, vitamin D, bile acids, and steroid hormones (Goldstein and Brown, 1990; Brown and Goldstein, 1997; Valle, 1999). This pathway also leads to the production of nonsterol isoprenoids, which are involved in a host of cellular functions. It is unlikely that the autoinflammatory phenotype of HIDS is due to a deficiency in cholesterol, because patients with HIDS usually have cholesterol levels in the low to normal range, and the autoinflammatory phenotype is not seen in patients with other more profound disorders of the mevalonate pathway, such as Smith-Lemli-Opitz syndrome, in which cholesterol deficiency is more significant (Kelley, 2000).

There are two current hypotheses on the pathogenesis of HIDS. The first proposes that the inflammatory phenotype is due to the buildup of mevalonic acid, the substrate for the mevalonate kinase enzyme (Simon et al., 2004). The second hypothesis holds that the disorder is due to deficiencies in isoprenoids normally synthesized through the mevalonate pathway (Frenkel et al., 2002). Although there are in vitro data demonstrating accentuated IL-1 $\beta$  secretion in HIDS leukocytes that can be reversed by the addition of farnesol and geranyl-geraniol (isoprenoid compounds), the issue remains controversial. Some investigators have proposed that small GTP-binding proteins may provide the link between isoprenoids and inflammation (Takada et al., 2003), but this possibility awaits direct confirmation.

Both the isoprenoid deficiency and mevalonate accumulation hypotheses predict a worsening of symptoms with decreased mevalonate kinase enzymatic activity. In vitro studies of cell lines harboring wild-type or HIDS-mutant *MVK* indicate that the mutant enzyme functions best at 30°C, with a diminution at 37°C and further decreases at 39°C (Houten et al., 2002). This provocative finding may account for the association of HIDS attacks with immunizations and infections, and may also account for the increased urinary mevalonic acid levels seen during HIDS attacks.

### Mutation Analysis

A very high percentage of HIDS patients harboring *MVK* mutations have at least one copy of the substitution of isoleucine for valine at residue 377 (V377I) (Cuisset et al., 2001; Houten et al., 2001; D'Osualdo et al., 2005). Population-based surveys of

newborns in The Netherlands indicate a carrier frequency of 0.6% for the V377I mutation among the Dutch (Houten et al., 2003), with haplotype data supporting a founder effect (Houten et al., 2003). Analysis of *MVK* genotypes among HIDS patients indicate an underrepresentation of V377I homozygotes, relative to the expected Hardy-Weinberg distribution, suggesting a milder phenotype or reduced penetrance for V377I homozygotes (Houten et al., 2003).

Because many patients with HIDS are heterozygous for V377I, commercial and academic laboratories often perform an initial screen for the V377I mutation by restriction endonuclease analysis, sometimes also adding an assay for the second-most common mutation, the substitution of threonine for isoleucine at residue 268 (I268T). More extensive screening, usually by DNA sequencing, is reserved for patients who are heterozygous for either mutation (but not for compound heterozygotes, in whom the molecular diagnosis of HIDS would be already established).

### Strategies for Diagnosis

There are currently three possible strategies for diagnosing HIDS: clinical, molecular, and biochemical. Consistent with practice before the identification of the underlying gene, the clinical diagnosis of HIDS is established by documenting elevations in serum IgD levels ( $>100$  IU/ml, or  $>14.1$  mg/dl) on two occasions at least a month apart, with a compatible clinical history. The molecular diagnosis is established by documenting two mutations in *MVK*, while the biochemical diagnosis is established by documenting elevations in urinary mevalonic acid during attacks, or decreased enzymatic activity in cells cultured from the patient. In many cases, all three strategies agree, in which case the patient is sometimes said to have “classic-type HIDS” (Simon et al., 2001a).

Although there is strong concordance between molecular and biochemical diagnosis, clinical and molecular diagnoses sometimes diverge. About one-quarter of patients satisfying clinical criteria for HIDS have no demonstrable *MVK* mutations (Simon et al., 2001a). These patients tend to have milder disease and lower IgD levels than patients with classic-type HIDS and are said to have “variant-type HIDS.” There is also a small number of patients who meet genetic and biochemical criteria for HIDS, with a compatible clinical picture, except for persistently normal IgD levels (Houten et al., 1999; Frenkel et al., 2000; Saulsbury, 2003; Takada et al., 2003). This discrepancy is more frequent in young children, who may eventually exhibit increased serum IgD levels (Drenth and van der Meer, 2001). The term *Dutch-type periodic fever* has been proposed for periodic fever patients meeting genetic or biochemical criteria, regardless of their IgD levels (Frenkel et al., 2000).

Further complicating the picture is the finding that a small percentage of patients with FMF and TRAPS may have modest elevations in their serum IgD, although not to the very high levels seen in some HIDS patients (Livneh et al., 1997a; Medlej-Hashim et al., 2001; Simon et al., 2001c; Dodé et al., 2002a). The differential diagnosis of an elevated serum IgD level also includes IgD multiple myeloma, Hodgkin disease, cigarette smoking, diabetes mellitus, pregnancy, hyperimmunoglobulinemia E syndrome, ataxia telangiectasia, acquired immunodeficiency syndrome, and recurrent infections such as tuberculosis and aspergillosis (Hiemstra et al., 1989; Boom et al., 1990; Drenth et al., 1994b).

Given these complexities, it is reasonable to take a combined approach for patients in whom there is a suitable index of suspicion for HIDS/mevalonate kinase deficiency, combining serum IgD measurement with genetic and/or biochemical analysis. In

light of the divergence between IgD and molecular findings and the apparent lack of correlation between IgD and disease severity, some investigators have suggested a change in nomenclature, but this appears unlikely in the face of firmly established convention.

### Mode of Inheritance, Carrier Detection, and Prenatal Diagnosis

As noted above, HIDS is inherited as an autosomal recessive trait. There are currently no data on the penetrance of individual HIDS genotypes, although population-genetic studies suggest that V377I homozygotes may not always manifest HIDS symptoms. In light of the likelihood of reduced penetrance, the generally favorable prognosis for HIDS, and the possibility of genetic discrimination, genetic testing is usually reserved for symptomatic individuals. Prenatal diagnosis of HIDS is possible but raises a number of ethical issues if undertaken with the possibility of terminating a pregnancy for what is usually a nonfatal disorder with a number of new treatment options.

### Treatment and Prognosis

Until recently, no cases of systemic amyloidosis had been associated with HIDS (Obici et al., 2004; D’Osualdo et al., 2004), and this still remains a very rare complication. Hence, the overwhelming majority of patients with HIDS have a normal life expectancy (Drenth et al., 1994b). Moreover, as noted above, symptoms usually ameliorate in adulthood.

Most patients with HIDS do not respond to colchicine, although a few patients do show some improvement with daily treatment. Corticosteroids, cyclosporine, and intravenous immunoglobulin are not generally effective in HIDS, although intra-articular steroids and nonsteroidal antiinflammatory drugs may be of benefit for HIDS arthritis.

Ongoing therapeutic trials in HIDS focus on the mevalonate pathway and on cytokine inhibition. The statin class of drugs inhibits HMG CoA reductase, the enzyme immediately preceding mevalonate kinase in the mevalonate pathway. Although one member of this pharmacologic family, lovastatin, caused exacerbations in the more severe mevalonic aciduria, simvastatin appears safe in HIDS, and preliminary data suggest a possible benefit (Simon et al., 2004). A small trial of thalidomide, which, among other effects, inhibits TNF- $\alpha$  production, resulted in a nonsignificant decrease in acute-phase reactants and no effect on the attack rate (Drenth et al., 2001). In contrast, the more potent TNF inhibitor etanercept produced substantial improvement in two patients with HIDS (Takada et al., 2003). IL-1 inhibition may represent yet another possible therapeutic strategy.

### Animal Models

There are currently no animal models reported for HIDS.

### The Cryopyrinopathies

The cryopyrinopathies—familial cold autoinflammatory syndrome (FCAS, MIM 120100), Muckle-Wells syndrome (MWS, MIM 191100), and neonatal-onset multisystem inflammatory disease (NOMID, MIM 607115, also called chronic infantile neurologic cutaneous and articular [CINCA] syndrome)—are a group of autosomal dominant autoinflammatory conditions consisting of episodic or fluctuating inflammation with associated cutaneous and synovial symptoms. Although some symptoms

may resemble those of FMF or TRAPS, the cryopyrinopathies are distinct clinical phenotypes. A large family with what is now called FCAS was described first (Kile and Rusk, 1940), and Muckle and Wells reported on a family with their eponymous syndrome in 1962. NOMID/CINCA was first recognized as a clinical entity in the early 1980s (Prieur and Griscelli, 1981; Hassink and Goldsmith, 1983), although it was not initially apparent that this condition is a genetic disorder because of decreased reproductive fitness in patients carrying the diagnosis.

Between 1999 and 2000, genetic markers associated with FCAS, MWS, and a clinical overlap syndrome sharing features of both conditions were independently mapped to the distal region of the long arm of chromosome 1 (Cuisset et al., 1999; Hoffman et al., 2000; McDermott et al., 2000), a finding suggesting that all three disorders are linked to the same gene. In 2001, several missense mutations associated with FCAS and MWS were identified in an exon of a newly discovered gene denoted *CIAS1* (cold-induced auto-inflammatory syndrome-1) (Hoffman et al., 2001a). This gene, which is also called *PYPAFI* (Manji et al., 2002), *NALP3* (Aganna et al., 2002a), and *CATERPILLER1.1* (O'Connor et al., 2003), is expressed mainly in hematopoietic tissue. Similarities between clinical features of NOMID/CINCA and MWS led to the discovery in 2002 of de novo missense mutations in *CIAS1* in a significant percentage of patients with NOMID/CINCA as well (Aksentijevich et al., 2002; Feldmann et al., 2002). None of the mutations associated with FCAS, MWS, or NOMID/CINCA were found in healthy controls.

Currently, over 35 mutations linked to disease have been found in *CIAS1* (Hoffman et al., 2001a; Aganna et al., 2002a; Aksentijevich et al., 2002; Dodé et al., 2002c; Feldmann et al., 2002; Granel et al., 2003; Hoffman et al., 2003; Rösen-Wolff et al., 2003; Arostegui et al., 2004; Frenkel et al., 2004; Neven et al., 2004; Stojanov et al., 2004). As is the case for the other periodic fever syndromes, an updated list of mutations is available at <http://fmf.igh.cnrs.fr/infevers/>. Several mutations are shared by more than one condition and many patients evince symptoms that fall between the established diagnostic boundaries (Lieberman et al., 1998; McDermott et al., 2000; Aganna et al., 2002a; Granel et al., 2003; Hawkins et al., 2004b). Variability in phenotype among patients with the same mutation suggests that other genetic or environmental factors influence disease severity.

## Clinical and Pathological Manifestations

### Familial cold autoinflammatory syndrome

FCAS, also called familial polymorphous cold eruption and cold hypersensitivity, is considered the mildest of the cryopyrinopathies. Symptoms include episodes of fever, urticaria-like rash, arthralgia, and, less commonly, drowsiness, headache, nausea, and extreme thirst (Hoffman et al., 2001b; Johnstone et al., 2003; Wanderer and Hoffman, 2004). Febrile attacks are brought on by generalized exposure to cold temperatures. In one study, less than an hour on average of cold exposure was needed to precipitate symptoms (Hoffman et al., 2001b). Approximately 2.5 hours later, these patients experienced symptoms that lasted about 12 hours. Longer exposure to cold correlated with worse symptoms. In some individuals, attacks occur nearly daily, often worse in the evening and resolving by morning. Most patients have their first attack by 6 months of age.

The rash associated with FCAS can present as petechiae, erythematous patches, or confluent plaques, usually beginning on the face or extremities and spreading (Johnstone et al., 2003).

Although the rash appears hive-like, skin biopsies reveal infiltrates of neutrophils and lymphocytes (Hoffman et al., 2001b), rather than mast cells, indicating that the rash is not true urticaria. In areas of rash, there is also endothelial cell swelling and vacuolization, with capillary luminal narrowing.

Polyarthralgia involving the hands, knees, ankles, and occasionally the feet, wrists, and elbows usually accompanies flares. Some patients may develop a nonerosive arthropathy with deformities of the metacarpophalangeal and proximal interphalangeal joints (Commerford and Meyers, 1977). Some patients also complain of ocular symptoms, including watering and blurred vision.

### Muckle-Wells syndrome

The first published description of MWS was a 1962 report on a Derbyshire kindred (Muckle and Wells, 1962). Affected individuals suffered from "aguey bouts" of inflammation consisting of fever, malaise, an urticaria-like rash, and stabbing pains in the large joints. In addition, affected members of the family developed bilateral sensorineural hearing loss and renal amyloidosis. Attacks were not usually linked to cold and tended to be more severe than those associated with FCAS.

Most patients with MWS have their first attack by adolescence. MWS-associated episodes last about 24–48 hours (Muckle and Wells, 1962; Muckle, 1979; Cuisset et al., 1999) and in addition to the symptoms noted above may also include abdominal pain, conjunctivitis, and episcleritis (Watts et al., 1994; Cuisset et al., 1999). Skin manifestations similar to those associated with FCAS usually accompany episodes (Color Plate 27.IV). Although arthralgia is much more common than arthritis, oligoarticular synovitis and sterile pyogenic arthritis occur occasionally (Schwarz et al., 1989; Watts et al., 1994). Approximately three-fourths of patients in one series developed sensorineural hearing loss, usually beginning in childhood with high-frequency hearing loss (Schwarz et al., 1989). About one-third of adult patients in the same series developed systemic AA amyloidosis (Muckle, 1979) affecting primarily the kidneys. Other target organs include the thyroid, adrenals, spleen, and testes (Schwarz et al., 1989). Hearing loss appears not to be due to amyloid deposition in the inner ear or auditory nerve, and current hypotheses focus on either possible inflammation of the inner ear or expression of *CIAS1* in the cochlea.

### Neonatal-onset multisystem inflammatory disease/chronic infantile neurologic cutaneous articular syndrome

NOMID/CINCA is the most severe of the cryopyrinopathies. In addition to the fevers, arthralgias, hearing loss, and amyloidosis seen in MWS, patients with NOMID/CINCA may have a distinct, deforming arthropathy (Prieur and Griscelli, 1981; Hassink and Goldsmith, 1983; Hashkes and Lovell, 1997; Prieur, 2001) as well as chronic aseptic meningitis, intellectual impairment, and loss of vision. Approximately 20% of patients die before age 20 (Prieur et al., 1987; Hashkes and Lovell, 1997).

The rash associated with NOMID/CINCA is similar to that associated with FCAS and MWS and is nearly always present to some degree (Prieur, 2001). Articular symptoms are variable (Prieur et al., 1987; Hashkes and Lovell, 1997; Prieur, 2001), with some patients exhibiting mild swelling and pain, but no radiographic changes, whereas others have severe deformities involving symmetric overgrowth of the epiphyses and growth cartilage of the long bones, especially prominent in the knees, ankles, elbows, and hands. The latter changes may occur within the first

year of life and contractures may severely restrict movement (Prieur et al., 1987; Hashkes and Lovell, 1997; Prieur, 2001). Joint radiographs from severe cases may show enlarged, irregular ossification of the epiphyses of the long bones, especially the tibias, often with a "bread crumb" appearance. There may be irregularity in the epiphyseal plates of the femur, radius, and tibia, as well as early growth plate closure and shortening of the long bones (Kaufman and Lovell, 1986; Hashkes and Lovell, 1997). Skull radiographs show frontal bosselation, delayed closure of the anterior fontanelle, and increased cranial volume. Synovial biopsy usually shows only modest inflammation.

The neurosensory manifestations of NOMID/CINCA are potentially of great concern. Many patients develop chronic aseptic meningitis, with increased cerebrospinal fluid (CSF) pressure, an elevation in CSF protein concentration, and a pleiocytosis consisting mostly of polymorphonuclear leukocytes (Torbiak et al., 1989). Brain imaging studies may reveal mild ventricular dilatation, cerebral atrophy, and prominent sulci (Prieur, 2001). Although some patients perform well at school, other children with NOMID/CINCA have developmental delays and learning deficits and still others exhibit mental retardation (Torbiak et al., 1989; Dollfus et al., 2000). As in MWS, sensorineural hearing loss is frequent. Ocular involvement may range from conjunctivitis to anterior or posterior uveitis, sometimes leading to blindness (Dollfus et al., 2000). Funduscopic examination frequently reveals optic disc edema, papilledema, or optic atrophy.

Other findings include hepatosplenomegaly and lymphadenopathy, as well as vasculitis, thrombosis, and the aforementioned amyloidosis (Prieur et al., 1987; Torbiak et al., 1989; Hashkes and Lovell, 1997; Prieur, 2001). Profound growth delay and reduced reproductive potential are also common.

### Laboratory Findings in the Cryopyrinopathies

Laboratory features of the cryopyrinopathies include an accelerated ESR, polymorphonuclear leukocytosis, thrombocytosis, and anemia of chronic disease. Elevated acute-phase reactants, such as CRP and SAA, are also observed. High-titer autoantibodies are not observed, although some patients do have modest titers of anticardiolipin antibodies.

### Molecular Basis of the Cryopyrinopathies: the *CIAS1* Gene

*CIAS1* is located on chromosome 1q44 and consists of nine exons, encoding a 3105 bp potential open reading frame (Hoffman et al., 2001a). Via alternative splicing, exons 1–3, 5, and 7–9 are included in the coding sequence for cryopyrin, producing a 920-amino acid, 106 kDa protein. Expression analyses detect the cryopyrin message in leukocytes and chondrocytes, with little expression in other tissues (Hoffman et al., 2001a; Feldmann et al., 2002).

The *CIAS1* protein product was named *cryopyrin* to emphasize the existence of an N-terminal PYRIN domain, like that in the pyrin protein, as well as the association with cold-induced symptoms in FCAS (Hoffman et al., 2001a). Besides the PYRIN domain (amino acids [a.a.] 13–83), cryopyrin contains a central NACHT domain (a.a. 217–533) (Koonin and Aravind, 2000), named for its presence in neuronal apoptosis inhibitor protein (NAIP), the major histocompatibility complex class II transactivator (CIITA), the incompatibility locus protein from *Podospira anserina* (HET-E), and mammalian telomerase-associated proteins (TP1). At the C terminus of cryopyrin are seven leucine-

rich repeats (LRRs) (a.a. 697–920). This arrangement of PYRIN–NACHT–LRRs is found in at least 14 proteins in the human genome (Harton et al., 2002; Tschopp et al., 2003), many of which are expressed in leukocytes and hematopoietic tissue.

### Function of Cryopyrin, the *CIAS1* Gene Product

The PYRIN domain of cryopyrin has been shown to interact specifically with ASC (Gumucio et al., 2002; Manji et al., 2002; Dowds et al., 2003), as noted with pyrin, a finding suggesting that cryopyrin too is involved in the caspase-1/IL-1 $\beta$  pathway. This macromolecular complex of cryopyrin (NALP3), ASC, and caspase-1, with a fourth protein called *Cardinal*, has been denoted the inflammasome (Agostini et al., 2004; Martinon and Tschopp, 2004). Transfection studies indicate that cryopyrin potentiates inflammation through its interaction with ASC. Cryopyrin regulates IL-1 $\beta$  secretion (Wang et al., 2002; Stehlik et al., 2003), NF- $\kappa$ B activation (Gumucio et al., 2002; Manji et al., 2002; Stehlik et al., 2002; Dowds et al., 2003; O'Connor et al., 2003), and apoptosis (Dowds et al., 2003).

The NACHT domain contains seven conserved motifs, including an ATPase-specific P loop and a Mg<sup>2+</sup> binding site, and is involved in protein oligomerization (Koonin and Aravind, 2000). Disease-associated mutations are found almost exclusively in the NACHT domain, suggesting an important role for this motif in the function of cryopyrin.

LRRs are common components of the extracellular domains of Toll-like receptors (TLRs), as well as several cytoplasmic proteins. The LRRs of TLRs appear to recognize pathogen-associated molecular patterns (PAMPs), common molecules in bacterial cell walls, such as peptidoglycan and lipopolysaccharide (Inohara et al., 2002; Chamillard et al., 2003; Girardin et al., 2003). Upon contact with a PAMP, TLRs transduce signals into the cell to up-regulate proinflammatory mediators such as costimulatory molecules, cytokines, and inducible nitric oxide synthase (iNOS). LRRs on cytoplasmic proteins such as cryopyrin may serve a similar purpose in detecting intracellular bacteria or bacterial products. Muramyl-dipeptide (MDP), a common PAMP, may activate formation of the cryopyrin (NALP3) inflammasome (Martinon et al., 2004). Thus, in this setting cryopyrin appears to be a proinflammatory molecule, up-regulating caspase-1 and IL-1 $\beta$  upon sensing bacterial MDP.

Under normal conditions, cryopyrin is kept from activating caspase-1 unnecessarily, possibly in two different ways. First, pyrin may compete with cryopyrin for binding to ASC (Dowds et al., 2003), preventing formation of the cryopyrin (NALP3) inflammasome. Second, studies of LRR deletion mutants of both cryopyrin and NALP1 (Martinon et al., 2002; Agostini et al., 2004), a related protein, suggest that the LRRs have an autoinhibitory function, maintaining the protein in an inactive state. Upon sensing intracellular bacteria, the LRRs may release the rest of the protein from inhibition, allowing formation of the cryopyrin (NALP3) inflammasome (Fig. 27.4).

### Mutation Analysis

Nearly all of the known mutations occur in six small clusters in exon 3, encoding the NACHT domain (Hoffman et al., 2001a, 2003; Aganna et al., 2002a; Aksentjevich et al., 2002; Dodé et al., 2002c; Feldmann et al., 2002; Granel et al., 2003; Rösen-Wolff et al., 2003; Arostegui et al., 2004; Frenkel et al., 2004; Neven et al., 2004; Stojanov et al., 2004). Although the crystal

**Figure 27.4.** Formation of the cryopyrin (NALP3) inflammasome. Depicted on the left are the domain structures of the four proteins that comprise this macromolecular complex. At baseline, interaction of the leucine-rich repeats (LRR) with the NACHT domain of cryopyrin prevents assembly of the complex. Muramyl-dipeptide, a bacterial cell-wall product, may bind the LRR of cryopyrin, allowing assembly of the inflammasome. Mutations in the NACHT domain associated with familial cold autoinflammatory syndrome (FCAS), Muckle-Wells syndrome (MWS), and neonatal-onset multisystem inflammatory disease (NOMID) may alter the LRR–NACHT interaction in such a way that the threshold of activation is diminished. Assembly of the inflammasome leads to interaction of the catalytic domains (p20/p10) of caspase-1 molecules, leading to autocatalysis, release of p20 and p10, and subsequent IL-1 $\beta$  activation. PYD, PYRIN domain.

structure of cryopyrin has not been solved, computational modeling suggests that many of the disease-causing mutations are located along the nucleotide binding cleft or near a region that senses when a nucleotide is bound (Neven et al., 2004).

Mutations in cryopyrin appear to increase its proinflammatory properties, perhaps by increasing the binding affinity of cryopyrin for ASC or rendering the protein more labile, so that minor stimuli (such as cold temperatures) release the LRR-mediated autoinhibition. Such mutations may be considered gain-of-function genetic changes, consistent with the dominant inheritance patterns observed in the cryopyrinopathies.

Multiple substitutions at residues 260, 264, 303, 436, 439, and 523 exist. Only limited genotype–phenotype correlations can be made, as disease severity does not segregate among clusters of mutations. Although D303G/N, Q306L, and F309S are associated with NOMID/CINCA, L305P is associated with FCAS.

### Strategies for Diagnosis

Similar to FMF, the diagnosis of these disorders is often a combination of clinical observations and genetic testing. For FCAS, a clinical diagnosis may be established by the presence of at least four of the following: fever and rash induced by generalized cold exposure, short (<24 hour) episodes, autosomal dominant inheritance, age of onset <6 months, conjunctivitis during attacks, and absence of deafness, periorbital edema, lymphadenopathy, and serositis (Johnstone et al., 2003). Longer episodes, hearing loss, lack of association with cold temperatures, and amyloidosis are more suggestive of MWS (Muckle, 1979), whereas aseptic meningitis, uveitis, and the characteristic arthropathy support the di-

agnosis of NOMID/CINCA (Hashkes and Lovell, 1997; Prieur, 2001; Neven et al., 2004). Genetic testing can provide an unequivocal diagnosis, if positive. However, the sensitivity is not 100%, and in fact only about half of patients meeting clinical criteria for NOMID/CINCA have demonstrable mutations in *CIAS1* (Aksentijevich et al., 2002; Neven et al., 2004). Possibly, *CIAS1* mutation-negative patients have defects in related genes. A positive genotyping result also may not distinguish among the three conditions, as several mutations are shared by more than one disease entity (Hoffman et al., 2001a; Aganna et al., 2002a; Aksentijevich et al., 2002; Dodé et al., 2002c; Feldmann et al., 2002; Granel et al., 2003; Rösen-Wolff et al., 2003; Neven et al., 2004).

### Mode of Inheritance, Carrier Detection, Prenatal Diagnosis

*CIAS1* mutations are inherited in an autosomal dominant fashion, a pattern recognized early in families with FCAS and MWS (Kile and Rusk, 1940; Muckle and Wells, 1962; Johnstone et al., 2003). The inheritance pattern for NOMID/CINCA is less clear, as patients have reduced reproductive potential. Most cases are sporadic, resulting from de novo mutations in children of healthy individuals, although a small number of familial cases have been documented (Feldmann et al., 2002).

Thus far, most mutations in *CIAS1* show a high degree of penetrance, such that carriers nearly always show some clinical manifestations. Disease severity may vary extensively, even among individuals harboring the same mutations, indicating that other factors influence phenotype. Findings in some patients blur the boundaries between diagnoses, with some features of FCAS, such as cold sensitivity, and other findings consistent with MWS, such as amyloid nephropathy (Hoffman et al., 2001a; Aganna et al., 2002a; Dodé et al., 2002c; Neven et al., 2004). Other patients may represent an overlap between MWS and NOMID/CINCA at the more severe end of the phenotypic continuum (Lieberman et al., 1998; Aksentijevich et al., 2002; Dodé et al., 2002c; Feldmann et al., 2002; Granel et al., 2003; Rösen-Wolff et al., 2003; Neven et al., 2004).

Recurrence risks to siblings depend on whether the mutation in the proband is de novo. If it is, then it is highly unlikely that another such event will occur, and hence the recurrence risk is low. However, if the affected child has inherited the mutation from either parent, then there is a 50% chance that any further child from that parent will also carry the mutation. Again, it should be noted that family members with the same mutations may not exhibit all the same signs and symptoms with equal severity.

### Treatment and Prognosis

Patients with the cryopyrinopathies generally do not respond well to colchicine (Hoffman et al., 2001b). Corticosteroids are helpful in some cases, but carry a high risk of side effects and often have minimal effect on the arthropathy or central nervous system manifestations of NOMID/CINCA (Hashkes and Lovell, 1997; Prieur, 2001). Nonsteroidal anti-inflammatory drugs offer some relief for arthralgias and constitutional symptoms but do little to control overall inflammation. Recently, promising results have been obtained with the IL-1 $\beta$  receptor antagonist, anakinra (Dailey et al., 2004; Hawkins et al., 2004a, 2004b; Hoffman et al., 2004). Patients with FCAS and MWS reported essentially complete remission of all disease symptoms (Hoffman et al., 2004). NOMID/CINCA-induced uveitis, rash, and fever resolved

and patients' cerebrospinal pressure dropped significantly at anakinra doses of 1–2 mg/kg per day (Dailey et al., 2004). It will be important to follow children with NOMID/CINCA on anakinra to observe long-term academic performance and physical growth, as well as to determine whether very early treatment can avert joint deformities.

Untreated, FCAS appears not to be associated with long-term sequelae, save for one report of renal amyloidosis occurring late in life (Hoffman et al., 2001b). Prognosis in MWS patients is highly dependent on the development of amyloidosis, which occurs in approximately one-third of individuals. Many patients with MWS develop significant bilateral sensorineural deafness. Patients with NOMID/CINCA often have a reduced life expectancy; currently, about 20% die before the age of 20 of infection or amyloidosis (Prieur et al., 1987; Hashkes and Lovell, 1997). Morbidities include intellectual impairment, vision loss, sensorineural hearing loss, and physical disability due to contractures.

Early and continued treatment with anakinra may reduce the risk of developing amyloidosis in both MWS and NOMID/CINCA patients, possibly averting or delaying renal failure and the attendant complications. The role of IL-1 inhibition in reversing preexisting deficits will probably depend on the circumstances. Since amyloidosis is thought to involve an equilibrium between deposition and resorption, it is possible that aggressive treatment soon after the discovery of proteinuria could prevent the progression to renal failure, but later intervention may not be as successful. A similar logic may apply to the hearing loss associated with MWS and NOMID/CINCA.

## Animal Models

As yet, no animal models for the cryopyrinopathies have been reported. However, four groups recently reported the production of cryopyrin knockout mice (Kanneganti et al., 2006; Mariathasan et al., 2006; Martinon et al., 2006; Sutterwala et al. 2006). These animals confirm the importance of cryopyrin for caspase-1 and IL-1 $\beta$  activation in response to a number of stimuli, including LPS, bacterial RNA, *Staphylococcus aureus*, *Listeria monocytogenes*, and monosodium urate crystals.

## Inherited Disorders of the Interleukin-12/23-Interferon Gamma Axis

MELANIE J. NEWPORT, STEVEN M. HOLLAND, MICHAEL LEVIN,  
and JEAN-LAURENT CASANOVA

Over the past 50 years there have been a number of reported cases of severe disseminated infection with weakly virulent mycobacteria in individuals without recognized predisposing immunodeficiency. Mycobacterial species included various environmental mycobacteria (EM) and several *Mycobacterium bovis* bacillus Calmette-Guérin (BCG) vaccine substrains. High rates of affected siblings and parental consanguinity suggested the existence of a novel primary immunodeficiency syndrome, subsequently named *Mendelian susceptibility to mycobacterial disease* (MSMD, MIM 209950). Molecular investigation of these families has identified mutations in five genes in the interleukin (IL)-12/23-dependent interferon-gamma (IFN- $\gamma$ ) axis, highlighting the importance of this pathway in human immunity to mycobacteria. There remain a number of patients for whom a genetic etiology has yet to be identified; mutations in other genes await discovery.

Sporadic cases of disseminated EM infection in the absence of recognized immunodeficiency are well described (e.g., Buhler and Pollack, 1953; van der Hoeven et al., 1958). Familial-disseminated EM infection was first reported in 1964—three members of the same Danish family had fatal disseminated *M. avium* complex (MAC) (Engbaek, 1964). Uchiyama et al. (1981) identified two siblings with *M. avium* infection. More recently, Holland and colleagues reported three male members of one family with disseminated EM infection (Holland et al., 1994; Frucht and Holland, 1996; Frucht et al., 1999).

Idiopathic disseminated BCG infection following vaccination was first reported in 1951 (Mimouni, 1951). A sporadic case born to consanguineous parents was described in 1973 (Ulgenalp et al., 1973), and families with more than one affected member were first reported at around the same time (Sicevic, 1972; Fedak, 1974). That patients with inherited susceptibility to mycobacterial infections may also be at increased risk of *Salmonella* infection was first highlighted in a report by Heyne (1976), who described a

brother and sister from Germany who both developed generalized infection after neonatal BCG vaccination. The boy later developed *Salmonella* enteritis and osteomyelitis. In Prague, a 3-year-old boy who had been vaccinated with BCG at the age of 3 days developed disseminated *Salmonella* and BCG infection resulting in his death 3 years later (Doleckova et al., 1977). A first cousin of this child also had disseminated BCG infection (Dvoracek et al., 1959).

The first family in which the molecular basis of increased susceptibility to EM was elucidated was described in 1995 (Levin et al., 1995). Four children from the same village in Malta all developed disseminated EM infection. Two were brothers related to a third child as fourth cousins, while the fourth child was not knowingly related to the others. The parents of the brothers were second cousins and both related to both parents of the fourth cousin. Each child was infected with a different mycobacterial species (*M. chelonae*, *M. fortuitum*, and two different strains of MAC), a phenomenon suggesting that an innate defect in host immunity was responsible. However, extensive immunological investigation failed to identify any known defect predisposing to such infections. Patients had defective up-regulation of monocyte function in response to endotoxin and IFN- $\gamma$  (Levin et al., 1995) and defective antigen presentation (D'Souza et al., 1996). The high degree of consanguinity within the Maltese family suggested that the children were homozygous for a rare recessive mutation inherited from a common ancestor. Through a whole-genome search for homozygosity in three of the affected children, the gene was mapped to the region of chromosome 6q containing the gene encoding the IFN- $\gamma$  receptor ligand binding chain (IFN- $\gamma$ R1) of the IFN- $\gamma$  receptor complex (Newport et al., 1996). A mutation in the coding region of this gene (*IFNGR1*), which resulted in complete absence of IFN- $\gamma$ R1 expression at the cell surface, was subsequently identified as the cause of the defect (Newport et al., 1996).

**Table 28.1.** Genes Involved in Defective Macrophage Activation

Gene	Gene Product	Chromosomal Location	MIM No.
<i>IFNGR1</i>	Interferon- $\gamma$ receptor ligand binding chain	6q23-q24	107470
<i>IFNGR2</i>	Interferon- $\gamma$ receptor signal transducing chain	21q22.1-22.2	145659
<i>IL12RB1</i>	Interleukin-12 receptor $\beta$ -1 subunit	19p13.1	601604
<i>IL12B</i>	Interleukin-12p40 subunit	5q31.1-33.1	161561
<i>STAT1</i>	Signal transducer and activator of transcription 1	2q32.2-32.3	600555

Meanwhile, authors of a survey conducted in parallel to the work described above found that of 108 cases of disseminated infection following BCG vaccination reported since 1951, 50% were idiopathic (Casanova et al., 1995). A retrospective study of all cases of disseminated BCG infection following vaccination in France between 1974 and 1994 revealed that of 32 children identified, 16 had no recognized predisposing immunodeficiency (Casanova et al., 1996). Among a total of 60 children worldwide with idiopathic disseminated BCG infection for whom information was available, four pairs of siblings and one pair of first cousins were identified, and parental consanguinity was noted in 24 families. Clinical and histopathological features in a Tunisian child with disseminated BCG infection, born to consanguineous parents, were remarkably similar to those of the Maltese children with EM infections. A series of candidate genes involved in antimycobacterial immunity in the mouse model of BCG infection were tested by homozygosity mapping. The segregation of markers within *IFNGR1* suggested linkage, and a frameshift mutation resulting in the absence of IFN- $\gamma$ R1 was identified (Jouanguy et al., 1996).

Although mutations in *IFNGR1* were subsequently identified in other cases of MSMD, there were a number of patients in whom mutations within *IFNGR1* were not detected. Investigation of other candidate genes within the IFN- $\gamma$  pathway led to the identification of mutations in four other genes (Table 28.1), all of which are involved in the IL-12-dependent, IFN- $\gamma$ -mediated immunity (reviewed in Dorman and Holland, 2000; Lammas et al., 2000; Remus et al., 2001; Casanova and Abel, 2002, 2004).

### Clinical and Pathological Manifestations

The central feature of MSMD is infection with weakly pathogenic mycobacteria. In keeping with the genetic heterogeneity there is a clinical spectrum of MSMD. At one end of the spectrum, mutations in *IFNGR1* or *IFNGR2*, which result in a lack of functional protein at the cell surface (complete receptor deficiency), have a very poor prognosis, with the development of disseminated infection in early childhood and progressively fatal disease (Jouanguy et al., 1996; Newport et al., 1996; Dorman and Holland, 1998; Dorman et al., 2004). At the other end, through screening of family members, individuals have been identified who carry mutations involving *IFNGR1*, *STAT1*, *IL12B*, and *IL12RB1* but have not developed infection with either mycobacteria or salmonella (Jouanguy et al., 1999b; Altare et al., 2001; Dupuis et al., 2001; Picard et al., 2002; Caragol et al., 2003). Other *IFNGR1* and *IFNGR2* mutations resulting in the expression of an abnormal protein causing partial receptor deficiency are associated with milder phenotypes and response to IFN- $\gamma$  treatment (Jouanguy et al., 1997, 1999b; Doffinger et al., 2000; Dorman et al., 2004). Similarly, mutations in the genes encoding the IL-12p40 subunit (*IL12B*) or the IL-12 receptor  $\beta$ 1 subunit (*IL12RB1*) resulting in complete deficiency of either protein result in a less severe phenotype and good

response to antimicrobial and IFN- $\gamma$  treatment. The signal transducer and activator of transcription 1 (*STAT1*) mutation is phenotypically similar to partial IFN- $\gamma$ R deficiency (Dupuis et al., 2000).

A striking feature of MSMD is the specific susceptibility to poorly pathogenic mycobacterial species. Various mycobacteria species have been isolated, including slow-growing species such as *M. kansasii*, *M. avium*, and *M. szulgai*, and rapid-growing species such as *M. smegmatis*, *M. abscessus*, *M. chelonae*, *M. fortuitum*, and *M. peregrinum*. *M. smegmatis* (Pierre-Audigier et al., 1997) and *M. peregrinum* (Koscielniak et al., 2003) had not previously been documented as causes of disseminated EM disease. The more virulent *M. tuberculosis* has been implicated in or isolated from individuals with IFN- $\gamma$ R1, IL-12p40, and IL-12R $\beta$ 1 deficiency (Jouanguy et al., 1997; Altare et al., 2001; Picard et al., 2002). The mycobacterial species identified correlate with the genetic defect; for example, rapid-growing mycobacterial species are mostly observed in children with complete IFN- $\gamma$ R1 or IFN- $\gamma$ R2 deficiency (Table 28.2). Salmonella infections ranging from protracted gastroenteritis to septicemia and disseminated infection occurred in about a quarter of reported cases, more commonly in association with IL-12p40 and IL-12R $\beta$ 1 deficiency (MacLennan et al., 2004). Other pathogens isolated from MSMD cases include *Listeria monocytogenes* (Roesler et al., 1999), *Histoplasma capsulatum* (Jouanguy et al., 1999b), and *Nocardia asteroides* (Picard et al., 2002). Fungal and bacterial pathogens such as candida and staphylococci have not caused infection, despite the presence of indwelling intravenous catheters in many patients. Increased susceptibility to viral infections, particularly with herpes viruses, has been noted in some patients in whom MSMD has been shown to be due to IFN- $\gamma$ R1 deficiency (Dorman et al., 1999; Cunningham et al., 2000; Uzel et al., 2000; Novelli and Casanova, 2004). Recently, a 11-year-child with complete IFN- $\gamma$ R1 deficiency who had developed mycobacterial disease at the age of 5 months was diagnosed with Kaposi sarcoma (Camcioglu et al., 2004). Histologic appearance of the lesions was characteristic for Kaposi sarcoma; human herpesvirus-8 (HHV-8)—associated antigen was detected in situ by immunohistochemistry, and HHV-8 DNA was amplified by polymerase chain reaction (PCR) from the lesions. However, this situation is not universal, and most other patients have had classical childhood viral infections without problems. Mutation of *STAT1* has not resulted in increased susceptibility to viral infection despite the role of *STAT1* in both IFN- $\gamma$ - and IFN- $\alpha$ -mediated immunity (see section Molecular Basis of Disease, below).

Patients with MSMD due to complete IFN- $\gamma$ R1 deficiency may present in childhood with a characteristic syndrome of chronic fever, weight loss, lymphadenopathy, hepatosplenomegaly, and evidence of disseminated infection that may involve bone, skin, soft tissues, lung, and meninges. The clinical presentation appears to vary according to the genetic defect involved. For example, dominant partial IFN- $\gamma$ R1 deficiency is almost always associated with osteomyelitis (Jouanguy et al., 1999b; Villela et al., 2001;

Sasaki et al., 2002; Dorman et al., 2004), whereas lymphadenopathy is a very common feature of IL-12p40 or IL-12R $\beta$ 1 deficiency (Altare et al., 1998a, 1998c, 2001; de Jong et al., 1998; Aksu et al., 2001; Sakai et al., 2001; Picard et al., 2002). The clinical features of each genetic defect remain to be carefully described as more patients with MSMD are identified. The age of onset varies according to the gene involved, the type of mutation, and whether the affected individual received BCG vaccination at birth or acquired EM infection via natural routes (Dorman et al., 2004). A correlation between clinical phenotype and histopathological findings has been observed (Emile et al., 1997). Two distinct histological types have been documented that appear to be associated with distinct clinical phenotypes (Color Plate 28.I). Approximately half the patients with disseminated BCG infections had tuberculoid (type I) granulomata with well-defined epithelioid and giant cells surrounded by lymphocytes and fibrosis containing only occasional acid-fast bacilli. The remaining patients had lepromatous-like (type II) lesions with poorly formed granulomata containing large numbers of acid-fast bacilli. Patients with

type I granulomata had a good prognosis but virtually all the children with poor granuloma formation (type II) died. EM granulomata tend to be poorly formed irrespective of the clinical outcome and underlying genetic defect.

### Laboratory Findings

Chronic infection leads to normochromic, normocytic anemia and raised inflammatory markers. Immune function in patients with MSMD has been extensively investigated in an attempt to identify a known immunodeficiency and is in general remarkably normal. CD4<sup>+</sup> T helper cells are often normal but may be low secondary to chronic infection. Levels of serum immunoglobulin isotypes, including IgG subclasses, are normal or elevated, and antigen-specific antibody titers are normal. T cell proliferation in vitro in response to various mitogens and recall antigens are also normal. Polymorphonuclear cells are normal in terms of morphology, CD18 expression, chemotaxis, and respiratory burst. Delayed-type hypersensitivity (DTH) testing in vivo and

**Figure 28.1.** Mutations identified to date in the five MSMD genes. The gene-coding regions are indicated with vertical bars separating the exons, designated by roman numerals. <sup>a</sup>Nonsense, splice-site mutations and frameshift insertions and deletions (recessive) causing complete deficiency with no detectable protein expression at the cell surface (small font in bold); <sup>b</sup>missense mutations and in-frame deletions (recessive)

causing complete deficiency with detectable surface protein expression (small font); <sup>c,d</sup>mutations that are recessive (large font, italic)<sup>c</sup> or dominant (large font)<sup>d</sup> causing partial deficiency; \*indicates two patients with homozygous STAT1 mutation who were susceptible to not only mycobacterial but also severe or eventual lethal viral infections.

blastogenesis in vitro to purified protein derivative (PPD) are normal in patients with complete IFN-γR1 and IL-12Rβ1 deficiency, results indicating that IL-12 and IFN-γ are not required for DTH or blastogenesis to mycobacterial antigens.

### Molecular Basis of the Disease

Mutations in five genes of the IL-12/IFN-γ axis causing increased susceptibility to mycobacteria have been identified to

date (summarized in Fig. 28.1). This pathway is central to the immune response to intracellular pathogens such as mycobacteria. The functions of these genes are described in more detail in Functional Aspects of the Proteins, below.

### IFNGR1

Mutations in this gene were the first to be identified as the cause of MSMD (Jouanguy et al., 1996; Newport et al., 1996). Subsequent

investigation of patients with increased susceptibility to poorly pathogenic mycobacteria has led to the identification of at least 15 null-recessive mutations in this gene (Fig. 28.1) (Pierre-Audigier et al., 1997; Altare et al., 1998b; Holland et al., 1998; Vesterhus et al., 1998; Roesler et al., 1999; Cunningham et al., 2000; Jouanguy et al., 2000; Allende et al., 2001; Rosenzweig et al., 2002; Koscielniak et al., 2003; Dorman et al., 2004). The identification of families in which mycobacterial infections occurred in more than one generation suggested dominant mutations might also exist (Jouanguy et al., 1999b). Investigation of 18 individuals from 12 kindreds led to the identification of a small deletion hot spot within *IFNGR1*. A 4 base pair (bp) deletion at nucleotide position 818 (818del4) was identified in 11 of the unrelated kindreds and the 12th family had a single nucleotide deletion (T) in this position (818delT). The 818del4 mutation leads to a premature stop codon at position 827–829 within the intracellular domain of the receptor. The receptor is expressed on the cell surface but the mutant receptor lacks the three motifs required for intracellular signaling (the JAK1 and STAT1 binding sites, and the tyrosine phosphorylation site). It also lacks a recycling motif, so the truncated receptor accumulates on the cell surface and interferes with signaling by the normal receptor encoded by the normal copy of *IFNGR1*. Thus, the mutant allele has a dominant effect (in comparison to the recessive form of IFN- $\gamma$ R1 deficiency, in which parents are healthy carriers of the mutations). Subsequently, other *IFNGR1* mutations resulting in a dominantly inherited phenotype were identified (Dorman et al., 1999; Villela et al., 2001; Sasaki et al., 2002). A second small deletion hot spot was recently identified in *IFNGR1*, in this case with a recessive phenotype (Rosenzweig et al., 2002).

In summary, a range of mutations including frameshift, insertion, deletion, nonsense, missense, and splice mutations have been identified in *IFNGR1* (Fig. 28.1). All recessive mutations identified to date occur in the part of the gene encoding the extracellular domain of the receptor chain, the majority of which result in complete lack of receptor expression. Two of the recessive mutations allow expression of a poorly functioning protein, leading to partial deficiency (Jouanguy et al., 1997). Partial receptor deficiency may also result from dominant mutations leading to a receptor being deprived of its intracytoplasmic segment.

### IFNGR2

Complete deficiency of IFN- $\gamma$ R2 was found in a child with disseminated *M. fortuitum* and MAC infections in whom cell surface expression of IFN- $\gamma$ R1 and *IFNGR1* sequence was normal (Dorman and Holland, 1998). Sequence analysis of *IFNGR2* led to the identification of a 2 bp deletion (277–278delAG), which in turn led to a premature stop codon (Fig. 28.1). The truncated protein lacked both the transmembrane and intracellular (signaling) domains and was not expressed at the cell surface. Both parents, though unrelated, carried this mutation, for which the child was homozygous. A case of partial IFN- $\gamma$ R2 deficiency has also been described (Doffinger et al., 2000). A child born to related Portuguese parents developed disseminated infection following BCG vaccination. At the age of 16 she developed *M. abscessus* infection. A point mutation was identified in the *IFNGR2* sequence: the patient was homozygous for the mutation whereas both parents were heterozygous. This mutation results in an amino acid substitution at position 114 (arginine  $\rightarrow$  cysteine) within the extracellular domain (Fig. 28.1). The mutant IFN- $\gamma$ R2 is expressed normally on the cell surface, but presumably the affinity between IFN- $\gamma$ R1 and IFN- $\gamma$ R2 is impaired.

### IL12B

Complete IL-12B (IL-12p40) subunit deficiency leading to MSMD and *Salmonella* infections has also been described. The first case was born to consanguineous Pakistani parents and was immunized with BCG at birth (Altare et al., 1998c). Sequencing of *IL12B* revealed a large deletion involving two coding exons resulting in a frameshift deletion of 374 nucleotides between positions 482 and 854 (Fig. 28.1). The parents and a healthy sibling were carriers of this mutation; the affected child was homozygous. Eleven additional patients from five other families have been identified to date (Picard et al., 2002; Fieschi and Casanova, 2003). One child had only salmonellosis. All other patients had mycobacterial disease, BCG-osis in 10 children and *M. chelonae* in 1 child. Four children with BCG-osis also had salmonellosis, one had tuberculosis, and one has nocardiosis. Five children died but all survivors are well and no longer on treatment. Interestingly, one kindred from India had the same large deletion previously reported in the Pakistani kindred. A founder effect was documented and dated to approximately 29 generations ago (95% confidence interval [CI] 9–115) and 700 years ago (95% CI 216–2760) by means of a novel mutation dating method (Genin et al., 2004). The other four kindreds originated from the Arabic peninsula and were all found to carry the same *IL12B* frameshift insertion (315insA) (Picard et al., 2002). A founder effect was again documented and dated to 47 generations ago (95% CI 22–110) and 1100 years ago (95% CI 528–2640). The fact that all patients with IL-12B deficiency identified to date have *IL12B* mutations resulting from a founder effect, one in the Indian subcontinent and another in the Arabic peninsula, is consistent with the rarity of IL-12p40 deficiency among patients with MSMD. It is the first example of a founder effect among Mendelian mycobacterial susceptibility genes. IL-12p40 has recently been shown to be to be a component of IL-23. Thus IL-12p40 deficiency probably results in IL-23 deficiency; however, owing to the lack of human IL-23-specific antibodies, this cannot be ascertained as yet.

### IL12RB1

Mutations in *IL12RB1* (which encodes the  $\beta$ 1 subunit of the IL-12 receptor) have been identified in 41 patients from 29 different families (Altare et al., 1998a, 2001; de Jong et al., 1998; Verhagen et al., 2000; Asku et al., 2001; Sakai et al., 2001; Fieschi et al., 2003; Staretz-Haham et al., 2003). Most patients had BCG or nontuberculous mycobacteria (NTM) disease, often with salmonellosis, but several were found to suffer from salmonellosis only and some from tuberculosis only (Fieschi et al., 2003; Fieschi and Casanova, 2003). A significant fraction of patients were asymptomatic. A total of 21 unique mutations have been identified, including nonsense, splice, and frameshift mutations, which lead to premature termination of translation in the extracellular domain (Fig. 28.1). This abrogates cell surface expression resulting in complete IL-12R $\beta$ 1 deficiency. Two missense mutations, also resulting in a lack of receptor expression at the cell surface, were validated by gene transfer studies (Altare et al., 2001; Sakai et al., 2001). Recently, a complete IL-12/IL-23 receptor  $\beta$ 1 deficiency with cell surface-expressed nonfunctional receptors was reported (Fieschi et al., 2004). IL-12 and IL-23 did not bind normally to the patient's cells; STAT4 was not phosphorylated and IFN- $\gamma$  production was not induced in the patient's cells (upon stimulation with IL-12 or IL-23). Only recessive, loss-of-function mutations have been identified in *IL12RB1* to date. The recent observation that IL-12R $\beta$ 1 also serves as a subunit in the IL-23 receptor suggests

that *IL12RB1* mutations prevent IL-23 activation, but this has not been experimentally tested as yet.

### STAT1

The identification of two unrelated families presenting with MSMD in the absence of mutation in any of the genes discussed above led to the discovery of the fifth MSMD gene. A 33-year-old French woman with a history of disseminated BCG infection following childhood vaccination and a 10-year-old North American girl with disseminated *M. avium* infection were found to carry a de novo mutation (the parents of both patients had two wild-type copies of *STAT1*) in the coding region of *STAT1* (Dupuis et al., 2001). Both were heterozygous for a single T > C nucleotide change at position 2116, which results in L706S in the COOH-terminal region (Fig. 28.1). The abnormal protein exerts a dominant negative effect on the normal protein in terms of STAT-1 dimer (also known as gamma activating factor [GAF]) activation but not in terms of STAT-1/STAT-2/p48 trimer (also known as interferon-stimulated gamma factor 3 [ISGF3]) activation. The *STAT1* mutation is loss of function for the two cellular phenotypes (it impairs phosphorylation of tyrosine 701) but dominant for one (GAF activation) and recessive for another (ISGF3 activation) in heterozygous cells stimulated with either type of IFN. To our knowledge it is the first reported mutation in a human gene to be dominant and recessive for two cellular phenotypes. Vulnerability to mycobacteria and resistance to viruses thus imply that GAF mediates antimycobacterial IFN- $\gamma$  activity, whereas the antiviral effects of IFNs are either STAT-1-independent or ISGF3-dependent. This novel disorder proves that IL-12-induced, IFN- $\gamma$ -mediated immunity against mycobacteria is both STAT-1- and GAF-dependent.

The interpretation of the effect of the heterozygous *STAT1* mutation L706S on its function has recently been confirmed by the observation of two unrelated infants found to be homozygous for two unique mutations of *STAT1* in exon 20 (Fig. 28.1) (Dupuis et al., 2003). Neither IFN- $\alpha/\beta$  nor IFN- $\gamma$  was able to activate STAT1-containing transcription factors in patient cells. Like individuals with IFN- $\gamma$ R deficiency, both infants suffered from mycobacterial disease. Unlike patients with IFN- $\gamma$ R deficiency, both died of viral disease. Furthermore, viral multiplication in vitro was not inhibited by adding recombinant IFN- $\alpha/\beta$  to cell lines from the two individuals. Thus, complete impairment of STAT1-dependent responses to human IFN- $\alpha/\beta$  results in increased susceptibility to both mycobacteria and viral disease.

### Functional Aspects of the Proteins

The receptor for IFN- $\gamma$  consists of two subunits: IFN- $\gamma$ R1, the ligand-binding chain (previously known as the  $\alpha$  chain), and IFN- $\gamma$ R2, the signal-transducing chain (previously known as the  $\beta$  chain or accessory factor-1) (Bach et al., 1997). As the ligand-binding chains interact with IFN- $\gamma$  homodimers, they dimerize and become associated with two signal transduction chains. This leads to the activation of specific members of two protein families—the Janus kinases (JAK) and the signal transducers and activators of transcription (STAT). JAK1 and JAK2 phosphorylate key tyrosine residues on the ligand-binding chains. This leads to the recruitment and activation of STAT1, which translocates to the nucleus as a phosphorylated homodimer (GAF) to activate a wide range of IFN- $\gamma$ -responsive genes. After signaling, the receptor complex is internalized and dissociates. The IFN- $\gamma$ R1 chain is then recycled to the cell surface. IFN- $\gamma$ R1 is expressed constitutively at

**Figure 28.2.** Cytokine interactions between the macrophage or dendritic cell and T or NK cell in the context of mycobacterial infection, illustrating the interaction between IL-12 and IFN- $\gamma$ . Upon infection, primary host response cells such as macrophages release a range of cytokines including IL-12, which stimulate T and NK cells to secrete IFN- $\gamma$ , activate macrophages to kill intracellular pathogens, and enhance the differentiation of IFN- $\gamma$ -producing T helper cells.

moderate levels on the surface of all nucleated cells. IFN- $\gamma$ R2 is also constitutively expressed at low levels but expression is regulated by external stimuli, including IFN- $\gamma$  itself (Bach et al., 1995).

Interleukin-12 is a heterodimeric cytokine comprised of two subunits, p40 and p35, which together form the biologically active p70 molecule. The IL-12p40 subunit is shared by IL-23 (Fieschi and Casanova, 2003). IL-12 and IL-23 are produced by activated antigen-presenting cells such as dendritic cells and macrophages in response to a number of microorganisms and microbial products, including lipopolysaccharide, lipoarabinomannan, and bacterial superantigens (Trinchieri, 1998). It can also be secreted upon stimulation by T cells in a CD154-CD40-dependent and IFN- $\gamma$ -dependent manner. The stimulation of whole blood by live BCG was shown to trigger the IL-12/IFN- $\gamma$  axis by an IRAK-4 and NEMO-dependent, noncognate interaction among monocytes and natural killer (NK) cells and T lymphocytes (Feinberg et al., 2004). It promotes cell-mediated immunity to intracellular pathogens by inducing the production of IFN- $\gamma$  by both T and NK cells. The IL-12 receptor complex, expressed on activated T and NK cells, consists of two subunits known as the  $\beta$ 1 and  $\beta$ 2 subunits. Binding of IL-12 to the heterodimeric IL-12 receptor complex induces the phosphorylation of tyrosine kinase 2 (Tyk2) and JAK2 and subsequent activation of STAT4, which dimerises and translocates to the nucleus to activate IL-12-inducible genes. The IL-12R $\beta$ 1 subunit is also part of the IL-23 receptor. Figure 28.2 shows the cytokine interactions between the macrophage and T or NK cell in the context of mycobacterial infection, illustrating the interaction between IL-12 and IFN- $\gamma$ .

### Mutation Analysis

Mutations in *IFNGR1*, *IFNGR2*, *STAT1*, *IL12B*, and *IL12RB1* can be detected by single-strand conformation polymorphism (SSCP) and/or direct sequencing (Fig. 28.1). Primers to amplify and sequence all exons and flanking intron regions have been published and are available upon request.

### Strategies for Diagnosis

#### Clinical Diagnosis

Inherited defects of the IL-12-IFN- $\gamma$  axis may be considered in the differential diagnosis of all patients presenting with severe

infection (including disseminated and recurrent diseases) with intracellular microorganisms, particularly when the organism is considered to be nonpathogenic in the “immunocompetent” individual. However, these defects should be sought aggressively in patients with severe nontuberculous mycobacterial or salmonella infections. Furthermore, a high index of suspicion is warranted in patients presenting with chronic fever, wasting, hepatosplenomegaly lymphadenopathy, and anemia in whom a pathogen is not isolated, as cultures may be persistently negative (Levin et al., 1995; Pierre-Audigier et al., 1997). Diagnosis may also be confounded by the lack of usually diagnostic granulomata, in which microbes may or may not be visible. An initial diagnosis of histiocytosis X has occasionally been made, hence MSMD should be considered in chemotherapy-resistant children with a tentative diagnosis of histiocytosis without formal histological criteria (Edgar et al., 2001). In many individuals, MSMD becomes apparent following BCG vaccination, thus vaccination history is essential. Because of the high incidence of parental consanguinity and affected relatives, family history is important. Specific attention must be directed at possible parental relatedness. Defects in the IL-12–IFN- $\gamma$  axis should not only be sought in patients with disseminated or recurrent BCG/EM disease but also considered in patients with acute local BCG/EM, severe tuberculosis, severe histoplasmosis, listeriosis, and severe viral infections. Despite the progress outlined in this chapter, our understanding of the molecular basis of MSMD is still in its relative infancy; it is likely that there are many aspects of the disease that are yet to be unraveled. It is therefore prudent to consider the disorder in those diagnostic conundrums in which infectious, malignant, or inflammatory diagnoses are entertained.

### Laboratory Diagnosis

In vitro testing is based on (1) circulating IFN- $\gamma$  levels, (2) protein expression (FACS, ELISA), (3) functional studies, and (4) DNA analysis.

Measurement of circulating IFN- $\gamma$  in either plasma or serum is a simple means of differentiating patients with complete IFN- $\gamma$ R deficiency from those with other MSMD mutations (Fieschi et al., 2001). These children have high levels of plasma IFN- $\gamma$ , whereas IFN- $\gamma$  is low or undetectable in plasma taken from healthy controls or from MSMD patients with IL-12p40 or IL-12R $\beta$ 1 receptor deficiency or partial IFN $\gamma$ R1 or 2 deficiency. These high levels are thought to be due to sustained production of IFN- $\gamma$  in the most severe form of MSMD and/or the requirement for an intact IFN- $\gamma$ R for ligation and removal of IFN- $\gamma$  from the circulation. This observation provides a simple diagnostic assay for individuals having severe BCG/EM disease. It should be kept in mind, however, that elevated plasma or local (e.g., pleural tuberculosis) IFN- $\gamma$  levels may also be seen in normal hosts with tuberculosis.

The IFN- $\gamma$ R is expressed ubiquitously on all nucleated cells, whereas the IL-12 receptor is found only on NK and T cells. Analysis of Epstein-Barr virus (EBV)-induced B lymphoblasts, SV-40 fibroblasts, or peripheral blood mononuclear cells (PBMC) for IFN- $\gamma$ R cell surface expression by fluorescence-activated cell sorting (FACS) is a simple means to assess the presence or absence of these receptors, as demonstrated for the first reported cases of complete IFN- $\gamma$ R1 deficiency (Jouanguy et al., 1996; Newport et al., 1996). Mutations causing the dominant form of IFN- $\gamma$ R1 deficiency abrogate the receptor recycling motif leading to high levels of cell surface IFN- $\gamma$ R1 expression (up to 10-fold), which is easily detectable by FACS staining (Jouanguy et al., 1999b; Villela et al., 2001; Sasaki et al., 2002). Normal expression

of IFN $\gamma$ -R1, as detected by FACS, even using blocking antibodies, does not exclude partial or even complete IFN $\gamma$ -R1 deficiency from mutations that result in the surface expression of an abnormal protein (Jouanguy et al., 1997, 2000). Antibodies that recognize low levels of IFN- $\gamma$ R2 present on resting cells are not yet adapted to routine laboratory use. Antibodies that recognize IL-12R $\beta$ 1 work well on phytohemagglutinin (PHA) blasts and allow a diagnosis of IL-12R $\beta$ 1 deficiency. To date, all *IL12RB1* mutations identified cause a loss of expression of the encoded chain. Staining of *Herpesvirus saimiri*-transformed T cell lines also works well; this is not the case for other cell lines such as EBV-transformed B lymphoblasts and SV40-transformed fibroblasts. Secreted IL-12p40 and p70 can be detected by ELISA in the supernatant of PBMC stimulated by BCG or in the supernatant of EBV-transformed B lymphoblasts stimulated with phorbol 12,13-dibutyrate (PDBu). To date, all *IL12B* mutations identified have been associated with a lack of detectable IL-12p40 and IL-12p70. However, prolonged stimulation of IL-12R $\beta$ 1 deficient T cell lines appears to rescue some degree of IL-12 responsiveness (Verhagen et al., 2000).

Expression of IFN- $\gamma$ R or IL-12R does not imply function, and therefore other in vitro assays are required to identify which component(s) of the IL-12/IFN- $\gamma$  pathway are defective. Upon binding to its receptor, IFN- $\gamma$  induces pleiotropic effects, including the up-regulation of major histocompatibility complex (MHC) class II expression and TNF- $\alpha$  production by monocytes. These effects are mediated by the binding of phosphorylated STAT1 to gamma-activating-sequences (GAS) in gamma-responsive genes. Thus IFN- $\gamma$ R deficiency may be diagnosed functionally by studying in vitro responses to IFN- $\gamma$ . A simple whole-blood assay was used to demonstrate defective responses to IFN- $\gamma$  in the Maltese kindred (Levin et al., 1995), and this technique was modified to study PBMC responses in a patient with partial IFN- $\gamma$ R1 deficiency (Jouanguy et al., 1997). MHC class II expression is easily studied by flow cytometry (Altare et al., 1998b), whereas phosphorylation and nuclear translocation of STAT1 in response to IFN- $\gamma$  can be assessed using electrophoretic mobility shift assays (Bach et al., 1997; Dupuis et al., 2001) or, more simply, by flow cytometry with a STAT1-specific monoclonal antibody (Fleischer et al., 1999). Cellular responses to IFN- $\gamma$  should be tested at low and high concentrations of IFN- $\gamma$  to differentiate between partial and complete receptor deficiency. In vitro studies in patients with IL-12p40 deficiency show defective IFN- $\gamma$  production by PBMC or whole blood following stimulation with BCG. This defect was restored by the addition of recombinant IL-12 to the culture medium. IL-12R $\beta$ 1-deficient patients also have diminished mitogen-induced IFN- $\gamma$  production, but IL-12 p70 production in response to lipopolysaccharide (LPS), tuberculin, or mycobacteria is normal. A flow-cytometric assay that detects phosphorylated STAT4 has also been developed (Uzel et al., 2001). Notably, children with complete IFN- $\gamma$ R deficiency have low in vitro production of IFN- $\gamma$  because of impaired production of IL-12 (Holland et al., 1998).

With the exception of the dominant *IFNGR1* hot-spot mutations and the two *IL12B* mutations (founder effects), every MSMD family has a unique mutation. It is therefore not cost-effective to set up mutation screening assays looking for known mutations. A combination of in vitro phenotyping (expression and functional studies) and direct gene sequencing is recommended. Once the causative mutation has been established in a family, other family members can be screened directly for the mutation. Accurate molecular diagnosis by biochemical, functional, and genetic studies is of the utmost importance for predicting clinical outcome and guiding the treatment of patients.

### Genetic Counseling and Prenatal Diagnosis

Defects in the IL-12-IFN- $\gamma$  pathway may be inherited either as dominant or recessive disorders, depending on the mutation. All mutations reported in *IFNGR2*, *IL12RB1*, and *IL12B* are recessive: many patients are homozygous for recessive mutations, reflecting the high frequency of parental consanguinity within this group of patients. *IFNGR1* mutations were initially identified as homozygous recessively inherited, but dominant mutations have subsequently been identified as well. Compound heterozygotes have also been identified. The *STAT1* mutation identified in three individuals to date is dominant. Finally, X-linked recessive inheritance has been suggested in one kindred, although the molecular basis of increased susceptibility to EM in this family has yet to be established (Holland et al., 1994; Frucht and Holland, 1996; Frucht et al., 1999).

Given the heterogeneity of this syndrome, coupled with its rarity, carrier detection or screening is not currently feasible. In one family with recessive IFN- $\gamma$ R1 deficiency, heterozygous carriers had an intermediate cellular phenotype in vitro (Levin et al., 1995; Newport et al., 1996), although this may have been dependent on the assay used. To date, there is no clinical phenotype associated with heterozygosity for any of the recessive alleles. Once the molecular basis is known within a family, it is simplest to screen other members by directly sequencing their DNA. Counseling within families where the mutation is known is straightforward in terms of the risk of inheriting a "susceptible" genotype (25% risk of an affected child if recessive, 50% risk of an affected child if dominant inheritance). However, any discussion must also take into account the following: (1) the clinical phenotype depends on the gene affected and whether the mutation leads to complete or partial protein deficiency; (2) development of disease is dependent on pathogen exposure; and (3) there are individuals who have inherited a susceptible genotype without developing disease, presumably thanks to the impact of modifier genes that result in residual antimycobacterial immune function. To date, there are no known individuals with complete IFN- $\gamma$ R1, IFN- $\gamma$ R2, or STAT1 deficiency who have not been clinically affected. Complete IFN- $\gamma$ R1 or IFN- $\gamma$ R2 deficiency is the most severe phenotype and is frequently lethal despite the use of antibiotics. BCG vaccination must be withheld from potentially affected children until IFN- $\gamma$ R status is clarified. Bone marrow transplantation (BMT) has proved very difficult and less successful than would be anticipated (see below), perhaps because transplantation has typically been attempted after disseminated mycobacterial disease occurred.

Once a molecular diagnosis has been established, prenatal diagnosis can be offered to affected families with severe disease—i.e., complete IFN- $\gamma$ R deficiency. The role of prenatal diagnosis for other mutations is less obvious as the phenotype is less severe, disease is preventable, and many individuals carrying mutations are disease-free.

### Treatment and Prognosis

The treatment of defects in the IL-12-IFN- $\gamma$  axis should be tailored to the individual patient according to their mutation, the clinical pattern of disease, and the pathogens involved (Holland, 2000b). Established infection should be treated with appropriate antimicrobial drugs as determined by the genus and species. Thus microbiological isolation and characterization of the causative pathogen at an early stage are desirable. The role for in vitro susceptibilities in directing treatment of EM is still unproven and poorly defined. EM are notoriously resistant to a number of

antimicrobials. Cytokine therapy has helped clear mycobacterial infection in patients with full or partial function of the IFN- $\gamma$  receptor (Holland et al., 1994; Holland, 2000a). Patients with IL-12B (IL-12p40) or IL-12R $\beta$ 1 deficiency or partial IFN- $\gamma$ R deficiency respond well to IFN- $\gamma$  treatment. However, intestinal, mesenteric, and splenic infections can be resistant to antibiotics and IFN- $\gamma$ . Splenectomy was helpful in two children with splenic sequestration (IFN- $\gamma$  induced in one child); on occasion abdominal lymph node resection may be indicated (Kaufman et al., 1998; J.-L. Casanova, unpublished report). Overall, patients with partial IFN- $\gamma$ R/STAT1 deficiency or complete IL-12R $\beta$ 1 deficiency can achieve prolonged clinical remission after antibiotics and IFN- $\gamma$  are discontinued. Relapses may occur years after the initial episode. Treatment with antibiotics and IFN- $\gamma$  should be prolonged, even after clinical remission is obtained.

In contrast, children with complete IFN- $\gamma$ R deficiency achieve full clinical remission less often and mycobacterial infections often relapse weeks to months after antibiotics are discontinued. Therefore, successful antibiotic therapy should not be discontinued. Because of the lack of specific receptors, IFN- $\gamma$  therapy is not indicated. The role for other cytokines such as IFN- $\alpha$ , granulocyte-macrophage colony-stimulating factor (GM-CSF), or IL-12 is undefined. The only curative treatment available for patients with complete IFN- $\gamma$ R deficiency is BMT (Reuter et al., 2002). An international survey identified eight unrelated patients with complete IFN- $\gamma$ R1 deficiency who underwent BMT (Roesler et al., 2004). The results were disappointing; BMT in complete IFN- $\gamma$ R1 deficiency is associated with high morbidity and mortality. The only child receiving a human leukocyte antigen (HLA)-haploidentical transplant died after the second transplant (HLA identical) of EBV-induced lymphoproliferative disease. Of the seven patients transplanted with an HLA-identical intrafamilial graft, despite an initial full engraftment in most cases four are alive, but only two have a functional graft and are free of infection. There appears to be a selective advantage of IFN- $\gamma$ R-deficient over wild-type hemopoietic progenitors in IFN- $\gamma$ R-deficient children (which makes gene therapy for patients with IFN- $\gamma$ R deficiency challenging). Moreover, chronic EM/MAC infection before and during stem cell transplantation carries an unfavorable outcome. Prevention of infection is desirable, although many pathogens to which these individuals are susceptible are ubiquitous in the environment. BCG should be avoided and mycobacterial infection (both primary and secondary) may be prevented by the use of a macrolide such as clarithromycin or azithromycin. In patients with mild MSMD, prophylactic antibiotics are not absolutely required, as infectious episodes are relatively infrequent and can be controlled by IFN- $\gamma$  and antibiotics if treated promptly. However, physicians and patients should weigh carefully the risks and benefits of recurrence of infection, especially if it recurs in bone, as is often the case with the dominant form of IFN- $\gamma$ R1 deficiency. In these patients recurrence of infection can have serious consequences, despite curative therapy.

In patients with complete IFN- $\gamma$ R deficiency, antibiotics should be continued indefinitely after therapy for acute infections. There is considerable diversity of pathogenic EM (particularly rapidly growing species), making absolute recommendations difficult. Most EM are susceptible to macrolides, and these should be strongly considered for long-term prophylaxis regardless of cure of other acute infections. Immunosuppressive agents such as corticosteroids should be avoided as a rule, particularly in children with complete IFN- $\gamma$ R deficiency, although in some circumstances they may be helpful. Children with MSMD should be treated on an individual basis, and treatment should be undertaken in close collaboration with a center specialized in the care of such patients.

### Animal Models

The study of gene-disrupted mice has greatly enhanced our understanding of the IL-12–IFN- $\gamma$  pathway. Although not completely concordant, the phenotypic similarities between these animal models and patients with mutations in this axis are striking (Jouanguy et al., 1999a). Mice lacking *Ifngr1* are highly susceptible to BCG infection, with poorly defined granuloma formation and death (Kamijo et al., 1993). Mice lacking Ifn- $\gamma$  also fail to control BCG, *M. avium*, or *M. tuberculosis* growth (Cooper et al., 1993; Dalton et al., 1993). More recently, *Ifngr2* knockout mice were shown to have defective Ifn- $\gamma$  production and susceptibility to *L. monocytogenes* infection (Lu et al., 1998). *IL12b* (il-12p40) knockout mice are more susceptible to *M. tuberculosis* infection than normal mice, leading to higher bacterial loads and disseminated disease (Cooper et al., 1997). Granulomata were poorly formed and multibacillary. *IL12rb1* knockout mice have defective Ifn- $\gamma$  responses to mitogens and LPS (Wu et al., 1997). Disruption of *Ifng* in mice also leads to lethal infection with an attenuated strain of *S. typhimurium*, whereas wild-type mice clear infection within 4 weeks (Hess et al., 1996; Bao et al., 2000). However, comparisons between mice and humans are limited in several ways: most of the infections in MSMD patients are naturally occurring, whereas those in mice are experimental and often administered intravenously, and the strain and dose of pathogen are controlled. There are certain infections, such as *Toxoplasma gondii* and *Cryptococcus neoformans*, to which *Ifng*/IL-12 knockout mice have increased susceptibility that have not been observed in humans (Decken et al., 1998; Yap et al., 2000). This may reflect lack of exposure, experimental design, or the fact that knockout mice are generated in highly inbred strains. Genetic variation at other immunity-modifying loci is low in inbred mice whereas humans are outbred, even in the setting of consanguinity. Experimental infections in mice probably highlight even minor effects of the IL-12–Ifn- $\gamma$  axis. Alternatively, mice and humans may differ in their handling of some of these nonmycobacterial infections.

### Concluding Remarks and Future Challenges

Mutations in five genes involved in the IL-12–IFN- $\gamma$  axis have been associated with the syndrome of MSMD, which encompasses a range of clinical phenotypes. The severity of the clinical phenotype depends primarily on the gene involved and the specific mutation. IFN- $\gamma$ -mediated immunity appears to be a genetically controlled quantitative trait that determines the outcome of mycobacterial invasion (Dupuis et al., 2000). IFN- $\gamma$  immunity to mycobacteria is dependent on IL-12 stimulation, and mediated by STAT1 and its homodimeric complex GAF. These defects are most pronounced with respect to mycobacteria and, to a lesser extent, salmonella and viruses. (Casanova and Abel, 2002). The investigation of more patients is necessary to broaden our knowledge of these genotype–phenotype correlations. Clinically, molecular diagnosis guides rational treatment based on pathophysiology.

#### Are There Other MSMD Genes?

There remain patients with the clinical syndrome of MSMD who do not have mutations in *IFNGR1*, *IFNGR2*, *STAT1*, *IL12B*, or *IL12RB1* (approximately 50% at our centers, S. Holland, M. Levin, and J.-L. Casanova, unpublished results). Characterization of the molecular defects in these patients will help in the identification of other MSMD genes and contribute further to our

understanding of human mycobacterial immunity. Relevant genes upstream of IL-12 and downstream of STAT1 are expected to expand and define the limits of the IL-12–IFN- $\gamma$  axis, especially the inducer and effector mechanisms of immunity to mycobacteria.

### Definition of Clinical Boundaries of MSMD

The genetic defects of the IL-12–IFN- $\gamma$  axis were found by investigating patients with disseminated, often lethal, BCG/EM disease. Subsequently, it was found that some affected individuals have recurrent local disease, whereas others are asymptomatic. The clinical boundaries of IL-12R $\beta$ 1 deficiency (Fieschi et al., 2003) and IFN- $\gamma$ R1 deficiency (Dorman et al., 2004) were made possible thanks to international collaboration. Other international surveys are currently under way to define the clinical features of each inherited disorder on the basis of clinical history of the patients identified. The question arises as to whether patients with unexplained local BCG/EM disease may suffer from these or related genetic defects. For example, EM pneumonitis in the elderly and EM adenitis in childhood are currently unexplained. Because of these considerations, patients with various forms of BCG/EM disease need to be studied in terms of the IL-12–IFN- $\gamma$  axis to define the clinical frontiers of each genetic defect.

### Role of MSMD Genes in Susceptibility to Tuberculosis and Leprosy

It is estimated that approximately 2 billion individuals worldwide are infected with *M. tuberculosis* (Dolin et al., 1994). The World Health Organization estimates that there were 8 million new cases of tuberculosis (TB) and 1.9 million deaths from the disease in 1998. The fact that only 10% of individuals infected with *M. tuberculosis* go on to develop clinical disease suggests that exposure to virulent mycobacteria alone is not sufficient and that the host immune response is an important determinant of susceptibility (or resistance) to disease (Murray et al., 1990). Several studies demonstrate a role for host genetic factors as determinants of susceptibility to TB (Casanova and Abel, 2002, 2004). However, the identification of specific genes involved in susceptibility to infectious diseases in outbred human populations is difficult. Complex interactions among the pathogen, which also has a genome, the environment, and host factors determine whether an individual is resistant or susceptible to disease. It is likely that a number of genes are involved, but it is not known exactly how many or how they interact. Population-based studies have reported associations between candidate genes and TB, but the effects have been modest and the functional relevance of these findings is yet to be established (Newport and Levin, 1999; Wilkinson et al., 1999; Abel and Casanova, 2000; Casanova and Abel, 2002, 2004).

There is a spectrum of disease within the MSMD syndrome ranging from severe disease that is fatal in early childhood (complete IFN- $\gamma$ R deficiency) to moderate disease in individuals with partial IFN- $\gamma$ R1 deficiency (Jouanguy et al., 1997). The IL-12p40/IL-12R $\beta$ 1 mutations have a less severe clinical course. Mutations in *IL12RB1* and *IL12B* have been identified as a susceptibility factor for the development of abdominal *M. tuberculosis* infection (Altare et al., 2001) and tuberculous adenitis (Picard et al., 2002). Furthermore, two families have been observed whose affected members lacked IL-12 $\beta$ 1 and suffered from disseminated tuberculosis; however, none of them had a history of clinical disease caused by BCG/EM (Caragol et al., 2003; Özbeck

et al., 2005). Disorders of the IL-12-IFN- $\gamma$  axis should thus be considered in selected children with severe tuberculosis, even in the absence of infection with poorly virulent mycobacteria or salmonella. Partial deficiency of either IL-12p40 or IL-12R $\beta$ 1 would be expected to have a less severe phenotype than complete deficiency and to show susceptibility to only the most virulent pathogens. More subtle polymorphisms in the MSMD genes identified thus far could result in impaired expression of a normal protein or normal expression of a slightly altered, less efficient protein. It is also likely that mutations or polymorphisms will be identified in other genes known to be involved in mycobacterial immunity that may play a different role and cause a different immune defect. Such individuals may retain immunity to organisms of low virulence while remaining susceptible to more virulent species.

## Ataxia-Telangiectasia

MARTIN F. LAVIN and YOSEF SHILOH

Ataxia-telangiectasia (A-T) is a complex multisystem disorder characterized by progressive neurological impairment, variable immunodeficiency, and ocular and cutaneous telangiectasia. A-T has proven a fascinating but elusive subject of investigation since its first description 80 years ago (Syllaba and Henner, 1926). Only three reports of this syndrome were made between 1926 and its establishment as a disease entity 30 years later by Boder and Sedgwick (1957). While these physicians noted absence of the thymus, A-T was not recognized as an immunodeficiency syndrome until 6 years later (Peterson et al., 1963). Recurrent sinopulmonary infections and variable degrees of immunodeficiency, both cellular and humoral, were shown to be hallmarks of this disease during the 1960s and 1970s.

An adverse response to radiotherapy was reported by several groups in the same decade (Gotoff et al., 1967; Morgan et al., 1968), and hypersensitivity to X-rays and  $\gamma$ -rays was later established for A-T cells in culture (Taylor et al., 1975; Chen et al., 1978). These observations played a dominant role in determining the research direction into the nature of the defect in this syndrome for the following 20 years.

Gatti et al. (1988) used linkage analysis to map the A-T gene to chromosome 11q22–23, and the gene was eventually identified by positional cloning by Savitsky et al. (1995a). During that 7-year period, a scarcity of suitable microsatellite markers and unavailability of more recently described gene-hunting techniques were responsible for what appeared to be an inordinately long time between mapping and cloning of the gene. The identification of the gene *ATM* (Ataxia-Telangiectasia Mutated) as a member of a family of phosphatidylinositol-3-kinase (PI3K)-related genes involved in cellular responses to DNA damage, cell cycle control, and intracellular protein transport, together with the myriad of data accumulated on cell and molecular biology studies over the

previous 20 years, provided a basis for initial understanding of the pleiotropic nature of A-T.

The disease A-T has been assigned MIM #208900 and is inherited as an autosomal recessive trait with full penetrance (Tadjoedin and Fraser, 1965; McKusik and Cross, 1966; Ferak et al., 1968). The gene *ATM* has MIM number \*607585. The disease has been reported in all races throughout the world, and, as expected from the type of inheritance, it is represented equally in males and females. The first estimate of disease prevalence was provided by Boder and Sedgwick (1970) at 1 in 40,000 live births. This estimate, derived from the number of children with A-T in schools for the physically handicapped as a proportion of the total school enrollment in the Los Angeles School District, appears to be too high. A more comprehensive case-finding study in Michigan by Swift et al. (1986) produced a maximum incidence of A-T of 1 case per 88,000 births. The incidence from studies conducted in 1970–1972 and 1980–1984 was fourfold lower, closer to 3 per  $10^6$  live births. This estimate is in good agreement with that calculated in a later study (Woods et al., 1990).

In this chapter we will provide insight into the clinical and cellular abnormalities associated with A-T, an overview of the function of the product of the *ATM* gene, the ATM protein, and our current understanding of how a defect in this function leads to the clinical manifestations. Some attention is also paid to hereditary aspects of A-T and methods of diagnosis, past and potential. Finally, we will outline some of the experimentation in human cells and animal models being used to address the pathogenesis of the disease.

### Clinical and Pathological Manifestations

In the initial report of A-T, Syllaba and Henner (1926) observed progressive choreoathetosis and ocular telangiectasia in three

**Table 29.1.** Clinical Features in Ataxia-Telangiectasia

<i>Clinical Feature</i>	<i>Cases With Feature (No.)</i>	<i>Cases With Data Available (No.)</i>	<i>Cases With Feature (%)</i>
I. Neurologic abnormalities			
Cerebellar ataxia, infantile or childhood onset	101	101	100
Diminished or absent deep reflexes	54	61	89
Flexor or equivocal plantar response	60	61	98
Negative Romberg sign	28	36	78
Intact deep and superficial sensation	51	52	98
Choreoathetosis	61	67	91
Oculomotor signs			
Apraxia of eye movements	47	56	84

members of a single family. There was a gap of some 15 years before the next report, by Louis-Bar (1941), who described progressive cerebellar ataxia and cutaneous telangiectasia in a Belgian child. The syndrome subsequently bore the name of Louis-Bar. A-T was not described as a distinct clinical entity for a further 16 years, until Boder and Sedgwick (1957) and Biemond (1957), with the aid of autopsies, reported organ developmental abnormalities, neurological manifestations, and a third major characteristic of the disease, recurrent sinopulmonary infection. Several additional reports confirmed the major manifestations of this syndrome (Wells and Sly, 1957; Centerwall and Miller, 1958; Boder and Sedgwick, 1958; Sedgwick and Boder, 1960). The main clinical features of the disease are outlined in Table 29.1 (Boder, 1985; Boder and Sedgwick, 1963).

### Cerebellar Ataxia

It is evident from the earliest reports that neurological features figure prominently in this syndrome. According to Boder (1985), A-T is stereotyped in its neurological symptomatology in contrast to the variable immunological characteristics of the disease. Ataxia, generally the presenting symptom in this syndrome, becomes evident when a child begins to walk at the end of the first year of life, manifesting ataxic gait and truncal movements. As with other major characteristics of A-T, ataxia is progressive, spreading to affect the extremities and then to speech. Eventually, involuntary movements become evident, and the child may require a wheelchair by the end of the first decade of life.

The underlying pathology appears to be primarily progressive cerebellar cortical degeneration. The neuropathological features of A-T have been comprehensively detailed in two reviews by Boder (1985) and Sedgwick and Boder (1991). Cortical cerebellar degeneration involves primarily Purkinje and granular cells, but basket cells are also affected. While degenerative changes in the brain are seen predominantly in the cerebellum, it is clear from an increasing number of autopsies that changes to the central

nervous system (CNS) in A-T are more widespread. Degenerative changes in the dentate and olivary nuclei were noted in early studies, and these observations were extended to include changes in the spinal cord and spinal ganglia, the cerebrum, the basal ganglia, and the brain stem, especially in older patients. Amromin et al. (1979) have described distinctive gliovascular abnormalities in the cerebral white matter and also in the brain stem and spinal cord. These consist of dilated capillary loops, many with fibrin thrombi, with perivascular hemorrhages and hemosiderosis, surrounded by demyelinated white matter, reactive gliosis, and numerous atypical astrocytes (Boder, 1985). These vascular changes are seldom seen in the basal ganglia or cerebral cortex and have not been reported in the cerebellum. Since they are seen only in older patients, it is unlikely that they are a primary cause of cerebellar or spinal cord degeneration.

### Telangiectasia

A second major clinical manifestation of the disease is telangiectasia. It usually has a later onset than ataxia, between 2 and 8 years of age (McFarlin et al., 1972; Boder, 1985). However, telangiectasia can be observed considerably earlier, particularly if the clinician suspects A-T, such as in children with a prior family history. Telangiectasia represents a dilation of blood vessels, primarily in the ocular sclerae, and often gives the impression of bloodshot eyes (Color Plate 29.I). The telangiectasias are not confined to the eyes but may also appear in the butterfly area of the face and as hairline telangiectasias on the ears. Patches of telangiectasia elsewhere in the skin are less common. Ocular telangiectasias may be mistaken for conjunctivitis but can be readily distinguished because they are characterized by dilated vessels against a white background, whereas in conjunctivitis the background is pink. It is not clear how the defect in an enzyme involved in intracellular cell signaling (ATM protein, see below) would give rise to telangiectasia, but it has been suggested that the blood vessel abnormality represents a progeric change, as it

mimics telangiectasias in normal aged individuals (Boder, 1985). The occurrence of telangiectasias in tissue of normal individuals undergoing radiotherapy may also be related to the telangiectasia in A-T. A-T is characterized by hypersensitivity to radiation and to compounds capable of generating active oxygen radicals. A decreased ability to cope with endogenously generated damage from oxygen radicals may contribute to the development of telangiectasias in A-T. Indeed, there is now good evidence that A-T cells are in a state of oxidative stress (Barlow et al., 1999; Watters et al., 1999; Gatei et al., 2001a; Kamsler et al., 2001). However, telangiectasias in the eyes and on the skin might also be due to light or sun damage.

### Predisposition to Sinopulmonary Infection

The third major feature of A-T is abnormal susceptibility to infections. Recurrent infections have been described in up to 80% of patients in some studies (Waldmann, 1982). Increased infections become evident by the age of 3, and the major sites are sinopulmonary (Centerwall and Miller, 1958; Andrews et al., 1960; McFarlin et al., 1972). These include otitis and sinusitis as well as recurrent pneumonia, which may progress to bronchiectasis and pulmonary fibrosis severe enough to cause clubbing of fingers and toes, and, eventually, to respiratory insufficiency and death (Sedgwick and Boder, 1991). Boder and Sedgwick (1963) have reported frequent respiratory infections in 83% of cases and chronic bronchitis with or without bronchiectasis in 52% of cases. Patients with A-T are particularly susceptible to common bacterial pathogens and viruses, but do not appear to be subject to generalized or persistent fungal or protozoan infections (Peterson and Good, 1968; McFarlin et al., 1972).

McFarlin et al. (1972) demonstrated a correlation between the severity of the respiratory infections and reduced immune responses. The observation of Boder and Sedgwick (1957) that the thymus is absent or poorly developed in A-T, together with reports of hypogammaglobulinemia (Williams et al., 1960; Gutmann and Lemli, 1963), suggested a basis for the predisposition to infection. It is now obvious that there is a more generalized defect in multiple aspects of the immune response in A-T patients (Waldmann, 1982).

### Cancer Predisposition

The fourth of the major hallmarks of A-T is the predisposition to develop a range of lymphoid malignancies (Boder and Sedgwick, 1963). The association between a defective thymus, immunodeficiency, and the high frequency of lymphoid malignancy became evident early (Peterson et al., 1964a; Leveque et al., 1966; Miller, 1967). Chromosome instability as an explanation for the increased incidence of malignancy was suggested by the observation that leukemic cells from an A-T patient had a translocation involving chromosomes 12 and 14 (Hecht et al., 1966). Regular monitoring of this patient revealed a progressive increase in translocation-bearing, abnormal lymphocytes to 78% of the total lymphocytes before the patient succumbed to infection (Hecht et al., 1973). However, while translocations involving chromosome 14 have been associated with malignancy in Burkitt's lymphoma (Klein, 1981), patients with A-T but with no signs of leukemia or lymphoma may have clonal expansion of cells with chromosome 14/14 translocations to as much as 80% of the total lymphocytes (Al Saadi et al., 1980; Beatty et al., 1986).

Lymphoid malignancies in A-T are of both B cell and T cell origin and include non-Hodgkin lymphoma, Hodgkin lymphoma,

and several forms of leukemia (Spector et al., 1982; Hecht and Hecht, 1990). At autopsy, non-Hodgkin lymphoma accounted for approximately 40% of neoplasms detected, leukemias about 20%, and Hodgkin lymphomas 10%. The increased frequency of lymphoid tumors in A-T could be accounted for by a defect in immune surveillance as part of the underlying immunodeficiency; but the picture is more complex, as malignancies are not confined to the lymphoid system. In an analysis of 108 A-T patients with 119 neoplasms, Hecht and Hecht (1990) reported that 31 of these (26%) were solid tumors varying in type and location. Determination of subsequent risk in A-T patients diagnosed with one type of neoplasm revealed that approximately 25% of patients with solid tumors subsequently developed non-Hodgkin lymphoma or leukemia. A very low risk of subsequent neoplasms existed when the first tumor was lymphoid in origin. In a retrospective study in the United States, mortality from all causes in A-T was 50-fold and 147-fold higher for white and black A-T patients, respectively, than expected, based on overall U.S. mortality rates (Morrell et al., 1986). Among 263 A-T patients there were 52 primary cancers—a 61-fold cancer excess for white probands and a 184-fold excess for black probands. Morrell et al. (1986) also found that the cancer excess was most pronounced for lymphoma, with 252-fold and 750-fold excesses observed for whites and blacks, respectively. As a cause of death in A-T, neoplasia is the second-most frequent after pulmonary disease. Of 62 complete autopsy reports (Sedgwick and Boder, 1991), 29 deaths (47%) were caused by pulmonary complications, 14 (22%) by malignancy, and 16 (26%) by a combination of both. The lifetime cancer risk among A-T patients has been estimated to be between 10% and 38% (Spector et al., 1982; Morrell et al., 1990).

### Immunodeficiency

A-T is a highly variable primary immunodeficiency involving both cellular and humoral immunity (Peterson et al., 1963; McFarlin et al., 1972). Some patients have a history of chronic sinopulmonary infections, others have repeated infections, and yet another group shows no higher incidence of infections than their unaffected siblings (McFarlin et al., 1972). The major sites of infection are the upper and lower respiratory system, including the nasal sinuses and the middle ear. In the more persistent cases, progressive destructive changes in the lung, such as bronchiectasis, are common and eventually lead to fatal respiratory failure.

#### Humoral immunity

The presence of hypogammaglobulinemia has been equated with the high frequency of infections in A-T (Centerwall and Miller, 1958; Andrews et al., 1960; Williams et al., 1960; Gutmann and Lemli, 1963). The first insight into the nature of the immune defect was provided by Thieffry et al. (1961), who showed that IgA was absent in a number of patients with A-T. It was subsequently found that up to 80 of patients had low or absent IgA (Epstein et al., 1966; McFarlin et al., 1972; Boder, 1975). IgE deficiency has been reported in approximately the same frequency (Ammann et al., 1969; McFarlin et al., 1972). In a smaller percentage of patients, IgG, especially IgG2, is reduced. The presence of low-molecular weight IgM has also been reported in up to 80% of patients (Stobo and Tomasi, 1967; McFarlin et al., 1972). The disturbances in immunoglobulin levels in A-T are not due to reduced B cell numbers but appear to result from a defect in B cell differentiation (Lawton et al., 1972; Gail-Peczaska et al., 1973). A spectrum of responsiveness to bacterial antigens, from normal

to severely reduced, is observed among A-T patients (McFarlin et al., 1972; Sedgwick and Boder, 1972). On the other hand, natural antibody and antibody responses to challenges with viral antigens are dramatically depressed compared to those of controls (Waldmann, 1982). Circulating autoimmune antibodies against immunoglobulin, muscle, and mitochondria are seen in A-T patients (Ammann and Hong, 1971). The deficiency in IgA and IgE is due primarily to a reduced rate of synthesis, but autoimmune antibodies against these molecules may increase their destruction rates (Strober et al., 1968; Waldmann, 1982). The defect in humoral immunity in A-T is best explained by either an intrinsic defect in the maturation of B cells into IgA and IgE plasma cells or by reduced T cell helper activity or both. Since two of the chromosomes that contain the immunoglobulin and T cell receptor genes, chromosomes 7 and 14, show frequent breaks, rearrangements, and translocations in lymphocytes from A-T patients, it has been suggested that the defect may also be due to disorders in gene regulation or in the recombination mechanisms required to generate mature T and B cell receptor genes (Hecht et al., 1973; Cohen et al., 1975; Taylor et al., 1976).

### Cellular immunity

Faulty development of the thymus is very characteristic of A-T (Fireman et al., 1964; Peterson et al., 1964b; McFarlin et al., 1972). The thymus often cannot be identified grossly at autopsy, but only recognized microscopically as a scattered collection of thymic reticular elements with a marked paucity of thymocytes and absence of Hassell's corpuscles and corticomedullary demarcations. These abnormalities reflect a developmental defect rather than atrophy of the thymus (Peterson et al., 1964b). Approximately one-third of patients display unequivocal lymphocytopenia, but this is usually mild in degree. Roifman and Gelfand (1985) described severe and persistent lymphopenia in 1 patient and moderate lymphopenia in 5 others out of a total of 25 patients studied. The proportion of lymphocytes bearing T cell markers is reduced, and cells with receptors for IgM are also diminished in number (Waldmann, 1982). The *in vivo* and *in vitro* functional activity of T cells is variable; but when considered as a group, A-T patients are deficient in their responses (McFarlin et al., 1972). Variability is also evident in responses to skin test antigens such as mumps, tuberculin purified protein derivative (PPD), and dinitrochlorobenzene (Fireman et al., 1964; Epstein et al., 1966; McFarlin et al., 1972). Delayed rejection of a skin graft from a donor differing in human leukocyte antigen (HLA) type has been described in up to 80% of A-T patients (Waldmann, 1982). The poor *in vivo* immune responses of A-T patients are reflected in their depressed *in vitro* lymphocyte proliferation to several mitogens. McFarlin et al. (1972) reported reduced responses to phyto-hemagglutinin (PHA) in 80% and to pokeweed mitogen in 70% of patients. Because of the variability in responses to mitogens even in the same individual, McFarlin et al. (1972) suggested that a plasma inhibitor could be dampening the response. An alternative explanation for the defective blastogenesis was provided by O'Connor and Scott-Linthicum (1980), who demonstrated that bound PHA could be efficiently internalized by A-T lymphocytes, but that a defect existed at the level of intracellular signaling. This explanation was quite prophetic, now that we know the identity of the gene product defective in A-T.

Disruption of the *Atm* gene in mice gives rise to a phenotype that largely reflects that seen in the human disease (Barlow et al., 1996; Elson et al., 1996; Xu et al., 1996). Immune defects observed in *Atm*<sup>-/-</sup> mice include a smaller size of lymphoid tissues,

a reduction of CD4 and CD8 single-positive T lymphocytes, an increase in premature double-positive mature T lymphocytes, greatly reduced peripheral T cells, and defective T cell responses. There is evidence that a productively rearranged TCR  $\beta$ -chain gene is required for thymocyte proliferation and TCR $\alpha\beta$  rearrangement for the transition of double-positive to single-positive T cells (Shinaki et al., 1993; von Boehmer, 1994). Since *Atm*<sup>-/-</sup> mice were defective in both processes, Chao et al. (2000) introduced a functional TCR $\alpha\beta$  transgene into these mutant mice to delineate the basis of the T cell developmental defect. This approach led to the rescue of defective T cell differentiation and partial rescue of thymus hypoplasia, indicating that positive selection of thymocytes is normal in *Atm*<sup>-/-</sup> mice (Chao et al., 2000). However, normal T cell-independent antibody responses suggested that B cells are functionally normal in *Atm*<sup>-/-</sup> mice. The overall conclusion was that the defective T cell-dependent immune response in *Atm*<sup>-/-</sup> mice must be secondary to reduced T cell numbers. It is also of interest that when quiescent mature T cells are exposed to DNA intercalating agents they readily undergo apoptosis in an *Atm*-dependent manner (Bhandoola et al., 2000). Immature thymocytes, by contrast, are resistant to apoptosis induced by this DNA damage signaling pathway, even though double-strand breaks (DSBs) are present in DNA. This resistance may be due to down-regulation of this pathway in immature cells, consistent with the observation that freshly prepared peripheral blood mononuclear cells from humans have low levels of ATM protein and a low basal level of ATM kinase (Fukao et al., 1999).

The availability of monoclonal antibodies specific for cell surface markers together with flow cytometry has allowed for the identification of subpopulations of T cells. With this information it was shown that the CD4/CD8 ratio in A-T patients is reversed compared to controls because of a decrease in the total number of CD4 T cells (Fiorilli et al., 1983). Furthermore, A-T patients have a relative increase in T cells bearing  $\gamma/\delta$  antigen receptors compared to those with  $\alpha/\beta$  receptors, unlike T cell populations in most other immunodeficiency syndromes. Carbonari et al. (1990) suggested that a defect in recombination may explain the defects in both T cell and B cell differentiation. Such a defect could also account for the high incidence of chromosomal rearrangements involving primarily chromosomes 7 and 14 (Aurias et al., 1980). Four common sites of chromosome breakage have been described in A-T patients: 7p14, 7q35, 14q11.2, and 14q32. The T cell receptor genes and the Ig heavy-chain genes map to these sites (Hedrick et al., 1984; Sim et al., 1984). Thus, a defect in DNA recombination could explain the immunodeficiency, the hypersensitivity to radiation, and the lymphoid malignancies seen in A-T. In support of this concept, Meyn et al. (1993) demonstrated spontaneous intrachromosomal recombination rates 30–200 times higher in A-T fibroblasts than in fibroblasts from controls. However, extrachromosomal test DNA substrates were recombined in normal fashion in A-T fibroblasts. Hsieh et al. (1993), also using extrachromosomal DNA substrates to analyze V(D)J recombination, failed to observe abnormalities in the signal and coding joint formation in an A-T complementation group D cell line. Taken together, these studies suggest that a defect in intrachromosomal recombination could contribute to genetic instability and predispose to cancer as well as cellular immunodeficiency in A-T.

### Phenotypic Heterogeneity

Phenotypic heterogeneity has long been recognized in both the laboratory and clinical features of A-T. Susceptibility to pulmonary infection, presence and degree of mental retardation, and

**Table 29.2.** Comparison of Ataxia-Telangiectasia, Nijmegen Breakage Syndrome, and Ataxia-Telangiectasia-Like Disorder

<i>Ataxia Telangiectasia</i>	<i>A-TLD</i>	<i>Nijmegen Breakage Syndrome</i>

Genomic instability	Genomic instability	Genomic instability
Cancer predisposition	?	Cancer predisposition

A-TLD, ataxia-telangiectasia-like disorder; DSB, double-strand break.

predisposition to leukemia were used as a tentative classification of subgroups (Hecht and Kaiser-McCaw, 1982). Cellular biology techniques pointed in the early 1980s to a possible genetic heterogeneity underlying this phenotypic variability, with the description of four cellular complementation groups (Jaspers and Bootsma, 1982; Murnane and Painter, 1982; Chen et al., 1984). However, the identification of a single gene, *ATM*, which is mutated in A-T patients (Savitsky et al., 1995a), made it clear that all complementation groups with a classical A-T phenotype represented mutations in the same gene.

Two separate genetic disorders resulting from defects in a DNA damage response pathway that is functionally linked to ATM share phenotypic features with classical A-T. The first, Nijmegen breakage syndrome (NBS) (see Chapter 30 and Table 29.2), shares the radiosensitivity, immunodeficiency, and cancer predisposition of A-T; but unlike A-T, NBS involves microcephaly with various degrees of mental deficiency, and patients do not have ataxia or telangiectasias (Jaspers et al., 1988a, 1988b; Curry et al., 1989; Digweed et al., 1999; Digweed and Sperling, 2004). As discussed in more detail in Chapter 30, the link between A-T and NBS became more clear with the identification of NBS1 (nibrin), the product of the gene defective in NBS that is functionally linked to ATM (Carney et al., 1998; Matsuura et al., 1998; Varon et al., 1998).

The second disease, A-T-like disorder (ATLD), was first described by Taylor et al. (1993) in a family in which two first cousins presented with some of the features of A-T. The gene defect in this family did not map to the chromosomal location for A-T (11q23), and the clinical course of the disease was mild. Unlike classical A-T patients, these cousins were still ambulatory in their third decade of life. Both had progressive unsteadiness in walking, dysarthria, drooling, vertical nystagmus, and intention tremors, all characteristic of A-T, but there was no evidence of telangiectasia, and immunoglobulin and  $\alpha$ -fetoprotein (AFP) levels were normal. Stewart et al. (1999) identified the gene responsible for ATLD as *MRE11* that encodes the Mre11 protein, which is part of the hMre11/hRad50/Nbs1 complex that senses DSBs in DNA (Nelms et al. 1998; Stracker et al., 2004). The *MRE11* gene locus is near the *ATM* locus on human chromosome 11q21, and only detailed linkage analysis allows separation of these loci, necessitating analysis of the *MRE11* and *ATM* genes to distinguish between A-T and ATLD. Mutations in the

*MRE11* gene lead to many of the characteristics observed in both A-T and NBS. These results provide evidence for a common involvement of both ATM and members of the Mre11/Rad50/Nbs1 in the cellular response to DSBs in DNA. Ataxia without telangiectasia has also been reported by Aicardi et al. (1988), Maserati et al. (1988), and Chessa et al. (1992).

Even in classical A-T with ataxia and telangiectasia the onset of clinical symptoms and rate of progression are variable. Several reports describe differences in the age of presentation and rates of progression (Sedgwick and Boder, 1991; Hernandez et al., 1993). In a study of 70 A-T patients, the incidence of onset of symptoms of ataxia was 20% prior to 1 year of age, 65% before 2 years, and 85% by 4 years of age (Woods and Taylor, 1992; Taylor et al., 1993). Variability in the appearance of telangiectasias has also been reported and is evident even between affected siblings (Sedgwick and Boder, 1991). Sanal et al. (1993) have identified 30 A-T patients with variant characteristics, including severity of the ataxia, presence of telangiectasia, degree of growth retardation, mental ability, facial appearance, and immunological abnormalities.

The types and frequencies of spontaneous chromosome aberrations including translocations and inversions, largely involving chromosomes 7 and 14, are remarkably consistent in A-T patients (Taylor and Edwards, 1982). These translocations are also observed in lymphocytes from normal individuals, but at a much lower frequency. Exposure of A-T cells to ionizing radiation gives rise to increased levels of chromatid damage compared to controls (Taylor et al., 1976; Kidson et al., 1982). Comparison of lymphocytes from different A-T patients indicates that heterogeneity exists in the extent of induced damage. This is also observed when cell survival is the end point (Cox et al., 1978; Fiorilli et al., 1985; Jaspers et al., 1988b; Ziv et al., 1989). Chessa et al. (1992) designated 14 A-T patients from several studies as being intermediate in their response to ionizing radiation. In 13 of the 14 cases, there was a correlation between radiosensitivity as determined by chromosomal breakage and cell survival. On the other hand, radioresistant DNA synthesis ranged from normal to equally defective as in classical A-T, indicating that this parameter is less significant in causing the radiosensitivity in A-T. Twelve of the 14 patients in this study had definite ataxia and either frank telangiectasia or an increase in conjunctival vascularity.

In summary, there is considerable phenotypic heterogeneity in A-T. Even among classical A-T patients there is some variability in clinical symptoms. Some patients are intermediate in their radiosensitivity, and others have normal radiosensitivity. How do we explain this heterogeneity in light of the identification of the *ATM* gene? Several studies on *ATM* mutations predict that 70%–80% give rise to truncated proteins, while the remainder represent small to large in-frame deletions and missense mutations (Savitsky et al., 1995a; Byrd et al., 1996; Gilad et al., 1996a, 1996b; Telatar et al., 1996; Wright et al., 1996; Chun and Gatti, 2004; Lavin et al., 2004). Most patients are compound heterozygotes with different mutations in the two *ATM* alleles. This information has been useful in accounting for milder forms of the disease in some A-T patients. A missense mutation in *ATM* that activates a cryptic splice/donor acceptor site resulting in the insertion of 137 nucleotides of intronic sequence (5762ins137) was present in the heterozygous state in 15% of A-T patients in the United Kingdom with a milder phenotype (McConville et al., 1996). A second missense mutation 7271T-G is also associated with a mild-variant A-T phenotype (Stankovic et al., 1998). Thus, allelic diversity might explain much of the heterogeneity in clinical severity in A-T. When sufficient mutations have been mapped, it will be possible to compare genotypes with the clinical, cellular, and molecular abnormalities found in this disease.

### Other Clinical Characteristics

In addition to the major clinical hallmarks, a variety of other features characterize A-T (Table 29.1). Retardation of somatic growth was reported for about 70%, particularly evident in adolescents and older patients, whose heights were often below the third percentile. Stunting of growth may be due to the pulmonary complications, hypogonadism, and/or thymic dysplasia (Good et al., 1964; Boder, 1985). Female hypogonadism is quite common in A-T, evident at autopsy as absence or hypoplasia of the ovaries. This form of dysplasia is usually associated with infantile uterus and fallopian tubes (Boder and Sedgwick, 1957; Bowden et al., 1963). Its appearance in A-T may be due to an underlying mesenchymal abnormality (Dunn et al., 1964; Miller and Chatten, 1967). Hypogonadism is also observed in male A-T patients, but to a lesser extent than in females (Boder and Sedgwick, 1958). Puberty is delayed, there is abnormal testicular histology, and spermatogenesis is impaired (Strich, 1966; Aguilar et al., 1968).

An unusual type of diabetes mellitus has been described in patients with A-T, with marked hyperinsulinism, hyperglycemia without glycosuria or ketosis, and peripheral resistance to insulin action (Barlow et al., 1965; Schlach et al., 1970). Resistance to insulin could be explained by abnormalities in the number and affinity of insulin receptors in A-T (Bar et al., 1978). Furthermore, as discussed below, the product of the gene mutated in A-T, *ATM*, is related to phosphatidylinositol 3-kinase (Jackson and Jeggo, 1995; Lavin et al., 1995; Savitsky et al., 1995a; Zakian, 1995), an enzyme involved in signal transduction and glucose transport. Recent data demonstrate that the kinase activity of ATM is activated by insulin through a non-DNA-damage signaling pathway to phosphorylate 4E-BP1 (PHAS-I), a regulator of protein synthesis (Yang and Kastan, 2000). Thus a loss of ATM function in A-T patients could disrupt insulin signaling, thereby contributing to insulin resistance and glucose intolerance.

Mild hepatic dysfunction, as evidenced by abnormalities of serum alkaline phosphatase, serum glutamic oxalacetic transaminase (SGOT), serum glutamic pyruvic transaminase (SGPT), and lactate dehydrogenase (LDH), is also seen in A-T (McFarlin et al., 1972). Diffuse fatty infiltration of hepatic parenchymal

cells, round cell infiltration in portal regions, and parenchymal cells with nuclear swelling and vacuolation are characteristic changes. It seems likely that the hepatic dysfunction is related to the generalized metabolic changes in A-T rather than to the immunodeficiency or infection. Elevated serum levels of AFP and carcinoembryonic antigen (CEA) in A-T patients are common and thought to be indicative of some form of abnormal development in the liver (Waldmann and McIntyre, 1972; Sugimoto et al., 1978). A widespread cellular histological abnormality, nucleocytemegaly, manifested as large, bizarre, hyperchromatic nuclei (Boder and Sedgwick, 1958; Aguilar et al., 1968; Amromin et al., 1979) occurs in most organs including the central nervous system, anterior pituitary, thyroid, adrenal glands, liver, kidney, lung, heart, and thymus, in smooth muscle cells, and in capsular cells of the spinal ganglia.

## Laboratory Findings and Cellular Characteristics

### Cellular Radiosensitivity and Chromosomal Instability

A number of cellular and molecular features characterize A-T (Lavin, 1992) (Table 29.3). Frequent chromosome breakage was described four decades ago (Hecht et al., 1966; Miller, 1967). Other reports led to the classification of A-T as a chromosomal instability syndrome together with Bloom's syndrome and Fanconi's anemia (Gropp and Flatz, 1967; Hecht et al., 1973; Higurashi and Conen, 1973; Cohen et al., 1975). Clinical radiosensitivity in A-T became evident about the same time (Gotoff et al., 1967; Morgan et al., 1968; Feigin et al., 1970) as adverse reactions in patients treated with X-rays were noted (Table 29.1). This adverse response was also demonstrated in A-T cells in vitro. Higurashi and Conen (1973) reported a higher level of radiation-induced chromosomal changes in lymphocytes from A-T patients than in controls, and a greater increase in chromosomal aberrations after G2 irradiation was also demonstrated (Rary et al., 1975). Taylor et al. (1975) found that A-T fibroblasts were three to four times more sensitive to ionizing radiation than control fibroblasts. These observations were confirmed and extended by others for radiation (Paterson et al., 1976; Chen et al., 1978; Edwards and Taylor, 1981; Lehmann et al., 1982), bleomycin (Cohen and Simpson, 1982; Morris et al., 1983), and treatment with neocarzinostatin (Cohen and Simpson, 1982; Shiloh et al., 1982a, 1982b, 1983).

While A-T cells were hypersensitive to ionizing radiation and radiomimetic chemicals, early studies failed to detect a defect in DNA single-strand break repair. It became evident later that A-T cells did not have a gross defect in DNA strand break repair, but rather residual DSBs were evident in these cells up to 72 hours post-irradiation (Table 29.3). Approximately 10% of breaks remained unrepaired. A number of other cellular and molecular abnormalities have been reported in A-T cells exposed to radiation (Table 29.3). A specific DNA binding protein, induced by ionizing radiation in control cells to translocate from the cytoplasm to the nucleus, was shown to be constitutively present in the nucleus in several A-T cell lines (Singh and Lavin, 1990; Teale et al., 1992, 1993). As discussed below, specific molecular tests, including mutation analysis of *ATM*, immunoblotting to detect the ATM protein, and specific ATM kinase assays have all been added to laboratory tests for A-T.

### Cell Cycle Anomalies

Eukaryotic cells progress through the cell cycle in an ordered series of events called G1, S (DNA synthesis), G2, and M (mitosis).

**Table 29.3.** Cellular and Molecular Features of Ataxia-Telangiectasia Related to Radiation Response

<i>Characteristic</i>	<i>Assay</i>	<i>Reference</i>
Adverse clinical response to radiotherapy	Clinical assessment	Gotoff et al., 1967 Morgan et al., 1968 Feigin et al., 1970
Radiation-induced chromosome breaks	Cytogenetics	Higurashi and Conen, 1973 Rary et al., 1975
Cell death post-irradiation	Colony survival Cell viability	Taylor et al., 1975 Chen et al., 1978
Cell death with neocarzinostatin, bleomycin (radiomimetic drugs)	Colony survival Cell viability	Cohen and Simpson, 1982 Shiloh et al., 1982a, 1982b Morris et al., 1983
Residual DNA double-strand breaks	Premature chromosome condensation Pulsed-field gel electrophoresis	Cornforth and Bedford, 1985 Pandita and Hittelman, 1992 Foray et al., 1997
Abnormalities in DNA topoisomerase II	DNA unwinding	Mohamed et al., 1987 Davies et al., 1989
Covalent modification of deoxyribose phosphate in DNA	HPLC analysis	Karam et al., 1990
Constitutive presence of DNA-binding protein in nucleus	Gel retardation	Singh et al., 1990 Teale et al., 1992, 1993

Events occurring later in the cycle depend on the completion of earlier events, with control maintained through a series of checkpoints (Hoyt et al., 1991; Kastan et al., 1991; Weinert et al., 1994). Checkpoints introduce pauses to ensure the integrity of the genome by allowing for correction of episodic DNA damage or replication delays (Lukas et al., 2004). A series of yeast checkpoint null mutants have been described that lose chromosomes spontaneously and are hypersensitive to ionizing radiation (Weinert and Hartwell, 1990; Li and Murray, 1991; Al-Khodairy and Carr, 1992; Jimenez et al., 1992). These mutants fail to undergo arrest at either the G1/S or G2/M checkpoints in response to radiation damage and/or they fail to maintain the dependence of mitosis upon completion of DNA synthesis.

There are obvious parallels between the data for these yeast mutants and some of the early observations with A-T cells. However, unlike yeast, defective checkpoints do not account for the radiosensitivity in A-T cells, which is more likely due to failure to repair damage in DNA while allowing subsequent passage through the cycle. The first evidence for an abnormality in cell cycle control in A-T cells came from the observation that DNA synthesis continued after irradiation (radioresistant DNA synthesis), allowing cells to proceed through S phase unchecked (Houldsworth and Lavin, 1980; Painter and Young, 1980; de Wit et al., 1981; Edwards and Taylor, 1981). It is still not clear why A-T cells exhibit radioresistant DNA synthesis, but a defect in a signaling pathway from ATM through the checkpoint kinase Chk2 and Cdc25A phosphatase may be responsible. Falck et al. (2001) have shown that ionizing radiation exposure normally leads to the loss of Cdc25A, preventing dephosphorylation of Cdk2 kinase and producing a transient blockade in DNA replication. This blockade is defective in A-T cells, allowing DNA replication to proceed. A delay in radiation-induced phosphorylation of replication protein A, a component of the single-strand DNA binding protein complex, has also been implicated (Liu and Weaver, 1993). Furthermore, ultraviolet (UV)-induced hyperphosphorylation of RPA (p34 subunit) depends on expression of ATM (Oakley et al., 2001).

The physiologic transitory delay in DNA synthesis post-irradiation also appears to be mediated through a calmodulin-dependent regulatory cascade (Mirzayans et al., 1995), and this

pathway is defective in A-T. A reduction of radiation suppression of mitotic index in A-T fibroblasts resulted from a failure to prevent cells irradiated in G2 phase from proceeding into mitosis (Scott and Zampetti-Bosseler, 1982). This finding appeared at first to contradict evidence that A-T lymphoblastoid cells and SV40-transformed fibroblasts experienced more prolonged delay in G2/M at longer times after irradiation (Ford et al., 1984; Bates et al., 1985; Smith et al., 1985). However, it is now evident that A-T cells that are in G2 phase at the time of irradiation undergo less delay in proceeding into mitosis at short times after irradiation, but cells irradiated at other phases of the cycle proceed through to G2 phase where they are for the most part irreversibly blocked (Beamish and Lavin, 1994). A-T cells also fail to undergo normal delay in progression from G1 to S phase post-irradiation (Imray and Kidson, 1983; Nagasawa and Little, 1983). The overall picture that emerges for A-T is a failure of cell cycle checkpoints at G1/S, during DNA synthesis, and at G2/M to respond to radiation damage (Beamish and Lavin, 1994).

An understanding of the molecular defect in A-T at the level of cell cycle checkpoints was enabled by recent advances in cell cycle control in yeast and mammalian cells (Hartwell and Smith, 1985; Nurse, 1985; Lukas et al., 2004). Passage of cells through the cycle is controlled by cyclin-dependent kinases (Pines and Hunter, 1991; Xiong et al., 1991), cyclin-kinase inhibitors (El-Deiry et al., 1993; Gu et al., 1993; Harper et al., 1993), other kinases and phosphatases, and a variety of other proteins, including the retinoblastoma protein and the transcription factor E2F (Hinds et al., 1992; Hall et al., 1993). The best-described disruption of this intricate pattern of control is the inhibition of DNA synthesis and slowing of cell division in response to radiation damage (Painter, 1985; Weinert and Hartwell, 1988). Kastan et al. (1991) provided an explanation for this inhibition when they demonstrated that the normal product of the tumor suppressor gene *p53* is induced by radiation and brings about delay in the passage of cells from G1 to S phase. These investigators subsequently showed that the G1/S checkpoint in A-T cells was impaired because of a defect in the *p53* radiation signal transduction pathway at the level of *p53* (Kastan et al., 1992). Khanna and Lavin (1993) then found that the defect in *p53* induction by radiation extended to all four complementation groups of A-T, but there was normal induction

of p53 in A-T cells in response to UV damage. In addition, inhibitors of protein kinase C and serine/threonine phosphatases interfered with the pathway.

Failure to observe a correlation between absence of p53 or mutated p53 and radiosensitivity (Clarke et al., 1993; Lee and Bernstein, 1993; Lowe et al., 1993; Slichenmyer et al., 1993) suggested that the A-T gene product operates in more than one pathway affecting cell cycle control and perhaps at other levels of cellular control. Sensitivity to ionizing radiation might be explained by a defect at the level of the G2/M checkpoint, since A-T cells accumulate at this checkpoint with time after exposure to radiation (Beamish and Lavin, 1994; Hong et al., 1994). In recent years the molecular basis for the cell cycle checkpoint defects in A-T have been further elucidated. ATM-dependent stabilization and activation of p53 are of central importance to the operation of the G1/S checkpoint in response to radiation damage to DNA. Radiation induces phosphorylation, dephosphorylation, and acetylation of p53 (Meek, 2004). Some of these modifications are ATM-dependent (Banin et al., 1998; Canman et al., 1998; Saito et al., 2002). ATM is responsible for the rapid phosphorylation of human p53 at serine 15 post-irradiation, and serine 20 phosphorylation is carried out by Chk2 in an ATM-dependent manner (Chehab et al., 1999). Serine 20 phosphorylation interferes with p53's binding to its inhibitor, Mdm2, which plays a major role in its degradation. ATM also phosphorylates Mdm2 itself, to inhibit the nuclear export of the p53Mdm2 complex, thus ensuring the stabilization of p53 after irradiation (Khosravi et al., 1999; Maya et al., 2001). Thus it is evident that ATM controls G1/S checkpoint through multiple interactions.

Stabilization of p53 by radiation and other DNA-damaging agents leads to the induction of a cyclin kinase (Cdk) inhibitor, WAF1 (p21, Cip1) (El-Deiry et al., 1993; Gu et al., 1993; Harper et al., 1993; Xiong et al., 1993). WAF1 binds to cyclin E/cdk2 and cyclin A/cdk2 kinase complexes and by inhibiting their activities prevents the progress of cells from G1 to S phase (Dulic et al., 1994; Waga et al., 1994). In keeping with the defective p53 response in A-T cells, Canman et al. (1994) showed a defective induction of WAF1, and the induction of Mdm2, another downstream effector of p53, was also shown to be defective (Price and Park, 1994). Khanna et al. (1995) subsequently demonstrated that the radiation signal transduction pathway operating through p53, its target gene *WAF1*, cyclin-dependent kinases, and the retinoblastoma protein (Rb) are all defective in A-T cells. Correction of the defect at the G1/S checkpoint was observed when wild-type p53 was constitutively expressed in A-T cells (Khanna et al., 1995). As expected, the WAF1 response in irradiated control cells resulted in an inhibition of cyclin-dependent kinase activity including cyclin E/cdk2, which plays an important role in the transition from G1 to S phase. No inhibition of cyclin-dependent kinase activity was observed in A-T cells, correlating with the delayed WAF1 response. An accumulation of the hypophosphorylated form of Rb protein occurred in irradiated control cells compatible with the G1/S-phase delay observed in these cells after exposure to radiation. In unirradiated A-T cells the amount of Rb protein was much higher than that in controls, and it was mainly in the hyperphosphorylated (inactive) form.

The discovery of the *ATM* gene and its protein product suggested that there might be a common defect in cell cycle control in A-T operating through the cyclin-dependent kinases that control multiple checkpoints (Savitsky et al., 1995a). In agreement with this, Beamish et al. (1996) demonstrated that several cyclin-dependent kinases in A-T cells are not inhibited by ionizing radiation, associated with insufficient induction of WAF1. Exposure

of control lymphoblastoid cells to radiation during S and G2 caused rapid inhibition of cyclin A/cdc2 and cyclin B/cdc2 activities, respectively. Irradiation led to a 5- to 20-fold increase in cdk-associated WAF1 in these cells, accounting at least in part for the decrease in cyclin-dependent kinase activity. In contrast, radiation did not inhibit any of the cyclin-dependent kinase activities in A-T cells at short times after irradiation, nor was there any significant change in the level of cdk-associated WAF1 compared to unirradiated cells (Beamish et al., 1996). These results were similar to those reported previously for the G1 checkpoint and provided additional evidence for the involvement of ATM at multiple points in cell cycle regulation. In relation to the abnormality in S phase, Mirzayans et al. (1995) had indirect evidence that radiation-induced cessation of DNA synthesis is mediated through a calmodulin-dependent signal transduction pathway, independent of protein kinase C (PKC) and p53; in addition to the p53 pathway, this signaling system is also defective in A-T cells.

As referred to above, A-T cells exhibit radioresistant DNA synthesis and defective S-phase checkpoint activation (Houldsworth and Lavin, 1980; Painter and Young, 1980). Falck et al. (2001) provided a functional link between ATM, the checkpoint signaling kinase Chk2, and the Cdc25A phosphatase that activates the cyclin kinase Cdk2 and control of the S-phase checkpoint. Exposure of cells to radiation leads to the activation of ATM kinase, which in turn activates Chk2 to phosphorylate Cdc25A phosphatase. This leads to the degradation of Cdc25A and thus Cdk2 remains phosphorylated and inactive, giving rise to a transient block in DNA replication. In cells with absent or mutated ATM this pathway does not function, Cdc25A remains stable, and cells continue to replicate DNA in the presence of damage (radioresistant DNA synthesis).

While considerably less is known about activation of the G2/M checkpoint, maintenance of inhibitory phosphorylations on Cdc2 leads to arrest of cells in G2 (Jin et al., 1996). In response to DNA damage Cdc25C phosphatase is phosphorylated and inactivated, again in this case preventing the dephosphorylation of Cdc2 kinase, which is required for passage of cells through G2 phase (Nilsson and Hoffmann, 2000). It is not established which kinase phosphorylates Cdc25C, but both Chk1 and Chk2 can phosphorylate this protein at serine 216 in vitro (Sanchez et al., 1997; Matsuoku et al., 1998). Phosphorylation creates a binding site for 14-3-3 protein, which results in inactivation of the phosphatase (Peng et al., 1997). Since ATM phosphorylates and activates Chk2 in response to DNA damage, it is likely that this is the pathway operating to activate the G2/M checkpoint (Blasina et al., 1999; Brown et al., 1999).

To account for the defective radiation response in A-T cells, a "damage surveillance network" model has been proposed in which certain types of DNA damage trigger a signal transduction network with resulting activation of a group of pathways to promote genetic stability by temporarily arresting the cell cycle and enhancing DNA repair (Meyn et al., 1994; Meyn, 1995). It appears likely that ATM is recruited to sites of DSBs in DNA and subsequently signals via downstream substrates such as p53 and Chk2 to the cell cycle machinery to delay the passage of cells between the various phases prior to completion of DNA repair. Evidence for recruitment of ATM to DNA breaks was provided by Smith et al. (1999a), who showed that ATM binds preferentially to DNA ends in both monomeric and tetrameric forms. In addition, a combination of single-strand and sheared DNA is capable of stimulating ATM kinase activity for RPA substrate (Gately et al., 1998; Chan et al., 2000). Resistance to detergent

extraction of a fraction of the ATM pool post-irradiation, together with colocalization of this ATM with the phosphorylated form of histone H2AX and with Nbs1 foci, suggests further that ATM associates with sites of DSBs (Andegeko et al., 2001).

### The ATM Gene and A-T Mutations

The placement of an A-T locus by Gatti et al. (1988) on chromosome 11q22–23 spurred extensive positional cloning efforts (McConville et al., 1994; Rotman et al., 1994; Lange et al., 1995; Vanagaite et al., 1995), which culminated in identification of *ATM*, the gene mutated in A-T patients (Savitsky et al., 1995a, 1995b). *ATM*, occupies 150 kb of genomic DNA and encodes a large transcript of about 13 kb representing 66 exons (Savitsky et al., 1995b, 1996; Uziel et al., 1996; Platzer et al., 1997). There is no evidence of alternative splicing within the open reading frame of the *ATM* transcript. However, extensive variability has been detected in the untranslated regions (UTRs) of the transcript, creating multiple species of ATM mRNA. Several 3' UTRs are formed via polyadenylation of alternative sites, while at least 12 5' UTRs are obtained via alternative splicing of the first four exons of the gene (Savitsky et al., 1997). This complex pattern suggests that synthesis of the ATM protein might be subject to post-transcriptional regulation.

Several experiments confirmed that the deficiency of the ATM protein is indeed responsible for the A-T cellular phenotype. Thus, ectopic expression of recombinant ATM protein in A-T cells complemented various features of this phenotype (Zhang et al., 1997; Ziv et al., 1997), while down-regulation of ATM by means of antisense strategies conferred A-T features to various cell lines (Zhang et al., 1998; Uhrhammer et al., 1999; Fan et al., 2000). Furthermore, expression of ATM fragments containing the leucine zipper of this protein abrogated the S-phase checkpoint and increased the radiosensitivity of the human tumor cell line RKO (Morgan et al., 1997). Such protein fragments appear to act in a dominant-negative fashion, possibly by competing with ATM for specific interactor(s).

Extensive screening of the *ATM* transcript for mutations in A-T cells has been performed using a variety of methods (Savitsky et al., 1995a; Bryd et al., 1996; Gilad et al., 1996a, 1996b, 1998a, 1998b; McConville et al., 1996; Telatar et al., 1996; Wright et al., 1996; Concannon and Gatti, 1997; Watters et al., 1997; Broeks et al., 1998; Fukao et al., 1998; Laake et al., 1998, 2000; Sasaki et al., 1998; Sandoval et al., 1999; Teraoka et al., 1999; Becker-Catania et al., 2000; Paganini et al., 2002; Angele et al., 2003; Saviozzi et al., 2003). To date, over 400 separate mutations have been described and these have been compiled by Concannon and Gatti ([http://www.benaroyaresearch.org/investigators/concannon\\_patrick/atm.htm](http://www.benaroyaresearch.org/investigators/concannon_patrick/atm.htm)). These mutations are distributed along the length of the gene with the majority predicted to cause premature truncations (70%–80%) and others causing small deletions, in-frame deletions, and missense changes (Stankovic et al., 1998). Thus *ATM* gene mutations in patients with classical A-T are expected to inactivate the ATM protein by truncating it or by deleting large segments from it. This mutation profile points to predominance of null alleles in classical A-T. Hence, mutations with milder effects on the protein might lead to non-A-T phenotypes. Most A-T mutations are unique to single families, and the majority of patients in Europe and North America are compound heterozygotes. Interestingly, a founder effect was observed among patients of Moroccan Jewish origin, in whom one mutation is predominant (Gilad et al., 1996b). Evidence for founder mutations has also been reported for patients in Japanese (Ejima and Sasaki, 1998),

Norwegian (Laake et al., 1998) and other populations (Teletar et al., 1998).

Compared to the predominance of null alleles among patients with classical A-T, a different mutation profile is emerging in "A-T variants," which show a milder phenotype, usually with later age of onset and less pronounced radiosensitivity. These patients may have leaky splicing mutations giving rise to a mixture of normal and aberrant transcripts, small in-frame deletions, or truncations of just the last few carboxy-terminal amino acids or in the *Mre11* gene (McConville et al., 1996; Gilad et al., 1998a; Teraoka et al., 1999; Stewart et al., 2001; Saviozzi et al., 2002; Dörk et al., 2004; Eng et al., 2004; Sutton et al., 2004).

### Function of the ATM Protein

The open reading frame of *ATM* transcripts predicts a large protein of 3056 amino acids (Savitsky et al., 1995b). The predominant domain of this protein is the carboxy-terminal region of about 350 residues, which contains sequence signatures similar to those of the catalytic subunit of phosphatidylinositol 3-kinases (PI3Ks). These motifs, shared with the lipid kinases that play major roles in various signaling pathways, suggest a signaling role for ATM. They also place it within a multibranched family of large proteins with the carboxy-terminal PI3K signatures (PIK-related kinases [PIKKs]), which is represented in all eukaryotes (Abraham, 2004b). Most members of the PIKK family possess a protein kinase activity directed at serine/threonine residues. These kinases function at the top of various signaling cascades that sense specific types of stresses or stimuli related to cellular growth and are critical for the activation of cellular responses to these stimuli. Importantly, most of the PIK-related kinases are involved in sensing and responding to DNA damage and in maintaining genomic stability (Table 29.4).

The ATM ortholog in the budding yeast *Saccharomyces cerevisiae* is Tel1p, whose ectopic expression in human A-T cells partially complements their phenotype (Fritz et al., 2000). Tel1p and another PIK-related protein kinase in the budding yeast, Mec1p (see below), closely collaborate in maintaining telomere length and mediating cellular responses to DNA damage. Tel1p, which has protein kinase activity (Mallory and Petes, 2000), has been studied mainly with regard to its role in maintaining telomere length (Greenwell et al., 1995; Morrow et al., 1995; Ritchie et al., 1999). *TEL1* mutations lead to shortened telomeres, a typical characteristic of human A-T cells. Interestingly, in this function Tel1p cooperates with the double-strand breakage repair complex Mre11/Rad50p/Xrs (Ritchie and Petes, 2000), whereas in human cells ATM functionally interacts with the orthologous protein complex in the DNA damage response. The synergism between Tel1p and Mec1p in both telomere maintenance and cellular responses to DNA damage has been clearly documented in double-mutant *tel1/mec1* yeast, which are extremely sensitive to DNA damage and senesce prematurely (Greenwell et al., 1995; Vialard et al., 1998; Ritchie et al., 1999). While *tel1* mutants are not hypersensitive to DNA damaging agents, an extra copy of *TEL1* can largely complement such sensitivity in *mec1* mutants (Morrow et al., 1995).

The closest human ATM homolog is the ATR (homolog of ATM and Rad3) protein, which represents a separate branch of the PIK-related kinase family. ATR is a protein kinase that shares many substrates with ATM and acts in partial redundancy with ATM in a number of damage response pathways (Shechter et al., 2004). Recent evidence suggests that ATR and ATR-interacting protein (ATRIP) control S-phase progression in response to DNA

damage and replication fork stalling, ultimately resulting in the downstream inhibition of the S-phase kinases that function to initiate DNA replication at origins of replication (Shechter et al., 2004).

Importantly, disruption of the *ATR* gene in mice leads to early embryonic lethality before embryonic day 8.5 (Brown and Baltimore, 2000; de Klein et al., 2000). While the embryonic lethal effect of complete *ATR* deficiency is indisputable, a hypomorphic mutation (A2101G) in the human *ATR* gene was found to cause a rare form of Seckel syndrome (O'Driscoll et al., 2003) designated ATR-Seckel (Alderton et al., 2004; O'Driscoll et al., 2004). Genetically and clinically Seckel syndrome is a heterogeneous disorder characterized by severe intrauterine growth retardation, proportionate dwarfism, and microcephaly, with skeletal and brain abnormalities (OMIM # 210600) (reviewed by O'Driscoll et al., 2004). Although lymphoma has been reported in some Seckel patients, they tend not to have ataxia or immunodeficiency. Patients with Seckel syndrome display features including microcephaly and dysmorphic facies that are commonly found in other syndromes associated with impaired responses to DNA damage. Alderton et al. (2004) found that ATR-Seckel cells exhibit a range of aberrant responses to agents that cause replication stalling. They also exhibit supernumerary centrosomes in mitotic cells, demonstrating a novel role for ATR in the maintenance of centrosome stability.

Overexpression of a “kinase-dead” form of ATR gives rise to a dominant-negative effect leading to increased sensitization to

DNA damaging agents and defective cell cycle checkpoint activation (Cliby et al., 1998; Wright et al., 1998). ATR-deficient cells are hypersensitive to UV and hydroxyurea (HU), in contrast to A-T cells, in which  $\gamma$ -radiation causes hypersensitivity. Indeed, the phosphorylation of Rad17 induced by UV and HU is dependent on ATR, whereas that induced by  $\gamma$ -rays is dependent on ATM (Bao et al., 2001). Evidence has also been provided that ATR lies directly upstream from the checkpoint protein Chk1, which it activates in response to DNA replication blockage and agents that cause genotoxic stress to delay cells at the G2 checkpoint (Zhao and Piwnicka-Worms, 2001).

In contrast to ATM, whose intrinsic kinase activity is contained in a single protein molecule, ATR is constitutively complexed and dependent on an accessory protein, ATRIP (Cortez et al., 2001). ATRIP is phosphorylated by ATR, regulates ATR expression, and is essential for proper ATR activity. ATR and ATRIP both localize to intranuclear foci after DNA damage or inhibition of replication. Small, interfering RNA directed against ATRIP caused the loss of both ATRIP and ATR expression and the loss of checkpoint responses to DNA damage, indicating the mutual dependence of these two proteins (Cortez et al., 2001). Replication protein A (RPA), a protein complex that associates with single-stranded DNA (ssDNA), is required for the recruitment of ATR to sites of DNA damage and for ATR-mediated Chk1 activation in human cells. In vitro, RPA stimulates the binding of ATRIP to ssDNA. The binding of ATRIP to RPA-coated ssDNA enables the ATR/ATRIP complex to associate with DNA and stimulates

phosphorylation of the Rad17 protein that is bound to DNA (Zou and Elledge, 2003).

ATR orthologs are typically involved in maintaining genome stability and responding to DNA damage. The yeast ATR orthologs, Mec1p in the budding yeast and Rad3p in the fission yeast, maintain genomic stability and activate DNA damage responses by phosphorylating key proteins in these pathways (reviewed in Zhou and Elledge, 2000; Humphrey, 2000). As mentioned above, Mec1p collaborates with the ATM ortholog, Tellp, in the damage response pathway and telomere maintenance in *S. cerevisiae* (Neecke et al., 1999; Longhese et al., 2000). Notably, Mec1p-dependent processes include cell cycle checkpoints induced by DNA damage or replication arrest (Santocanale and Diffley, 1998; Clarke et al., 1999; Vallen and Cross, 1999), redistribution of the Sir3 silencing protein from telomeres to DSBs (Mills et al., 1999); meiotic recombination (Grushcov et al., 1999); and silencing of gene expression at telomeres (Craven and Petes, 2000). The Rad3p of *S. pombe* is critical for the immediate activation of cell cycle checkpoints following DNA damage and for the activation and maintenance of responses to replication arrest. The mechanisms in each response are different and carried out by different effectors (Martinho et al., 1998). Many of the relevant pathways are conserved through evolution; hence, in mammalian cells, ATM and ATR phosphorylate orthologs of Mec1p and Rad3p substrates. In *Drosophila melanogaster* mutants in the ATR ortholog *mei-41* exhibit chromosomal instability, radiation sensitivity, and defective activation of cell cycle checkpoints by ionizing radiation (Hari et al., 1995). Recombination-defective lines of flies reveal a role for Mei-41 protein in meiotic precocious anaphase in females (McKim et al., 2000). The catalytic subunit of the DNA-dependent protein kinase (DNA-PKcs) is another major member of the PIK-related kinase family (reviewed by Burma and Chen, 2004). DNA-PKcs is recruited to DSB sites by the Ku70/Ku80 heterodimer and appears to play a central role in the rejoining process, in V(D)J recombination, and in triggering apoptosis in response to severe DNA damage or critically shortened telomeres. DNA-PK also appears to be involved in mounting an innate immune response to bacterial DNA and to viral infection. Because DNA-PK localizes very rapidly to DNA breaks and phosphorylates itself and other damage-responsive proteins, it appears that DNA-PK serves as both a sensor and a transducer of DNA-damage signals. ATM- and ATR-dependent pathways appear to be independent of DNA-PK (Araki et al., 1999; Khosravi et al., 1999). However, the critical role of DNA-PK in DSB response is underscored by the *scid* phenotype of DNA-PK-deficient mice, which includes radiosensitivity, chromosomal instability, immunodeficiency, and cancer predisposition (Jhappan et al., 1997).

The TOR subfamily of the PIK-related kinases represents a group of proteins whose role is to convey, via their kinase activity, extracellular signals rather than deal with DNA damage (Proud, 2004). The TOR proteins signal nutrient availability (e.g., amino acids levels) and pass on certain mitogenic stimuli to the mRNA translation machinery. One known mechanism is TOR-dependent phosphorylation of the p70<sup>S6k</sup> kinase. The pathways controlled by the mammalian homolog in this group, mTOR/FRAP/RAFT, may end up regulating both protein translation and transcription of rRNA and tRNA. Importantly, TOR-mediated pathways appear to intersect with certain P13K pathways.

A recent newcomer to the PI3K-related protein kinase family is the hSMG1 protein (Abraham, 2004a). The protein kinase activity of hSMG-1 resembles that of ATM, both in terms of substrate

specificity and its sensitivity to inhibition by the fungal metabolite wortmannin. hSMG-1 is the ortholog of a *Caenorhabditis elegans* protein, CeSMG-1, which has been genetically linked to a critical mRNA surveillance pathway termed *nonsense-mediated decay* (NMD). The function of NMD is to mark for rapid degradation mRNAs that bear a premature termination codon. Compelling evidence now indicates that hSMG-1 is also a central player in the NMD pathway in human cells. In addition, hSMG-1, like ATM, appears to be involved in the recognition and/or repair of damaged DNA in these cells.

Finally, members of the TRRAP branch of the PIK-related kinase superfamily are devoid of kinase activity because of inactivating sequence alterations in their kinase domains. The mammalian (TRRAP/PAF400) and yeast (Tra1p) homologs are part of large protein complexes involved in transcriptional regulation and chromatin remodeling via their histone acetyltransferase activity (Grant et al., 1998; Saleh et al., 1998; Vassilev et al., 1998). TRRAP/PAF400 is a co-activator of the c-Myc and E2F transcription factors and recruits the histone acetyltransferase GCN5 to c-Myc (McMahon et al., 1998, 2000). The existence of the TRRAP group in the PIK-related kinase family raises the possibility that members residing in other branches of the PIK-related kinase phylogenetic tree are involved in gene regulation and shaping of chromatin. In general, despite the apparently diverse functions of the different branches of this important protein family, they may share more functions than meet the eye.

## ATM Functions

### ATM activation

ATM is a predominantly nuclear protein with a strong serine/threonine kinase activity. Similar to DNA-PK and ATR, ATM's kinase activity appears to be directed at serine or threonine residues that are immediately followed by a glutamine (Kim et al., 1999; O'Neil et al., 2000). ATM's major function is to play a crucial role in the early response to the induction of DSBs in the DNA (Shiloh, 2003; Kurz and Lees-Miller, 2004). Immediately after the formation of DSBs in the DNA, ATM's kinase activity is enhanced (Banin et al., 1998; Canman et al., 1998; Khanna et al., 1998). The activated ATM then phosphorylates an extensive array of target proteins, each of which is a key player in a specific damage response pathway (Fig. 29.1). Bakkenist and Kastan (2003) found that ATM molecules are inactive in undamaged cells, being held as dimers or higher-order multimers. In this configuration, the kinase domain of each molecule is blocked by a region called the *FAT domain* of the other. Following DNA damage, each ATM molecule phosphorylates the other on a serine residue at position 1981 within the FAT domain, a phosphorylation that releases the two molecules from each other's grip, turning them into fully active monomers. Within minutes after the infliction of as few as several DSBs per genome, most ATM molecules become vigorously active. Another immediate step in ATM activation following DNA damage is rapid adherence of a portion of activated ATM to DSB sites (Andegeko et al., 2001). Both chromatin-bound and free ATM are autophosphorylated on serine 1981 (Uziel et al., 2003). So, following DSB induction, activated ATM seems to divide between two fractions: one is chromatin bound and the other is free to move throughout the nucleus. Importantly, many ATM substrates are phosphorylated by the chromatin-bound fraction of ATM, at the damaged sites (Lukas et al., 2003).

The early events in the DSB response are usually depicted by a linear scheme beginning with sensor proteins that sense the

**Figure 29.1.** Scheme of ATM-dependent pathways in the double-strand break (DSB) response network, highlighting ATM effectors. Arrows indicate stimulation, while T-shaped lines represent inhibition. The transition from inactive ATM homodimers into active monomers and the role of the Rad50/Mre11/Nbs1 (MRN) complex upstream of this process are indicated. ATR phosphorylates at least some of ATM's substrates in response to these DNA lesions at later time points and slower kinetics. (Reproduced from Shiloh et al., 2004, with permission.)

damage and convey it to the transducers, such as ATM and ATR. Growing evidence suggests, however, that the DSB signal may be initially amplified via a cyclic process rather than by a series of steps with a linear hierarchy. One of the first processes initiated by DSBs is the massive phosphorylation of the tail of a histone protein variant called *H2AX* (Fernandez-Capetillo et al., 2004). Foci of phosphorylated *H2AX* are rapidly formed at the DSB sites and are thought to be essential for further recruitment of repair factors such as the Mre11/Rad50/Nbs1 (MRN) complex (see below), Rad51, and Brca1 (Celeste et al., 2002). *H2AX* phosphorylation, a very early event in the cascade induced by DSBs, was reported to be ATM-dependent following DSB induction (Burma et al., 2001), and ATR-dependent following replicative stress (Ward and Chen, 2001). This process could thus serve as a rapid and powerful mechanism for amplification of the damage signal via repeated cycles of *H2AX* phosphorylation and recruitment of processing factors that facilitate further recruitment of damage transducers to the damaged sites, along with repair proteins.

Other cyclical processes of signal amplification may characterize ATM activation and subsequent phosphorylation of ATM substrates. An important player in this cycle is the Mre11/rad50/Nbs1 (MRN) complex (Stracker et al., 2004). The MRN complex serves as a sensor of DSBs caused by damaging agents. It is involved in the initial processing of such DSBs by virtue of the nuclease activity of one of its component—the Mre11 protein. MRN is also involved in processing DSBs that are formed during meiotic recombination and in telomere maintenance. The Nbs1 protein is a direct substrate of ATM (see below), but also seems to serve as an adaptor in the phosphorylation of other ATM substrates such as Chk2 (Buscemi et al., 2001; Girard et al., 2002) and Smc1 (Kim et al., 2002b; Yazdi et al., 2002), particularly at low damage levels. Similarly, the Brca1 protein, itself an ATM substrate, is an adaptor in the phosphorylation of other ATM substrates (Foray et al., 2003). So, in this interesting pathway, the phosphorylation of one substrate is required for the phosphorylation of others. A molecular explanation for the adaptor role of the MRN complex was provided by Lee and Paull (2004), who showed that MRN facilitates in vitro the binding between ATM and some of its

substrates. However, this is not the complete story of the complex, intimate relationships between ATM and the MRN complex. It turns out that MRN also plays a role in the actual activation of ATM. The presence of a functional MRN complex is required for full activation of ATM, particularly at low damage levels (Carson et al., 2003; Uziel et al., 2003; Horejsi et al., 2004) and for recruitment of ATM to the damaged sites (Kitagawa et al., 2004). A molecular explanation for these observations was provided by Costanzo et al. (2004), who showed that in *Xenopus* extracts, ATM, MRN, and broken DNA fragments assemble into an “activation complex” whose formation is required for full activation of ATM.

Another protein that appears to facilitate the phosphorylation of certain ATM substrates is 53BP1 (Mochan et al., 2004). Like Nbs1, 53BP1 contains a BRCT (breast cancer C-terminus) domain, is recruited to DSB-induced nuclear foci, is required for proper activation of certain cell cycle checkpoints, and is itself an ATM substrate (DiTullio et al., 2002; Fernandez-Capetillo et al., 2002; Wang et al., 2002). Another newly discovered, BRCT-containing protein, Nfbd1/Mdc1, may have similar characteristics (Stucki and Jackson, 2004). The emerging complex relationships between ATM, the MRN complex, and these BRCT proteins are drawing new flow charts for the DNA damage signal that deviate from the traditional linear ones and assign to several proteins more than one role “upstream” and “downstream” of the transducers of the DNA damage alarm.

#### ATM substrates and downstream pathways

The list of published ATM substrates is far from complete, and the study of the pathways associated with ATM targets is gradually disclosing a remarkably broad cellular response to DSBs that is meticulously orchestrated by ATM. The network of ATM-mediated pathways (Fig. 29.1) uses several sophisticated strategies. The first strategy is to approach the same effector from several different directions. A prime example is the G1/S checkpoint (reviewed by Shiloh, 2003; Kurz and Lees-Miller, 2004). A main component in this cell cycle checkpoint is activation and stabilization of p53, which in turn activates transcription of the gene that encodes the CDK2–cyclin-E inhibitor WAF1 (also

known as p21 and CIP1) (Oren, 2003; Meek, 2004). p53 is phosphorylated by ATM on Ser15 (Banin et al., 1998; Canman et al., 1998). This contributes primarily to enhancing p53's activity as a transcription factor (Ashcroft et al., 1999; Dumaz and Meek, 1999; Khosravi et al., 1999). ATM also phosphorylates and activates Chk2 (Ahn et al., 2004), which phosphorylates p53 on Ser20. This process interferes with the p53-MDM2 interaction. The oncogenic protein Mdm2 is both a direct and indirect inhibitor of p53, as it serves as a ubiquitin ligase in p53 ubiquitylation, which mediates its proteasome-mediated degradation (Alarcon-Vargas and Ronai, 2002; Brooks and Gu, 2004). ATM also directly phosphorylates Mdm2 on Ser395, which interferes with nuclear export of the p53-Mdm2 complex and hence the degradation of p53 (Khosravi et al., 1999; Maya et al., 2001). Finally, it has been reported that phosphorylations of p53 on Ser9 and Ser46 (Saito et al., 2002) and dephosphorylation of Ser376 (Waterman et al., 1998) are ATM-dependent as well, although the function of these changes is unclear.

This series of ATM-dependent modifications that activate and stabilize p53, although perhaps not complete, illustrates the elaborate way in which ATM handles a single effector, and indicates that ATM might regulate several effectors within the same pathway. This principle is also seen in ATM-mediated activation of the Brca1 tumor suppressor protein following DNA damage. Brca1 is involved in the early stage of the DNA damage response as well as in activating downstream pathways (Ting and Lee, 2004). Brca1 was found to be associated with large protein complexes that contain DSB repair and mismatch repair enzymes as well as ATM (Wang et al., 2000b). It also activates the expression of certain damage-responsive genes and is involved in the S-phase and G2-M checkpoints (El-Deiry, 2002; Jasin, 2002; Venkiteraman, 2002; Yarden et al., 2002). ATM phosphorylates Brca1 on several sites (Cortez et al., 1999; Gatei et al., 2000a, 2001b). Importantly, whereas ATM-mediated phosphorylation of Brca1 on Ser1387 activates Brca1 as a regulator of the intra-S-phase checkpoint (Xu et al., 2002), its phosphorylation by ATM on Ser1423 spurs its involvement in the G2-M checkpoint (Xu et al., 2001). Thus, phosphorylation on different sites may direct an effector to act in different pathways. The Chk2 kinase, which is activated by ATM, adds yet another phosphorylation on the Brca1 molecule (Lee et al., 2000), while at the same time ATM phosphorylates CtIP, an inhibitor of Brca1, on two residues, inhibiting its function and further stimulating Brca1 (Li et al., 2000).

ATM's hold on downstream pathways is demonstrated by not only its multipronged grip of specific pathways but also its ability to approach the same end point from several different directions. A notable example is, again, the intra-S checkpoint: several ATM-controlled pathways converge to regulate this crucial cellular response to DSBs (Fig. 29.1). At least five ATM-mediated pathways seem to be involved in this checkpoint. In addition to Brca1, ATM phosphorylates Nbs1 (Gatei et al., 2000b; Lim et al., 2000; Wu et al., 2000; Zhao et al., 2000), a component of the multifunctional Mre11Rad50Nbs1 (MRN) complex involved in DSB sensing (Stracker et al., 2004). Of several ATM phosphorylation sites on Nbs1, Ser343 and Ser278 seem to be particularly important for its unknown role in this checkpoint (Lim et al., 2000; Zhao et al., 2000). Another ATM substrate in the intra-S checkpoint pathway is the Smc1 (structural maintenance of chromosomes 1) protein. This protein, known primarily for its involvement in sister chromatid cohesion, is phosphorylated by ATM on two serine residues; interference with this phosphorylation abrogates the S-phase checkpoint (Kim et al., 2002b; Yazdi et al., 2002). Im-

portantly, cells from mice in which ATM phosphorylation sites on Smc1 had been abolished had an S-phase checkpoint defect, decreased survival, and increased chromosomal aberrations after DNA damage (Kitagawa et al., 2004). A recently identified effector of ATM in the intra-S checkpoint is the FancD2 protein, which is phosphorylated by ATM on Ser222 following DSB induction and undergoes Brca1-mediated mono-ubiquitylation (Taniguchi et al., 2002). FancD2 is a member of a multiprotein complex, defects of which lead to another genomic instability syndrome, Fanconi's anemia (see Chapter 30). At the same time, Chk2 and another ATM/ATR-activated kinase, Chk1, take care of several checkpoints. Both of them phosphorylate the checkpoint phosphatase Cdc25A, which marks it for degradation (Mailand et al., 2000, 2002; Falck et al., 2001, 2002; Zhao et al., 2002). Cdc25A's duty is to dephosphorylate—and hence maintain the activity of—the cyclin-dependent kinases Cdk2 and Cdk1. Cdk2 drives both the G1/S transition and S phase, and Cdk1 mobilizes the G2 phase onto mitosis. Therefore, the destruction of Cdc25A contributes to the G1/S, intra-S, and G2/M checkpoints (Fig. 29.1). Of interest is the observation that the Cdc25A-mediated component of the G1-S checkpoint is rapid and, unlike the p53-mediated component, is not dependent on gene activation and protein synthesis (Falck et al., 2002).

Notably, in addition to ATM's versatility as a protein kinase with numerous substrates, the ATM web contains protein kinases that are themselves capable of targeting several downstream effectors simultaneously, and so concomitantly control subsets of pathways. Chk2 is known to phosphorylate p53, Brca1, Cdc25A, and Cdc25C (Bartek et al., 2001; McGowan, 2002) (Fig. 29.1). The Chk2-Cdc25C pathway is similar to the previously mentioned Chk2-Cdc25A pathway, but may act instead at the G2/M transition. Here, phosphorylation of Cdc25C by activated Chk2 is thought to lead to cytoplasmic sequestration of Cdc25C, which prevents activation of Cdk1.

Most of these pathways have not been completely characterized, and the involvement of ATM substrates in them has been inferred from defective activation of specific checkpoints following abrogation of ATM-mediated phosphorylation of these proteins. An interesting pathway is mediated by phosphorylation of hRad17, the human orthologue of Rad17 from the fission yeast *Schizosaccharomyces pombe*. hRad17 is phosphorylated in an ATM/ATR-mediated manner on two serine residues, and this phosphorylation is important for proper G1/S and G2/M checkpoint functions (Bao et al., 2001; Post et al., 2001). hRad17 is involved in a very early event in the DSB response: it loads a trimolecular complex onto the DNA that consists of the human orthologues of the fission yeast proteins Rad9, Hus1, and Rad1 ("the 9-1-1 complex"). This complex acts as a sliding clamp, probably a damage sensor (Parrilla-Castellar et al., 2004). Although this process may be upstream of the transducer recruitment, two essential proteins in this process, hRad17 and hRad9, are also phosphorylated in an ATM/ATR-dependent manner and participate in downstream checkpoint pathways (Bao et al., 2001; Chen et al., 2001; Post et al., 2001).

#### ATM and gene transcription

Many damage responses end up modulating gene expression. Indeed, a major ATM target, p53, is a transcription factor. Another transcription factor with a central role in cell cycle control, E2F1, has been reported to be phosphorylated and stabilized in an ATM-dependent manner (Lin et al., 2001). In addition, it is becoming evident that stress-response pathways that are best known for responding to other triggers in an ATM-independent

manner, such as those mediated by the mitogen-activated protein kinases or the transcription factor NF- $\kappa$ B, also contain a DNA damage-responsive component (Pearce and Humphrey, 2001). Interestingly, when these pathways are activated by DSBs, their response becomes ATM-dependent (Wang et al., 2000a; Li et al., 2001; Bar-Shira et al., 2002). The direct targets of ATM in these pathways have not been elucidated, but these observations expand the ATM-dependent network considerably.

#### ATM and damage-independent genomic stability

ATM helps maintain genomic stability through mechanisms other than responding to DSBs caused by damaging agents. T cells from A-T patients have abnormally shortened telomeres, abnormal association of chromosome ends, telomere clustering, and altered interaction between the telomeres and the nuclear matrix (Pandita, 2001). Evidence is accumulating that ATM is functionally linked to telomere maintenance, a process crucial to aging and cancer (Pandita, 2001; Chan and Blackburn, 2002; Kim et al., 2002a; Maser and DePinho, 2002). Here, ATM may be responding continuously to an ongoing process rather than abruptly and vigorously to an acute insult (Karlseder et al., 1999). The functional relationships between ATM and the telomere maintenance machinery have been illuminated by a study that generated mice doubly null for *Atm* and the telomerase RNA component *Terc* (Wong et al., 2003). These animals showed increased genomic instability, enhanced aging, and premature death, with a general proliferation defect extending into stem and progenitor cell compartments. Interestingly, the rate of T cell malignancies in these mice was reduced rather than enhanced.

A substrate of ATM-dependent phosphorylation in the telomere maintenance system is TRF1, which negatively regulates telomere elongation. Phosphorylation of TRF1 seems to suppresses TRF1-mediated apoptosis following DNA damage (Kishi et al., 2001). Interestingly, inhibition of TRF1 in A-T cells rescues telomere shortening and decreases the radiosensitivity of these cells, providing further evidence of the link between telomere metabolism and the DNA damage response (Kishi and Lu, 2002).

Further evidence of ongoing activity of ATM at sites of normally occurring breakage and reunion of DNA was provided by its presence at sites of V(D)J recombination (Perkins et al., 2004). At those sites, p53 phosphorylated at the ATM target residue was also present, indicating that ATM continuously surveys the V(D)J recombination process and can induce a damage response if DSBs are not sealed in a timely manner. Indeed, A-T patients often show clonal translocations involving the sites of the T cell receptor and immunoglobulin genes, demonstrating the consequences of absence of this surveillance. These translocations often herald the onset of lymphoid malignancy (Xu, 1999).

### ATM-Deficient Mice: An Animal Model of A-T

Mouse models of A-T were established in several laboratories by forming null alleles of the mouse homologue, *Atm* (Barlow et al., 1996; Elson et al., 1996; Herzog et al., 1996; Xu et al., 1996; Borghesani et al., 2000). *Atm*<sup>-/-</sup> mice share many clinical features of human A-T and highlight several features that have not received sufficient attention in humans and might be essential to understanding the functions of ATM. The reduced number and abnormal function of B and T cells, radiosensitivity, and a strong predisposition to cancer are similar between humans and mice. However, *Atm*<sup>-/-</sup> animals die almost exclusively from thymic lymphomas,

whereas human patients develop leukaemias, lymphomas, and solid tumors. Growth retardation is much more pronounced in *Atm*<sup>-/-</sup> mice than in human A-T patients. Fibroblasts from *Atm*<sup>-/-</sup> mice grow slowly and exhibit inefficient progression from G1 to S phase following serum stimulation (Xu and Baltimore, 1996). *Atm*-deficient mouse fibroblasts manifest radiosensitivity, genome instability, and defective radiation-induced cell cycle checkpoints. An *Atm* knock-in mutant mouse harbors a 9 nucleotide in-frame deletion (7666del9) corresponding to a common human mutation (7636del9) and producing near full-length *Atm* protein (Spring et al., 2001). The overall phenotype is similar to *Atm*<sup>-/-</sup> mice except for longer life span in nonspecific pathogen-free conditions, a lower incidence of thymic lymphomas, and more varied tumor types in older animals.

The neurologic deficit in *Atm*<sup>-/-</sup> mice is much less pronounced than in humans and can be elicited only by special testing. Moreover, the cerebella of these animals appear normal upon histopathological examination. The use of electron microscopy has provided evidence for degeneration of several different neuronal cell types in the cerebral cortex in 25% of neuronal profiles of 2-month-old *Atm*<sup>-/-</sup> mice (Kuljis et al., 1997). Degenerating Purkinje cells had abnormalities in nucleoplasm and cytoplasm as well as crenated cell membranes from which filiform appendages originated. Degeneration was also observed in other types of neurons and glial cells. Replacement of the Rad3 homology domain of *Atm* with a *neol*<sup>r</sup> gene generated an *Atm*<sup>-/-</sup> mouse with ectopic and abnormally differentiated Purkinje cells (Borghesani et al., 2000). Although gross neurologic abnormalities were found, none of the other *Atm*<sup>-/-</sup> mice exhibited such changes. However, *Atm*<sup>-/-</sup> mice show age-dependent defects in Ca<sup>2+</sup> spike bursts and calcium currents (Chiesa et al., 2000), and cerebellar Purkinje cells from *Atm*<sup>-/-</sup> animals are in a state of oxidative stress (Barlow et al., 1999; Watters et al., 1999; Kamsler et al., 2001).

Male and female sterility due to absence of mature gametes is another striking feature that has not received special attention in human patients. *Atm* is clearly essential for mouse germ cell development. Xu et al. (1996) noticed that meiosis is arrested in these mice at the zygotene/pachytene stage of the first meiotic prophase as a result of abnormal chromosomal synapsis and subsequent fragmentation. Using electron microscopy, Barlow et al. (1998) showed that male and female gametogenesis is disrupted in *Atm*<sup>-/-</sup> mice as early as leptotene of prophase 1, resulting in apoptotic degeneration. These results are corroborated by the observation that *Atm* is physically associated with synapsed chromosomal axes at meiosis (Keegan et al., 1996; Plug et al., 1997). These findings provide direct evidence of the role of *Atm* in recognizing specific DNA structures formed during meiotic recombination.

In summary, observations in mouse knockout models highlight the role of *Atm* in normal somatic cell growth and chromosomal recombination in meiosis, in addition to its recognized function in radiation-induced signal transduction. Further genetic manipulation of *Atm*<sup>-/-</sup> mice will enable the elucidation of additional features of A-T previously undisclosed in the human disease (Barlow et al., 1996; Elson et al., 1996; Xu and Baltimore, 1996; Xu et al., 1996).

### Diagnosis of Ataxia Telangiectasia

Diagnosis of A-T remains chiefly clinical and depends on age of presentation. Where no family history is present, the disease is usually detected by a pediatric neurologist on the basis of anomalies in station and gait accompanied by telangiectasias. However,

before the telangiectasias appear (between 2 and 8 years of age), diagnosis may be difficult. Ataxia could be part of another syndrome, for example, Friedreich's ataxia, or due to a cerebral neoplasm or hematoma. The differential diagnosis includes infectious encephalitis, postinfectious encephalomyelitis, progressive rubella panencephalitis, and subacute sclerosing panencephalitis. Ataxia may also occur in a number of metabolic diseases of infancy and childhood, such as Gaucher disease, Niemann-Pick disease, GM1 and GM2 gangliosidoses, metachromatic leukodystrophy, and Krabbe leukodystrophy. However, metabolic diseases can be diagnosed with the assistance of laboratory assays. Careful history and physical examination allow discrimination between A-T and two other metabolic disorders, Hartnup disease (an aminoaciduria) and maple syrup urine disease; in both of these diseases ataxia is episodic rather than progressive, as in A-T. Friedreich's ataxia typically has later onset and pes cavus and kyphoscoliosis, which are unusual in A-T.

A-T can also be readily distinguished from the hereditary motosensory neuropathies Charcot-Marie-Tooth disease (distal weakness, pes cavus, hyporeflexia, and mild to moderate sensory loss), type III disease (distal weakness, nerve hypertrophy, and electromyographic abnormalities), and Refsum disease (polyneuropathy and ataxia). Other syndromes exhibiting ataxia include Joseph disease, dentatorubral degeneration of Ramsay Hunt, and olivopontocerebellar atrophy, but each of these differs from A-T in having a different pattern of inheritance or age of onset. Perhaps the closest to A-T is ataxia/ocular-motor apraxia, a syndrome characterized by progressive ataxia, choreoathetosis, and oculomotor apraxia (Aicardi et al., 1988). However, these patients do not have the immunodeficiency seen in A-T, nor the other laboratory markers.

Prior to the cloning of the *ATM* gene there were a host of laboratory tests to support the clinical diagnosis of A-T (Table 29.5). Reduced or absent IgA and elevated AFP were nonspecific but supportive of the clinical diagnosis. The description of a frequent chromosome breakage by Hecht et al. (1966) and demonstration that A-T cells in culture were hypersensitive to ionizing radiation provided the basis for tests developed in several laboratories to aid in the diagnosis of A-T.

**Table 29.5.** Laboratory Tests to Support Diagnosis of A-T

Assay	A-T Phenotype	Reference
<i>Antibodies</i>		
Serum IgA, IgE	Reduced	Thieffry et al. (1961)
Serum IgM	Monomeric form	Peterson et al. (1963)
<i>Serum Proteins</i>		
$\alpha$ -fetoprotein	Elevated	Waldmann and McIntire (1972)
Carcinoembryonic antigen	Elevated	Sugimoto et al. (1978)
<i>Radiosensitivity</i>		
Cell survival	Reduced	Taylor et al. (1976)
Chromosome aberrations	Elevated	Hecht et al. (1965)
G2 phase delay	Exaggerated	Higurashi and Conon (1973)
p53 induction	Reduced/delayed	Ford et al. (1984)
		Beamish and Lavin (1994)
		Kastan et al. (1992)
		Khanna and Lavin (1993)
Radioresistant DNA synthesis	Present	Houldsworth and Lavin (1980)

None of these assays has been successful in identifying family members at risk, with the occasional exception of their application to prenatal diagnosis. When mammalian cells are exposed to radiation, a biphasic pattern of inhibition of DNA synthesis is observed. The extent of this inhibition is markedly reduced in A-T cells and has been referred to as radioresistant DNA synthesis (Houldsworth and Lavin, 1980; Painter and Young, 1980; Lavin and Schroeder, 1988). Assay for radioresistant DNA synthesis has been used for prenatal diagnosis in A-T (Jaspers et al., 1981).

Once the *ATM* gene was identified, mutation diagnosis became theoretically possible. However, a large number of mutations have been found, distributed along most of the length of the cDNA. Unless specific mutations in a family are known, mutation detection for carrier and prenatal diagnosis remains a research tool. As an alternative to mutation detection, it is possible to carry out immunoblotting to detect ATM protein. Since most mutations in ATM are truncating and some missense mutations also destabilize the protein, ATM protein is either undetectable or reduced in amount in most A-T patients. In cases where mutant ATM protein is detectable by immunoblotting, it should have no ATM kinase activity. This is determined by immunoprecipitation of ATM and assay using a substrate such as p53 and <sup>32</sup>P-ATP (Banin et al., 1998; Canman et al., 1998).

### A-T Heterozygotes and Elevated Cancer Risk

Although A-T heterozygotes do not exhibit symptoms of the disease, they do have radiosensitivity to a lesser extent than homozygotes, a finding first reported by Chen et al. (1978). A number of other assays have been used to confirm this finding (Paterson et al., 1985; Roisin and Ochs, 1986; Shiloh et al., 1986; Rudolph et al., 1989; Chen et al., 1994). However, there is considerable variation among heterozygotes, and none of the assays is sufficiently reliable for A-T carrier diagnosis without reference to a known homozygote relative.

A Hardy-Weinberg estimate for heterozygote using the early data of Boder and Sedgwick (1970) predicts a frequency of 1 in 100 individuals, whereas that of Swift et al. (1986) would give a value between 0.3 and 0.4 per 100. Because A-T is autosomal recessive, it would be expected that heterozygotes would show no symptoms. However, mortality from cancer among blood relatives of A-T patients is higher than expected. Swift et al. (1991) found an increased cancer risk in 1599 adult blood relatives of A-T patients from 161 A-T families, compared to 821 of their spouses as controls. A subgroup of 294 obligate heterozygotes had relative risks of 3.8-fold above controls for men and 3.5-fold for women for all types of cancer. The relative risk for breast cancer in women was 5.1-fold. Several other epidemiological studies also support an increased risk of breast cancer in A-T heterozygotes but with smaller relative risk (Pippard et al., 1988; Janin et al., 1999; Inskip et al., 1999; Geoffroy-Perez et al., 2001; Olsen et al., 2001). Molecular genotyping and mutation analysis have produced apparently conflicting data on the incidence of *ATM* mutations in different cohorts of breast cancer patients. In A-T family studies, Athma et al. (1996) detected 25 heterozygotes among 33 women with breast cancer where only 15 were expected by chance alone. Fitzgerald et al. (1997) detected heterozygous mutations in 2 of 202 healthy women with no history of cancer, whereas the figure was 2 of 410 for women with early-onset breast cancer. Other smaller studies support these observations (Chen et al., 1998; Bay et al., 1998; Bebb et al., 1999). However, Broeks et al. (2000) detected 7 germ-line *ATM* mutations in 82 breast cancer patients with either early-onset disease or bilateral breast

cancer. In most of these studies truncating mutations were screened for, since they represent the bulk of mutations seen in A-T patients. One explanation for the disparate findings might reside in possible differences between truncating and missense mutations in *ATM*. Indeed, Gatti et al. (1999) proposed a model to explain the relationship between *ATM* mutations and cancer susceptibility discriminating between missense and truncating mutations. They envisaged that an *ATM* missense mutant expressing mutant protein could act in a dominant negative capacity to interfere with normal *ATM* function. There is evidence that missense mutations in the kinase domain of *ATM* have a dominant interfering effect (Lim et al., 2000). Recent evidence for an increased frequency of *ATM* missense mutations in breast cancer patients adds support for this model (Izatt et al., 1999; Broeks et al., 2000; Dörk et al., 2001; Teraoka et al., 2001).

Swift et al. (1991) asked whether diagnostic or occupational exposure to ionizing radiation increases the risk of breast cancer in women heterozygous for A-T. However, Norman and Withers (1993), estimating that annual mammography for 35 years would give a woman a total exposure of only 10 cGy, argued that on the basis of an increased sensitivity to radiation on the order of 30% (Cole et al., 1988), the lifetime risk for breast cancer from mammography would be 2 cases per 100 women. This would not significantly add to the natural lifetime risk of 1 in 9 in the general population. Additional studies of cancer and heterozygous *ATM* mutation are needed that also address the potential combined effects of mutations in the breast cancer susceptibility genes *BRCA1* and *BRCA2* as well as better-defined environmental risk factors.

### Future Directions and Treatments

Progress in our understanding of the role of *ATM* has been rapid since the gene was cloned. More than 40 substrates have been identified for *ATM*, including the proteins shown to be defective in other genome instability syndromes such as A-T-like syndrome, Nijmegen breakage syndrome, Fanconi's anaemia, and Bloom's syndrome (Chapter 30). Clearly *ATM* is involved in many different signaling pathways. Challenges ahead include identifying additional substrates, establishing the physiological importance of specific *ATM*-mediated phosphorylations, and assembling these events into signaling pathways. The overlap of A-T with other genomic instability syndromes promises to shed light on cellular processes associated with maintaining the integrity of the genome and preventing the development of tumors.

To date, only the kinase domain has been identified as a functional domain in *ATM*. This represents only a small part of the total protein and it is likely that other important functions will be assigned to other regions of the molecule. A proline-rich region binding to c-Abl has been described that is likely to be important in radiation-induced signaling. The N terminus of *ATM* binds substrates such as p53, *BRCA1*, *BLM*, and *Nbsl*. It remains to be determined whether this binding facilitates the kinase activity of *ATM*. Further mapping of the region of binding is required, as well as demonstration of its importance for *ATM* function. A particularly important mission is understanding the structural aspects of *ATM* activation. Since full-length *ATM* cDNA has been cloned and used to correct the A-T cellular phenotype, it is now also possible to introduce changes into this cDNA for investigations into the importance of individual sites on the molecule (e.g., sites of phosphorylation) for structural and functional studies (Lavin et al., 2004). This cDNA resource will also be instrumental in distinguishing between genomic missense mutations in

*ATM* and rare allelic variants that do not interfere with *ATM* function. In this context, it will be possible to use the methodology to address the issue of mutations and cancer predisposition in non-A-T families. Production of mutant *ATM* mice with knock-in missense mutations will also assist in investigations into the role of *ATM* mutations in breast cancer.

The progressive neurodegeneration that represents the most debilitating aspect of A-T has been more difficult to address. Most mouse models fail to recapitulate the neurodegeneration, but mouse models show abnormalities indicative of oxidative stress in the cerebellum. Treatment with antioxidants in an attempt to slow the progression of neurodegeneration has had mixed results in limited clinical trials. The advent of stem cell technology, with prospects for efficient delivery of genes to the brain, and the possibility of using other animal models (e.g., monkeys) provide greater hope of developing approaches that may prevent neurodegeneration.

Recent thoughts about drug screening for A-T treatments are based on new insights into the molecular basis of this disease. The crucial role of *ATM* in the DNA damage response calls for a laboratory assay for drug screening based on this response. The redundancy between *ATM* and other transducers provides hope that drugs that will stimulate enzymes partially redundant with *ATM* may alleviate some of the symptoms of A-T or at least slow its relentless progression. The available clear readouts for this response (e.g., the phosphorylation and activation of *ATM* effectors) could lead to a high-throughput drug screen for A-T. This kind of search would be conducted for small molecules that allow *ATM*-deficient cells to mount at least a partial DSB response despite *ATM*'s absence (Shiloh et al., 2004). Drug screening attempts based on this rationale are expected in view of our growing understanding of the function and mode of activation of the *ATM* protein.

### Acknowledgments

We wish to thank many colleagues for helpful discussion and critical reading of the manuscript. We apologize for inadvertently overlooking relevant work on this subject, being aware of the rapid rate of accumulation of knowledge in this area. This work was supported by the National Health and Medical Research Council of Australia, the Queensland Cancer Fund, the National Institute of Neurological Disorders and Stroke, The A-T Medical Research Foundation, the A-T Children's Project, and the A-T Medical Research Trust. We thank Tracey Laing and Ian Dillon for typing the manuscript.

## Chromosomal Instability Syndromes Other Than Ataxia-Telangiectasia

ROLF-DIETER WEGNER, JAMES J. GERMAN, KRYSTYNA H. CHRZANOWSKA,  
MARTIN DIGWEED, and MARKUS STUMM

A number of syndromes exist in which an increased incidence of spontaneous and/or induced chromosomal aberrations is the unifying diagnostic criterion. These disorders, called *chromosomal instability syndromes*, include the classical chromosomal instability syndromes—namely, ataxia-telangiectasia (A-T), Fanconi anemia (FA), and Bloom syndrome (BS). On the basis of this definition, Nijmegen breakage syndrome (NBS) and A-T-like disorder (A-TLD) must also be added to this group. More recently, case reports of patients with ligase I (LIG1) deficiency, ligase IV (LIG4) deficiency, NHEJ1, and RAD50 deficiency have provided evidence for the existence of a long list of diseases belonging to this group.

There is growing evidence that the following genes mutated in chromosomal instability syndromes are involved in protecting—directly or indirectly—human genome integrity by contributing to the complex regulation of double-strand break (DSB) repair: *ATM* in A-T, *NBS1* in NBS, *BLM* in BS, *MRE11* in A-TLD, *Lig1* in ligase I deficiency, *Lig4* in ligase IV deficiencies, NHEJ1 in Cernunnos deficiency, *RAD50* (in *rad50*-deficient mice) (Luo et al., 1999), and the group of at least 12 genes known to be affected in the heterogenous disorder of FA. Recent studies of protein–protein interactions suggest that the normal gene products associated with most of these syndromes are in fact involved in forming or regulating a huge protein complex active in the surveillance and maintenance of genomic integrity. Results from these studies indicate that the gene products of *ATM*, *BLM*, *NBS1*, *MRE11*, and *RAD50* are all members of a complex named *BASC* (BRCA1-associated genome surveillance complex). They might appear as a single protein subunit or as a stable subcomplex such as nibrin, MRE11, and RAD50 (Wang et al., 2000). As described below, most of the known FA genes may be also linked indirectly or even directly to the BASC complex (Ahmad et al., 2002).

Most of these syndromes exhibit features of immunodeficiency or at least hematological symptoms resulting from a clinically relevant deficiency of cells in the immune system. In this chapter, the term *immunodeficiency* is used in this broader sense. The triad immunodeficiency, neoplasia, and infertility is typical for most of the syndromes associated with chromosomal instability. This observation can best be explained by defects in the complex system of DSB repair, affecting either nonhomologous end joining (NHEJ) or homologous rejoining (HR). Thus tumor development in these syndromes is a direct consequence of defective DNA repair, which leads to mutations of cancer susceptibility genes acting as gatekeepers or caretakers (Kinzler and Vogelstein, 1997; Duker, 2002). Since meiotic recombination requires the production and repair of DSBs, the high incidence of infertility observed in patients with chromosomal instability syndromes is not surprising. Because the production of immunoglobulins relies on the network of proteins supporting the process of NHEJ (reviewed in van Gent et al., 2001), failure of a member of this group of proteins could lead to immunodeficiency. Thus, although primary immunodeficiency is not a typical symptom of chromosomal instability syndromes, these disorders may further our understanding of the relationship between DSB induction, DSB repair, and immunoglobulin production.

In this chapter, we will focus on three clinically defined syndromes—Fanconi anemia, Nijmegen breakage syndrome, and Bloom syndrome, followed by a short presentation of more recently discovered chromosomal instability syndromes that show A-T-like or NBS-like phenotypes due to specific gene mutations (*Mre11*, *Rad50*, *Lig1*, *Lig4*, *NHEJ1*). Other diseases, for example, Rothmund-Thompsen syndrome (MIM 268400) and Werner syndrome (MIM 277700), listed in Table 30.1, will either be briefly described or are beyond the scope of this text because the clinical presentation does not suggest a defect of

AFP,  $\alpha$ -fetoprotein; A-T, ataxia-telangiectasia; A-TLD, ataxia-telangiectasia-like disease; Bloom, Bloom syndrome; FA, Fanconi anemia; LIG1, ligase I deficiency; LIG4, ligase IV deficiency; NBS, Nijmegen breakage syndrome; NHEJ1, non-homologous end-joining factor 1 (NHEJ1) responsible for SCID with microcephaly and chromosomal instability; RAD50, RAD50-deficiency; RS-SCID, radiosensitive severe combined immunodeficiency syndrome; UV, ultraviolet; WRNS, Werner Syndrome.

the immune system or published data are insufficient to classify them as immunodeficiency diseases. The preceding chapter is dedicated to ataxia-telangiectasia, a chromosomal instability syndrome with specific expression of immunodeficiency. Moreover, subgroups of patients with severe combined immunodeficiency (SCID) expressing radiosensitivity, and most probably also chromosomal instability, are excluded from this

chapter. This subgroup of SCID is presented in greater detail in Chapter 11.

### Fanconi Anemia

Fanconi anemia (MIM 227650) is an autosomal recessive chromosome instability syndrome characterized by bone marrow

**Figure 30.1.** Chromosomal instability in Fanconi anemia (FA). (A) Lymphocyte chromosomes of a patient with Fanconi anemia. Only some of the chromatid breaks in this massively damaged metaphase are indicated. (B) Schematic representation of the chromosome aberrations seen in lymphocyte chromosomes from patients with chromosomal instability syndromes. (C) Examples of characteristic chromosome reunion figures seen in FA patients.

failure and an increased risk of neoplasia, particularly leukemia. In addition, a range of congenital abnormalities, such as growth retardation, radius aplasia, and hyperpigmentation of the skin, are observed in some patients.

The clinical presentation of FA is highly variable. As is often the case, the more severe phenotypes have been overemphasized and one-third of FA patients have no congenital abnormalities (Glanz and Fraser, 1982; Giampietro et al., 1997). The generally accepted critical diagnostic criterion for FA is an increase in chromosome breakage after *in vitro* treatment of patient cells, usually peripheral blood lymphocytes, with bifunctional alkylating agents such as mitomycin C (MMC) (Sasaki and Tonomura, 1973).

## Clinical and Pathological Manifestations

### Hematological complications

The bone marrow of FA patients deteriorates, usually within the first decade of life, although this aspect also varies considerably. Thrombocytopenia and macrocytosis, for example increased erythrocyte volume (mean cell volume >100 fl) associated with increased fetal hemoglobin levels, are followed by granulocytopenia, leukopenia, and eventually pancytopenia. Although aplastic anemia is accompanied by recurrent infections, FA is clearly a genetic hematological disorder rather than a primary immunodeficiency. Pancytopenia, however, results in a clinically relevant deficiency of cells attributed to the immune system.

Acute myeloblastic leukemia occurs 15,000 times more frequently in FA patients than in the general population. In addition, squamous cell carcinoma of the skin and gastrointestinal tract are frequent. The true cancer risk cannot be estimated, since some patients have died prematurely from infections or during bone marrow transplantation; at least 15% of FA patients develop neoplasia (Alter, 1996).

### Cytogenetics

The involvement of the FA gene(s) in the “metabolism and mechanics of the chromosome” was postulated by Schroeder and German (1974) on the basis of characteristic chromosome breaks observed in lymphocytes of FA patients (Fig. 30.1). These breaks are particularly chromatid breaks and translocations in-

volving nonhomologous chromosomes leading to triradial and quadriradial forms. This increased mutation rate in lymphocytes of FA patients is thought to explain the predisposition to acute myelogenous leukemia and other malignancies. A highly specific feature is a hypersensitivity to cross-linking agents. This phenomenon is still used as the diagnostic marker when a gene mutation cannot be proven. Detailed protocols describing common cytogenetic techniques are provided by Wegner and Stumm (1999).

The observation that peripheral blood lymphocytes of some FA patients apparently contain two populations of cells was first reported in 1983 by Kwee et al. Increasing doses of MMC shift one population to higher levels of chromosome damage while a second population remains as unaffected as wild-type cells. Although chromosome breakage analysis probably does not detect low-level mosaicism, such cases can be revealed by the isolation of MMC-resistant Epstein-Barr virus (EBV)-immortalized lymphoblasts. On the basis of this criterion, up to 25% of all FA patients are likely to be mosaic (Lo Ten Foe et al., 1997). In all mosaic patients analyzed, skin fibroblasts show the characteristic chromosome instability suggesting that the reversion events leading to a wild-type cell population are specific for lymphocyte progenitors (Waisfisz et al., 1999a; Gregory et al., 2001). The high incidence of mosaics may require cytogenetic analysis of fibroblasts from patients suspected of having FA but no increased breakage in standard lymphocyte cultures.

### Cell Cycle

Analysis of the cell cycle in FA has consistently shown increased numbers of cells in G<sub>2</sub> phase (Seyschab et al., 1993), where they are presumably arrested to repair DNA lesions. Treating FA cells with cross-linkers increases the proportion of cells in G<sub>2</sub> and has become an alternative and/or substantiating diagnostic criterion for FA. This disturbance of the cell cycle explains the poor growth of FA cells *in vitro*.

Interestingly, the slow growth of FA cells and their accumulation in G<sub>2</sub> can be normalized by keeping the cell cultures at reduced oxygen tension (Schindler and Hoehn, 1988). Even the spontaneous chromosomal breakage is lost at 5% O<sub>2</sub> (Joenje et al., 1981). These and other findings have led to the suggestion that the primary defect in FA is related to the avoidance of oxygen radicals or to repair of the DNA lesions caused by these highly reactive molecules.

**Table 30.2.** Fanconi Anemia (FA) Complementation Groups and Genes

## Genetics

Fanconi anemia is genetically heterogeneous and this heterogeneity can be assessed by somatic cell fusion and analysis of cross-linker sensitivity in the cell hybrids. Currently 12 complementation groups are known, these are denoted by the abbreviation *FA* followed by a letter—for example, FA-A, FA-B. FA-A is the largest group (approximately 60%) followed by FA-G (approximately 10%), and FA-C (approximately 10%). Identification of the underlying gene has been achieved for 11 of the groups, mostly by the technique of functional cloning by selecting cDNAs that enable patient cells to survive an otherwise lethal dose of MMC. The genes are denoted by the abbreviation *FANC*, followed by a letter—for example, *FANCA*, *FANCG*. In some cases a chromosomal localization for the gene had been previously established by linkage analysis in families (Pronk et al., 1995; Saar et al., 1998; Waisfisz et al., 1999a). After the demonstration by Garcia-Higuera et al. (2001) that *FANCD2* interacts with *BRCA1*, *BRCA2* was identified as an FA gene after analysis of FA-B and FA-D1 patients for mutations in this gene (Howlett et al., 2002). *FANCL* (Meetei et al., 2003), *FANCM* (Meetei et al., 2005), and the X-chromosomal gene *FANCB* (Meetei et al., 2004) were identified through the finding that many FA proteins interact to form a stable complex. *FANCI* was identified by a candidate gene approach as the *BRCA1* binding protein *BRIP1* (Levrin et al., 2005). The current status of gene identification is given in Table 30.2 together with some details of the known FA genes.

While many FA genes were novel when they were identified, some were previously known or showed significant homology to known genes. *FANCG* (de Winter et al., 1998) proved to be identical to the gene *XRCC9*, which had been isolated through its ability to correct (or cross-complement) an X-ray sensitive hamster cell mutant from complementation group 9 (Liu et al., 1997a). *FANCD1* is identical to *BRCA2* and *FANCI* is a *BRCA1* binding protein. *FANCM* shows homology to the archaeal *Hef* gene that has ATP-dependent helicase activities and is involved in DNA repair (Meetei et al., 2005). *FANCD2* shows homology with sequences in lower organisms, such as *Drosophila* (Timmers et al., 2001). The protein product of the *FANCD2* gene is rather unique among FA proteins, as discussed below. Other functional motifs have so far not been identified in FA proteins.

Despite repeated efforts, a correlation between complementation group and clinical features or course of the disease has not generally been possible. Patients with and without congenital abnormalities are found in all groups with sufficient numbers of

patients for analysis. Leukemia seems to occur earlier in FA-G patients than in FA-A or FA-C patients (Faivre et al., 2000).

## Mutation Analysis

The FA genes have been extensively analyzed for mutations. Most patients are compound heterozygotes with private mutations, but there are also founder mutations in the three largest groups, FA-A, FA-C, and FA-G. Whereas particular deletions of *FANCA* exons are common in the Afrikaner population in South Africa (Tipping et al., 2001), a nonsense mutation, E105X, accounts for 44% of mutant *FANCG* alleles in Germany (Demuth et al., 2000). In *FANCC*, the mutation IVS4 + 4a > t is homozygous in the majority of Ashkenazi Jewish FA patients and is associated with a particularly severe disease in terms of both congenital abnormalities and hematopoietic failure (Whitney et al., 1993). In contrast, Japanese patients with the same mutation are not severely affected (Futaki et al., 2000). This finding indicates the strong influence of genetic background on disease manifestation and explains the difficulties in establishing a genotype–phenotype correlation, even within one complementation group. On the whole, truncation mutations strongly outweigh missense mutations in the FA genes. *FANCA* in particular has many deletions due to the Alu-repeat elements in and around the gene (Levrin et al., 1998).

The biallelic mutations in the *BRCA2/FANCD1* gene found in FA-D1 patients are hypomorphic (Howlett et al., 2002). Presumably the amorphic mutations are embryonically lethal in the homozygous state, as in *Brca2* null-mutant mice (Ludwig et al., 1997).

For diagnostic purposes, the complementation group can be established by fusion of patient cells to reference cell lines or by retroviral transfer of the known FA genes, followed by examination of cross-linker sensitivity. DNA from patients assigned to a complementation group can be analyzed for mutations, and this information is then available for further diagnoses in the family, including prenatal diagnosis. The ongoing collection of clinical data and mutation analyses in Europe and the United States is facilitating attempts at a genotype–phenotype correlation (Gillio et al., 1997; Faivre et al., 2000).

## Fanconi Anemia Mosaics

The molecular basis of reversion has been elucidated for at least six mosaic cases (Lo Ten Foe et al., 1997; Waisfisz et al.,

1999a). In one case, mitotic recombination with a break point within the *FANCC* gene placed both mutations on one allele and generated a heterozygous cell. In another patient, one mutation was lost in the reverted cells; retention of heterozygosity indicated that gene conversion was probably responsible for this reversion. The same mechanism was responsible for reversion in cells of this patient's affected brother. In three additional cases, all homozygous for *FANCA* or *FANCC* mutations, reversion was due to additional de novo mutations in *cis*. Thus a single base deletion was corrected by two further single base deletions that restored the reading frame. Similarly, a 5 bp insertion corrected the effects of an inherited single base insertion. Finally, a C>T transition corrected a missense mutation. This latter correction was found independently in two affected mosaic siblings, suggesting a specific molecular mechanism, whereas the other reversions are presumably due to random insertion or deletion events and selection.

Although reversions have been shown to occur in lymphohematopoietic stem cells and may be associated with a seemingly milder hematological disease, bone marrow failure and leukemia have been reported for several patients with revertant mosaicism (Gregory et al., 2001).

### Molecular Biology of Fanconi Anemia

The chromosome breakage observed in FA is specific for agents like MMC, which are capable of intercalating into a DNA double helix and forming covalent cross-links between the two strands. Thus the DNA lesion to which FA cells are particularly sensitive is the interstrand cross-link. The hypothesis based on this observation postulates that FA cells are deficient in the repair of DNA cross-links.

This hypothesis has been difficult to prove, however; there are few biochemical demonstrations of a failure to repair DNA cross-links in FA cells. Thus a number of other primary defects have been suggested: regulation of the cell cycle, regulation of DNA synthesis, apoptosis, and the avoidance of DNA damage caused by active oxygen radicals. The similarity in the cellular and clinical phenotype within the complementation groups was taken as evidence for involvement of the FA proteins in a common pathway. Indeed, association of the FA proteins in multimeric complexes has been proven by immunoprecipitation studies and by yeast two-hybrid analyses (Medhurst et al., 2001). The currently understood order of events is that the *FANCA* protein binds to the *FANCC* and *FANCG* proteins in the cytoplasm and then moves as a complex to the nucleus; *FANCA* is at some point modified by phosphorylation. In the nucleus, the *FANCB*, *FANCE*, *FANCF*, and *FANCL* proteins join to form the FA core complex (Fig. 30.2) (de Winter et al., 2000; Meetei et al., 2003, 2004).

A direct link to DNA repair processes in the cell was not made until the cloning of *FANCG*, which was found to be identical to the gene mutated in UV40, a hamster cell DNA-repair mutant, and implicated in post-replicative repair (Busch et al., 1996; Liu et al., 1997a). Further and even stronger evidence for a role in DNA repair was provided by the cloning of the *FANCD2* gene and the discovery that its protein is monoubiquitinated as a response to DNA damage and relocates to discrete nuclear foci, where it associates with BRCA1 (Garcia-Higuera et al., 2001). These nuclear foci are almost certainly sites where DNA lesions (e.g., double-strand breaks, cross-links) are being actively repaired (see also the section on NBS, below).

BRCA1 is a binding partner of BRCA2/FANCD1, and both of these are required for the recruitment of RAD51, the RecA

homologue, to the sites of DSBs for error-free repair by HR and gene conversion. BRCA2/FANCD1-deficient cells have been shown to be inefficient in the formation of RAD51 foci (Yuan et al., 1999). This finding correlates with a loss of repair by gene conversion, an increase in repair by alternative error-prone pathways, and extreme cross-linker-induced chromosomal instability (Tutt et al., 2001).

The finding that the FA protein complex of *FANCA*, *FANCB*, *FANCC*, *FANCG*, *FANCE*, *FANCF*, and *FANCL* is required for modification of the *FANCD2* protein (Fig. 30.2) has linked these proteins nicely into the same pathway (Garcia-Higuera et al., 2001; Pace et al., 2002; Meetei et al., 2003, 2004). The recent finding that RAD51 foci formation is reduced in FA cells from all complementation groups suggests that *FANCD2*-L (L, long isoform; derived by monoubiquitination of the short [S] isoform), like BRCA1 and BRCA2/FANCD1, is involved in RAD51-mediated DNA repair (Digweed et al., 2002b). Furthermore, *FANCD2* has been shown to interact directly with BRCA2/FANCD1 (Hussain et al., 2004). Figure 30.2 shows a model for these protein interactions.

The reliance on error-prone DNA repair pathways in the other FA complementation groups, may lead to the characteristic chromosomal instability of FA and be a direct result of the inability to modify *FANCD2*-S to *FANCD2*-L and efficiently recruit RAD51 for repair by gene conversion. Convincing data have been presented showing reduced homologous recombination in chicken DT40 cells mutated in *FANCG* (Yamamoto et al., 2003) and *FANCC* (Niedowitz et al., 2004). Similarly, using sophisticated plasmid reporters, defects in homologous recombination have been demonstrated in human and mouse cells with mutations in *FANCA*, *FANCD2*, and *FANCG* (Nakanishi et al., 2005; Yang et al., 2005). In contrast to previous studies, in the mutant mouse and human cells the error-prone repair pathway of single

**Figure 30.2.** Network of Fanconi anemia (FA) proteins. A highly simplified schematic representation of interactions of the FA gene products. A core complex of eight of the FA proteins (*FANCA*, *FANCB*, *FANCC*, *FANCE*, *FANCF*, *FANCG*, *FANCL*, and *FANCM*) is required for monoubiquitination of a further FA protein, *FANCD2*, in response to DNA damage. Modified *FANCD2* then relocates to the sites of DNA damage where it associates with BRCA1 and BRCA2, which is identical to *FANCD1*. BRCA1 and BRCA2 bind the important effector of homologous recombination, RAD51.

strand annealing (SSA) was also affected suggesting further roles for the monoubiquitinated FANCD2 protein. It is possible, even likely, that the individual FA proteins are involved in further interactions and that these may influence their activity in monoubiquitination of FANCD2. Thus the demonstrated oxygen sensitivity and cell cycle disturbance described in FA cells have yet to be incorporated logically into the FA pathway or, perhaps more appropriately, into the FA network. Interestingly, a functional link between FANCD2 and the NBS1/MRE11/RAD50 pathway has been indicated by several reports (Digweed et al., 2002a; Nakanishi et al., 2002; Pichierri et al., 2002).

### Animal Models

Knockout mice for the *Fanca*, *Fancc*, and *Fancg* genes have been produced but show few of the disease symptoms observed in patients (Whitney et al., 1996; Cheng et al., 2000; Yang et al., 2001). They do not have skeletal malformations, nor, surprisingly, do they show anemia or increased neoplasia. Although cells from these animals show the characteristic chromosomal breakage and cross-linker sensitivity, the animals are hematologically healthy unless treated with cross-linkers, in which case they suffer bone marrow failure. The only feature that is similar to the human clinical phenotype is reduced fertility. Perhaps not surprisingly, double-knockout *Fanca/Fancc* mice are not more severely affected than the single-knockout animals, indicating that these genes probably do not have further functions over and above those of the protein core complex (Noll et al., 2002).

Spontaneous defective hematopoiesis has been reported in double-knockout mice, with disruptions in both *Fancc* and in the Cu/Zn superoxide dismutase genes (Hadjur et al., 2001). These results provide evidence that abnormal regulation of the cellular redox state in FA may be involved in the bone marrow failure of patients. Increased tumorigenesis was reported for a *Fancc/p53* double-knockout mouse with a spectrum of malignancies similar to those of FA patients (Freie et al., 2003). Increased frequencies of epithelial tumors were reported for the *Fancd2* knockout mouse, suggesting perhaps a phenotypic overlap with hypomorphic *Brca2/Fancd1* mice (Houghtaling et al., 2003).

### Treatment and Prognosis

Several treatment possibilities are available for patients with FA. Erythrocyte and thrombocyte transfusions can compensate for bone marrow failure, although hemosiderosis is a concern. The bone marrow abnormalities of many patients respond to androgen and cytokine therapy, even if only temporarily. Allogeneic bone marrow transplantation from a histocompatible sibling can cure the bone marrow failure. Transplantations from matched unrelated donors have poor outcomes in FA (MacMillan et al., 2000). Bone marrow transplantation is complicated by the increased sensitivity of FA patients to pretransplant conditioning treatment. However, new cytoreductive regimens, particularly those including fludarabine, are encouraging (Kapelushnik et al., 1997; McCloy et al., 2001). The occurrence of expanding clonal aberrations in bone marrow, particularly those involving chromosome 3q, has been shown to correlate with a poor prognosis (Tönnies et al., 2003).

The relative accessibility of hematopoietic stem cells made FA an obvious candidate disorder for gene therapy, and the first trials were conducted in 1997 (Liu et al., 1997b, 1999). The expectation was that corrected stem cells would have a strong selective advantage in the hypoplastic bone marrow of FA patients, as suggested

by the finding of mosaic patients in whom total hematopoiesis is driven by a reverted clone. Gene transfer experiments with the knockout *Fancc* mouse have shown that positive selection can indeed be achieved (Gush et al., 2000). Currently the main obstacle to the development of gene therapy in FA is the poor efficiency of gene transfer into hematopoietic stem cells.

### Future Directions

The cloning of most of the FA genes and the final demonstration of a link to DNA repair have changed the course of current FA research. It is realistic to expect that much more detailed information on this novel network for DNA repair will be forthcoming. The availability of mouse models will enable the evaluation of treatment proposals including gene therapy, when gene transfer methodology is advanced enough to make this an alternative therapy for FA patients. In the meantime, the considerable improvement in bone marrow transplantation from unrelated donors must be extrapolated to the treatment of FA patients and new therapies for the treatment of squamous cell carcinoma in FA patients have to be developed. The finding that modification of the FANCD2-S protein does not occur in cells from most FA patients after DNA damage may be exploited in the future as a biochemical assay for diagnosis of the disease. Finally, the role of FA genes in the occurrence of malignancy in the general population will have to be addressed, in view of reports that indicate a role for *FANCF* silencing in acute myeloid leukemia (Tischkowitz et al., 2003) and cervical cancer (Narayan et al., 2004).

### Nijmegen Breakage Syndrome

The Nijmegen breakage syndrome (NBS) (MIM 251260), a rare autosomal recessive disorder belonging to the group of chromosomal instability syndromes, was first described 26 years ago (Hustinx et al., 1979). The clinical hallmarks of NBS patients are severe microcephaly, growth retardation, typical facial appearance, combined immunodeficiency, radiosensitivity, and an increased cancer risk. On the cellular level, the NBS abnormalities are closely related to those observed in A-T patients. Cells of both syndromes reveal chromosomal instability, a marked sensitivity to ionizing irradiation (IR) and radiomimetic agents, a radioresistant DNA synthesis (RDS), and additional defects in cellular checkpoint control. Nevertheless, on the molecular genetic level, both syndromes are clearly distinguishable from each other. Whereas A-T is caused by mutations in the *ATM* gene located on chromosome 11q23 (Savitsky et al., 1995), NBS is typically caused by mutations in the *NBS1* gene localized on chromosome 8q21 (Varon et al., 1998). The *NBS1* gene product, nibrin, is part of the hRAD50/hMRE11/nibrin complex (Carney et al., 1998), which seems to function in concert with ATM in a damage response pathway that affects a DNA repair process as well as cell cycle checkpoint control (Girard et al., 2000).

### Demographics

Whereas in the first edition of this text the number of diagnosed NBS patients amounted to 58, this figure has increased to approximately 170 patients at the end of 2004. Detailed clinical data on 55 patients collected in the NBS Registry in Nijmegen are included in the report of an international study group (International Nijmegen Breakage Syndrome Study Group, 2000). Among the remaining patients, not yet entered into the registry, there are 52 Polish (K. Chrzanowska, personal observation), 17

Czech (E. Seemanova, personal communication.), 21 German (R. Varon, personal communication), 8 Russian (Resnick et al., 2002), several American (Cerosaletti et al., 1998; Bakhshi et al., 2003), and single patients originating from Chile (Pincheira et al., 1998), Bosnia (Kleier et al., 2000), Argentina (Rosenzweig et al., 2001), Marocco (Maraschio et al., 2001), Turkey (Tekin et al., 2002), Yugoslavia (Pasic, 2002), and Italy (Barth et al., 2003). Thus, the majority of NBS patients known thus far are of Slavic origin (particularly of Polish and Czech descent, with 83 and 35 patients identified to date, respectively) and carry a common founder mutation 657del5 in exon 6 of the *NBS1* gene (Varon et al., 1998). The prevalence of this founder mutation was estimated by Varon et al. (2000) in the Czech Republic, Poland, and the Ukraine by the screening of Guthrie cards. A mean prevalence of 1:177 for NBS heterozygotes was found in these three populations. The highest prevalence was found in the Czech population (1:154), followed by the Ukraine (1:182) and Poland (1:198). However, marked regional differences were observed in Poland, ranging from 1:90 to 1:314. Further studies performed recently on populations of three large regions in Poland established a mean prevalence of 1:166 for the 657del5 mutation in Poland (Cybulski et al., 2004; Steffen et al., 2004; M. Mosor, personal communication). All of these frequencies were much higher than the prevalence of 1:866 reported for the same mutation in Germany (Carlomagno et al., 1999). On the basis of these data, the prevalence for NBS homozygotes in the Czech Republic can be estimated at 1 per 95,000. Interestingly, the actual frequency of 1 per 271,000 is much lower than expected. The most likely explanation for this discrepancy is the underdiagnosis of NBS patients because of the rarity of NBS and its relatively mild phenotype. This assumption is corroborated by two observations: (1) the late diagnosis of many NBS patients, often in cases where a malignancy requires examinations that finally disclose the presence of NBS; (2) detection of 3 new NBS patients in a cohort of 23 Czech patients with primary microcephaly tested for the major Czech mutation, the 657del5, in the *NBS1* gene (Seeman et al., 2004). This underdiagnosis is likely a general problem worldwide, thus more attention should be spent on the correct diagnosis of this disease.

### Clinical and Pathological Manifestations

Since the first reports on two siblings from Nijmegen (Hustinx et al., 1979; Weemaes et al., 1981), NBS is recognized as a multisystem disorder similar to A-T. The main clinical manifestations (Table 30.3) indicate that various tissues and organs are affected, including brain, skin, blood, and gonads.

#### Growth and development

**Growth.** Microcephaly, the most striking symptom of the disorder, has been observed in the great majority of children at birth (van der Burgt et al., 1996). Those who are born with a normal head circumference (OFC) will develop progressive and severe microcephaly during the first months of life. The primary cause of small head size in NBS patients is the genetically determined stunted growth of the brain (see Pathologic Findings, below). Thus, the observed premature closing of the sutures and fontanelles can be considered a developmental sequence (no increased intracranial pressure was noted, except in the two cases with coexisting hydrocephalus). Among the observed Polish patients, the decrease in OFC ranged from  $-9.0$  SDS to  $-4.4$  SDS, whereas the proportions among the diminished head measurements, i.e., length and breadth, were retained. Only one case with a normal OFC has

**Table 30.3.** Clinical Features of Nijmegen Breakage Syndrome

Microcephaly—severe and progressive
Characteristic face
Sloping forehead and receding mandible
Prominent midface
Retardation of statural growth
Ovarian failure
Immunodeficiency
Predisposition to malignancies
Intelligence level
Normal or borderline in early childhood
Progressive deficiency of IQ scores in later life

been described (Chrzanowska et al., 2001). Growth retardation may occur prenatally in some NBS patients, but in most cases birth weight and length correlate to gestational age. After an initial period of distinct growth retardation lasting from birth to about the second year of life, a slight improvement of growth rate (body height and weight, but not head circumference) is usually observed. Most affected individuals show growth below or around the third percentile whereas a few patients achieve a height around the 10th or even 25th percentile (International Nijmegen Breakage Syndrome Study Group, 2000; Chrzanowska et al., 2001). Intestinal malabsorption, cardiac defects, or hormonal abnormalities related to thyroid or pituitary gland functions have all been excluded as a cause of the growth retardation.

**Sexual maturation.** Longitudinal studies of growth and development of Polish patients, of whom three females and six males reached puberty, drew attention to the lack of development of secondary sexual characteristics in teenage girls. They presented with primary amenorrhea, absent breast development, and scanty pubic or axillary hair. In two of the three girls, all older than 18 years, repeated pelvic ultrasonography revealed small ovaries, resembling streak gonads, and infantile uteri. All three had markedly elevated plasma concentrations of follicle-stimulating hormone (FSH) and luteinizing hormone (LH) and very low estradiol levels indicating primary ovarian failure (Chrzanowska et al., 1996). A study of the pituitary–gonadal axis performed on a large group of Polish patients including 25 females confirmed the preliminary findings predicting a very high incidence of ovarian failure in this syndrome. Markedly elevated plasma concentrations of FSH, in relation to age, and very low estradiol levels (hypergonadotropic hypogonadism) were found in all but one of the tested females. Serum FSH concentrations exceeding 30 IU/L, a value indicative of ovarian failure, were documented in the majority (76% of those tested), both at pubertal and prepubertal ages (Chrzanowska, 1999; Chrzanowska et al., 2000). Single cases of hypergonadotropic hypogonadism had been reported earlier, including a 21-year-old female with NBS phenotype (Conley et al., 1986) and a now 24-year-old woman described earlier (Wegner et al., 1988) who subsequently developed primary amenorrhea. In males there was only a slight delay in onset of puberty and the levels of gonadotropins and testosterone corresponded to Tanner's classification of sexual maturity stages (Chrzanowska, 1999). Offspring from affected subjects have never been reported, and firm conclusions on fertility are hampered by the young age of the patients and their short life span. Thus, hypergonadotropic hypogonadism in females, indicative of either ovarian dysgenesis or hypoplasia, must be included in the clinical spectrum of NBS.

*Psychomotor development and behavior.* In general, developmental milestones are reached at expected times during the first years of life. Patients with normal intelligence (Seemanová et al., 1985; Wegner et al., 1988; Barbi et al., 1991; Green et al., 1995) or mental retardation of variable degree (Weemaes et al., 1981; Conley et al., 1986; Stoppa-Lyonnet et al., 1992; Chrzanowska et al., 1995a) have been reported. Follow-up studies of Polish patients showed that the level of intellectual function decreases with age. Most of the children tested in infancy and early childhood had IQ scores indicating a normal or borderline intelligence with striking psychomotor hyperactivity. When tested or retested after the age of 7, difficulties in concentration became more pronounced. At school age, lower levels of intellectual function were observed and became more evident in subjects over 14 years of age when all tested patients were mildly or moderately retarded (Chrzanowska, 1999). Most of the mentally retarded patients need educational support and should attend special education classes or schools. All of the children have a gentle and cheerful personality and, despite being shy, are usually capable of good social interactions.

*Craniofacial manifestations.* The craniofacial characteristics become more obvious with age because of the severe and progressive microcephaly. The facial appearance is very similar among NBS patients and is characterized by a sloping forehead and receding mandible, prominent midface with a relatively long nose (slightly beaked in most patients or upturned in some), and upward slanting of palpebral fissures (Fig. 30.3). In some individuals the ears seem to be relatively large and dysplastic.

#### Other manifestations

*Central nervous system malformations.* Developmental abnormalities of the brain are relatively frequent and appear to be more common than expected. Partial agenesis of the corpus callosum was documented in one-third (6/18) of Polish patients who underwent cranial magnetic resonance imaging (MRI) (Bekiesińska-Figatowska et al., 2000; 2004 Chrzanowska et al., 2001) as well as in at least three others (Maraschio et al., 2001; Resnick et al., 2002; Nortrop, personal communication). Agenesis of the corpus callosum was associated developmentally with colpocephaly—i.e., disproportionate enlargement of the trigones, occipital horns, and usually temporal horns of the lateral ventricles. Large collections of cerebrospinal fluid (arachnoid cysts) in the pari-etooccipital and/or occipitotemporal regions were found in four patients (Stoppa-Lyonnet et al., 1992; Bekiesińska-Figatowska et al., 2000; Chrzanowska et al., 2001; Nortrop, personal communication). The cysts resulted from an anomalous splitting of the arachnoid membrane and are a congenital anomaly of the developing subarachnoid system. Both defects, callosal hypoplasia and arachnoid cysts, may frequently be underdiagnosed in NBS patients because they are asymptomatic. Hydrocephalus was reported in several patients, including one pair of sibs (Taalman et al., 1989; Bekiesińska-Figatowska et al., 2000; Muschke et al., 2004). Neuronal migration disorder in the form of schizencephaly and focal pachygyria has been diagnosed each in a single patient (Der Kaloustian et al., 1996; Bekiesińska-Figatowska et al., 2000).

*Skin and vascular anomalies.* Skin pigmentation abnormalities expressed as café-au-lait-like spots (rather irregular in shape) and/or depigmented spots can be seen in most patients; in three Polish patients, progressive vitiligo was observed at the age of

adolescence. Sun sensitivity of the eyelids is less frequent. Multiple pigmented nevi and cavernous or flat hemangiomas occur in a proportion of patients (Peréz-Vera et al., 1997; Chrzanowska, 1999; International Nijmegen Breakage Syndrome Study Group, 2000).

*Skeletal anomalies.* Minor skeletal defects such as clinodactyly of the fifth fingers and/or partial syndactyly of the second and third toes is encountered in about half of the patients (International Nijmegen Breakage Syndrome Study Group, 2000); less common is hip dysplasia (~15%) (Chrzanowska, 1999; unpublished observation). Uni- or bilateral preaxial polydactyly was observed in four patients (Chrzanowska et al., 1995a; Maraschio et al., 2001) and sacral agenesis was found in one (K. Chrzanowska, unpublished observation).

*Urogenital, anal, and miscellaneous malformations.* Anal atresia or stenosis was noted in six cases (Wegner et al., 1988; Chrzanowska, 1999; Tekin et al., 2002; Nortrop, personal communication). Among the urogenital anomalies, ectopic single kidney or dystopic kidneys were diagnosed in eight patients (Chrzanowska, 1999; International Nijmegen Breakage Syndrome Study Group, 2000; Muschke et al., 2004) and hydronephrosis in three additional patients (Seemanová et al., 1985; Taalman et al., 1989). Congenital cardiovascular or heart defect were noted in two cases (Chrzanowska et al., 2001; Tekin et al., 2002). Hypospadias (Der Kaloustian et al., 1996), cryptorchism (Pincheira et al., 1998), and genitourinary fistula (Chrzanowska, 1999) were observed each in only a single patient, as were other miscellaneous congenital anomalies such as cleft lip/palate (Seemanová et al., 1985), choanal atresia (Seemanová et al., 1985), and tracheal hypoplasia (Chrzanowska, 1999). Ultrasonographic evaluation of a large group of Polish patients revealed a high frequency of polysplenia (20%), a peculiarity with no clinical significance (Chrzanowska, 1999).

#### Infections and autoimmune disorders

As in A-T (see Chapter 29), the extent of immunodeficiency or proneness to infection in NBS patients showed striking intra- and interfamilial variability. Respiratory tract infections were present in most children. Recurrent pneumonia and bronchitis may result in bronchiectasis, respiratory insufficiency, and premature death from respiratory failure (Weemaes et al., 1981; Seemanová et al., 1985). Meningitis, sinusitis, and otitis media with draining ears and mastoiditis were observed in some children, as were gastrointestinal infections with diarrhea and urinary tract infections. Opportunistic infections are very rare, as in A-T (International Nijmegen Breakage Syndrome Study Group, 2000). Other diseases, probably caused by a defective immune system, have been observed in single cases: autoimmune hemolytic anemia, hemolytic anemia followed by thrombocytopenia, childhood sarcoidosis with ocular and cutaneous manifestations (Chrzanowska, 1999), and a juvenile rheumatoid arthritis-like polyarthritis (Rosenzweig et al., 2001). In two unrelated Polish patients, coexistence of NBS and Gilbert syndrome (familial idiopathic unconjugated hyperbilirubinemia associated with a partial reduction of hepatic glucuronyl transferase activity) has been noted (Chrzanowska, 1999).

#### Predisposition to malignancies

Both the immunodeficiency and the chromosome instability may predispose NBS patients to tumor development at an early age. In A-T, approximately 10% to 15% of the homozygotes develop

**Figure 30.3.** Characteristic facial features of a 7-year-old male patient with Nijmegen breakage syndrome (upper row) and his 5-year-old sister. Note microcephaly, microgenia, sloping forehead, slightly upward slanting of palpebral fissures, and prominent midface.

malignancy in early adulthood (Taylor et al., 1996). The rate is even higher in NBS. Cancer before the age of 21 years was noted in 40% (22/55) of the patients included in the NBS Registry in Nijmegen (International Nijmegen Breakage Syndrome Study Group, 2000). Updates from the two largest national NBS registries, the Polish registry (K. Chrzanowska, unpublished data) and the Czech registry (Seemanová et al., reported at the International Workshop on NBS, Prague, Czech Republic, 2002) indicated cancer development in 54% (45/83) and 65% (19/29) of

patients, respectively. The great majority of malignancies were of lymphoid origin, found in 41 and 15 patients, respectively. In the Polish series, the most frequent malignancies were non-Hodgkin lymphomas (NHL): in 30 patients (those of B cell origin slightly exceeded those of T cell origin), followed by lymphoblastic leukemia/lymphoma in 8 patients (T-LBL/ALL, T-ALL, pre-B-ALL) and Hodgkin disease in 3 patients (Gładkowska-Dura et al., 2000). Acute myeloblastic leukemia (AML) has been diagnosed in two NBS patients (Resnick et al., 2002; K. Chrzanowska,

unpublished observation). Moreover, Michallet et al. (2003) described the first case of T cell prolymphocytic leukemia (T-PLL) in NBS.

At least seven patients are known to have developed a second malignancy. One German patient (Rischewski et al., 2000) and two Polish patients had two consecutive lymphomas of the same type, with complete remission of 5–7 years in between (Gładkowska-Dura et al., 2000, 2005). Two additional Polish patients developed a different type of lymphoma as a second event (Gładkowska-Dura et al., 2005), and two other patients (Dutch and Czech) developed a different type of tumor after 10 and 4 years of remission, respectively (Weemaes et al., 2002). One Polish patient was recently diagnosed to have a third consecutive lymphoma of the same type (time interval between the two relapses, 7 and 6 years, respectively; Gładkowska-Dura et al., 2005). Both concordance of tumor type in a pair of NBS siblings (Wegner, 1991) and discordance in another pair (Wegner et al., 1999) have been reported.

Solid tumors have been less frequently noted, probably because the tumors usually develop at an older age. Five patients have developed a medulloblastoma (Chrzanowska et al., 1997; Bakskhi et al., 2003; Distel et al., 2003; E. Seemanová, personal communication; F. Tzortzatou-Stathopoulou, personal communication) and two have a rhabdomyosarcoma (Der Kaloustian et al., 1996; Tekin et al., 2002). Other tumors are represented only in single cases and include malignant meningioma, gonadoblastoma, Ewing sarcoma (E. Seemanová, personal communication), and ganglioneuroblastoma (K. Chrzanowska, unpublished observation).

At least three patients who had medulloblastoma and received radiation therapy before being diagnosed with NBS were fatally injured and eventually died from complications of the therapy (Chrzanowska et al., 1997; Bakskhi et al., 2003; Distel et al., 2003). Alopecia was a side effect observed in a Polish patient with AML given an 18 Gy dose of cranial irradiation for central nervous system (CNS) prophylaxis. However, another Polish patient with T cell acute lymphoblastic leukemia (T-ALL) tolerated well an identical dose of prophylactic cranial irradiation. Both patients were treated for malignancy before the diagnosis of NBS was established (K. Chrzanowska, unpublished observation).

Most malignancies develop before the age of 20 years (median age, 9 years; range, 1 to 34 years), and in about 20% to 30% of patients cancer appears prior to the diagnosis of NBS (Varon et al., 2000). On the basis of available records, an approximately 50-fold risk of early onset of cancer and a >1000-fold risk of lymphoma are estimated for patients with NBS.

The precise mechanism(s) leading to the increased cancer prevalence in NBS is (are) still unclear. Thus it is an open question as to whether the *NBS1* gene has a general function as a tumor suppressor gene. Molecular investigation of the frequency of the most common *NBS1* mutation, 657del5, in two NHL cohorts with 109 and 62 German children, respectively, failed to detect this mutation in the *NBS1* gene (Rischewski et al., 2000; Stanulla et al., 2000). Furthermore, a fluorescence in situ hybridization (FISH) analysis of tumor samples from 16 German NHL patients detected no deletions of the *NBS1* gene (Stumm et al., 2001b). Sequencing studies on 20 Japanese lymphomas (Hama et al., 2000) and tumor samples from 91 NHL patients in the United States (Cerosaletti et al., 2002) provided no evidence that *NBS1* mutations play a major role in the development of NHL. These studies demonstrate that neither a NBS heterozygote status nor mutations or deletions of the *NBS1* gene in the tumor itself are

frequent events in patients with B and T cell lymphomas. However, a Polish study of 456 children with lymphoid malignancies (208 with NHL and 248 with ALL) revealed five heterozygous carriers of a germ-line 657del5 mutation, in contrast to the expected incidence of 2.75 (Chrzanowska et al., 2004). This study has been expanded showing similar results and suggesting that *NBS1* gene heterozygosity is not a major factor in lymphoid malignancies in childhood and adolescence (Chrzanowska et al., 2005).

In contrast to NHL, Varon et al. (2001) detected mutations in *NBS1* in 15% of cases of childhood ALL, whereas none was observed in controls, a finding indicating a possible involvement of the *NBS1* gene in development of ALL. There is evidence that heterozygotes for NBS also show a significantly increased rate of malignancies (Seemanová et al., 1990). Recently performed studies on 1683 nonselected Polish patients with malignant tumors detected increased germ-line mutation frequencies for the 657del5 mutation and increased frequencies for the R215W amino acid exchange variant, indicating that heterozygous carriers of NBS mutations may indeed have an increased risk of developing tumors, especially in breast cancer and melanoma (Steffen et al., 2004). These data have been corroborated by recent findings of increased translocation frequencies in NBS heterozygotes (Stumm et al., 2001a; see Cytogenetics, below). Recently Shimada et al. (2004) reported the first case of aplastic anemia with a homozygous missense mutation in the *NBS1* gene (I171V) and hypothesized that the *NBS1* gene may play an important role in the pathogenesis of this complication.

#### Pathologic findings

Premature death of more than 70 NBS patients has been ascertained. Less than 10 died from infections that led to fatal respiratory failure, and two from renal insufficiency due to amyloidosis. Two others died as a result of bone marrow aplasia (Resnick et al., 2002), a hallmark of another chromosomal instability syndrome, FA. All the remaining patients died from malignancies. The oldest survivors were a 33-year-old Polish patient and a 31-year-old Dutch patient, both males.

Autopsies performed on several patients showed a reduced brain weight of more than 50% in all patients examined and internal hydrocephalus in some (Seemanová et al., 1985; van de Kaa et al., 1994; Muschke et al., 2004). A clear neuropathologic difference from A-T has been demonstrated with a cerebellum of normal size and development in NBS (van de Kaa et al., 1994).

A simplified gyral pattern, especially in the frontal lobes, with a severely diminished number of neocortical neurons was recently documented (Lammens et al., 2003). Marked hypoplasia of the thymus, absent thymus, or thymus replacement by fibrous tissues was reported in several other cases (Seemanová et al., 1985; van de Kaa et al., 1994; Muschke et al., 2004).

Suspicion of a lymphoproliferative disorder is the most frequent indication for lymph node biopsy, but only a few reports have appeared on the histologic and immunophenotypic features of lymphomas (van de Kaa et al., 1994; Elenitoba-Johnson and Jaffe, 1997; Paulli et al., 2000). A detailed description of 10 cases of NHL and one of Hodgkin disease revealed morphologic and immunotypic diversity of these NBS-linked lymphomas, ranging from immature, precursor-type lymphoid malignancies to mature T cell lymphomas to immunoglobulin-producing, large B cell phenotypes (DLBCL), a spectrum that appears to be more characteristic for adult rather than pediatric patients (Gładkowska-Dura et al., 2000, 2002, 2005). Further immunophenotypic and rearrangement studies have revealed clonal *IgH* gene

**Table 30.4.** Immune Defects in Patients with Ataxia-Telangiectasia Variant or Nijmegen Breakage Syndrome

Lymphopenia, T and B cells
Humoral immunity
Absent or low serum levels of IgA, IgG, IgM, or IgE
Abnormal IgG subclass distribution (deficient in IgG2, IgG4)
Cellular immunity
Low numbers of CD4 <sup>+</sup> subset
Decreased CD4 <sup>+</sup> /CD8 <sup>+</sup> ratio
High number of NK cells
Impaired proliferative response to mitogens in vitro

rearrangements in all but one DLBCL case, clonal *IgK* gene rearrangements in all cases, and *IgL* gene rearrangements in two (Gladkowska-Dura et al., 2002). None of the cases showed a Bcl-2/IgH translocation.

### Laboratory Findings

Laboratory tests helpful in the diagnosis of NBS include evaluation of humoral and cellular immunity, quantitation of serum  $\alpha$ -fetoprotein (AFP) levels, karyotyping, and radiosensitivity assays. Molecular analysis is possible in most cases (see Genetics, below).

#### Immunological data

The immune deficiency in NBS patients is very heterogenic and concerns the humoral and cellular immune systems (Table 30.4).

A longitudinal follow-up study of 40 NBS patients, diagnosed and monitored at a single medical center, the Children's Memorial Health Institute (CMHI) in Warsaw, offered a unique opportunity to gather clinical and laboratory data on a large series of patients (Gregorek et al., 2002). This study extends and supplements data collected earlier to assess the immune system in individuals with NBS (Chrzanowska et al., 1995b; International Nijmegen Breakage Syndrome Study Group, 2000).

The most important observation is the considerable variability in immunodeficiency seen among different patients and in the same individual over the course of time (Gregorek et al., 2002). At diagnosis, severe hypogammaglobulinemia with IgG concentrations below 2.0 g/l, low or undetectable IgA, and decreased IgM was observed in approximately 21% of patients, while an additional 20% had normal concentrations of all three major immunoglobulin classes. The most common finding was a combined deficit of IgG and IgA (31%), followed by isolated IgG deficiency (28%). IgG subclass distribution was abnormal in most patients, affecting predominantly IgG4 (74%), followed by IgG2 (66%) and IgG1 (63%). It is worth noting that in about 37% of NBS patients, normal levels of total serum IgG can mask deficiency of IgG subclasses. This phenomenon points to the importance of determining IgG subclasses, especially in those NBS patients who suffer from frequent infections. The concentrations of IgM and IgG3 are rarely affected; in fact, IgM levels may be elevated (Wegner et al., 1988; Chrzanowska et al., 1995b; Gregorek et al., 2002). These observations suggest that the process of class switching to C<sub>H</sub> genes downstream of  $\gamma 3$  ( $\gamma 1$ ,  $\alpha 1$ ,  $\gamma 2$ ,  $\gamma 4$ ,  $\epsilon$ , and  $\alpha 2$ ) is frequently blocked in NBS. Recently, Pan et al. (2002) provided the first evidence linking ATM and nibrin to class switch recombination (CSR). Lahdesmaki et al. (2004) have suggested that MRE11, nibrin, and ATM might play both common and independent roles in CSR.

Similar to A-T patients, both normal (Green et al., 1995; Der Kaloustian et al., 1996) and disturbed (Wegner et al., 1988; Weemaes et al., 1991) antibody responses to diphtheria and

tetanus vaccination have been reported. One NBS patient failed to mount a primary antibody response to *Helix pommatia* hemocyanin (Weemaes et al., 1991). Naturally acquired IgG-specific antibodies to most invasive pneumococcal polysaccharides (e.g., serotypes 3, 19, 23) were not detectable or were found in very low titers in 75% of patients investigated at CMHI. Moreover, only 25% of patients vaccinated against hepatitis B virus (HBV) developed antibodies to hepatitis B surface antigen of the protective IgG isotype, which are restricted to two IgG subclasses: IgG1 (present in all positive samples) and IgG3 (found in one patient only). In 65% of the individuals, only IgM antibodies to hepatitis B surface antigens were found; in the remaining 10%, no specific antibodies were detectable, despite normal or only moderately decreased levels of total IgG (Gregorek et al., 2002). Systematic longitudinal observations of 17 available NBS patients at CMHI showed a progressive deterioration of the immune system in 9 of 17 patients (53%). There was no correlation between immunodeficiency profile (or its severity) and duration of the disease, age or gender of the patients studied.

T cell immunity is abnormal in most tested patients. The most evident defects are reduced numbers of CD3<sup>+</sup> T cells observed in 93%, a reduced number of CD4<sup>+</sup> T cells in 95%, and a reduction in CD8<sup>+</sup> T cells in 80%. A decreased CD4/CD8 ratio is also a characteristic feature of this syndrome (Chrzanowska et al., 1995b; van der Burgt et al., 1996; International Nijmegen Breakage Syndrome Study Group, 2000). The number of B cells is reduced in most patients (~75%), but may also be normal or even elevated in some patients despite marked deficiency of serum immunoglobulins, suggesting an intrinsic B cell defect affecting class switch recombination (Gregorek et al., 2002). Detailed characteristics of lymphocyte surface receptors have been reported in a large group ( $n = 42$ ) of NBS patients (Michalkiewicz et al., 2003).

A deficiency of CD4<sup>+</sup>,CD45RA<sup>+</sup> (naive) cells and an excess of CD4<sup>+</sup>,CD45RO<sup>+</sup> (memory) T cells has been observed in all patients tested (Chrzanowska et al., 1995b). A relatively high number of natural killer (NK) cells was noted in the majority of NBS patients (Green et al., 1995; Der Kaloustian et al., 1996). In vitro lymphocyte proliferation in response to mitogens (phytohemagglutinin [PHA], concanavalin A [Con A], pokeweed mitogen [PWM]) is defective in most patients (Weemaes et al., 1981; Seemanová et al., 1985; Conley et al., 1986; Der Kaloustian et al., 1986; Wegner et al., 1988; Chrzanowska et al., 1995b; International Nijmegen Breakage Syndrome Study Group, 2000). In one case lymphocyte proliferation in the presence of specific antigens (tetanus, tuberculin, candidin) was absent, in spite of normal response to PHA (Stoppa-Lyonnet et al., 1992). Recall antigens (Merieux) given intradermally produced no delayed-type hypersensitivity reactions (Wegner et al., 1988).

#### $\alpha$ -Fetoprotein level

Serum AFP concentration is within the normal range in NBS (van der Burgt et al., 1996), in contrast to A-T, where elevated levels are found in >90% of patients (Woods and Taylor, 1992).

#### Cytogenetics

In most cases, the diagnosis of NBS is entertained on clinical findings and confirmed by cytogenetic and/or molecular analysis of the *NBS1* gene. T lymphocytes of NBS patients often show a poor response to mitogens, consequently, cultures exhibit a low mitotic index. This limitation to cytogenetic characterization of patient's cells, particularly when testing for mutagenic sensitivity, can be overcome in most cases by using EBV-transformed lymphoblastoid cell lines.

**Table 30.5.** Cytogenetic and Cellular Features of Nijmegen Breakage Syndrome Cells

Normal constitutive karyotype
Increased spontaneous chromosomal instability
Open chromatid and chromosome breaks
Rearrangements of chromosomes 7 and 14
Telomere fusions
Radioresistant DNA synthesis
Hypersensitivity to ionizing radiation and radiomimetic agents
Increased sensitivity to alkylating agents

NBS cells express the typical cytogenetic features of a chromosomal instability syndrome (Table 30.5). In general, NBS patients have a normal karyotype, but chromosomal instability, as in A-T patients, is a consistent finding. One of the most striking features of NBS is the high level of chromosome rearrangements in cultured T lymphocytes involving chromosomes 7 and 14. Most of these rearrangements occur in chromosome bands 7p13, 7q35, 14q11, and 14q32 (as in A-T), which are the location of the human immunoglobulin and T cell receptor genes (Aurias et al., 1980; Aurias and Dutrillaux, 1986). Generally, translocations are detectable in 10% to 35% of NBS cells and in 5%–10% of A-T cells (van der Burgt et al., 1996). The most frequently detected aberration in T lymphocytes is inv(7)(p13q35), followed by other rearrangements such as t(7;14)(p13;q11), t(7;14)(q35;q11), t(7;7)(p13;q35), and t(14;14)(q11;q32) (van der Burgt et al., 1996; Hiel et al., 2001). Other less frequently reported NBS breakpoints, for example, t(X;14)(q27–28;q11–13), have also been found in A-T cells (Wegner, 1991).

Open chromosomal aberrations, such as chromatid breaks, chromosome breaks, and acentric fragments, as well as marker chromosomes and unspecific chromatid exchanges have been frequently found in lymphocytes and fibroblasts of NBS patients (Weemaes et al., 1981; Seemanová et al., 1985; Conley et al., 1986; Wegner et al., 1988; Taalman et al., 1989; Barbi et al., 1991; Stoppa-Lyonnet et al., 1992; Chrzanowska et al., 1995a; Der Kaloustian et al., 1996; Pérez-Vera et al., 1997; Tupler et al., 1997; Kleier et al., 2000; Chrzanowska et al., 2001; Maraschio et al., 2001). In contrast, chromosomal instability has not been observed in NBS bone marrow cells (Weemaes et al., 1981). An additional uncommon chromosomal abnormality has been described in a 5-year-old NBS patient who showed in addition to the typical 7/14 translocations monosomies of nearly all chromosomes in 64% of the analyzed lymphocyte metaphases (Der Kaloustian et al., 1996). This finding points to deficiencies in the fidelity of mitotic chromosome separation. Whether nibrin, the product of *NBS1*, is involved in chromosome segregations remains unclear. An elevated rate of spontaneous chromosomal instability has been observed in EBV-positive immortalized B lymphoblasts from many NBS patients (Conley et al., 1986; Tupler et al., 1997; Maraschio et al., 2001).

However, there are some NBS cell lines that have a low frequency of chromosomal aberrations or no chromosomal instability at all (Wegner, 1991; Stumm et al., 1997; Chrzanowska et al., 2001). In contrast to primary T lymphocytes, the spontaneous instability in lymphoblastoid cell lines (LCLs) is expressed as unspecific chromosomal aberrations, including a tendency of chromosomes to form telomeric associations resulting in dicentric chromosomes. Recent molecular and cellular data on NBS suggest that this cytogenetic phenomenon is a direct consequence of a functional deficiency of nibrin, a protein found at telomeres, where it associates with the telomeric repeat binding factor TRF2

(Lombard and Guarente, 2000; Zhu et al., 2000). Chromosomes from NBS patients have shortened telomeres that can be corrected by reintroduction of nibrin into patient fibroblasts (Ranganathan et al., 2001). Thus, the absence of nibrin might interfere with telomere metabolism, resulting in illegitimate fusion of telomeres between different chromosomes. Siwicki et al. (2003) have provided evidence that telomere length maintenance is intact in T lymphocytes in the absence of full-length nibrin, presumably because of an alternatively spliced NBS protein of 70 kDa.

All of the cytogenetic aberrations discussed above were obtained by standard microscopic analysis of Giemsa-stained and/or GTG-banded chromosomes. Very recently, more distinct insight into the chromosomal instability of NBS cells was obtained by use of FISH with a three-color whole-chromosome painting assay (WCP 1, 2, 4) (Color Plate 30.I). Through use of this technique, an increased frequency of spontaneous translocations was detected (Stumm et al., 2001a). The presence of chromosomal aberrations, which might escape detection by conventional cytogenetic techniques, demonstrates that the degree of spontaneous genomic instability in NBS might be even higher than previously thought and may be an important risk factor for tumor development. The WCP 1, 2, 4 assay is also suitable for the detection of radiation induced chromosomal instability in NBS and A-T patients (Neubauer et al., 2002).

Sister chromatid exchange (SCE) frequencies were found to be normal in lymphocytes (Weemaes et al., 1981; Conley et al., 1986; Wegner et al., 1988; Barbi et al., 1991; Der Kaloustian et al., 1996), fibroblasts, and LCLs (Conley et al., 1986) from all NBS patients investigated to date. The induction of chromosomal breakage in NBS lymphocytes and fibroblasts by irradiation proves a strong hypersensitivity to ionizing irradiation (IR) as well as to radiomimetic agents, such as bleomycin (Wegner et al., 1988; Taalman et al., 1989; Green et al., 1995; Hiel et al., 2001). These characteristics clearly separate NBS cells from normal cells (Fig. 30.4) and has been used in our laboratories to confirm the diagnosis. A metaphase with a typical spectrum of lesions is shown in Figure 30.5. Increased radiosensitivity of NBS cells is also apparent from a decrease in colony-forming ability following exposure to IR (Taalman et al., 1983; Jaspers et al., 1988a). Controversial results have been published concerning the hypersensitivity of NBS cells to alkylating agents. Seemanová et al. (1985) found weak evidence for increased chromosomal sensitivity to the bifunctional alkylating agent diepoxybutane (DEB) in one of two analyzed patients; Der Kaloustian et al. (1996) found normal DEB sensitivity in a third NBS patient. However, a clearly increased response to Trenimon was reported in siblings with NBS as early as 1991 (Wegner, 1991). Results obtained from these patients, now proven to carry the typical Slavic mutation 657del5, are shown in Figure 30.6. The speculation that the functionally deficient nibrin plays a central role in the aberrant repair processes of different types of DNA damage in NBS cells has been proven correct. Nakanishi et al. (2002) provided evidence for cooperation between the FA gene product FANCD2 and nibrin in the DNA cross-linking response (see Fanconi Anemia, above and Molecular Interactions Between Nibrin and Other Proteins, below). Extensive studies of a cohort of NBS and a group of typical A-T patients corroborated the finding of marked sensitivity to the trifunctional alkylating agent Trenimon (Wegner et al., 1994). At doses of  $10^{-8}$  M Trenimon, the chromosomal breakage rates of some NBS cell lines exceeded the control rate by more than 10 times (Wegner, 1991; Wegner et al., 1994; Stumm et al., 1997) (Fig. 30.6). A moderate sensitivity to MMC has been observed in one NBS patient (Chrzanowska et al.,

**Figure 30.4.** Spontaneous and bleomycin-induced chromosomal breakage rates in lymphoblastoid cell line metaphases from Nijmegen breakage syndrome (NBS) patients and a control, respectively. Bleomycin was added 1 hour before harvesting: 50 cells/column were counted in each situation. Note that there is an unequivocal discrimination between affected and control individuals at the higher bleomycin concentration. Patients are identified by family number (first digit) and individual number (second digit).

2001). This moderate sensitivity to MMC is lower than in FA patients but has also been found in cell lines from other NBS patients (Kraakman-van der Zwet et al., 1999; Nakanishi et al., 2002; M. Stumm and R. Wegner, unpublished observation). These findings are of significance with respect to chemotherapy for NBS patients: the intensity of the treatment should be adjusted to the patient's individual risk factors and tolerance (Seidemann et al., 2000). Therefore, testing cells for their response to cytostatic agents should be considered and might reduce the risk of therapeutic side effects in sensitive patients.

#### Cell cycle

Although the function of nibrin in cell cycle control is far from fully understood, its involvement in cell cycle checkpoints is

supported by cellular, molecular, and cytogenetic data. Unlike in normal cells, DNA synthesis after IR or bleomycin treatment is not inhibited in NBS cells (Jaspers et al., 1988a; Wegner et al., 1988; Chrzanowska et al., 1995a). This feature, called *radiore-sistant DNA synthesis* (RDS), was initially described in A-T cells (Cramer and Painter, 1981; deWit et al., 1981). RDS in NBS cells seems to be linked to a pathway involving the interaction of nibrin and SMC1. The inhibition of DNA synthesis after IR seems to depend on phosphorylation of SMC1, a member of the cohesion proteins. Efficient phosphorylation of SMC1 by ATM requires nibrin (reviewed by Digweed and Sperling, 2004). In addition to this highly characteristic defect in an S-phase-dependent cell cycle checkpoint, there are further disturbances in cell cycle progression in some NBS cell lines. The role of *NBS1*

**Figure 30.5.** Lymphoblastoid cell line metaphase of a bleomycin-treated Nijmegen breakage syndrome cell showing chromatid breaks (chtb) and chromatid exchanges (chte).

**Figure 30.6.** Trenimon-induced chromosomal breakage in lymphoblastoid cell line metaphases from Nijmegen breakage syndrome (NBS) and ataxia-telangiectasia (AT) patients. Trenimon exposure ( $10^{-8}$  M) lasted 24 hours. At least 50 cells/column were analyzed.

in G1/S checkpoint control is controversial, because the extent of p53 accumulation and strength of expression of G1/S arrest after irradiation differ substantially in individual NBS cell lines (Jongmans et al., 1997; Sullivan et al., 1997; Matsuura et al., 1998; Yamazaki et al., 1998; Antoccia et al., 1999; Girard et al., 2000). An explanation for these variations might be dose-dependent differences in the response, as Girard et al. (2002) showed G1/S arrest in NBS cells at 1 Gy that was abolished at 5 Gy. Irrespective of differences in p53 induction and G1/S checkpoint control, NBS and A-T cells show comparable chromosome aberrations, both in quantity and in quality. This means that there is no simple correlation between checkpoint control and radiation-induced chromosomal instability. Therefore, factors other than those related directly to G1/S cell cycle checkpoint control seem to be involved mainly in radiation sensitivity and chromosomal instability in NBS cells (Antoccia et al., 1999). The role of NBS1 in G2 checkpoint control is also controversial, because the G2/M-phase transition appears to be extremely variable among different NBS cell lines. Some NBS cells, like A-T cells, fail to stop entry into mitosis after irradiation, a finding suggesting that NBS1 deficiency may disturb the G2/M checkpoint (Pincheira et al., 1998; Buscemi et al., 2001; Maraschio et al., 2001). In contrast, other NBS cells show a normal G2/M transition (Antoccia et al., 1997, 2002; Yamazaki et al., 1998; Girard et al., 2000). Because recent reports suggest an impaired ability of NBS cell lines to phosphorylate checkpoint kinase 2 (CHK2) (Buscemi et al., 2001; Girard et al., 2002), it is reasonable to expect effects of nibrin mutations on G2/M checkpoint control (see Molecular Interactions Between Nibrin and Other Proteins, below).

The expression of checkpoint impairment in NBS cells appears to vary considerably and be dose-dependent. Therefore, checkpoint disturbance is likely not the main reason for the strong radiation sensitivity in these cells over a broad range of doses.

## Genetics

### Identification of the *NBS1* gene

Despite clear differences in the clinical characteristics of NBS and A-T, cells from patients with these diseases express nearly identical cytogenetic and cellular features. This phenomenon led to the suggestion that NBS and A-T are two disorders due to al-

lelic mutations (Curry et al., 1989). In contrast to this proposal, linkage analysis in six NBS families, formerly called ataxia-telangiectasia variant (AT-V) families, with at least two affected siblings proved unequivocally that the underlying *NBS* gene was not localized in the *ATM* region at 11q23.1 (Stumm et al., 1995). In agreement with this linkage exclusion, chromosome 11 could not complement the NBS phenotype on the cellular level in chromosome transfer studies (Komatsu et al., 1996). In 1988 it was postulated that NBS is a heterogeneous disease and that NBS patients fall into two complementation groups, AT-V1 (Nijmegen breakage syndrome) and AT-V2 (Berlin breakage syndrome) (Jaspers et al., 1988a, 1988b; Wegner et al., 1988). This conclusion was based on complementation studies using differentially labeled parental fibroblast cell lines in fusion experiments and comparing the rate of DNA synthesis in homokaryons with that in heterokaryons after irradiation or bleomycin treatment. Doubts about the reliability of this assay came with the report that A-T patients assigned to four complementation groups by employing the same assay actually all carried allelic mutations in the same gene, the *ATM* gene (Savitsky et al., 1995). Subsequent cell fusion studies between AT-V1 and AT-V2 LCLs failed to achieve complementation, although there was clear normalization in the rate of chromosomal aberrations after fusion with normal cells (Stumm et al., 1997).

Finally, mapping of the *NBS* gene was initiated using two approaches. One was a whole-genome scan by polymerase chain reaction (PCR)-based microsatellite markers, the other followed the concept of unmasking heterozygosity. The latter study involved linkage studies in NBS families with markers spanning the potential gene loci at the breakpoints of a constitutional translocation t(3;7)(q12;q31.3) in a NBS patient, where the derivative chromosomes were transmitted from the unaffected father to the affected daughter. Both linkage and haplotype analysis with markers spanning both translocation breakpoints on chromosomes 3 and 7 in 12 NBS families allowed the clear exclusion of an AT-V gene from the translocation breakpoints (Chrzanowska et al., 1997) but failed to identify the gene location. In contrast, the whole-genome scan was successful in localizing the gene. The analysis of 20 NBS patients from 14 families proved linkage to a 1 cM interval between markers D8S171 and D8S170 on chromosome 8q21 in all families. Furthermore, these results indicate that there is only one single *NBS* gene (Saar et al., 1997).

**Figure 30.7.** The *NBS1* gene and protein(s). Shown here is a physical map of the *NBS1* region as defined by haplotype analyses of Nijmegen breakage syndrome (NBS) patients of Slavic origin. The positions of genes and genetic markers are indicated. The numbers below the line representing the DNA indicate the distances in kb between restriction enzyme sites (S, Sall; N, NotI; B, BamHI). Below the physical map, the exon structure of the *NBS1* gene is shown expanded. The position of mutations

and the location of forkhead-associated (FHA) and breast cancer carboxy-terminal (BRCT) protein domains within the 754 residue p95 sequence are indicated. Serine residues that are phosphorylation targets are shown together with regions demonstrating similarity to yeast Xrs2 or implicated in binding to MRE11. Two protein fragments, p26 and p70, are found in NBS patient cells carrying the 657del5 mutation because of premature termination of translation and alternative translation, respectively.

### The *NBS1* gene

The gene underlying NBS, designated *NBS1*, was identified independently by two groups. Varon et al. (1998) employed the positional cloning strategy, whereas Carney et al. (1998) studied the hMre11/hRad50 double-strand repair complex and identified a third member of this complex, p95, as being the product of the *NBS1* gene, now called *nibrin*. As shown in Figure 30.7, the *NBS1* gene spans about 50 kb of genomic DNA, has 16 exons, codes for a protein with 754 amino acids, and has a calculated molecular weight of 85 kDa. The mRNA is polyadenylated at two alternative sites, leading to mRNAs of 4.4 and 2.4 kb in all tissues examined thus far. Altogether, nine different mutations have been identified so far in NBS patients (Varon et al., 1998; Hiel et al., 2001; Maraschio et al., 2001; Resnick et al., 2002; Digweed and Sperling, 2004; P.J. Concannon and R.A. Gatti, www.geneclinics.org). The 657del5 mutation is the most widespread Slavic founder mutation, which results in a frameshift causing the largest truncation of nibrin. Seven additional truncation mutations were identified in exons 6, 7, 8, and 10, all downstream of the FHA/BRCT domains (Fig. 30.7). Therefore, all NBS patients studied to date have large sequence losses on the C-terminal portion of the protein. Nevertheless, all patients express a truncated protein containing the N-terminal domains, a finding suggesting

that these sequences may be essential during embryonic development and that *NBS1* null mutants would result in fetal death. In 2001, Maser et al. reported that NBS cells with the common 657del5 mutation produce a 70 kDa protein fragment (*NBS1*<sup>p70</sup>) lacking the native N terminus, which associates with the hRAD50/hMRE11 complex. This *NBS1*<sup>p70</sup> fragment is produced by internal translation initiation within the *NBS1* mRNA using an open reading frame generated by the 657del5 frameshift. Therefore, the common *NBS1* 657del5 mutation seems to be a hypomorphic mutation, encoding a partially functional protein that diminishes the severity of the NBS phenotype. This hypomorphic mutation might be essential for fetal development in humans and other mammals, because null mutations have not been found in humans, and mouse null mutants are nonviable (Zhu et al., 2001; Dumon-Jones et al., 2003). Interestingly, null mutations in *MRE11* and *RAD50* are also lethal in mammals (Xiao and Weaver, 1997; Luo et al., 1999). Although the amino acid sequence of nibrin shows no global homology to other known proteins, there are two domains within the N-terminal 200 residues that can be found in other proteins: a breast cancer carboxy-terminal (BRCT) domain, first described in the *BRCA1* gene, and a fork-head-associated (FHA) domain, named after the transcription factor family in which it was initially found (Fig. 30.7). Both of these domains are expected to be involved in protein-protein

interaction. Two members of the NHEJ repair pathway of DNA DSBs, hMRE11 and hRAD50, were identified as molecular partners of nibrin (Carney et al., 1998). Nibrin shows a weak similarity (46%) to the yeast protein XRS2, restricted only to the first 115 amino acids. In contrast, the entire amino acid sequences of the MRE11 and RAD50 proteins are widely conserved from yeast to mammals.

### Molecular Biology of Nibrin

Nibrin appears to exert multifunctional activity. The identification of nibrin as a member of the human NHEJ repair complex of DSB suggests that defective DSB repair may be the central problem in NBS. The impasse involving p53 activation and cell cycle arrest indicate that nibrin may also be involved in signal transduction. Another possible role of nibrin involves its interaction with histone  $\gamma$ -H2AX, forming a complex that associates with irradiation-induced DSBs (Kobayashi et al., 2002). However, nibrin seems to have a much more important role in the processing of DSB. Within 30 minutes of irradiation, discrete nuclear foci can be visualized in the irradiated nuclei of cells by staining with antibodies to the repair proteins hMRE11 or hRAD50. Staining with antibodies to nibrin produces exactly the same pattern, demonstrating that nibrin remains in the nuclei for more than 8 hours post-irradiation. The formation of nuclear foci is fully abrogated in NBS cells (Color Plate 30.II). Even the diffuse nuclear staining found in unirradiated normal cells is lacking in NBS cells, and considerable proportions of hRAD50 and hMRE11 are localized in the cytoplasm rather than in the nucleus. Since hRAD50 and hMRE11 are still found as a complex in NBS cells, a functional nibrin is clearly responsible for the location of these repair enzymes to the sites of DNA damage (Carney et al., 1998; Ito et al., 1999). In addition, nibrin is essential for the phosphorylation of hMRE11 after DNA damage (Dong et al., 1999) and it potentiates the ATP-driven DNA unwinding and endonuclease activity by the hRAD50/hMRE11 complex (Paull and Gellert, 1999). The hRAD50/hMRE11/nibrin complex has manganese-dependent, single-stranded DNA endonuclease and 3' to 5' exonuclease activities, thus it may be directly responsible for preparation of DNA ends for rejoining (Trujillo et al., 1998). Taken together, these findings indicate that nibrin plays an important regulatory role in the hRAD50/hMRE11/nibrin complex that responds to irradiation-induced DNA damage. The whole complex may act as a key factor in signaling and processing of DSB to initiate NHEJ and possibly homologous recombination as well.

### Molecular interactions between nibrin and other proteins

Considering the strong similarities in the cellular phenotypes of A-T and NBS, an important finding was the discovery that ATM and the hRAD50/hMRE11/nibrin complex function in the same network. Four laboratories reported that ATM modifies the hRAD50/hMRE11/nibrin complex by phosphorylation of nibrin (Gatei et al., 2000; Lim et al., 2000; Wu et al., 2000; Zhao et al., 2000). Following exposure to IR, rapid phosphorylation of at least two serine residues of nibrin occurs. It is possible that the phosphorylation of distinct residues could modify the hRAD50/hMRE11/nibrin complex in different ways and therefore play a concerted regulatory role. This function is disturbed in NBS cells, because cells expressing mutant nibrin cannot be phosphorylated by ATM. ATM-dependent activation of CHK2, a key protein in cell cycle control in response to DNA

damage, requires functional nibrin (Buscemi et al., 2001). Thus, apart from the function in DSB repair, the hRAD50/hMRE11/nibrin complex appears to be specifically required to activate checkpoint control pathways following the formation of DSBs (reviewed in D'Amours and Jackson, 2002).

Nibrin physically interacts with histone by direct binding to  $\gamma$ -H2AX, which is phosphorylated in response to the introduction of DSB and may therefore act as a very early responder to the DNA repair machinery. The FHA/BRCT domain of nibrin is essential for physical interaction with  $\gamma$ -H2AX and seems to play a crucial role in the binding to histone and in localization of the hMRE11/hRAD50 repair complex to damaged DNA (Kobayashi et al., 2002). Additionally, as Nakanishi et al. (2002) were able to show, nibrin and the FA subtype D2 protein (FANCD2) cooperate in two distinct cellular functions, one involved in the response to DNA cross-links and another involved in the S-phase checkpoint control. Therefore, nibrin functions at the intersection of two main signaling pathways. In response to the DNA cross-linking agent MMC, nibrin assembles in subnuclear foci with hMRE11/hRAD50 and FANCD2. Ionizing radiation activates an S-phase checkpoint through the ATM- and NBS1-dependent phosphorylation of FANCD2. Thus the involvement of nibrin in the pathway of DNA cross-linking repair, as shown by molecular and cellular analysis, fits with earlier cytogenetic results of a significant increase in chromosomal aberrations above normal levels in NBS cells exposed to Trenimon (Wegner, 1991; Stumm et al., 1997) or other cross-linkers as discussed above (in Cytogenetics).

Moreover, there is evidence that the hMRE complex also plays an important role in prevention of DSB formation during the normal replicative process. It has been shown that certain helicases, for example, proteins mutated in Werner syndrome (WRN) (Cheng et al., 2004) and in Bloom syndrome (BLM) (Franchitto and Pichierri, 2002a, 2002b), associate with the hMRE complex via binding to NBS1 in vitro, and in vivo after IR or MMC exposure, preventing the accumulation of DSB during chromosomal DNA replication (Costanzo et al., 2001). These observations provide convincing evidence for a functional link of multiple proteins that are mutated in many of the known chromosomal instability syndromes, including FA, NBS, BS, Werner syndrome, and A-T (see Chapter 29).

### Heterogeneity of Nijmegen Breakage Syndrome

Some patients indistinguishable from NBS by clinical and cellular criteria do not carry mutations in the *NBS1* gene (Cerosaletti et al., 1998; Hiel et al., 2001; Maraschio et al., 2003). These observations strongly suggest mutations in one or more other genes that may cause NBS-like phenotypes. Indeed, a novel non-homologous end-joining factor, NHEJ1, also called Cernunnos protein, has recently been identified and found to be mutated in patients with an NBS-like phenotype characterized by microcephaly, SCID, and chromosomal instability (Ahnesorg et al., 2006; Buck et al., 2006).

### Prenatal Diagnosis

Prenatal diagnosis of NBS is based on molecular methods whenever the underlying gene mutations in the index patient or parents are known. When no informative molecular data are available, RDS analysis in cultured chorionic villi or amniotic fluid cells is a reliable method for identifying NBS in a fetus (Jaspers et al., 1990; Kleijer et al., 1994; Der Kaloustian et al., 1996). Heterozygotes

cannot be diagnosed by cytogenetic means (Wegner, 1991). Detailed protocols for cytogenetic analysis of NBS and other chromosomal instability syndromes are provided by Wegner and Stumm (1999).

### Treatment and Prognosis

There is no specific therapy for NBS. All treatments are symptomatic and must be individualized. Intravenous administration of immunoglobulins (IVIG) and antibiotic prophylaxis may be an effective treatment in patients with significant immune deficiency and recurrent infections. One should also keep in mind that immunodeficiency mandates avoidance of live vaccines. Because cellular susceptibility to radiation and chemotherapy is increased in NBS patients, as in those with A-T, diagnostic irradiation should be reduced as much as possible and management of cancer therapy must be modified (Hart et al., 1987; Busch, 1994; Seidemann et al., 2000; Barth et al., 2003). NBS females presenting with hypergonadotropic hypogonadism require hormonal replacement therapy to induce and complete puberty and to avoid osteoporosis (Pozo and Argente, 2003). The overall prognosis for patients with NBS is unfavorable as compared to normal individuals, with premature death occurring due to either overwhelming infection or malignancies.

### Bloom Syndrome

Bloom syndrome (BS) (MIM 210900) is an autosomal recessive chromosomal instability syndrome. The most consistent physical feature of BS is a strikingly small but well-proportioned body size and predisposition to the early development of a variety of cancers (German, 1993; German and Ellis, 2002). BS is the consequence of either homozygosity or compound heterozygosity of mutations in *BLM*, a gene that encodes the phylogenetically highly conserved nuclear RECQL2-helicase.

### Clinical and Pathological Manifestations

Bloom syndrome was first recognized as a clinical entity by a dermatologist (Bloom, 1954). The most striking clinical feature, besides the small body size, is a sun-sensitive erythematous skin lesion in the butterfly area of the face, a feature that diagnostically sets the smallness of BS apart from other growth deficiencies (Color Plate 30.III). The full spectrum of BS has been defined by collecting clinical data through the Bloom Syndrome Registry (German and Passarge, 1989), in which a cohort of 169 patients diagnosed before 1991 has been enrolled and a second cohort of 60 additional cases added after January 1991. The clinical features and complications that constitute the phenotype BS, based on the Registry data, are summarized in Table 30.6 (German 1993; German and Ellis, 2002; unpublished registry data). Following Bloom's original report (1954) of a sun-sensitive "telangiectatic erythema resembling lupus erythematosus in dwarfs," additional classic features of BS were reported: (1) a striking sparsity of adipose tissue throughout infancy and childhood, (2) serious gastrointestinal problems during infancy, (3) susceptibility to respiratory tract and middle ear infections, and (4) sub- or infertility and an unusually early menopause. Nevertheless, at least five women with BS have become pregnant (Chisholm et al., 2001). Major complications of BS, subsequently observed and confirmed by findings from the registry, include chronic lung disease, which developed in at least 9 of the 169 individuals from cohort I, causing premature death in 5 at a mean age of 24.6 years. Although

**Table 30.6.** Clinical Phenotype, Immunodeficiency, and Chromosomal Abnormalities of Bloom Syndrome

---

<i>Growth and Development</i>
Abnormally small body size
Sparseness of subcutaneous fat
Slightly disproportional microcephaly
Characteristic facial and head configuration
Minor anatomical malformations
<i>Skin Lesions</i>
Sun-sensitive erythema limited almost exclusively to the face and dorsa of hands and forearms
Non-sun-sensitive hyper- and hypopigmented areas
<i>Gastrointestinal Symptoms</i>
Most consistent during infancy
Gastroesophageal reflux, vomiting
Anorexia
Diarrhea
<i>Infertility</i>
Lack of sperm production
Premature menopause
<i>Complications</i>
Chronic lung disease
Diabetes mellitus, type II
Neoplasia
<i>Immunodeficiency</i>
Hypogammaglobulinemia
Depressed delayed type hypersensitivity
Susceptibility to infections, mostly bacterial
Upper and lower respiratory tract
Otitis media
<i>Genomic Instability in Somatic Cells</i>
Aberrant DNA replication
Increased chromosomal interchanges
Sister chromatid exchange
Quadriradials, telomeric association

---

considered to be a consequence of recurrent lung infections, an alternative etiology, gastroesophageal reflux, has been proposed as cause of the chronic lung pathology. Diabetes mellitus, diagnosed at the mean age of 25.7 years, developed in 31 individuals of cohort I. A total of 143 episodes of cancer have been diagnosed in 90 of the 169 patients with BS. This remarkable predisposition to the early development of cancer is a hallmark of BS (German et al., 1997) and of the other chromosomal instability syndromes described in this chapter and in Chapter 29. By age 25, approximately half of the patients with BS will have developed a malignancy, many of them more than one type. In the first two decades of life, the predominant types are leukemia and NHL. Later, carcinoma affecting predominantly the colon, skin, and breast are common. An increased risk of colorectal cancer in *BLM* heterozygosity has been observed in one study of Ashkenazi Jews (Gruber et al., 2002), but not in another (Cleary et al., 2003).

### Laboratory Findings

#### Cytogenetics

Once BS is suspected, the diagnosis can be confirmed by karyotyping: the chromosomes of PHA-stimulated lymphocytes of an individual with BS exhibit an excessive number of sister-chromatid

**Figure 30.8.** The characteristic and diagnostic elevation in number of sister chromatid exchanges (SCEs) in a cultured Bloom syndrome cell exposed to bromodeoxyuridine (BrdU) for two cell division cycles. Differentiation of the sister chromatids, dark or light, is accomplished by exposure of the BrdU-substituted chromosomes to the Hoechst dye 33258, then to light, and finally to Giemsa stain. The approximately 135 SCEs in this cell contrast with the fewer than 10 SCEs seen in similarly treated normal cells. A quadriradial chromosome is visible in the left field.

exchanges (SCE) (Fig. 30.8), a finding uniquely characteristic of BS (German et al., 1977).

In addition to the high numbers of SCEs, cultured B and T lymphocytes and skin fibroblasts from individuals with BS exhibit enhanced chromosome instability—"breakage"—as indicated by an increased number of chromatid gaps and breaks and structurally rearranged chromosomes. Approximately 1% of cultured lymphocytes in metaphase display a symmetrical four-armed configuration, designated as *quadriradial* (QR), composed of two homologous chromosomes. Opposite arms of the QR are of equal length, and the centromeres are positioned opposite one another (Fig. 30.8; see also Cytogenetics of Fanconi Anemia, above; Fig. 30.1). A QR of the type characteristic of BS is cytogenetic evidence that during the preceding S phase an interchange took place between chromatids of the members of a homologous chromosome pair, and the point of exchange apparently was at homologous sites. Historically, QRs constituted the first evidence that homologous recombination can occur in mammalian somatic cells in the form of somatic crossing-over.

#### Somatic cell mutability

Neither the SCEs nor the homologous chromatid interchanges exemplified by the QRs are necessarily mutagenic, although the interchanges would give rise to recombined chromosomes in half of the progeny of affected cells. However, the many gaps and breaks observed in metaphases do suggest that the excessive chromatid-exchange mechanism in BS cells is error prone. Direct evidence of increased spontaneous mutability of BS cells *in vivo* comes from studies that estimate the frequency of mutations affecting specific loci in human tissues. Coding loci that have been examined

cytogenetically (but not at the molecular level) include the enzyme hypoxanthine-guanine phosphoribosyltransferase (HGPRT) located on the X chromosome, the MN blood type (the glycophorin A locus on chromosome 4), and the major histocompatibility complex (on chromosome 6). For all three loci studied, the frequency of mutations in BS cells is greatly increased, for example, up to eight-fold for HGPRT (Vijayalaxmi et al., 1983) and 50- to 100-fold for the glycophorin A locus (Langlois et al., 1989). Finally, noncoding repetitive loci examined by molecular techniques were found to be hypermutable and molecular evidence confirming the cytogenetic evidence for excessive somatic recombination has been obtained in proliferating cells from a patient with BS (Gorden et al., 1990). Thus, BS has to be considered a "mutator phenotype" (German, 1992) with mutations of many types, arising from nucleotide substitutions, deletions, and homologous recombination, and presumably affecting any part of the genome, accumulating excessively in proliferating cells both *in vivo* and *in vitro*.

#### Hematologic studies

Standard hematologic parameters are normal except in those patients who have developed leukemia or preleukemia. Persistent anemia, usually mild and asymptomatic, is present in a subgroup of individuals with BS. Data submitted to the BS registry indicated that a myelodysplastic syndrome developed in 11 patients following cancer chemotherapy and spontaneously in one young adult BS patient.

#### Endocrine studies

Ten individuals with BS, 9 months to 28 years of age, underwent endocrine evaluation; three nondiabetic children were found to have glucose intolerance and insulin resistance; two young adults had unsuspected diabetes or prediabetes. Growth hormone production was normal in all 10 patients studied (M.I. New, unpublished results).

Semen from approximately a dozen men with BS lacked spermatozoa completely with one exception, an adolescent who had sperm of abnormal morphology (J. German, unpublished results). Men heterozygous for a BS-causing mutation (fathers of BS patients) produced an increased number of spermatozoa with multiple beaks and rearrangements (Martin et al., 1994), suggesting that the infertility in men with BS is the consequence of a disturbance in meiosis. Supporting this summation is the finding that in normal mouse testes the BS protein (BSM) (*vide infra*) colocalizes with the replication protein A in the meiotic bivalent at the time of crossing over (Walpita et al., 1999).

#### Immunologic studies

Abnormal immune function, a common finding in BS patients, is highly variable and usually not severe (Hutteroth et al., 1975; Weemaes et al., 1979, 1991; Taniguchi et al., 1982; Van Kerckhove et al., 1988; Etzioni et al., 1989; Kondo et al., 1992a, 1992b). Hypogammaglobulinemia has been present in 87% of patients entered in the BS registry and involves one or more serum immunoglobulin classes (IgM, IgA, and, less commonly, IgG). Although most BS patients have decreased *in vitro* production of immunoglobulin, the majority have normal *in vitro* antibody responses to vaccines. Delayed-type hypersensitivity skin tests are generally negative, but skin reactivity to DNCB has been induced. Absolute lymphocyte counts and percentages of CD4<sup>+</sup> and CD8<sup>+</sup> T cells, B cells, and NK cells are normal, and most BS patients have normal *in vitro* lymphocyte proliferation to mitogens. Abnormal NK cell function has been reported (Ueno et al., 1985).

It is unclear if the increased rate of infection is a direct consequence of usually mild and variable immune deficiency. Data

from the BS registries indicate that 86% of individuals who develop serious infections have a deficiency of one or more serum immunoglobulin isotypes, but in 14% immunoglobulin concentrations are normal. Of those patients without a history of infections, however, 28% have abnormally low immunoglobulin levels. V(D)J recombination (Hsieh et al., 1993) and somatic hypermutation of immunoglobulin genes (Sack et al., 1998) are normal and in agreement with the observation that most patients with BS respond normally to vaccinations.

### Genetics and Molecular Basis of Bloom Syndrome

Bloom syndrome had been recognized throughout the world as a very rare genetic disease, with the exception of the Ashkenazi Jewish population, in which approximately 1 in 110 individuals is a carrier of BS. Genetic analysis is consistent with autosomal recessive transmission: parents of BS patients are clinically unaffected; both sexes are equally affected; the ratio of affected to nonaffected siblings among those born after the index case are approximately 1:4; and, in non-Ashkenazi families, parental consanguinity is over 25%. The high parental consanguinity rate among non-Ashkenazi families with BS combined with the hypermutability of BS cells allowed for homozygosity mapping to localize the gene to chromosome band 15q26.1 (German et al., 1994). Subsequently, the gene responsible for BS was identified and found to be mutated in patients with BS (Ellis et al., 1995). The same group showed that 96% of patients whose parents were related were homozygous for a polymorphic marker in the pro-oncogene *FES*, strongly suggesting that the *BLM* gene is tightly linked to *FES* (Ellis et al., 1994). Ellis and associates (1995) observed that in some BS patients a minority of blood lymphocytes had normal SCE rates. Using lymphoblastoid cells established from patients with low SCE rates in peripheral blood lymphocytes, it was shown that polymorphic loci distal to the gene localization on 15q became homozygous, whereas markers proximal to the gene remained heterozygous. These findings were interpreted that low-SCE lymphocytes arose by recombination in patients who had inherited alleles from their (nonconsanguineous) parents that were mutated in different sites and thus had generated a functionally wild-type gene. On the basis of polymorphic markers used, the recombination must have occurred between the polymorphic loci D15S1108 and D15S127, a 250 kb region. Following the construction of a physical map of this region (Straughen et al., 1996), a candidate gene, designated *BLM*, was identified within the cDNA from this region (Ellis et al., 1995). Sequence analysis of this gene in BS patients revealed nonsense and missense mutations. The *BLM* cDNA consists of 4437 nucleotides and encodes a 1417-amino acid protein with homology to the RecQ family of helicases in *Escherichia coli*. The finding that the high SCE rate observed in BS cells could be reduced to control values if a normal *BLM* gene was transfected into cells obtained from BS patients further confirmed that *BLM* was indeed the gene responsible for BS. *BLM*, therefore, is a member of the same subfamily of helicases that includes the Sgs1 protein of *Saccharomyces cerevisiae* and the human proteins WRN and RECQ4, mutated, respectively, in Werner syndrome and some cases of Rothmund-Thomson syndrome. The fact that *BLM* is most closely related to the yeast proteins Rghlp and Sgs (Kusano et al., 1999) is of interest because *BLM* has been demonstrated to suppress premature aging and increased homologous recombination caused by mutations of the *Sgs1* gene (Heo et al., 1999). Studies of mutants for *Dmblm*, the *Drosophila* homolog of human *BLM*, suggests that this gene functions in DSB repair (Kusano

et al., 1999, 2001; Adams et al., 2003). *BLM* has been identified as a DNA binding protein with preference for DNA structures that resemble the presumed initial intermediate formed during homologous recombination; it can bind to and unwind such substrates in vitro, including holiday junctions and D loops (Van Brabant et al., 2000). These observations, together with the high rate of QR and SCE formation, support the hypothesis that *BLM* plays an antirecombinogenic function and that cells from BS patients, in which *BLM* function is lacking, are hyperrecombinogenic.

Western blot analysis and immunofluorescence microscopy demonstrate that cultured lymphoblastoid cells from most BS patients lack *BLM*. In normal cells, *BLM* protein is localized within the nucleus, where its total amount, distribution, and colocalization with other nuclear proteins varies at different phases of the cell division cycle (Sanz et al., 2000).

*BLM* has been identified as a member of a group of proteins that associate with BRCA1 to form a large complex that has been named *BASC* (BRCA1-associated genome surveillance complex). This complex consists of tumor suppressors and DNA damage repair proteins including MSH2, MSH6, MLH1, ATM, *BLM*, and the RAD50/MRE11/NBS1 protein complex (Wang et al., 2000). These proteins colocalize to large nuclear foci when cells are treated with agents that interfere with DNA synthesis. All members of this complex play roles in the recognition of abnormal DNA structures or damaged DNA, suggesting that *BASC* may serve as a sensor for DNA damage. Thus, *BLM* is part of a protein complex that coordinates the activities required for maintenance and genome integrity during the process of DNA replication, activities suggesting a central role for *BLM* as well as NBS1 in DNA repair.

Transfection of a normal *BLM* gene into cultured SV40-transformed BS fibroblasts results in nuclear transfer of the *BLM* protein and reduction of the SCE rate, indicating that the helicase activity of *BLM* is required for its function (Ellis et al., 1999; Neff et al., 1999). The most common mutation of *BLM* is a 6 bp deletion/7 bp insertion in exon 10, which is the homozygous mutation causing BS in Ashkenazi Jews (Ellis et al., 1995). More than 60 unique mutations in the *BLM* gene have been identified in families with at least one affected individual. Homozygosity for a given BS mutation is found in most BS patients whose parents are known to be cousins. In non-Ashkenazi families, in which the parents are not related, compound heterozygosity is most common. There is no obvious genotype-phenotype correlation.

Other human genes in the RecQ family include *RECQ4*, mutated in Rothmund Thomson syndrome (Lindor et al., 2000); *RECQ3* (WRN), mutated in Werner syndrome (Yu et al., 1996); and *RECQL/RecQ1* and *RECQ5*, for which no syndromes have yet been identified.

### Carrier Detection and Prenatal Diagnosis

Carrier females can be identified by DNA analysis if the mutation affecting the index case is known. A rapid method for detection of the Ashkenazi Jewish mutation is available (Straughen et al., 1998). Prenatal diagnosis of BS has been achieved by identifying a high rate of SCE in chorionic villi (Howell and Davies, 1994). Mutation analysis of fetal DNA is, however, the most reliable technique to establish the status of a fetus.

### Treatment and Prognosis

Adequate nutrition is a common problem in infants and young children with BS, who typically show little interest in eating. This is compounded by frequent episodes of vomiting and diarrhea

that may lead to life-threatening episodes of dehydration requiring hospitalization and may ultimately lead to the need for gastrostomy tube feeding. Infections require prompt diagnosis and adequate treatment with antibiotics. If hypogammaglobulinemia is documented and antibody deficiency demonstrated, the use of IVIG is recommended. In BS, as in patients with A-T, the extent of immune deficiency varies greatly.

Steps should be taken to protect the face of BS patients from sun exposure, especially during the early years of life. The diabetes mellitus observed in individuals with BS resembles that of the adult-onset condition, although it generally occurs earlier, usually in the 20s and 30s. Importantly, patients and their families should be informed about the high risk of developing cancer, so that appropriate surveillance mechanisms can be put into place. Because individuals with BS are hypersensitive to chemotherapeutic agents, use of these compounds may have to be adjusted. Interestingly, the tumors of BS patients seem to be more sensitive to these therapeutic agents and cures have been reported using approximately half the dose of standard protocols.

Measures to increase height in patients, including growth hormone administration, have been largely unsuccessful. It has been postulated that the absence of BLM from somatic cells places a restriction on cell number and size, possibly through the deregulation of the p53 tumor suppressor pathway, which may not be limited to malignant cells (Garkavtsev et al., 2001).

### Animal Models

Disrupting *Blm* gene function in mice has created useful models for BS. Depending on the defect created by a targeted mutation of *Blm*, homozygous mutant animals may exhibit embryonic lethality while in other mice homozygosity may yield viable and fertile animals with a cancer predisposition. In one model, a site upstream of the *Blm* helicase homology domain was targeted for disruption by use of homologous recombination. Whereas heterozygous mice appear normal and are phenotypically identical to wild-type littermates, mouse embryos homozygous for this mutation appear developmentally delayed and die by embryonic day 13.5 (Chester et al., 1998). *Blm*<sup>-/-</sup> littermates were smaller in size by 50% at 9.5 days post-conception and remained smaller until death at 13.5 days post-conception. Interestingly, the *Blm*<sup>-/-</sup> embryos were normal in their own body proportion and without structural abnormalities.

This BS knockout mouse model recapitulates many aspects of the human disease, including small size of the embryos, increased numbers of micronuclei in embryo blood cells, slow growth of cultured embryo fibroblasts, and, finally, a high number of SCE in cultured embryo fibroblasts, characteristically also seen in cells from Bloom patients. These data suggest that mutation of *BLM* in humans is sufficient to cause most aspects of the human disorder.

In addition, studies of mouse embryos clearly demonstrate increased programmed cell death, an observation not previously described in BS patients. There was also a marked reduction of the blood volume and the number of circulating red blood cells beginning at 9.5 days post-conception; the affected embryos had only 5% or 10% as much blood as their wild-type littermates. Furthermore, an increased number of macrocytes and an increased presence of nuclear fragments were present in mutant vs. wild-type erythrocytes (Chester et al., 1998).

Another knockout mouse model with a hypomorphic *Blm* protein produced a diminished quantity of normal mRNA and protein. These animals were viable and showed an inverse corre-

lation between the quantity of *Blm* protein and the level of chromosome instability and a similar genotypic relationship for tumor predisposition, suggesting that *Blm* protein is rate limiting for maintaining genome stability and the avoidance of tumors (McDaniel et al., 2003). These viable knockout mice had an 18-fold increase in the rate of somatic loss of heterozygosity (LOH), indicating a marked elevation of the mitotic recombination rate in mutated cells (Luo et al., 2000). Cell lines from these mice show elevations in the rate of mitotic recombination. These mice are also prone to a wide variety of cancers.

A unique mouse model was generated using gene targeting by homologous recombination to disrupt the mouse *Blm* gene to simulate *BLM*<sup>Ash</sup>, a BS-causing mutant allele of *BLM* carried by approximately 1% of Ashkenazi Jews (Li et al., 1998). This mutation causes a frameshift in exon 10 that results in premature translation termination. Homozygous disruption of *Blm* by this method resulted in embryonic lethality. Cell lysates from heterozygous animals (*Blm*<sup>+/-</sup>) had an approximately 50% reduction in *Blm* compared to wild type. There was a twofold increase in the number of micronuclei in BrdU-treated cultures of heterozygous deficient cells, a result suggesting that heterozygous cells have a subtle increase in genomic instability presumably related to the reduced *BLM* level. There was a slight acceleration in the development of murine leukemia virus-induced metastatic T cell lymphoma and an increased incidence of intestinal adenomas in mice heterozygous for this *Blm* mutation (Goss et al., 2002). These results demonstrate that *Blm* haploinsufficiency is sufficient to affect tumor formation in susceptible mice and probably to alter genome stability. This increased susceptibility to cancer in heterozygous mice supports the finding in human carriers for BS that they have an increased risk of colorectal cancer (Gruber et al., 2002).

### Rare Syndromes with Chromosomal Instability

Patients with the clinical and cytogenetic features of chromosomal instability syndromes, in particular NBS and AT, but without mutations in the respective genes are of particular interest because they may disclose clues about unknown gene products involved in the network of genome integrity surveillance. Ligase I (*LIG1*) deficiency (MIM 126391) was described in one female patient with typical features of a chromosomal instability syndrome: growth retardation, telangiectasia, immunodeficiency, and lymphoma, at the age of 19 years (Webster et al., 1992). Hypersensitivity to UV light, alkylating agents, and IR was observed at the clinical and cellular levels. Molecular analysis identified two missense mutations in the *LIG1* gene (Barnes et al., 1992). A link to the NHEJ repair network was suggested by the finding of a physical association of *LIG1* with *MRE11* (Petrini et al., 1995). Only one patient with *LIG1* deficiency has been described thus far. This low number might be explained by the minor role of *LIG1* in NHEJ, compared to that of ligase IV (*LIG4*) (see below), which can be substituted more easily. Another explanation might be the presence of undetected mutations in another gene involved in NHEJ.

More recently, mutations in the *LIG4* gene were shown to cause an NBS-like syndrome in four patients (O'Driscoll et al., 2001) (Table 30.1). On the cellular level, cell lines from *LIG4*-deficient patients show pronounced radiosensitivity similar to that in NBS. In contrast to NBS cells, *LIG4*-deficient cells show normal cell cycle checkpoint responses but impaired DSB rejoining. Since V(D)J recombination is also affected, immunodeficiency is part of the clinical phenotype. Thus, *LIG4*, if mutated,

**Figure 30.9.** The network of proteins mutated in chromosomal instability syndromes. This highly simplified schematic drawing shows the proteins acting in the double-strand break network. Only proteins mutated in chromosomal instability syndromes presented in this chapter are shown. Four complexes are present: (1) the Fanconi anemia (FA) complex, (2) the MRE11/RAD50/nibrin complex, (3) the LIG4 complex, and (4) the complex consisting of BRCA 1/BRCA 2/RAD51/FA-D2-L. The BASC complex (Wang et al., 2000) includes BRCA1, BLM, and RAD50/MRE11/nibrin. Lig, ligase; WRN, Werner syndrome; XLF, XLF/NHEJ1/Cernunnos Protein.

is responsible for the defective DSB repair, resulting in a novel primary immunodeficiency syndrome (LIG4 syndrome, MIM \*606593). By targeted disruption of both *LIG4* alleles in a human pre-B cell line studied for radiosensitivity, Grawunder et al. (1998) showed that LIG4 activity is responsible for the ligation step in nonhomologous DNA end joining and in V(D)J recombination.

It has been demonstrated that LIG4 forms a tight complex with the protein XRCC4 (Grawunder et al. 1998) to repair DSB by the NHEJ pathway. However, it took 8 more years to identify the third partner of this complex, which was suspected by Dai and colleagues (2003) while studying a patient with T-B-SCID whose cells showed dramatic radiosensitivity, decreased DSB rejoining, and reduced fidelity in signal and coding joint formation during V(D)J recombination. This patient (2BN), while sharing several characteristics of NBS and of LIG4 deficiency did not have mutations in the respective genes (Dai et al., 2003). Two groups recently reported independently mutations in a hitherto unknown gene through cDNA functional complementation cloning (Buck et al., 2006) and yeast two-hybrid screening for *XRCC4* interactors (Ahnesorg et al., 2006), respectively. This novel protein has been named Cernunnos (Buck et al., 2006) or XLF (Ahnesorg et al., 2006) and was officially designated as non-homologous end-joining factor 1 (NHEJ1). Mutations in this gene are responsible for the clinical phenotype mentioned above, including microcephaly, and for defective NHEJ and V(D)J recombination resulting in severe combined immune deficiency (Buck et al., 2006).

Bendix et al. reported (at the International Workshop on NBS, Prague, April 2002) a patient with a disorder resembling NBS who harbored different hypomorphic mutations, one in each allele of the *RAD50* gene. The girl, originally described in 1991 by Barbi et al., presented with many clinical characteristics of NBS, but not with immunodeficiency (Table 30.1). The Rad50 deficiency (MIM \*604040) resulted in increased spontaneous chromosomal instability, radiosensitivity, RDS, impaired nibrin phosphorylation, and impaired nuclear foci formation after irradiation. Since hRAD50 is one of the three partners of the hMRE11/hRAD50/nibrin complex, it is not surprising to find the

NBS phenotype in a compound heterozygous individual. The link between RAD50 deficiency and increased radiosensitivity points to the importance of a fully functional hMRE11/hRAD50/nibrin complex for reliable NHEJ.

More surprising is the clinical picture of patients carrying mutations in the *hMRE11* gene (Stewart et al., 1999). Because these patients show many similarities to A-T, although with a milder phenotype and without mutations in the *ATM* gene, this syndrome has been called ataxia-telangiectasia-like disorder (A-TLD) (MIM #604391). The protein hMRE11 is engaged in forming the hMRE11/hRAD50/nibrin complex, which plays an early role in a signal transduction pathway responding to DSB induced by IR and radiomimetic chemicals (Taylor et al., 2004). Both these events activate DNA repair as well as cell cycle checkpoint controls. All *hMRE11* mutations observed in this recessive disorder result in the expression of proteins with some residual function that may be necessary for the survival of affected patients. Typically, this residual function results from a hypomorphic mutation of at least one *hMRE11* allele.

## Concluding Remarks

The descriptive level of chromosomal instability syndromes of only one decade ago has been complemented by the discovery that the chromosomal instability syndromes not only form subgroups based on their descriptive features but are actually linked together at the molecular level. Most if not all genes mutated in the syndromes described in this chapter (including *ATM*) take part in the complex network of DSB sensing, signal transduction, and DNA repair. Although much more has to be done to determine specific functional aspects, the facts known to date allow a first glimpse into the complex network of genomic stability maintenance. A very simplified schema of this network is shown in Figure 30.9, which lists only those gene products mutated in chromosomal instability syndromes presented in this chapter. Their physiologic functions have been demonstrated by the analysis of gene mutations in relevant patients. The identification and investigation of additional pathological conditions are essential to a better understanding of these crucial cellular processes; for

the benefit of our patients, it is even more important to generate new ideas that lead to more effective treatments of these devastating genetic disorders.

## Wiskott-Aldrich Syndrome

HANS D. OCHS and FRED S. ROSEN

The first description of the Wiskott-Aldrich syndrome (WAS), published in 1937, defined accurately the clinical phenotype: three brothers, but not their sisters, presented shortly after birth with thrombocytopenia, bloody diarrhea, eczema, and recurrent ear infections (Wiskott, 1937). On the basis of this symptomatology, the early onset, and the predominance of male infants, Wiskott differentiated this entity from Morbus Werlhofii, a synonym for idiopathic thrombocytopenia. Seventeen years later, Aldrich described a large family with multiple affected males, clearly demonstrating X-linked inheritance (Aldrich et al., 1954). In 1957, additional cases were described (Huntley and Dees, 1957), including members of an African American family (Wolff and Bertucio, 1957).

Following these early clinical reports, the immunologic abnormalities characteristic of WAS were recognized, including progressive lymphopenia, absence of delayed-type hypersensitivity, and abnormal *in vivo* antibody production (Blaese et al., 1968; Cooper et al., 1968; Ochs et al., 1980; Sullivan et al., 1994). Most studies implicated a predominant T cell defect (Molina et al., 1993; Sullivan et al., 1994; Gallego et al., 1997). This idea was reinforced by the discovery that WAS protein (WASP), the protein mutated in this syndrome, plays a crucial role in cytoskeletal remodeling downstream of T cell receptor (TCR) engagement (Barda-Saad et al., 2005) and contributes to the immune synapse formation between T lymphocytes and antigen-presenting cells (Dupre et al., 2002). However, impaired maturation, decreased motility, reduced migration, and abnormal morphology of B cells from WAS patients have recently been recognized (Park et al., 2005; Westerberg et al., 2005). Abnormal natural killer (NK) cell function (Orange et al., 2002; Gismondi et al., 2004; Huang et al., 2005) and impaired migration of dendritic cells (Binks et al., 1998; de Noronha et al., 2004) indicate that innate immunity is also affected. In addition to the consistent microplatelet thrombocytopenia, characteristic functional and morphologic abnormalities of

WAS platelets were also recognized (Grøttum et al., 1969; Kuramoto et al., 1970; Ochs et al., 1980; Semple et al., 1997). The finding of eosinophilia, multiple food allergies (Huntley and Dees 1957), and elevated IgE levels suggested an allergic basis for the eczema (Berglund et al., 1968). An increased risk of malignancies, including lymphoma, malignant reticuloendotheliosis, and leukemia, was reported as early as 1961 (Kildeberg, 1961; ten-Bensel et al., 1966; Cotelingam et al., 1985; Sullivan et al., 1994).

Distinguishable from the classic WAS phenotype (MIM 301000) is a milder form designated *hereditary X-linked thrombocytopenia* (XLT, MIM 313900) (Canales and Mauer, 1967; Chiaro et al., 1972; Notarangelo et al., 1991; Stormorken et al., 1991). In patients with XLT, eczema, if present, is mild; immune functions are less disturbed or normal, autoimmune disorders are rare, and the incidence of malignancies appear to be less frequent. The thrombocytopenia may be present intermittently (Notarangelo et al., 2002).

The gene responsible for both WAS and XLT was initially mapped to Xp11.22 (Donnér et al., 1988; Kwan et al., 1991); it was subsequently identified by positional cloning and named *WASP* (Derry et al., 1994). *WASP* is composed of 12 exons containing 1823 base pairs and encodes a 502-amino acid protein with a predicted molecular weight of 54 kDa. *WASP* is constitutively expressed in all hematopoietic stem cell-derived lineages and is located predominantly in the cytoplasm with the highest protein density being toward the cell membrane (Riveo-Lezcano et al., 1995; Zhu et al., 1997). *WASP* belongs to a family of cytoskeleton regulatory proteins that include N-*WASP* and the Scar/*WAVE* proteins 1–3 (Oda et al., 2005). Several functional domains based on the genomic structure of *WASP* have been identified, including the N-terminal EVH1 (Ena/*VASP* homology 1) domain followed by a basic region (BR), a GTPase-binding domain (GBD), a polyproline-rich region, and a C-terminal Verprolin

homology/Central region/Acid region (VCA) domain (Burns et al., 2004).

One of the essential roles of WASP is the regulation of actin polymerization by actin-related protein (Arp) 2/3, as illustrated by the findings that WAS macrophages fail to organize the Arp2/3 complex in podosomes (Linder et al., 1999). In this model, WASP is present in two configurations: the active form, in which the C terminus of WASP is free to interact with the Arp2/3 complex, and the inactive form, in which the C terminus forms an autoinhibitory contact with the BR of the GBD (Kim et al., 2000).

The distinct domains of WASP form the basis for its multiple functions, which include self-regulation, cytoplasmic signaling, and, through the interaction with Arp2/3, actin polymerization. The identification of the WASP gene has not only provided new insight into the critical role played by this complex molecule in cell movement and cell–cell interaction but also has had an impact on establishing a genotype–phenotype correlation (Imai et al., 2004; Jin et al., 2004), carrier detection, and prenatal diagnosis. Early diagnosis is crucial for optimal therapy, which includes antibiotics and intravenous immunoglobulin (IVIG) substitution, and stem cell transplantation to cure this devastating disease.

## Clinical and Pathologic Manifestations

### Incidence, Onset of Symptoms, and Age at Diagnosis

The incidence of the classic WAS phenotype has been estimated to be between 1 and 10 in one million individuals (Ryser et al., 1988; Stray-Pederson et al., 2000). With broader awareness of the classic syndrome and the much milder XLT phenotype, along with the availability of reliable diagnostic tools, the true incidence is expected to be even higher.

Early manifestations of WAS and XLT are often present at birth and consist of petechiae, bruises, and bloody diarrhea (Wiskott, 1937). Because of the increased risk of intracranial bleeding during vaginal delivery, birth by cesarean section is an option if the diagnosis is known prenatally. Excessive hemorrhage following circumcision is an early diagnostic clue. Eczema, either mild and localized or severe and generalized, is a consistent early manifestation of classic WAS. The most persistent findings at diagnosis, both in classic WAS and in XLT, are thrombocytopenia and small platelets. Infections, including otitis media with drainage of mucoid purulent material, are frequent complaints during the first 6 months of life. In a retrospective study carried out in the United States, the average age at diagnosis was 21 months, with a range from birth to 25 years (Sullivan et al., 1994). The diagnosis was established earlier in patients with known affected family members (mean age at diagnosis 10 months) than in patients without a family history (24 months). Patients presenting with the XLT phenotype are often diagnosed as having idiopathic thrombocytopenia (ITP), considerably delaying the actual diagnosis, sometimes until adulthood.

### Infections

Because of the profound cellular and humoral immune deficiency, infections are common manifestations of classic WAS. Upper and lower respiratory infections, often caused by common bacteria, are frequent and include otitis media (reported by 78% of WAS patients), sinusitis (24%), and pneumonia (45%) (Sullivan et al., 1994). In the same retrospective study, sepsis was observed in 24%, meningitis in 7%, and “infectious” diarrhea in 13%. Severe viral infections do occur, but less frequently, and include varicella

with systemic complications that may require treatment with acyclovir and high-dose IVIG or varicella-zoster immunoglobulin (VZIG). Recurrent herpes simplex infections are observed in 12% of WAS patients. *Pneumocystis carinii* pneumonia (PCP), reported to affect 9% of WAS patients, is less prevalent than in patients with severe combined immune deficiency (SCID) or X-linked hyper-IgM syndrome (X-HIM) (Sullivan et al., 1994). Fungal infections, caused predominantly by *Candida* species, are relatively rare (10% of WAS patients) but may become more extensive during treatment with antibiotics. Patients with the XLT phenotype often lack a history of severe and frequent infections (Villa et al., 1995; de Saint-Basile et al., 1996; Imai et al., 2004; Jin et al., 2004).

## Defects of the Immune System

### Cognate immunity

The extent of the immune deficiency varies from family to family and depends largely on the mutation and its effect on WASP expression (Imai et al., 2004; Jin et al., 2004). Both T and B lymphocyte functions are affected. During infancy, the number of circulating lymphocytes may be normal or moderately decreased (Ochs et al., 1980; Park et al., 2004). By 6 years of age, lymphopenia due to loss of T lymphocytes is a common finding in patients with classic WAS (Ochs et al., 1980). This may be in part due to accelerated cell death observed in peripheral blood lymphocytes from patients with WAS but not from those with XLT (Rawlings et al., 1999; Rengan et al., 2000). Serum IgG levels are usually normal, IgM levels are depressed, and IgA and IgE are frequently elevated. The fact that serum immunoglobulin levels are normal or elevated suggests increased production, considering that the catabolism of immunoglobulin and albumin are twice that of normal controls (Blaese et al., 1971). The absolute number of B cells may be normal or moderately depressed (Park et al., 2005). Isohemagglutinin titers are frequently low (Ochs et al., 1980; Sullivan et al., 1994).

Antibody responses are normal to some antigens and insufficient to others. A consistent finding is a markedly depressed response to polysaccharide antigens (Cooper et al., 1968; Ochs et al., 1980). This characteristic pattern of antibody deficiency is further illustrated by the observation that antibody responses to staphylococcal proteins are often normal, whereas antibody responses to streptococcal polysaccharides are consistently abnormal in WAS patients (Ayoub et al., 1968). In a multicenter retrospective review, abnormal antibody responses to a variety of protein antigens, including diphtheria and tetanus toxoid and to Hib vaccine (conjugated and unconjugated), were reported to be abnormal in more than 50% of WAS patients; in contrast, antibody responses to live virus vaccines were normal (Sullivan et al., 1994). Antibody responses to intravenous immunization with bacteriophage  $\Phi$ X174 are severely depressed in patients with classic WAS (i.e., patients lacking the WAS protein in lymphocytes), characterized by lack of amplification and failure to switch from IgM to IgG (Fig. 31.1). These findings suggest abnormal class switch recombination and lack of somatic hypermutation. In contrast, patients with XLT mount a more robust response with amplification and isotype switching that may reach responses comparable to those of normal controls.

Abnormal T cell function is suggested by diminished but not absent lymphocyte responses to mitogens (Cooper et al., 1968), depressed proliferative responses to allogeneic cells (Ochs et al., 1980) and immobilized anti-CD3 monoclonal antibody (Molina et al., 1993), and complete lack of proliferation in response to pe-

**Figure 31.1.** Antibody responses to the T cell-dependent neoantigen, bacteriophage  $\phi$ X174 (phage), in patients with WAS/XLT. Phage was injected intravenously twice, 6 weeks apart (primary and secondary immunization) at a dose of  $2 \times 10^9$  PFU/kg body weight ( $\downarrow$ ), and the production of phage-specific antibody determined. Antibody titers were measured by a neutralizing assay expressed as rate of phage inactivation (Kv). The geometric mean antibody titers of normal males, following phage immunization, are indicated (0);  $\pm 1$  SD is indicated by broken lines. Percent IgG (in parentheses) was determined for serum samples obtained 2 weeks after secondary immunization by treatment with 2-mercaptoethanol (2-ME). Patients characterized by  $\blacklozenge$ ,  $\blacklozenge$  and  $\blacktriangle$ ,  $\blacktriangledown$  are two pairs of cousins from two unrelated families with severe classic WAS (scores 4 and 5). The two patients indicated by the symbols  $\blacksquare$  and  $\bullet$  are unrelated and also have classic WAS (score 3 and 4). The symbols  $\triangle$ ,  $\nabla$ ,  $\square$ ,  $\diamond$  indicate patients with XLT ( $n=3$ ).

riodate (Siminovitch et al., 1995). In a retrospective study of 154 patients, Sullivan et al. (1994) reported depressed proliferative responses to mitogens and allogenic cells in approximately 50% of the patients. Skin tests for delayed-type hypersensitivity were abnormal in 90% of the patients studied. Partial chimerism due to the engraftment of only donor T lymphocytes corrected the immune defect, including antibody responses to polysaccharides, which suggests that the abnormal antibody production observed in WAS patients is largely caused by defective T lymphocyte function (Parkman et al., 1978). The increased incidence of *Pneumocystis carinii* pneumonia also points to a significant T cell defect in classic WAS. More recent studies suggest, however, that B cell function is equally affected. Epstein-Barr virus (EBV)-transformed B lymphoblasts derived from WAS patients have reduced levels of filamentous (F) actin (Facchetti et al., 1998). B cells from WAS patients with mutations that lead to a complete absence of WASP, compared with normal B cells, have a defect in cell motility in response to CXCL13, and decreased ability to adhere homotypically and form long cytoplasmic protrusions after stimulation with anti-CD40 and interleukin (IL)-4 (Westerberg et al., 2005). By extending these studies to Wasp-deficient murine B cells, a reduced and delayed antibody response to not only T cell-dependent but also T cell-independent antigens was discovered, a finding suggesting an intrinsic functional B cell defect. It is possible, however, that this B cell deficiency is secondary to the abnormal migration, impaired homing of B cells, and reduced germinal-center formation observed in Wasp knockout mice (Westerberg et al., 2005). Additional experimental evidence is required to determine if the observed B cell deficiency is at least in part due to defective macrophage/dendritic or T cell function.

### Innate immunity

The susceptibility of WAS patients to viral infections and to malignancies may be the consequence of cytolytic or cytotoxic dysfunction. In normal NK cells, WAS can easily be detected in the immunologic synapse, together with F-actin. NK cells from patients with classic WAS lack WASP and show a markedly reduced accumulation of F-actin in the immunologic synapse. As a direct result, patients with WASP mutations have defective cytolytic NK cell function (Orange et al., 2002). These findings were confirmed and expanded in a recent study of NK cell cytotoxicity in both classic WAS and XLT patients (Gismondi et al., 2004). Although the percentage of NK cells was normal or increased, NK cell cytotoxicity was inhibited in all patients with classic WAS and in most patients carrying mutations associated with the XLT phenotype. This inhibition of NK cell-mediated cytotoxicity was associated with a reduced ability of WAS/XLT-NK cells to form conjugates with susceptible target cells and to accumulate F-actin on binding.

The involvement of the cytoskeleton in cell migration, active phagocytosis, and cell trafficking of myeloid cells, macrophages, dendritic cells, and Langerhans cells makes these cells vulnerable to WASP mutations. A large number of studies, some performed as early as 30 years ago (Altman et al., 1974), have investigated the functionality of WASP-deficient monocytes, macrophages, and dendritic cells. In both WAS and XLT patients and in *Wasp*<sup>-/-</sup> mice, a substantial defect in cell trafficking, pathogen clearance, and uptake of particulate antigen has been observed. Phagocytic cup formation and IgG-mediated and apoptotic cell phagocytosis are impaired in WASP-deficient macrophages (Lorenzi et al., 2000; Leverrier et al., 2001). A striking deficiency is the complete failure to assemble podosomes in monocytes or macrophages and dendritic cells, which results in a severe defect of adhesion and motility (Calle et al., 2004a). WASP-deficient macrophages have an abnormal, elongated shape, lack a clear lamellipodium front, and show impaired chemotactic responses (Calle et al., 2004a). Abnormalities are likely caused by defective filopodia formation, since filopodia are involved in sensing the immediate microenvironment of the cell. Transfection of full-length WASP cDNA into WASP-deficient macrophages restores chemotaxis in response to CSF-1 (Jones et al., 2002).

WASP is also involved in osteoclast function. In normal osteoclasts, during bone resorption, multiple podosomes are aggregated in actin rings, forming a sealing zone. Osteoclasts derived from *Wasp*<sup>-/-</sup> mice show abnormal morphology. The abnormalities observed in *Wasp*<sup>-/-</sup> osteoclasts result in defective bone absorption when these mice are exposed to resorption challenge (Calle et al., 2004b).

The number of circulating neutrophils, the efficiency of neutrophil migration into the tissue, phagocytosis, and bactericidal activity are normal. However, in vitro chemotaxis of WAS neutrophils in response to various chemoattractants is insufficient, an abnormality that is most pronounced in the early phase of chemotaxis (Ochs et al., 1980).

### Platelet Abnormalities

The platelet defect, thrombocytopenia and small platelet volume, is a consistent finding in patients with mutations of the WASP gene. Platelet counts vary from patient to patient and within individual patients; platelet counts may be as low as  $5000/\text{mm}^3$  or as high as  $50,000/\text{mm}^3$ . Higher counts, observed transiently, are often associated with inflammation or bacterial infections (Odda and Ochs, 2000). Families with intermittent thrombocytopenia associated with unique amino acid substitutions in the WASP gene

have been described (Notarangelo et al., 2002). In most patients, the mean platelet volume (MPV) is half that of normal control subjects (MPV = 3.8–5.0 fl; compared with 7.1–10.5 fl), resulting in a thrombocrit of approximately 0.01%, compared with a normal range of 0.14% to 0.31% (Ochs et al., 1980). After splenectomy, platelet counts and platelet volume increase but are still less than that of normal controls (Litzman et al., 1996; Haddad et al., 1999). Partial but significant recovery of platelet counts following splenectomy suggests that the development of thrombocytopenia is at least in part due to the destruction of platelets in the spleen or other reticular endothelial organs of patients with WAS or XLT (Grøttum et al., 1969; Baldini, 1972; Murphy et al., 1972). This interpretation is supported by the observation that platelet and macrophages colocalize in spleen sections from WAS patients, a finding strongly suggesting that damaged platelets are ingested by macrophages in the spleen (Shcherbina et al., 1999). Increased expression of phosphatidylserine (PS) on circulating platelets from WAS patients has been interpreted as one of the reasons for the increased phagocytosis of PS-positive platelets in WAS and XLT (Shcherbina et al., 1999). An alternative explanation is a decrease in platelet production. This possibility was suggested by the observation that autologous platelet survival in WAS and XLT patients was only reduced to half that of normal (5 days  $\pm$  1.3 days SD) (Ochs et al., 1980). A persistent finding was a decrease in platelet turnover, which was approximately 30% of the value found in normal subjects, indicating a significant platelet production defect. Because the marrow megakaryocyte mass is normal or increased in WAS and XLT patients (Ochs et al., 1980; Haddad et al., 1999), it has been suggested that ineffective thrombopoiesis is at least in part responsible for the low platelet count. The discrepancy between a normal to increased marrow substrate available for platelet production (megakaryocyte cytoplasmic mass) and the low rate at which platelets actually appear in the circulation (platelet turnover) characterizes the platelet production defect known as ineffective thrombopoiesis (Slichter and Harker, 1978). It was hypothesized that this abnormality was due to a defect in platelet demarcation and platelet release from megakaryocytes, possibly a direct consequence of the interaction of WASP with the cytoskeleton. This mechanism is supported by the observation of Kajiwar et al. (1999), who reported that in semi-solid culture assays, bone marrow CD34<sup>+</sup> cells from WAS patients failed to form efficiently megakaryocyte colonies and to mature fully into platelet-releasing megakaryocytes. Using a megakaryoblastic cell line (MEG-01), Miki and coworkers (1997) showed that WASP is indispensable for actin filament reorganization to microvesicles during megakaryocyte differentiation. In contrast, Haddad and coworkers (1999), studying megakaryocytes derived in vitro from CD34<sup>+</sup> cells, found normal megakaryocyte differentiation and proplatelet formation in both WAS and XLT patients. Interestingly, the in vitro-produced platelets were of normal size, whereas peripheral blood platelets from the same patient exhibited an abnormally small size. Moreover, F-actin distribution was abnormal in cultured megakaryocytes from WAS patients. In spite of these abnormalities, megakaryocytes from WAS patients migrated normally in response to stroma-derived factor-1 (SDF-1)  $\alpha$ . At this point, it is unclear if transendothelial migration of megakaryocytes is important for enhanced platelet formation, or if megakaryocyte movements would be abnormal if other chemotactic active factors were used. The observation that WASP is tyrosine phosphorylated after stimulation of platelets by collagen (Oda et al., 1998) may be relevant to megakaryocyte migration since collagen seems to be involved in the interaction between megakaryocytes and endothelial cells. It is possible that abnormal interaction between

WAS megakaryocytes and endothelial cells through adhesion signals other than SDF-1 $\alpha$  might have a direct impact on platelet formation. Several investigators have reported abnormal structure, function, and metabolism of WAS platelets (Kuramoto et al., 1970; Baldini, 1972). Because it is generally difficult to examine the function of platelets from thrombocytopenic patients, the data obtained may merely reflect the reduced size or damage of platelets. Platelet aggregation defects, as determined by abnormal responses to ADP, collagen, and epinephrine, have been reported (Grøttum et al., 1969; Kuramoto et al., 1970). These findings have been interpreted as platelet functional defects, but the severe thrombocytopenia compromises interpretation. One splenectomized XLT patient who had enough platelets for aggregation studies showed normal aggregation (Ochs et al., 1980). However, Tsuboi and colleagues have recently discovered that WASP binds to the calcium and integrin-binding (CIB) protein in platelets and that WASP altered by missense mutations affecting exons 1–3 show lower affinity for CIB than wild type WASP. This impaired complex formation between mutant WASP and CIB reduces  $\alpha$ IIb $\beta$ 3-mediated cell adhesion and causes defective platelet aggregation, contributing to the hemorrhagic diathesis of WAS/XLT patients (Tsuboi et al., 2006). Furthermore, the incidence of severe, life-threatening bleeding is relatively small, in spite of platelet numbers being as low as 5000/mm<sup>3</sup>, suggesting that WAS platelets function normally in vivo. Nevertheless, a pronounced bleeding tendency is often the first sign of WAS or XLT and may be the only clinically relevant symptom in XLT patients. The presence of petechiae or prolonged bleeding after circumcision in newborns may alert the physician and lead to early diagnosis. In a large retrospective study, the clinical manifestation of bleeding was present in 84% of WAS patients and consisted of petechiae and/or purpura (78%), hematemesis and melena (28%), epistaxis (16%), and oral bleeding (6%). Life-threatening bleeding, including oral, gastrointestinal, and intracranial hemorrhage, occurred in 30% of WAS patients, with intracranial hemorrhage being observed in only 2% (Sullivan et al., 1994).

Carrier females with mutations leading to classic WAS have normal platelet numbers, size, function, and survival time. This finding is explained by the nonrandom X chromosome inactivation in T cells, B cells, and platelets (Gealy et al., 1980; Fearon et al., 1988; Greer et al., 1989; Puck et al., 1990). However, carrier females in families with a mild XLT phenotype may have random X chromosome inactivation in hematopoietic cells, with occasional skewing in favor of the X chromosome with the mutation. In these rare situations, carrier females may present with the XLT phenotype, which is often confused with ITP (Inoue et al., 2002; Lutskiy et al., 2002; Zhu et al., 2002).

### Eczema and Other Atopic Manifestations

Eczema is another characteristic finding that differentiates WAS from ITP (Wiskott, 1937). The typical skin lesions resemble acute or chronic eczema in nature and distribution. A history of eczema, mild or severe, transient or consistent, was reported by 81% of a cohort of WAS patients (Sullivan et al., 1994). In the most severe cases, eczema is resistant to therapy and may persist into adulthood. *Molluscum contagiosum*, herpes simplex, or bacterial infections may develop in areas of the skin affected with eczema, often posing a therapeutic challenge. Patients with the XLT phenotype have either mild and transient eczema or none at all (Imai et al., 2004; Jin et al., 2004). Bacterial antigens appear to play an important role in the persistence of chronic eczema, because the skin lesions of WAS patients often respond promptly to treatment with systemic antibiotics. It has been hypothesized

that defective chemotaxis of dendritic and Langerhans cells may play a role in generating T cells responsible for the development of atopic diathesis (Thrasher et al., 1998). This mechanism is further supported by the observation that eczema disappears during conditioning but before the infusion of donor bone marrow stem cells has occurred. The eczema tends to be worse in families with atopic diathesis, a finding suggesting that other genes responsible for allergies may have a modifying effect.

Some WAS patients develop allergies to certain foods or drugs. Exposure to these antigens may result in anaphylactic shock.

### Autoimmune Manifestations

Autoimmune diseases are frequent and have been reported in 40% of a large cohort of WAS patients (Sullivan et al., 1994). The most common autoimmune manifestation reported has been hemolytic anemia, followed by vasculitis involving both small and large vessels, renal disease, Henoch-Schönlein-like purpura, and inflammatory bowel disease. Other less frequent autoimmune diseases include neutropenia, dermatomyositis, recurrent angioedema, uveitis, and cerebral vasculitis. Although the incidence of autoimmune diseases in XLT patients seems to be less frequent than in classic WAS (Sullivan et al., 1994), a recent report from Japan suggests that autoimmune diseases are equally frequent in patients with a low clinical score, representing XLT, as in those with a high score, representing WAS (Imai et al., 2004). IgA nephropathy, with or without Henoch-Schönlein purpura, often causing chronic renal failure requiring dialysis or renal transplantation, was a frequent complication in Japanese patients with the XLT phenotype (Imai et al., 2004). A recent report of risk factors, clinical features, and outcome of autoimmune complications from a single center in France further underlines the importance of this problem (Dupuis-Girod et al., 2003). Of 55 WAS patients, 40 had at least one autoimmune or inflammatory complication. Autoimmune hemolytic anemia was detected in 20 patients with onset before the age of 5 years. Arthritis was present in 29%, neutropenia in 25%, vasculitis including cerebral vasculitis in 29%, inflammatory bowel disease in 9%, and renal disease in 3%. A high serum IgM concentration was a significant risk factor for the development of autoimmune disease or early death. Of 15 patients with high serum IgM levels, 14 developed autoimmune hemolytic anemia. In contrast, low serum IgM concentration (a frequently observed finding in WAS/XLT) was a marker of a favorable prognosis. In an unpublished study by the European bone marrow transplantation/ESID working party, autoimmune diseases were observed in 21 of 97 long term survivors following hematopoietic stem cell transplantation. Of those with partial (mixed) chimerism, the incidence was 67% compared with only 14% in those with full chimerism (H. Ozsahin, personal communication).

### Malignancies

Malignancies can occur during childhood but are more frequent in adolescents and young adults with the classic WAS phenotype (Kildeberg, 1961; ten Bonsel et al., 1966; Brand and Marinkovich, 1969; Cotelingam et al., 1985; Sullivan et al., 1994). In a large North American cohort, malignancies were present in 13% (Sullivan et al., 1994). The average age at onset of malignancies was 9.5 years. Considering the increasing life expectancy of patients, it is reasonable to assume that the incidence of malignancies will further increase as WAS patients get older. The most frequent malignancy reported is lymphoma, usually an EBV-positive B cell lymphoma, which suggests a direct relationship with a defective immune system. Only 3 of 21 tumors—1 glioma, 1 acoustic neu-

roma, and 1 testicular carcinoma—were not of lymphoreticular origin (Sullivan et al., 1994). WAS-associated malignancies have a poor prognosis, as illustrated by the fact that only 1 of the 21 patients who developed a malignancy was alive more than 2 years after establishing the diagnosis. Bone marrow transplantation was attempted in five WAS patients with malignancies, but none survived more than 6 months (Sullivan et al., 1994). To our knowledge, no patient who underwent successful transplantation has subsequently developed a malignancy. The incidence of malignancies in patients with the XLT phenotype is unknown but is less than in classic WAS. In a series of 25 patients with XLT, age 30 years or older, two developed malignancies—one, a 43-year-old man, who died of a B cell lymphoma; and one who presented with acute lymphocytic leukemia at 37 years of age (H.D. Ochs, unpublished observation).

## Laboratory Findings

### Blood Cell Abnormalities

The finding that WASP is expressed in CD34<sup>+</sup> stem cells (Wengler et al., 1995) is compatible with the observation that in WAS all hematopoietic stem cell-derived lineages are functionally abnormal, including lymphocytes, platelets, neutrophils, and macrophages.

The most consistent laboratory abnormalities for WAS and XLT are thrombocytopenia, associated with small platelets. The other two findings of the classic triad of thrombocytopenia, immunodeficiency, and eczema are often absent at the initial evaluation, even in those developing a classic WAS phenotype later in life (Sullivan et al., 1994). Laboratory evidence to establish the diagnosis is therefore of prime necessity. Abnormal T and B lymphocyte functions are generally associated with classic WAS. Absence or a reduced quantity of WAS protein in lymphocytes of WAS patients is the best confirmatory test (short of mutation analysis), allowing rapid diagnosis by a simple flow-cytometric technique (Yamada et al., 1999).

Lymphopenia is a consistent finding in patients with classic WAS (Ochs et al., 1980) and may be present at an early age (Park et al., 2004).

Iron deficiency anemia is common in infants and children with WAS because of the constant loss of red blood cells. This can be corrected with increased dietary intake of iron. Chronic infection may further impair the production of red cells. Autoimmune Coombs-positive hemolytic anemia is a frequent complication and needs to be recognized early for proper therapy.

The thrombocytopenia and small platelet size are present at birth, are persistent, and do not respond to prednisone or high-dose IVIG. Platelet counts may vary and are usually between 10,000 and 40,000 platelets/mm<sup>3</sup>. During infection or acute autoimmune disease, the number of platelets may temporarily increase, without increasing in size. Thrombocytopenia may be intermittent in patients with characteristic missense mutations (Notarangelo et al., 2002) or absent as in boys with X-linked neutropenia due to mutations within the Cdc42-binding site (Devriendt et al., 2001; Burns et al., 2004, A.J. Thrasher and P.Y. Ancliff, unpublished observation).

### Other Laboratory Abnormalities

Patients with WAS respond to infections or to autoimmune diseases with increased sedimentation rates and elevated C-reactive protein (CRP). Vasculitis is a common complication affecting small and large arteries; deposits of IgA-containing immune complexes have been found in purpuric skin lesions and in the small

bowel of a WAS patient with a Henoch-Schönlein purpura-like vasculitis (H.D. Ochs, unpublished observation). Hemolytic anemia is often due to a warm autoantibody to red blood cell surface antigens that can be demonstrated by direct or indirect Coombs' test.

### Radiologic Findings

X-ray films may reveal chronic lung disease, sinusitis, or mastoiditis. Subperiosteal hemorrhage is seen occasionally. Brain scans are used if cerebral hemorrhage is expected.

### Histopathology

The lymphoid tissue and thymus are prime targets for pathologic changes in patients with *WASP* mutations, although the degree of involvement varies considerably. A gradual loss of cellular elements occurs in the thymus and lymphoid organs (Cooper et al., 1968). The pathologic findings in lymph nodes and spleens from WAS patients consistently reveal depletion of small lymphocytes from T cell areas, prominence of the reticulum cell stroma, the presence of atypical plasma cells with and without plasmacytosis, and extramedullary hematopoiesis (Snover et al., 1981). Progressive depletion of germinal centers is also observed (Color Plate 31.I). In a study of spleens obtained from XLT and WAS patients undergoing splenectomy, a significant depletion of the white pulp was noticed. This depletion was not limited to the T cell-dependent area but also involved the B cell compartment. Specifically, a remarkable depletion of the marginal zone (MZ) was observed in WAS patients, an abnormality that may be directly responsible for the defective antibody response to polysaccharide and selected protein antigens. There was a strong correlation between morphologic abnormalities in the splenic tissue and the clinical severity of the disease (Vermi et al., 1999). Patients with severe disease (scores of 4 and 5) had more severe depletion of the white pulp, including the T cell area, B cell area, and MZ thickness, than patients with lower scores (2–3). The lymphoid tissues and follicles of the gastrointestinal (GI) tract are usually normal (Cooper et al., 1968), although GI lymphoid depletion may occur (Wolff and Bertucio, 1957).

A variable degree of thymic hypoplasia has been observed. Cooper et al. (1968) described normal thymic architecture, normal corticomedullary differentiation, and intact Hassall's corpuscles despite a small thymus. Wolff (1967) reported two patients with thymic pathology, one with thymic hypoplasia and the other with thymic atrophy. The surface of peripheral blood lymphocytes from WAS patients, when scanned by electron microscopy, is devoid of microvillous projections, compared with normal lymphocytes (Fig. 31.2) (Kenney et al., 1986). However, more recent studies indicate that *WASP* deficiency allows an intact microvilli organization, strongly suggesting that *WASP* is dispensable for lymphocyte microvilli formation (Majstorovich et al., 2004). This finding is in keeping with the notion that *WASP*-mediated Arp2/3 activation results in the formation of a network of short-acting filaments bound in an end-to-side manner, as observed in macrophage and dendritic cell ruffles, whereas microvilli are composed of parallel bundles of side-to-side linked actin filaments.

### Molecular Basis

Through study of DNA from WAS families with multiple affected members, the *WASP* gene was mapped to the region Xp11.22–Xp11.3 (Kwan et al., 1991). On the basis of these mapping data, Derry and colleagues (1994) isolated the *WASP* gene

**Figure 31.2.** Scanning electron micrographs of normal T cells (left), and WAS T cells (right). The abundant microvilli covering the surface of the normal T cells are absent or sparse on the WAS T cells (from Kenney et al., 1986).

by positional cloning and demonstrated different mutations in lymphoblastoid cell lines derived from WAS and XLT patients.

### Structure of *WASP*

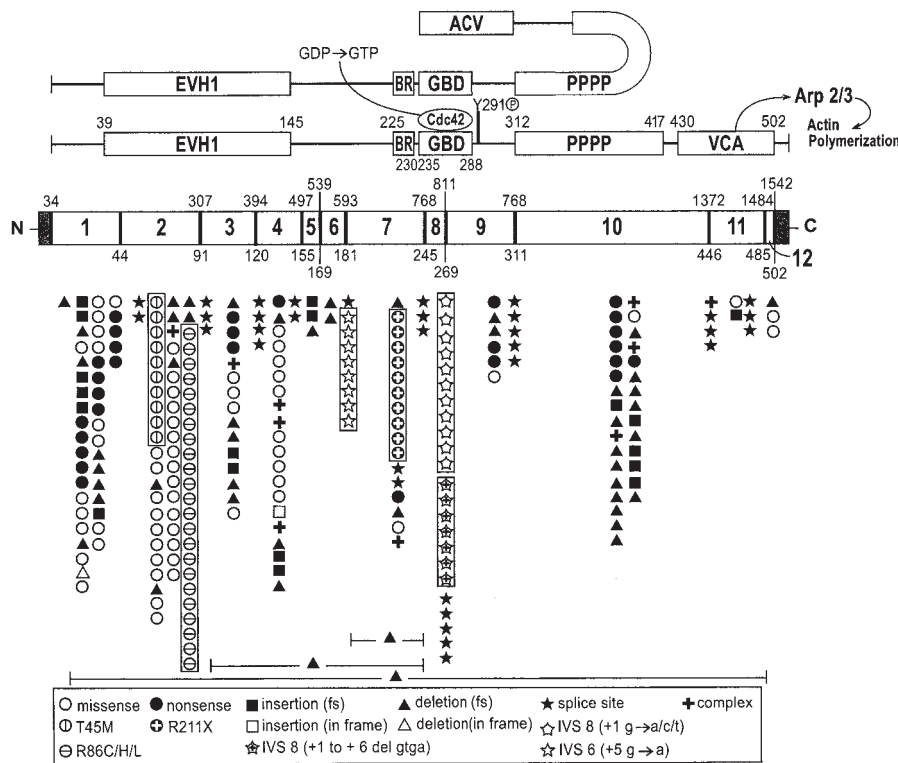

The *WASP* gene consists of 12 exons spanning 9 kb of genomic DNA (Fig. 31.3). The 1821 base pair cDNA generates a protein of 502 amino acids with a predicted molecular weight of 54 kDa. *WASP* is constitutively expressed in all hematopoietic stem cell-derived lineages and located predominantly in the cytoplasmic compartment, with the highest protein density being along the cell membrane (Rivero-Lezcano et al., 1995; Zhu et al., 1997). *WASP* is a key member of a family of proteins that link signaling pathways to actin cytoskeleton reorganization by activating Arp2/3-mediated actin polymerization. Several functional domains based on the genomic structure of *WASP* have been identified (Fig. 31.3), including the N-terminal pleckstrin homology (PH) domain, the Ena/VASP homology 1 (EVH1) domain overlapping the PH domain, a basic region (BR), a GTPase binding domain (GBD)/Cdc42 or Rho-interactive binding (CRIB) motif, a proline-rich region (PPPP), and a verprolin (V) homology domain, a cofilin (C) homology domain, and an acidic (A) region (VCA) (Miki et al., 1996; Symons et al., 1996; Thrasher, 2002; Burns et al., 2004).

#### Pleckstrin homology domain

The PH-like domain is located close to the N-terminal region of *WASP* and N-*WASP* (a neurotissue homologue of *WASP*) and spans amino acids 6–105. Functionally, the PH domain is considered important for the localization of proteins through interactions with other proteins or lipids and may play a role in the binding of cytoplasmic proteins to membranes (Lemmon et al., 1996). Ligands for PH domains reported to date include phosphatidylinositol 4,5 biphosphate (PIP<sub>2</sub>), which was shown to bind to the PH domain of N-*WASP*, resulting in actin polymerization in a PIP<sub>2</sub>-dependent manner (Miki et al., 1996). PIP<sub>2</sub> is also bound by the BR that is N-terminal to the CRIB domain (Prehoda et al., 2000; Rohatgi et al., 2000). There is evidence that PIP<sub>2</sub> synergizes with Cdc42 to fully activate *WASP*/N-*WASP* in vitro (Higgs and Pollard, 2000; Rohatgi et al., 2000).

#### *WASP* interactive protein binding domain

The EVH1 domain at the N-terminal region of *WASP* allows recruitment of *WASP*-interacting protein (WIP) (Ramesh et al., 1997). In resting lymphocytes, *WASP*/N-*WASP* constitutively

**Figure 31.3.** Schematic representation of WAS protein, representing 12 exons and the major functional WASP domains (center). The top panels illustrate autoinhibition of WASP. The VCA domain interacts with a region from residues 242 to 310, which include the C-terminal part of the GBD (Kim et al., 2000). If Cdc42 is activated (GDP  $\rightarrow$  GTP), WASP assumes the active form, allowing the C-terminal VCA domain to freely interact with Arp2/3 to initiate actin polymerization (see text for details). The mutations of WASP identified in WASP families cared for in three Centers (Seattle, Brescia, and Tokyo) are visualized according to their location in the exons and the exon-intron junctions. Each symbol represents a single family with WASP mutation. Missense mutations are located mostly in exons 1–4; deletions and insertions are distributed throughout the WASP gene and splice site mutations are formed predominantly in introns 6, 8, 9, and 10. Arp2/3, actin-related protein 2/3; Br, basic region; EVH1, Ena/VASP homology 1 domain; GBD, GTPase binding domain; PPPP, proline-rich region; VCA, verpolin/cofilin homology domains/acidic region.

associates with WIP, stabilizing the inactive conformation of WASP (Martinez-Quiles et al., 2001; Sasahara et al., 2002; Volkman et al., 2002). Following engagement of the T cell antigen receptor, WIP also binds to the adaptor Crkl, which is part of a multimolecular complex that includes Crkl, WIP, and WASP and is recruited by ZAP-70 to lipid rafts and the immunologic synapse. TCR ligation causes protein kinase C $\theta$  (PKC $\theta$ )-dependent WIP phosphorylation and disengagement of WASP from the WIP/WASP complex, thus allowing WASP activation by Cdc42 (Moreau et al., 2000; Sasahara et al., 2002). This leads to actin polymerization and stabilization of actin filaments (Volkman et al., 2002).

#### Cdc42 binding domain

The CBD or CRIB motif (amino acids 236–253) is located in exons 7 and 8 of the WASP gene (Aspenström et al., 1996; Kolluri et al., 1996; Symons et al., 1996; Abdul-Manan et al., 1999). Cdc42 is a member of the Rho family of GTPases and regulates the formation of filopodia and controls cell polarity and chemotaxis (Hall, 1998). Like other proteins containing a CRIB motif, WASP recognizes the GTP-bound but not the GDP-bound form of Cdc42 and binds to Cdc42-GTP with a 500-fold greater affinity than to Cdc42-GDP (Rudolph et al., 1998).

Computer modeling and binding experiments strongly suggest an autoinhibitory contact between the GBD and the carboxy-terminal region of WASP, which can be released by the activated (GTP) form of Cdc42 (Kim et al., 2000). Rho-like GTPases such as Cdc42 and Rac are key elements in the dynamic organization of the actin cytoskeleton (Lamarche et al., 1996). Thus, the GBD may have a direct effect on actin polymerization and an indirect effect on the interaction of the C terminus of WASP with the Arp2/3 actin nucleating complex (Fig. 31.3).

Toca-1 protein (transducer of Cdc42-dependent actin assembly) has recently been recognized as a crucial intermediate required for Cdc42/N-WASP/Arp2/3 complex-induced actin

polymerization (Ho et al., 2004). In order to mediate Cdc42-induced activation of purified N-WASP by toca-1, N-WASP must be complexed with WIP, thus demonstrating the importance of the WASP/N-WASP–WIP interaction in the regulation of actin polymerization.

#### SH3-Binding domain

A proline-rich region in exon 10 contains the PXXP binding consensus for SH3 binding domains. WASP was shown to interact with SH3 domains of selected signaling molecules, including the cytosolic adaptor proteins, Grb2, P47<sup>phox</sup>, Fyn, cFgr, Lck, c-Src, and p47<sup>phox</sup>. WASP also interacts with the Tec family cytoplasmic tyrosin kinases, Btk, Tec, PLC- $\gamma$ 1, and Itk. This interaction may influence the localization of WASP and its contribution to the conformational changes of WASP by regulating its phosphorylation. These observations suggest that WASP, through its interaction with the SH3 domain of multiple but selected molecules, plays an important role in cytoplasmic signaling of hematopoietic cells (reviewed in Imai et al., 2003).

The proline-rich region is also required for the optimal actin polymerization activity of WASP (Castellano et al., 2001; Yarrar et al., 2002) and for the recruitment of WASP to the immune synapse formed between T cells and antigen-presenting cells (Cannon et al., 2001; Badour et al., 2003; Barda-Saad et al., 2005).

#### Verprolin/Cofilin/Acidic region domain

The VCA domain, located in the C-terminus of WASP, plays a key role in the regulation of actin polymerization (Miki et al., 1996; Snapper and Rosen, 2003; Notarangelo and Ochs, 2003). If WASP is activated by GTP-Cdc42, the C-terminal region binds to Arp2 and Arp3 and to five unique polypeptides. The actin monomer that binds to the VC homology domain of WASP appears to be added to the Arp2/3 complex, thus promoting nucleation of the new daughter filament (Weaver et al., 2003).

## Function and Regulation of WASP

WASP, with its multifunctional domains, is responsible for key tasks of hematopoietic cells. The progress made over the last 10 years in understanding the biologic functions of this complex protein has provided new insight into the pathogenesis and clinical presentation of WAS and XLT patients. WASP is expressed in CD34<sup>+</sup> hematopoietic precursors and in all lineage-committed cells, which suggests a role in hematopoiesis and differentiation. However, the finding that hematopoietic stem cell migration is defective in Wasp-deficient mice (Lacout et al., 2003) suggests that the nonrandom X chromosome inactivation in CD34<sup>+</sup> precursors and in all subsequent blood cell lineages of WASP carriers (Wengler et al., 1995) is a direct result of the failure of mutated stem cells to transit successfully from the fetal liver to the bone marrow.

### Cytoskeleton and actin polymerization

WASP is a key member of a family of proteins that link signaling pathways to actin cytoskeleton reorganization by activating Arp2/3-mediated actin polymerization. This concept was suggested by Facchetti et al. (1998), who observed that the distribution of F-actin in EBV-transformed B lymphoblastoid cell lines from patients with classic WAS who lacked WASP was markedly reduced or completely absent compared with XLT subjects, who expressed reduced amounts of mutated WASP, and normal controls. In addition, cytoplasmic projections containing F-actin, recognizable as microvilli, were reduced in patients with WAS but not in patients with XLT.

Actin polymerization is initiated by the actin-related proteins (Arp), a group of proteins involved in the regulation of the actin cytoskeleton. WASP interacts directly with two of these proteins, Arp2 and Arp3, which form the Arp2/3 complex, leading to actin nucleation and formation of actin filaments (Carlier et al., 1999).

The binding of WASP to the Arp2/3 complex is mediated by the C-terminal acidic (A) region, which is preceded by the VC homology domain. This process is regulated by conformational changes in N-WASP (Rohatgi et al., 1999) and in WASP (Kim et al., 2000) by activated Cdc42 and PIP<sub>2</sub>. As discussed earlier, WASP is present in two configurations. In the active form, the C terminus of WASP is free to interact with the Arp2/3 complex; in the inactive form the VCA domains interact with the hydrophobic core of the GBD. This binding is reinforced by the interaction of the acidic region (A) with a BR located N-terminal to the GBD (Kim et al., 2000). To revert to the active form, GTP-bound Cdc42 and PIP<sub>2</sub> cooperatively disrupt this autoinhibitory loop and release the C-terminal region for binding to the Arp2/3 complex (Fig. 31.3).

The importance of this cell-inhibitory mechanism is exemplified by the observation that point mutations within the GBD of WASP can cause congenital X-linked neutropenia; these mutations will interfere with the autoinhibitory contact of the C terminus of WASP with the GBD, resulting in a permanently "active" configuration of WASP (Devriendt et al., 2001; Burns et al., 2004; A.J. Thrasher and P.Y. Ancliff, unpublished results). This unregulated activation of the actin cytoskeleton promotes hematopoietic cell death by enhanced apoptosis affecting mainly myeloid progenitors (Burns et al., 2004).

### Intracellular signaling

The proline-rich domain of WASP interacts with SH3 domains of selected cytoplasmic proteins, a finding suggesting that WASP is involved in intracellular signaling of hematopoietic cells.

Phosphorylation by tyrosine kinases regulates signal transduction by connecting upstream cell surface receptors to downstream pathways. WASP itself undergoes tyrosine phosphorylation following adherence of platelets to collagen (Oda et al., 1998). Baba and colleagues (1999) identified WASP as one of the major phosphoproteins associated with Btk. Together with Lyn and Btk, Hck has been shown to mediate phosphorylation of WASP Tyr291 (Scott et al., 2002). Tyr291 is conserved in N-WASP and is positioned adjacent to the Cdc42 binding site. Phosphorylation of Tyr291 stabilizes the active conformation of WASP and exposes the VCA domain, allowing them to interact with the Arp2/3 complex and to enhance cytoskeletal reorganization, which is required for the formation of the podosomes and filopodia (Cory et al., 2002). It is intriguing to speculate that the phosphorylation of Tyr291 modulates the affinity of WASP for its target, Cdc42. Dephosphorylation of Tyr291 by the tyrosine phosphatase PTP-PEST, by contrast, favors the formation of the autoinhibitory structure of WASP (Cote et al., 2002). The proline-rich region of WASP allows interaction with the SH3 domain of the linker protein, PSTPIP, which in turn binds PTP-PEST, thus establishing a physical link between WASP and PTP-PEST. This interaction results in the formation of a macromolecular complex that is recruited to the immunological synapse, where it initiates actin polymerization (Badour et al., 2003; Sasahara et al., 2002).

T cell antigen receptor engagement is crucial for the cytoplasmic signaling events that lead to cytoskeletal reorganization through actin polymerization. This process is essential for cellular shape change, cellular movement, and immune synapse formation. Recruitment of WASP to the site of actin polymerization depends on a series of biochemical events that follow TCR engagement. In mature T lymphocytes, activation of the TCR results in the phosphorylation of multiple tyrosine residues of LAT (linker for activation of T cells) and SLP-76, which leads to the migration of Nck and WASP to the cell periphery, where these molecules accumulate at an actin-rich circumferential ring. This process assures that the actin polymerization machinery is carried to the plasma membrane in the vicinity of the activated TCR. These events have recently been confirmed by direct visualization of the dynamic complexity of molecular recruitment, molecular interactions, and actin polymerization in single-living cells in time and space (Barda-Saad et al., 2005).

### Chemotaxes and phagocytosis

Podosomes are highly dynamic adhesion structures and are mainly found in monocytes, macrophages, osteoclasts, and dendritic cells. WAS macrophages are completely devoid of podosomes (Linder et al., 1999), resulting in defective adhesion and orientation in a chemotactic gradient (Badolato et al., 1998). Wasp-deficient murine dendritic cells fail to establish a leading edge, show defective attachment and detachment on fibronectin-coated surfaces, and display lack of chemokinesis to the chemokine CCL21 (de Noronha et al., 2005). Consequently, migration of Langerhans cells from the skin to the draining lymph node (Snapper et al., 2005) and accumulation of dendritic cells in the T cell area of the spleen following immunization are impaired in Wasp-deficient mice. Involvement of WASP in IgG-mediated phagocytosis has been demonstrated by the observation that this FcγR-dependent process is impaired in WASP-deficient peripheral blood macrophages (Lorenzi et al., 2000). In normal macrophages, WASP itself is actively recruited to the "actin cup"; in WASP-deficient macrophages, formation of the actin-cup and local recruitment of tyrosine-phosphorylated proteins

are markedly reduced. These findings suggest that the cytoskeletal structure responsible for phagocytosis is dependent on WASP expression.

Clearance of apoptotic cells by macrophages and dendritic cells requires recruitment of WASP to the phagocytic cup. Lack of WASP results in delayed phagocytosis, both in vitro and in vivo (Leverrier et al., 2001).

Reduced chemotaxis of WASP-deficient neutrophils was reported in WAS patients (Ochs et al., 1980) and in Wasp-knockout mice, both in vitro and in vivo (Snapper et al., 2005). Deficiency of WASP also leads to abnormal migration of T lymphocytes. Wasp<sup>-/-</sup> murine T cells respond with reduced migration when exposed to the chemokine CCL19. This defect leads to impaired homing of T cells into the Payer's patches (Snapper et al., 2005).

#### Accelerated apoptosis

A correlation between actin cytoskeletal function, mutations of WASP, and programmed cell death has been suggested (Kothakota et al., 1997; Melamed and Gelfand, 1999; Rawlings et al., 1999; Rengan et al., 2000). The morphologic changes that occur during apoptosis require actin cytoskeletal remodeling, a process necessary for the execution of programmed cell death. Defective actin polymerization may explain the accelerated in vitro cell death of lymphocytes and the progressive cellular and humoral immunodeficiency observed in individuals with classic WAS.

The precise role of WASP in apoptosis is not clearly defined. The down-regulation of a cell survival pathway or, conversely, the up-regulation of a cell death pathway in WAS lymphocytes has been considered. Accordingly, reduced Bcl-2 expression (Rawlings et al., 1999) and increased expression of caspase-3 and the cell death receptor CD95 (Fas) (Rengan et al., 2000) by WAS lymphocytes, compared with that in XLT and control lymphocytes, have been reported.

### Mutation Analysis

The cloning and sequencing of the gene responsible for WAS and XLT have provided a tool for confirming the diagnosis in affected males, identifying carrier females, and performing prenatal diagnosis. Techniques are available to screen peripheral blood lymphocytes for the presence or absence of WASP, sequence cDNA and/or genomic DNA for mutations of the WASP gene, and estimate the quantity of WASP by Western blot analysis or flow cytometry.

#### Spectrum of WASP Mutations

Following the discovery of the gene responsible for WAS and XLT, large series of WASP mutations were published from clinical centers of Europe, North America, and Asia (Schwarz, 1996; Jin et al., 2004; Imai et al., 2004; see WASPbase at: <http://home.page.mac.com/kohsukeimai/wasp/waspbase.html>). Figure 31.3 summarizes the results of sequencing studies computed from three centers: Brescia, Italy; Seattle, USA; and Tokyo, Japan. Of the 312 patients from 270 families included in this analysis, 184 (from 159 families) were studied molecularly at the University of Washington, Seattle; 78 patients (from 68 families) were studied at the University of Brescia, Italy; and 50 patients (from 43 families) were investigated at the Medical and Dental University, Tokyo (Imai et al., 2004; Jin et al., 2004). Participants in these studies included natives of North, Central, and South America, Western and Eastern Europe, the Middle East, South East Asia,

**Table 31.1.** Distribution of Mutations in 270 Families with Wiskott-Aldrich Syndrome or X-Linked Thrombocytopenia

<i>Mutation Type</i>	<i>Families Affected n (%)</i>
Missense	93 (34.5)
Splice	59 (22)
Deletion	46 (17)
Nonsense	39 (14.5)
Insertion	19 (7)
Complex + large deletions	14 (5)
Total	270 (100)

and Japan. As expected, the incidence and type of mutations are similar in all parts of the globe. In this cohort of 270 families with WAS or XLT, 158 unique WASP mutations were identified. As shown in Table 31.1, the most common mutations observed were missense mutations ( $n = 93$  families), followed by splice site mutations ( $n = 59$ ), short deletions ( $n = 46$ ), and nonsense mutations ( $n = 39$ ). Insertions, complex mutations, and large deletions made up 12% of the mutations identified. Most deletions and insertions result in frameshift and early termination of transcription.

As was observed in smaller series reported previously (Derry et al., 1994; Kwan et al., 1995; Villa et al., 1995; Wengler et al., 1995; Zhu et al., 1995; Greer et al., 1996; Schindelhauer et al., 1996; Schwarz, 1996; Schwartz et al., 1996; Remold-O'Donnell et al., 1997; Zhu et al., 1997; Lemahieu et al., 1999; Itoh et al., 2000; Fillat et al., 2001), the predominant mutations of WASP, amino acid substitutions, were typically located in exons 1–4. Only four missense mutations, one each in exons 7, 9, 10, and 11, were observed downstream of exon 4. One of those, P361T in exon 10, is the only missense mutation identified to date affecting a proline in the polyproline region of WASP. In addition, two unrelated families, both with the XLT phenotype, had a point mutation affecting the termination codon of exon 12 (503 X > S), resulting in the absence of WASP.

The second-most common WASP mutations, splice site alterations, occurred predominantly in the downstream half (introns 6–11) of the WASP gene, as has been reported by others (Wengler et al., 1995; Schwarz, 1996; Zhu et al., 1997; Lemahieu et al., 1999). Of 31 unique splice site mutations, 22 affected a donor site and 9 an acceptor site. Mutations affecting variant splice sites resulted in multiple splicing products that often included small amounts of normal WASP cDNA. Insertions and short deletions typically involving less than 10 nucleotides resulted in most instances in frameshift and premature stop of translation. Complex mutations were rare and involved double missense mutations, point mutations followed by a deletion, or a combination of deletions and insertions. Four large deletions were observed, resulting in the loss of several exons. In one case, the entire WASP coding region was deleted. Of all deletions and insertions, 58% were due to "slippage" caused by the deletion or insertion of an extra nucleotide within a stretch of identical basis.

#### Mutational Hot Spots

In the 270 unrelated families studied, we found six mutational hot spots, defined as occurring in seven or more unrelated families (> 2.5%) (Table 31.2). Three were point mutations within the coding region; all three involved CpG dinucleotides (C > T or G > A) caused by methylation and deamination of a cytosine to

**Table 31.2.** WASP Hot-Spot Mutations and Clinical Phenotype

Mutation	Affected Families (Patients)	% of Total Families	Patients with Scores of 1–2.5*	Patients with Scores of 3–5
168C>T (T45M)	10 (11 <sup>†</sup> )	3.7	10	1**
290C>N/291G>N (R86S/G/C/H/L)	23 (25)	8.5	23	2**
IVS6 + 5g>a, fs stop aa 190/normal	8 (14)	3.0	11	3**
665C>T (R211X)	10 (11)	3.7	1	10
IVS8 + 1g>a/c/t, fs stop aa246	11 (14 <sup>†</sup> )	4.1	5	7
IVS8 +1 to +6 del gtga, fs stop aa246	7 (7)	2.6	1	6
Total	69 (82)	25.6	51	29

\*A score of 2–3 is listed as a score of 2.5. Scores 1–2.5 are considered XLT; scores 3–5 represent the WAS phenotype.

<sup>†</sup>One patient with the T45M missense mutation and two patients with the IVS8 + 1g>a splice site mutation could not be scored because of insufficient clinical data.

\*\*Of the six patients with high scores, four developed autoimmune diseases and one died of lymphoma at age 44 years.

Three of the hot-spot mutations (T45M; R86N; IVS6 + 5g>a) are associated with low scores and three hot-spot mutations (R211X; IVS8 + 1g>a; IVS8 +1 to +6 del gtga) are associated with high scores ( $p < 0.001$ ). fs = frameshift

a thymidine in a sense or antisense strand. The other three hot-spot mutations involved splice sites.

The 168 C>T mutation, found in 10 families, results in the substitution of threonine with methionine at position 45; the 290 C>N/291G>N mutations, observed in 23 unrelated families, result in the substitution of arginine at position 86 with either a serine, glycine, cystidine, histidine, or leucine. The 665 C>T mutation, which converts arginine at position 211 to a stop codon, was found in 10 families. The IVS 6 + 5 g>a mutation, present in eight unrelated families, results in both abnormal and normal splicing products. The IVS 8 + 1 g>n mutation, identified in 11 families, results in the deletion of exon 8, leading to frameshift and premature stop of translation. The IVS8 + 1 to + 6 del gtga, resulting in the deletion of exon 8, frameshift, and early termination, was found in seven unrelated families. These six mutations account for 25.6% of all families included in this study. Three of these six mutations (168 C>T, 290 C>N/291 G>N, and IVS6 + 5g>a) were consistently found in WASP-positive patients with a mild phenotype (XLT) who had a low score, whereas the three other mutations (665C>T, IVS8 + 1g>n-N, and IVS8 + 1to + 6 del gtga) were predominantly WASP negative and had a high score ( $p < 0.001$ ) (Table 31.2).

### Spontaneous Reversion of Mutations

Several recent studies reported somatic mosaicism due to spontaneous reversion of mutations or second-site mutations that restored WASP function (Ariga et al., 1998, 2001; Wada et al., 2001, 2003; Jin et al., 2004). These reversions have been found molecularly in both T and B cell lineages, but only revertant T cells were detected in significant numbers in the peripheral blood. This finding demonstrates that a normal copy of the WASP allele provides advantage of growth and survival to T cells but not to B cells. T lymphocytes that underwent reversion responded normally to CD3 stimulation and demonstrated normal actin rearrangement. Some patients seemed to improve clinically (Wada et al., 2001). The recent report of an 8-year-old WAS patient with a single nucleotide insertion in exon 4, who presented with a reversion limited to his NK cells, suggests a selective growth advantage of WAS-positive NK cells (Lutskiy et al., 2005). Although it is unclear in which precursor cells the reversions originated, these observations suggest that gene therapy (if it is possible to safely insert a normal gene into hematopoietic stem cells) could result in normalization of T and NK cells. These results also underline the key role WASP plays

in T cell proliferation and in the survival and function of both T and NK cells in vivo.

### Genotype-Phenotype Correlation

Mutations of the WASP gene result in three distinct phenotypes: (1) the classic WAS triad of thrombocytopenia and microplatelets, recurrent infections as a result of immunodeficiency, and eczema (Wiskott, 1937; Sullivan et al., 1994); (2) the milder XLT variant, characterized predominantly by thrombocytopenia and small platelets (Villa et al., 1995; Zhu et al., 1995), which can be intermittent (Notarangelo et al., 2002); and (3) congenital neutropenia without the clinical findings characteristic of WAS and XLT (Devriendt et al., 2001). To clearly distinguish these clinical phenotypes, a scoring system, listed in Table 31.3, has been designed. The most consistent phenotype-genotype correlation was observed when the patients were divided into two categories: WASP positive if the mutated protein was of normal size, and WASP negative if the protein was absent or truncated. Patients with mutations that allowed the expression of normal-sized mutated

**Table 31.3.** Scoring System\* to Define Phenotypes of WASP Mutations

	IXLT	XLT	WAS Classic	XLN
Score	<1	1 2 3	4 5	0
Thrombocytopenia	(+)	+	+	+
Small platelets	+	+	+	+
Eczema	–	– (+)	++	(+)/+/++
Immunodeficiency	–	–/(+)	(+)	(+)/+
Infections	–	–	(+)	+/++
Autoimmunity and/or malignancy	–	–	–	+
Congenital neutropenia	–	–	–	–

IXLT, intermittent X-linked thrombocytopenia; WAS, Wiskott-Aldrich syndrome; WASP, Wiskott-Aldrich syndrome protein; XLN, X-linked neutropenia; XLT, X-linked thrombocytopenia.

\*Scoring system: –/(+), absent or mild; (+), mild, transient eczema or mild, infrequent infections, not resulting in sequelae; +, persistent but therapy-responsive eczema and recurrent infections requiring antibiotics and often intravenous immunoglobulin prophylaxis; ++, eczema that is difficult to control and severe, life-threatening infections. Because patients with XLT may develop autoimmune disorders or lymphoma, although at a lower rate than those with classic WAS, a progression from a score of 1 or 2 to a score of 5 is possible for XLT.

From Stiehm ER, Ochs HD, Winkelstein JA, editors. Immunologic disorders in infants and children. Fifth edn. Philadelphia: Elsevier Saunders, 2004, with permission.

protein, often in reduced quantity, developed the XLT phenotype, whereas those patients whose lymphocytes could not express WASP or expressed only truncated WASP were more likely to have the WAS phenotype ( $p < 0.001$ , Table 31.4). When patients within one of the six hot spots were analyzed there was a highly significant concurrence of the phenotype within each group (Table 31.2). Progression to a score of 5 due to either autoimmune disease or malignancy was observed in both groups but was far more frequent in WASP-negative patients with an initial score of 3–4.

When the Japanese patients were analyzed separately (Imai et al., 2004), autoimmune diseases were equally frequent in patients with a low symptom score, representing XLT, and in those with a high score, representing WAS; this result was predominantly due to the high incidence of IgA nephropathy in the Japanese patients. There were other exceptions to the rule, as is evident from data shown in Table 31.4, a clear indication that it may be difficult in individual cases to accurately predict the clinical course based solely on the type of mutations of the *WASP* gene.

It is important to consider the complexity of the disease, the differences in lifestyle and medical care, chance exposure to unusual microorganisms, and the influence of genes that affect allergic predisposition, autoimmunity, and malignancies. Splice site mutations, especially if affecting variant intronic nucleotide positions, often allow the generation of multiple splicing products, including the generation of normally spliced mRNA and the production of variable quantities of normal WASP. For example, the hot-spot mutation IVS6 + 5 g > a causes the insertion of 38 nucleotides from the proximal end of intron 6, which results in frameshift and early termination of transcription, but also in the production of a small amount of normal WASP mRNA. Somatic mosaicism due to reversion is another possibility for a more favorable phenotype than that expected from the type of mutation (Wada et al., 2001). Genes that determine an individual's probability of developing atopic disease, such as allergies and eczema, or genes that control the effectiveness of host defense against infections may modify the WAS/XLT phenotype. Similarly, environmental factors, such as exposure to common or uncommon infectious agents, failure to establish the diagnosis at an early age, or less than optimal care, may affect the severity of the clinical presentation. Phenotype scoring before the age of 2 years is unreliable because it often suggests a phenotype that is milder than expected from the type of *WASP* mutation identified (Jin et al., 2004).

**Table 31.4.** Effect of Mutations on Expression of WASP\*

Mutation Type	WASP <sup>+</sup> Families Affected n (%)	WASP <sup>−</sup> Families Affected n (%)
Missense	64 (73.6)	10 (8.9) <sup>†</sup>
Splice	12 [I = 3, V = 9] (13.8)	30 [I = 25, V = 5] (26.8) <sup>†</sup>
Complex	4 (4.6)	4 (3.6)
Deletion** or insertion	5 (5.7)	32 (35.1) <sup>†</sup>
Nonsense	2 (2.3)	25 (22.3) <sup>†</sup>
Total‡	87 (100)	112 (100)

I, invariant sites; V, variant sites.

\*Distribution of mutations in WASP-positive and WASP-negative families.

<sup>†</sup>Distribution of mutations observed in WASP<sup>+</sup> and WASP<sup>−</sup> families is significantly different ( $p < 0.001$ ).

\*\*Including large deletions.

‡Not all patients analyzed were studied for expression of WASP.

## Strategies for Diagnosis

Because of the wide spectrum of clinical findings, the diagnoses of WAS or XLT should be considered in any boy presenting with petechiae, bruises, and congenital or early-onset thrombocytopenia associated with small platelet size (Color Plate 31.II). The presence of transient, mild, or severe eczema supports the diagnosis of WAS or XLT. It is important to note that infections and immunologic abnormalities may be absent, mild, or severe and autoimmune disease may develop, more often in WAS than in XLT. Lymphopenia, characteristic for classic WAS, may be present during infancy but will develop invariably during childhood. Abnormal antibody response to bacteriophage Ø174 seems to be a consistent finding, even in patients with a mild phenotype (Fig. 31.1). Screening for WASP mutations can be successfully performed by flow cytometry, but patients with a substantial expression of mutated WASP may be missed. In atypical cases, mutation analysis of the *WASP* gene is essential for diagnosis; it may also assist in estimating the severity of the disease (with caution), and in performing carrier detection and prenatal diagnosis. It is vital to differentiate XLT from ITP patients because of the vulnerability of XLT patients to splenectomy, the need for different therapeutic approaches, and genetic implications.

## Females with Wiskott-Aldrich Syndrome

Sporadic cases of females with clinical and laboratory findings compatible with the diagnosis of WAS have been described (Evans and Holzel, 1970; Lin and Hsu, 1984; Conley et al., 1992). Two sisters, born to healthy parents, who presented with recurrent infections, thrombocytopenia, petechiae, and eczema had low serum IgM, normal IgG, and elevated IgA and IgE. They had decreased T lymphocyte subsets and absent isohemagglutinins (Kondoh et al., 1995). Autosomal inheritance was also suspected in a second family with multiple affected female members, displaying clinical and laboratory findings resembling classic WAS (Rocca et al., 1996).

Several symptomatic female patients have been identified as being heterozygous for mutations of *WASP*. They presented with either a classic WAS phenotype (Parolini et al., 1998) or an XLT phenotype (Inoue et al., 2002; Lutskiy et al., 2002; Zhu et al., 2002). In each case, the symptomatic females were found to have markedly skewed X chromosome inactivation in favor of the X chromosome with the *WASP* mutation.

## Carrier Detection and Prenatal Diagnosis

X-inactivation studies in WAS carrier females have shown that the normal X chromosome is preferentially used as the active X chromosome in all hematopoietic lineages, including CD34<sup>+</sup> cells (Wengler et al., 1995). Exceptions to this rule are families with a very mild form of XLT, in which X chromosome inactivation may be random (Inoue et al., 2002; Lutskiy et al., 2002; Zhu et al., 2002).

If the *WASP* mutation is known in a given family, carrier females can be identified by mutation analysis. Similarly, prenatal diagnosis of a male fetus at risk for WAS or XLT can be performed by DNA analysis with chorionic villi sampling or cultured amniocytes as the source of genomic DNA (Giliani et al., 1999).

## Treatment

Progress in nutrition, improved antimicrobial therapy including antiviral and antifungal drugs, and the prophylactic use of IVIG

have contributed to the prolonged expectancy and quality of life of WAS patients. Early diagnosis is most important for effective prophylaxis and treatment. If an infection is suspected, careful evaluation for bacterial, viral, or fungal causes followed by appropriate antimicrobial therapy is of crucial importance. Infants with *WASP* mutations and lymphopenia are candidates for PCP prophylactics. If antibody responses to protein and/or polysaccharide antigens are defective, which is most often the case in patients with the classic WAS phenotype, prophylactic IVIG infusions at a full therapeutic dose should be initiated. The dose of IVIG may have to be increased during infections, which may aggravate the already accelerated IgG catabolism. Continuous antibiotic therapy should be considered if infections are occurring despite IVIG therapy.

Killed vaccines can be given, including pneumococcal polysaccharides and protein-conjugated vaccines; the response, however, may be abnormal and should be determined. Live-virus vaccines are not recommended. Varicella-zoster immunoglobulin or high-dose IVIG (which has high antiviral antibody titers) and acyclovir are indicated following exposure to chickenpox. Antiviral drugs are also successfully used to treat recurrent herpes simplex infections.

Eczema, if severe, requires aggressive therapy including local steroids and, if indicated, short-term systemic use of steroids. Cutaneous infections are common and may necessitate local or systemic antibiotics. Lymphadenopathy is frequently observed and is often the consequence of infected eczema. Whether the newly approved tacrolimus ointment (Protopic 0.03%) or pimecrolimus cream (Elidel 1%) will be an alternative to steroid cream in the treatment of WAS-associated eczema remains to be seen. An appropriately restricted diet based on specific food allergies has to be selected for each patient.

Platelet transfusions are restricted to serious bleeding—for example, central nervous system hemorrhages or gastrointestinal bleeding. Blood products are best irradiated and should be cytomegalovirus negative. Aspirin, which interferes with platelet function, is contraindicated.

Splenectomy, sometimes recommended for XLT patients, effectively stops the bleeding tendency by increasing the number of circulating platelets. However, splenectomy increases the risk of septicemia and, if performed, requires continuous antibiotic prophylaxis. Data collected at the National Institutes of Health support the clinical experience that splenectomy does not effect the development of autoimmune diseases or malignancies (M. Blaese, personal communication). High-dose IVIG and systemic steroids may be considered for the treatment of autoimmune complications. Long-term immunosuppressive therapy, however, may cause the activation of viruses or increase the risk of fungal infections.

Because of poor dietary intake and constant loss of red cells, prophylactic treatment with iron is necessary to prevent chronic anemia.

### Transplantation

Hematopoietic stem cell transplantation, using as source bone marrow, peripheral blood, stem cells, or cord blood, is the only curative therapy for WAS patients (Filipovich et al., 2001). To prevent rejection, a conditioning regimen with cyclophosphamide, busulfan, and antithymocyte globulin with or without irradiation is necessary. Fully matched siblings are preferred donors; their use results in highly successful stem cell transplantation, even in older patients. Matched unrelated donors are safe if the recipient is less than 5–8 years of age. In older WAS patients, matched

unrelated donor transplants are less successful and not recommended (Filipovich et al., 2001). Cord blood stem cells, fully or partially matched, are excellent alternatives for boys with WAS who weigh < 25 kg, if a fully matched bone marrow donor is not available. Haploidentical bone marrow transplants have had disappointing results and are generally not recommended (Brochstein et al., 1991; Hong, 1996; Ozsahin et al., 1996), although a recent report describes successful engraftment of an unmanipulated HLA-haploidentical bone marrow transplantation from the patient's mother, resulting in stable chimerism 2 years after transplantation (Inagaki et al., 2005).

### Gene Therapy

The observation that a few WAS patients spontaneously underwent in vivo reversion of an inherited mutation of the *WASP* gene in T lymphocytes (Ariga et al., 2001; Wada et al., 2001, 2003), B lymphocytes (Konno et al., 2004) and NK cells (Lutskiy et al., 2005) supports the hypothesis that, in this syndrome, genetically corrected stem cells have an in vivo advantage of developing into T cells and possibly NK cells, a prerequisite for gene therapy. On the basis of these reports, experiments are being performed with *WASP*-deficient human cell lines and *Wasp* knockout mice.

Primary T lymphocytes or herpesvirus saimiri-immortalized cell lines derived from WAS patients have been successfully transduced with lentiviral vectors expressing the human *WASP* gene. Following transduction, the cells demonstrated a substantial growth advantage; responded to TCR signaling, including down-regulation of CD3 surface expression; formed stable B and T cell conjugates; and secreted normal amounts of IL-2 upon appropriate stimulation (Dupre et al., 2004; Miao et al., 2004; Martin et al., 2005).

In experiments with *Wasp* knockout mice and either oncoretroviral or lentiviral vectors, the irradiated recipients showed stable expression of *WASP* and correction of the immune defect and cytoskeletal abnormalities (Strom et al., 2002, 2003; Charrier et al., 2005; Humblet-Baron et al., 2005).

These in vivo experiments provide proof of the principle that the WAS-associated T cell signaling defect can be improved or corrected by transplanting retrovirally transduced hematopoietic stem cells. At this time it is unclear if this technique can be used successfully in correcting other hematopoietic cell lineages—for example, the defect in megakaryocytes and platelets, macrophages and dendritic cells, or B lymphocytes, which do not show a growth advantage following transduction of the *WASP* gene.

### Animal Models

Two mouse strains with *Wasp* deficiency have been generated by gene knockout technology (Snapper et al., 1998; Zhang et al., 1999). Hemizygous deficient male animals of both strains exhibit poor T cell proliferation and cytokine secretion in response to TCR activation by cross-linking of CD3. *Wasp* knockout mice have mild lymphopenia and moderate thrombocytopenia, which can be normalized by transplantation (Strom et al., 2002). However, *Wasp*<sup>-/-</sup> mice do not develop eczema or autoimmune diseases and susceptibility to infections is debatable and may not be clinically relevant (Strom et al., 2003; Andreansky et al., 2005). Importantly, these murine models have been used successfully to explore different techniques of gene therapy, including the evaluation of newly designed vectors and various conditioning regimens. However, to have access to a more relevant model of

human disease, an outbred model, for instance, canine WAS/XLT, is necessary.

## Conclusion and Future Directions

The clinical phenotype associated with mutations of *WASP* is as complex as the gene itself. By studying WAS, XLT, and XLN patients and their multiple *WASP* mutations, we have learned how a single gene defect can cause multiple and unique clinical symptoms. These investigations have provided new insight into the functions of *WASP* which facilitate not only TCR-initiated cytoplasmic signaling but also cytoskeletal reorganization and actin polymerization. The structure of *WASP* is responsible for two configurations of the molecule—the active form, in which the C-terminal end interacts with Arp2/3 to initiate actin polymerization, and the inactive form, in which the C-terminal end forms an autoinhibitory contact with the GBD. In the final analysis, *WASP* is required for efficient thrombocytopoiesis and platelet survival, T cell activation, T and B cell interaction and NK cell function, and function of the innate immune system. Since mutations of *WASP* interfere with the homing of hematopoietic stem cells, and thus affect all hematopoietic cell lineages, stem cell transplantation is the treatment of choice for curing this disease. For the same reason, gene therapy may work, and is one of the challenges for future WAS or XLT research.

## Acknowledgments

The work presented here was supported by grants from the National Institutes of Health (HD17427), the Jeffrey Modell Foundation, and the Immunodeficiency Foundation.

## X-Linked Lymphoproliferative Disease Due to Defects of *SH2D1A*

VOLKER SCHUSTER and COX TERHORST

X-linked lymphoproliferative disease (XLP; MIM 308240) is an inherited immunodeficiency involving primarily T, natural killer (NK) and natural killer T (NKT) cells that in most cases is exacerbated following exposure to Epstein-Barr virus (EBV). In older children and adults, EBV, one of the eight known human herpesviruses, is the causative agent of infectious mononucleosis (Henle and Henle, 1979). This is usually a self-limiting polyclonal lymphoproliferative disease with an excellent prognosis. In immunosuppressed individuals, EBV infection may lead to life-threatening lymphoproliferative disorders and lymphoma (Hanto et al., 1985). Moreover, EBV has been associated with certain malignancies, such as endemic Burkitt lymphoma, nasopharyngeal carcinoma, certain B and T cell lymphomas, and approximately 50% of Hodgkin disease (Zur Hausen et al., 1970; Ott et al., 1992; Weiss et al., 1989). In 1969 a family was described with two brothers suffering from hypogammaglobulinemia and malignant lymphoma following infectious mononucleosis (Hambleton and Cottom, 1969). This was the first report of XLP in the medical literature. In 1975, Purtilo et al. reported a large family, the Duncan kindred, in which multiple male members had died from fulminant infectious mononucleosis in early life, whereas others developed hypogammaglobulinemia after infectious mononucleosis or extranodal ileocecal malignant lymphoma during the next years of life. This apparently X-chromosomally inherited syndrome with a high vulnerability to EBV infection was classified as Duncan disease (in reference to the first described XLP family). Subsequently, when more families with similar signs and symptoms had been identified, and it became clear that only one XLP gene locus exists at Xq25 in all XLP families studied, the condition was named X-linked lymphoproliferative disease (Purtilo et al., 1991b). In 1978, an XLP registry was established for the

collection of clinical and laboratory data to facilitate basic research on the pathogenesis of XLP and to develop new diagnostic and therapeutic tools for XLP patients (Hamilton et al., 1980). As of the year 2000, 309 males with one or more XLP phenotype(s) from 89 unrelated families had been registered (Seemayer et al., 1995; Sumegi et al., 2000). The disease has been shown to occur worldwide with an estimated incidence of 1 to 3 per million in males (Purtilo and Grierson, 1991). Primary EBV infection in XLP males may lead to severe and frequently fatal infectious mononucleosis, lymphoproliferative disorders usually of B cell origin, dysgammaglobulinemia, and other less frequent manifestations (Seemayer et al., 1995). However, XLP manifestations such as dysgammaglobulinemia or malignant lymphoma may develop in a similar frequency during the life of XLP males who have never been exposed to EBV (Gross et al., 1994, 1995; Strahm et al., 2000; Sumegi et al., 2000), indicating that clinical manifestations of XLP are not EBV-specific and that EBV may only act as a potent trigger of the earliest and most serious clinical manifestation of XLP—i.e., fatal infectious mononucleosis.

In general, XLP has an unfavorable prognosis. However, transplantation of hematopoietic stem cells from a suitable donor may cure this immunodeficiency.

The gene responsible for XLP, named *SH2D1A* (SH2 domain-containing gene 1A) or *SAP* (SLAM-associated protein) has been identified and characterized (Coffey et al., 1998; Nichols et al., 1998; Sayos et al., 1998). The gene encodes a protein of 128 amino acids containing a single SH2 domain. SH2D1A is thought to play an important role in signal transduction. Through use of in vitro experiments and Sh2d1a-deficient mice, SH2D1A has been shown to interfere with the signaling pathways in T lymphocytes, NK and NKT cells.

### Clinical Phenotypes and Pathologic Manifestations

Prior to EBV infection, most boys carrying the defective XLP gene are clinically healthy. Some of them exhibit subtle immunological abnormalities before EBV infection (see Laboratory Findings, below).

Exposure to EBV may result in three clinical phenotypes in males carrying the defective XLP gene: fulminant and often fatal infectious mononucleosis occurs in more than half, lymphoproliferative disorders including malignant lymphoma develop in approximately one-third of affected males, and dysgammaglobulinemia is found in one-quarter of the patients (Table 32.1) (Seemayer et al., 1995; Sumegi et al., 2000). Less frequent manifestations are aplastic anemia, vasculitis, and lymphoid granulomatosis (each approximately 3% of cases), a hemophagocytic lymphohistiocytosis (HLH)-like clinical picture, and bronchiectasis (Seemayer et al., 1995; Schuster and Kreth, 2000; Strahm et al., 2000; Arico et al., 2001; Halasa et al., 2003). Several phenotypes (hypogammaglobulinemia, lymphoma, aplastic anemia) may manifest within the same XLP patient over time. Moreover, considerable intra- and interfamilial variations in XLP phenotypes exist.

XLP has an unfavorable prognosis: by 10 years of age more than 70% of affected boys are dead; only 2 XLP patients from the registered population of 272 males are older than 40 years of age (Seemayer et al., 1995). Only one man with XLP, who is not in the registry, is known to have survived for more than 60 years. He has a nonsense mutation of *SH2D1A* and a history of intestinal lymphoma at 21 years, and had hypogammaglobulinemia diagnosed at age 36 years (H.D. Ochs, unpublished observation, 2005). Survival rates for fulminant infectious mononucleosis, lymphoproliferative disorders, dysgammaglobulinemia, and aplastic anemia are 4%, 35%, 55%, and 50%, respectively (Seemayer et al., 1995).

#### Fulminant Infectious Mononucleosis

This is the most serious form of acute infectious mononucleosis. The median age of onset of illness is 2.5–3 years (range, 0.5–40 years) (Mroczek et al., 1987b; Sumegi et al., 2000); the median survival after onset of symptoms is 32 days (Mroczek et al., 1987b; Purtilo and Grierson, 1991). Signs and symptoms of disease are similar although more severe than those of infectious mononucleosis in older children and adults (Markin et al., 1987). Meningoencephalitis is common (Mroczek et al., 1987b; Sullivan and Woda, 1989; Schuster et al., 1993). During the course of fulminant mononucleosis, 89% of affected boys develop hepatic dysfunction, 81% have anemia, and 93% have thrombocytopenia (Mroczek et al., 1987b). Typically, polyclonal EBV-transformed B cells as well as CD4<sup>+</sup> and CD8<sup>+</sup> T cells (at approximately a 1:1 ratio of B to T cells) invade numerous organs, leading to infiltration and marked destruction of hematopoietic organs, liver, thymus, brain, heart, and other tissues (Markin et al., 1987; Mroczek et al., 1987a, 1987b; Sullivan and Woda, 1989).

The extensive destruction of liver and bone marrow often leads to fulminant hepatitis and virus-associated hemophagocytic syndrome (VAHS). In severe hepatitis, an intense periportal infiltration of EBV-positive B cells is typically found, surrounded by T cells, mainly of the CD8 phenotype (Markin et al., 1987). Liver failure with hepatic encephalopathy or hemorrhage involving the central nervous system, the gastrointestinal tract, or the lungs is the most frequent cause of death in these patients (Grierson and Purtilo, 1987).

**Table 32.1.** Common Manifestations of X-Linked Lymphoproliferative Disease\*

Manifestation	Patients (%)
Fulminant infectious mononucleosis	58
Lymphoma (mostly of B cell origin)	30
Dysgammaglobulinemia (mostly low IgG; increased IgM)	31 <sup>†</sup>

\**n* = 272 XLP boys from 80 families (Seemayer et al., 1995). Since XLP males may exhibit more than one phenotype, the sum of percentage values exceeds 100.

<sup>†</sup>This percentage may have been calculated too high, since verification of the diagnosis XLP by genotyping was done in only 35 families (Sumegi et al., 2000). In these 35 families, only 22% of 152 males affected by XLP showed dysgammaglobulinemia (17% of 114 EBV-positive XLP males, 39% of 38 EBV-negative XLP males; *p* = 0.3) (Sumegi et al., 2000).

VAHS, occurring in 90% of boys with fatal mononucleosis (Mroczek et al., 1987b; Seemayer et al., 1995), is characterized by the appearance of numerous highly activated histiocytes and macrophages in different compartments (bone marrow, liver, lymph nodes). The development of VAHS in bone marrow leading to pancytopenia has been shown to progress in three phases. Initially, moderate pancytopenia and a myeloid hyperplastic marrow develop, followed at 2–3 weeks by the appearance of numerous activated histiocytes and macrophages with erythrophagocytosis (Color Plate 32.I). Later, lymphoid infiltration associated with necrosis and hemorrhage develops (Mroczek et al., 1987b). The pathogenesis of VAHS in XLP is not clear. The overwhelming activation of histiocytes and macrophages may be due to an uncontrolled release of tumor necrosis factor (TNF)- $\alpha$  or other cytokines by activated T cells (Su et al., 1995; Lay et al., 1997).

#### Dysgammaglobulinemia

This phenotype occurs in approximately 22%–31% of XLP males after EBV exposure. Median age at onset is 6 to 9 years of age (Grierson and Purtilo, 1987; Seemayer et al., 1995; Sumegi et al., 2000). Affected males exhibit varying degrees of hypogammaglobulinemia, and some may have increased serum IgM levels. Histologically, these patients present with extensive necrotic lesions in lymph nodes, thymus, bone marrow, and spleen. Long-term survivors have an inverted ratio of helper/cytotoxic T cell subpopulations (CD4/CD8) in their peripheral blood (Grierson and Purtilo, 1987; Hügler et al., 2004; Malbran et al., 2004). Patients with hypogammaglobulinemia have a relatively favorable prognosis, particularly if they are treated with monthly intravenous immunoglobulin (IVIG) infusions.

Common variable immunodeficiency (CVID) is a heterogeneous disorder characterized by a decrease in all or some immunoglobulin isotypes and an impaired antibody response leading to increased susceptibility to infection (see Chapter 23). Two recent studies have reported mutations affecting the *SH2D1A* gene in patients with a CVID-like phenotype (Gilmour et al., 2000; Morra et al., 2001c; Nistala et al., 2001).

#### Lymphoproliferative Disorders

Malignant lymphomas occur in approximately 30% of XLP patients, often associated with dysgammaglobulinemia and/or fulminant mononucleosis. The median age of affected males at the time of diagnosis of lymphoma is 4 to 6 years (Grierson and Purtilo, 1987; Harrington et al., 1987; Seemayer et al., 1995; Sumegi

et al., 2000). Presenting symptoms are fever, nausea, vomiting, lymphadenopathy, weight loss, and abdominal pain (Harrington et al., 1987).

Most lymphomas studied so far occurred at extranodal sites; in approximately 75% the ileocecal region was primarily affected (Harrington et al., 1987). Other common sites of these tumors are the central nervous system, liver, and kidneys. Over 90% of malignant lymphomas are of B cell origin. These can be histologically subclassified as Burkitt lymphomas (small noncleaved; 53% of B cell lymphomas), immunoblastic lymphomas (18%), large noncleaved lymphomas (12%), small cleaved or mixed-cell lymphomas (12%), and unclassifiable lymphomas (5%) (Harrington et al., 1987). Only five cases have been classified as T cell lymphomas (6% of all lymphomas in XLP patients studied to date). Three brothers of one XLP family developed Hodgkin disease following EBV infection (approximately 3% of all lymphomas in XLP patients studied to date) (Donhuijsen-Ant et al., 1988). Malignant lymphomas with different histological subclassification may occur within the same family (Donhuijsen-Ant et al., 1988; Schuster et al., 1994). In at least four cases of Burkitt lymphomas, the characteristic 8;14 translocation (Egeler et al., 1992; Williams et al., 1993; Strahm et al., 2000) and in one case the 8;22 translocation (Turner et al., 1992) were demonstrated.

The prevalence of malignant lymphomas in XLP males is higher than in patients with other inherited immunodeficiencies such as the Wiskott-Aldrich syndrome, and the risk of developing a lymphoma has been estimated to be approximately 200 times greater than that in the general population (Grierson and Purtilo, 1987). In the case of Burkitt lymphoma, by using a mathematical model simulating lymphomagenesis, the cumulative lymphoma prevalence has been estimated to be 0.002% by chronological age of 18 years in the general population, 0.15% by chronological age of 6 years for endemic Burkitt lymphoma, 3% by chronological age of 10 years for Burkitt lymphoma in children with AIDS, and 25% by chronological age of 7 years for Burkitt lymphoma in boys with XLP (Ellwein and Purtilo, 1992). This markedly increased risk in XLP males, theoretically predicted and later statistically confirmed, may indirectly reflect the enhanced proliferation of B cells, which may be due to impaired immunosurveillance by T cells.

Characteristics that may distinguish malignant lymphomas in XLP patients from other malignant lymphomas include a family history of XLP, the early age of clinical manifestation (infectious mononucleosis), the ileocecal localization of the majority of XLP-associated lymphomas, and additional XLP phenotypes in the same affected male (such as dysgammaglobulinemia and severe or fulminant infectious mononucleosis). Approximately 30%–35% of XLP patients with malignant lymphoma survive for longer periods (>10 years) (Purtilo and Grierson, 1991; Seemayer et al., 1995).

### Other Rare XLP Phenotypes

A small number of XLP patients (approximately 3% of cases) develop isolated bone marrow aplasia (either pancytopenia or pure red cell aplasia) in the absence of any evidence for VAHS. A similar percentage of affected patients may develop necrotizing lymphoid vasculitis or lymphoid granulomatosis of the lung or the central nervous system leading to extensive tissue damage (Loeffel et al., 1985; Seemayer et al., 1995; Dutz et al., 2001; Kanejone et al., 2005). Another rare clinical manifestation of XLP is bronchiectasis, which has been found in association with (Metha et al., 1999; Dutz et al., 2001; Hügle et al., 2004) and without (Strahm et al., 2000) dysgammaglobulinemia. In certain

cases, HLH may be the only clinical manifestation in males with XLP (Arico et al., 2001).

### Clinical Manifestations and Immunological Findings in XLP Males with no Evidence of Previous Exposure to Epstein-Barr Virus

Thirty-eight (symptomatic) males with XLP, representing 12.5% of 304 registered males with clinical manifestations of XLP, had no evidence of prior EBV exposure (Sumegi et al., 2000). The number and percentage may be even higher, since the exact number of asymptomatic XLP males is not known.

Interestingly, EBV-negative XLP patients developed dysgammaglobulinemia and/or malignant lymphoma in a similar percentage to that of the EBV-positive group (Sumegi et al., 2000). In the EBV-negative group, median age at the onset of dysgammaglobulinemia was 4.5 years; for lymphoproliferative disease it was 8 years, which is not statistically different from the EBV-positive group. Infectious mononucleosis, which may be also caused by other herpesviruses such as cytomegalovirus (CMV), human herpes virus type 6 (HHV-6), and HHV-7 or by *Toxoplasma*, was never observed in the EBV-negative group. Survival for the EBV-negative group as a whole was significantly better, but this result is entirely accounted for by the poor survival of fulminant infectious mononucleosis in the EBV-positive group (Sumegi et al., 2000).

Thirty-two EBV-negative males carrying the defective XLP gene as shown by restriction fragment length polymorphism (RFLP) analysis have been further immunologically investigated (Grierson et al., 1991; Gross et al., 1994; Seemayer et al., 1995). Among these, only five males were clinically healthy and had normal serum immunoglobulin levels. The remaining 27 males showed, prior to EBV exposure, one or both of the following XLP phenotypes: 17 subjects had elevated serum IgA or IgM and/or variable deficiency of IgG, IgG1, or IgG3, and 18 males developed lymphoproliferative disease (15 of B cell origin, three of T cell origin) without serologic and/or genomic evidence of previous EBV infection (22% of all lymphomas in XLP studied thus far). Eight of these 27 males (30%) had both dysgammaglobulinemia and lymphoma. These phenotypes resemble that of late-onset CVID. The findings clearly show that the immunodeficiency in XLP is not strictly EBV related.

In the few XLP males without evidence of prior EBV infection studied thus far, the number of peripheral T, B, and NK cells; the expression of CD3, CD4, CD8, and CD28; the CD4/CD8 ratio; the proliferative response to phytohemagglutinin (PHA), concanavalin A (ConA), and pokeweed mitogen (PWM); and NK cell activity seem to be normal (Sullivan and Woda, 1989; Gilleece et al., 2000; Strahm et al., 2000). In one XLP patient interferon- $\gamma$  (IFN- $\gamma$ ) secretion by peripheral blood mononuclear cells was shown to be increased (ELISPOT assay) following stimulation with phorbol myristate acetate (PMA) but was decreased after stimulation with anti-CD3 and/or anti-2B4 (Sharifi et al., 2004).

The pattern of dysgammaglobulinemia appears to be due to a partial failure of the patient's B cells to undergo isotype switching from IgM to IgG. Moreover, EBV-seronegative (as well as EBV-seropositive) XLP patients exhibit a deficient switch to IgG antibody production following secondary challenge with bacteriophage  $\phi$ X174, a finding that has been used in the past for diagnostic evaluation of males at risk for XLP (Purtilo et al., 1989). However, for various reasons this test possesses only limited diagnostic validity and reliability, and may lead to false-positive and false-negative results (Purtilo, 1991). Therefore, the diagnosis of XLP in EBV-negative asymptomatic males depends on direct mu-

tation analysis of the *SH2D1A* gene or indirect genotype analysis by RFLP. The finding of abnormal immunoglobulin and IgG subclass concentrations (vide supra) in serum of males at risk for XLP is suggestive, but not diagnostic. Because of the high prevalence of EBV in the general population, most males with XLP will be infected with EBV in childhood. About 58% of them will develop the most severe XLP phenotype, i.e., fatal infectious mononucleosis.

### Laboratory Findings in XLP Males During Acute Epstein-Barr Virus Infection

During fulminant infectious mononucleosis a triphasic process develops along a continuum for several weeks within the blood and bone marrow (Purtilo, 1991). Initially (for 1–2 weeks), the leukocyte count is elevated, mostly because of increased numbers of atypical lymphoid cells, most of which are activated T cells. This abnormality is similar to but more extensive than that of immunocompetent children with uncomplicated infectious mononucleosis. At this time the bone marrow is hyperplastic with granulocytic hyperplasia with a left shift of maturation (Mroczek et al., 1987b). Later, severe pancytopenia develops (median leukocyte count,  $1.5 \times 10^9/l$ ; median platelet count,  $35.5 \times 10^9/l$ ; median hemoglobin level, 8.5 g/dl). The bone marrow shows extensive infiltration by lymphoid cells consisting of activated T cells, immunoblasts, and plasma cells. This is associated with cellular necrosis and VAHS (Color Plate 32.I) (Mroczek et al., 1987b). Terminally, the marrow shows massive necrosis with severe cellular depletion and marked histiocytic hemophagocytosis (Purtilo, 1991).

Elevation of serum transaminases, lactic dehydrogenase, and bilirubin, reflecting hepatic involvement, is found in all affected boys with fulminant mononucleosis. Hepatic encephalopathy or severe hemorrhages (central nervous system, gastrointestinal tract, lungs) due to liver failure are the most frequent cause of death in XLP boys with fatal mononucleosis (Grierson and Purtilo, 1987).

The age range of XLP males with fulminant mononucleosis is 5 months to 17–40 years (Mroczek et al., 1987b; Sumegi et al., 2000); the median age is 2.5–3 years. In most cases there is direct evidence of EBV infection as shown by the presence of heterophile antibodies and/or positive EBV-specific serology and/or the presence of EBV antigens or DNA in lymphoid tissues (positive in 100% of cases) (Mroczek et al., 1987b; Falk et al., 1990). Demonstration of EBV genomes in serum by polymerase chain reaction (PCR) analysis is also an indication of EBV infection (Sumazaki et al., 2001).

### Immunological Studies of XLP Patients After Epstein-Barr Virus Infection

Subjects with XLP surviving EBV infection exhibit, as a rule, combined T and B cell defects. Most XLP patients have normal numbers of peripheral blood B and T cells. The proliferative responses of lymphocytes to B and T cell mitogens such as PHA, ConA, and PWM and to anti-IgM antibody were shown to be abnormally low during and after primary EBV infection in four of four XLP patients (Sullivan and Woda, 1989). In contrast, others have found normal lymphocyte proliferation in response to PHA, PWM, EBV, and *Staphylococcus aureus* strain Cowan (SAC) in 9/9 XLP patients (Lindsten et al., 1982; Arkwright et al., 1998). A decreased ratio of CD4<sup>+</sup> to CD8<sup>+</sup> T cells with a predominance of CD8<sup>+</sup> cells has been observed in most XLP patients (Lindsten et al., 1982; Hügler et al., 2004). The in vitro production of immunoglobulins by peripheral blood lymphocytes in response to PWM, EBV, and SAC was markedly decreased compared with

healthy controls (Lindsten et al., 1982). Furthermore, in XLP patients with hypogammaglobulinemia, the in vitro synthesis of IgG, IgM, and IgA by B lymphoblastoid cell lines in the presence of autologous T cells was markedly decreased (Lai et al., 1987; Yasuda et al., 1991). The degree of this T cell-mediated “suppression” of immunoglobulin synthesis correlated with the decreased serum levels of IgM and IgG in these patients (Yasuda et al., 1991).

XLP patients have a marked reduction in the number of circulating CD27<sup>+</sup> memory B cells, which undergo normal somatic hypermutations, and a complete absence of switched memory B cells (Malbran et al., 2004; Ma et al., 2005; Ma et al., 2006). CD4<sup>+</sup> T cells from XLP patients do not efficiently differentiate in vitro into IL-10 secreting T helper cells and show reduced expression of inducible costimulator (ICOS) (Ma et al., 2005). These data suggest that in XLP the B cell defects are mainly extrinsic. It was recently reported that XLP patients have increased numbers of functionally immature CD24<sup>high</sup>CD38<sup>high</sup> B cells, which may further contribute to the humoral immunodeficient state (Cuss et al., 2006).

T cells from XLP patients failed to secrete normal amounts of IFN- $\gamma$  following stimulation with autologous B lymphoblastoid cell lines or via the NK cell activation receptor 2B4 (Yasuda et al., 1991; Sharifi et al., 2004). In contrast, in three unrelated XLP patients the frequency of IFN- $\gamma$ -producing CD3<sup>+</sup> T cells (measured intracytoplasmatically by FACS analysis after stimulation of the cells with PMA and ionomycin) was markedly increased (Ehl et al., 2002; Hügler et al., 2004). Furthermore, mononuclear cells from other XLP patients spontaneously produced normal or elevated levels of IFN- $\gamma$  during EBV infection (Sullivan, 1983; Okano et al., 1990). It is therefore not clear if deficient IFN- $\gamma$  production in XLP is a primary defect or only secondary to EBV infection. Skin tests with various antigens (purified protein derivative [PPD], tetanus toxoid, candida, and mumps) are frequently negative in XLP patients (Sullivan, 1983; Donhuijsen-Ant et al., 1988). A direct role of SH2D1A in early T cell antigen receptor-mediated signaling via CD3 was suggested by defective upregulation of IL-2 and IFN- $\gamma$  production by herpesvirus saimiri-immortalized CD4<sup>+</sup> T cell, (Nakamura et al., 2001) and by defective IL-2 production, CD25 expression and homotypic cell aggregation (Sanzone et al., 2003).

NK cell activity of XLP males was found to be normal before, high at the time of, and low after EBV primary infection, results suggesting that this defect might be acquired during EBV infection (Sullivan et al., 1980; Sullivan, 1983; Argov et al., 1986; Rousset et al., 1986; Sullivan and Woda, 1989; Okano et al., 1990). Recent studies, however, have shown that in XLP patients NK cell cytotoxicity mediated by the NK cell activating receptor 2B4 seems to be selectively impaired, whereas NK cell activation mediated by NKp46, NKp44, NKp30, CD2, or CD16 as well as natural cytotoxicity against K562 cells and major histocompatibility complex (MHC) class I-deficient cells seem not to be affected (Benoit et al., 2000; Nakajima et al., 2000; Parolini et al., 2000; Tangye et al., 2000b).

Patients with XLP have a nearly complete absence of CD1d-restricted natural NKT cells (Chung et al., 2005; Pasquier et al., 2005; Nichols et al., 2005), which are important for Ag-specific T cell responses such as the regulation of EBV-specific lymphocyte expansions (Ho et al., 2004) and for bridging innate and adoptive responses by activating NK cells and by fostering dendritic cell maturation (Chung et al., 2005).

EBV-specific T cell immune function has been studied in only a few XLP patients. Three of eight XLP patients (Harada et al., 1982) were shown to exhibit EBV-specific memory T cell activity as measured by an outgrowth inhibition assay (regression assay).

In two XLP patients with hypogammaglobulinemia, EBV-specific, HLA-restricted cytotoxicity was demonstrated (Rousset et al., 1986). In recent studies, EBV-specific CD8<sup>+</sup> T cells from XLP patients exhibited markedly decreased cytotoxic activity against autologous B cell lines (Sharifi et al., 2004; Dupre et al., 2005). The deficient EBV-specific cytotoxicity could be fully reconstituted by retroviral gene transfer of the *SH2D1A* gene into the T cell lines. These findings suggest that in XLP patients the lack of SH2D1A may result in severe disruption of cytotoxic T lymphocyte (CTL) function. XLP patients have normal numbers of EBV-specific CD8<sup>+</sup> T cells that are extremely differentiated as defined by loss of CCR7 and CD27, low telomerase activity, and very short telomeres (Plunkett et al., 2005). These observations suggest that excessive proliferation of CD8<sup>+</sup> T cells may lead to end-stage differentiation and loss of EBV-specific CD8<sup>+</sup> T cells through replicative senescence. Lack of cytotoxic T cells may contribute to the development of EBV-associated B cell lymphomas.

Interestingly, some of these pathological findings in XLP patients can also be found transiently and for a short period in patients with uncomplicated acute infectious mononucleosis. T lymphocytes obtained during acute infectious mononucleosis proliferate poorly in response to various mitogens such as PHA, ConA, and PWM as well as to antigens such as tetanus toxoid and *Candida albicans* (Tosato, 1989). Moreover, patients with acute infectious mononucleosis show low or absent delayed-type hypersensitivity reactions when challenged with recall antigens (Tosato, 1989) and respond poorly to the T cell-dependent neoantigen bacteriophage  $\Phi$ X174, both in vivo and in vitro (Junker et al., 1986).

T cell activation during acute infectious mononucleosis leads to the amplification of CD8<sup>+</sup> cytotoxic T cells, of which only a fraction is EBV-specific and HLA restricted (Tomkinson et al., 1989; Callan et al., 1996). It also leads to the proliferation of CD8<sup>+</sup> T cells, which seem to be able to inhibit proliferation and immunoglobulin production by B cells as well as to inhibit nonactivated T cells in a probably virus-nonspecific, HLA-nonrestricted manner (Tosato, 1989; Tosato et al., 1982; Wang et al., 1987). In healthy immunocompetent individuals, both cytotoxic and suppressor functions, displayed by CD8<sup>+</sup> T cells during infectious mononucleosis, appear to modulate and finally self-limit the course and severity of EBV infection. In XLP patients, the regulation of these interactions may be significantly disturbed possibly due to the lack of NKT cells. As a consequence, aberrant self-destructive killer cell populations and/or suppressor cells are not down-regulated or eliminated and may therefore proliferate in an uncontrolled manner leading to tissue and organ destruction (as found in fatal mononucleosis) and later on to hypogammaglobulinemia and diminished immunosurveillance against EBV-infected B cells, with an enhanced risk of B cell lymphomas.

### Epstein-Barr Virus-Host Interaction in X-Linked Lymphoproliferative Disease

Males with XLP show a range of abnormal antibody responses after primary EBV infection. Antibody titers to the Epstein-Barr virus nuclear antigen (EBNA) are decreased or absent, which may indirectly reflect a T cell immunodeficiency, as this is also seen in other inherited or acquired immunodeficiencies (Purtilo et al., 1985; Okano et al., 1992). Antibodies against the EBV capsid antigen (VCA) are variable in XLP males. In rare instances, XLP patients may not be able to produce any EBV-specific antibodies (anti-VCA-IgM, anti-VCA-IgA, anti-VCA-IgG, or anti-EBNA) despite overwhelming infection with EBV (Hayoz et al., 1988; Turner et al., 1992; Dutz et al., 2001). In these cases the detection

of EBV genomes by PCR or the demonstration of EBNA by immunohistochemical staining in lymphoid tissue will document EBV infection in spite of seronegativity. In a large study of patients with sporadic or XLP-associated fatal mononucleosis, it was shown that 13 of 15 patients had histologic changes that were characteristic for polyclonal proliferation of B cells which expressed—in most cases, all EBV nuclear antigens (EBNA1-6), an expression pattern as seen also in lymphoblastoid B cell lines from healthy controls. In two cases, the B cells were of monoclonal origin and expressed only EBNA1, a pattern also found in Burkitt lymphoma (Falk et al., 1990).

In one patient with a nonsense mutation in *SH2D1A* (Hügler et al., 2004), EBV DNA and proteins could be detected in most of his peripheral T cells during the acute phase of infectious mononucleosis (Baumgarten et al., 1994). In general, B cells are the primary target of EBV in patients with infectious mononucleosis and other EBV-associated disorders (Kurth et al., 2000). EBV-infected T cells have been found in only one case of fatal acute mononucleosis (Mori et al., 1992) and in patients with severe chronic active EBV (CAEBV) infection (Quintanilla-Martinez et al., 2000; Ohga et al., 2001). Whether XLP is associated with an increased rate of EBV infection of T cells is unknown, but this seems unlikely, since only 6% of XLP-associated lymphoma are of T cell origin (90% B cell lymphoma, 4% Hodgkin disease) (Seemayer et al., 1995; Schuster and Kreth, 2000).

Normally, EBV type 1 is found predominantly in immunocompetent subjects after EBV infection. In immunodeficient individuals (HIV infection, organ transplantation), increased infection rates with EBV type 2 have been observed (Sculley et al., 1990). EBV strains isolated from XLP patients have not yet been genotyped systematically. In at least two unrelated XLP patients, EBV type 2 could be identified in lymphoid tissues (Mulley et al., 1992; Vowels et al., 1993). In two brothers with XLP and in one unrelated male with XLP we have detected EBV type 1 in lymphoma biopsy or peripheral blood (Schuster et al., 1996). More patients need to be examined to determine if one of these two EBV types is predominant in XLP.

Patients with XLP are vulnerable only to EBV, whereas the immune response to other herpes viruses, such as CMV, herpes simplex virus (HSV), HHV-6, HHV-7, and HHV-8, does not seem to be impaired.

### Molecular Basis

In 1987 the XLP gene locus was mapped to the long arm of the X chromosome at Xq25 through RFLP analysis with polymorphic DNA markers from Xq24 to Xq26 (Skare et al., 1987, 1989a, 1989b, 1989c; Sylla et al., 1989). In several families with XLP, different partly overlapping deletions in the Xq25 region were identified and further characterized (Wyandt et al., 1989; Sanger et al., 1990; Skare et al., 1993; Wu et al., 1993; Lamartine et al., 1996; Lanyi et al., 1997; Porta et al., 1997; Coffey et al., 1998). In 1998, three groups independently identified the gene defective in XLP by positional cloning (Coffey et al., 1998; Nichols et al., 1998) or through a functional approach (Sayos et al., 1998). The gene (and its encoded protein) was originally designated *SH2D1A* (Coffey et al., 1998), *SAP* (Sayos et al., 1998), or *DSHP* (Nichols et al., 1998). The gene name approved by the Human Gene Nomenclature Committee (HGNC) is *SH2D1A*. The human, monkey, and mouse *SH2D1A* genes consist of four exons and three introns spanning 25 kb (Coffey et al., 1998; Wu et al., 2000; Morra et al., 2001a, 2001d). The human *SH2D1A* gene encodes a small cytoplasmic protein of 128 amino acid residues consisting of a 5– amino acid amino-terminal sequence, a single

**Figure 32.1.** Organization of the *SH2D1A* gene. Black regions: coding sequences; portion with diagonal pattern: SH2 domain (adapted from Coffey et al., 1998).

SH2 domain, and a 25– amino acid carboxy-terminal tail (Coffey et al., 1998; Nichols et al., 1998; Sayos et al., 1998) (Fig. 32.1). Two *SH2D1A* mRNA species with a size of 2.5 kb and 0.9 kb are transcribed (Sayos et al., 1998).

The highest level of human *SH2D1A* mRNA expression has been found in the thymus. It has been found to a lesser extent in spleen, liver, lymph nodes, and other lymphoid organs as well as in peripheral blood lymphocytes (Coffey et al., 1998; Nichols et al., 1998; Sayos et al., 1998). *SH2D1A* is expressed in all major subsets of human T cells, with activated cells expressing the highest amounts, as well as in CD56<sup>+</sup>CD3<sup>−</sup> NK cells (Coffey et al., 1998; Nichols et al., 1998; Sayos et al., 1998; Nagy et al., 2000, 2002). *SH2D1A* mRNA and/or protein expression has been reported to occur in different B and T cell lymphomas and Hodgkin disease as well as in different T cell lines, but not in EBV-immortalized B lymphoblastoid cell lines (Nichols et al., 1998; Sayos et al., 1998; Nagy et al., 2000, 2002; Kis et al., 2003). Similarly, in mice, *SH2D1A* expression is predominately found in T cells and NK cells (Sayos et al., 2000; Wu et al., 2000). In mice and in humans, *SH2D1A* expression is down-regulated in CD4<sup>+</sup> and CD8<sup>+</sup> T cells upon anti-CD3 stimulation (Wu et al., 2000; D. Howie, unpublished data).

### Function of the *SH2D1A* Protein

The *SH2D1A* protein, consisting of a single SH2 domain with a five–amino acid N-terminal tail, has been demonstrated to interfere, as a negative blocker, with the signaling pathways through the coreceptors SLAM (signaling lymphocyte activation molecule; CD150) (Sayos et al., 1998) and 2B4 (CD244), which is expressed on NK cells (Tangye et al., 1999; Benoit et al., 2000; Parolini et al., 2000; Sayos et al., 2001), CD8<sup>+</sup> T cells, and monocytes (Sayos et al., 2001). In both cases the SH2 domain of *SH2D1A* binds to the Thr-Ile-pTyr-x-x-Val/Ile (x = any amino acid; pTyr = phosphorylated Tyr residue) motif of phosphorylated SLAM or 2B4 and thus prevents recruitment of SHP-2 (SH2 domain–bearing tyrosine phosphatase-2) (Sayos et al., 1998; Poy et al., 1999). SHP-2 is involved in coupling signals from receptor tyrosine kinases and cytokine receptors (IL-3 receptor and others). SHP-2 is required for the activation of the Ras-mitogen-activated protein (MAP) kinase cascade and for the activation of cytokine-induced immediate to early gene expression (Huyer and Alexander, 1999). In agreement with these findings, it has been shown that 2B4-mediated NK cell cytotoxicity is selectively impaired in XLP patients, whereas NK cell activity against K562 target cells is not diminished (Benoit et al., 2000; Nakajima et al., 2000; Parolini et al., 2000; Tangye et al., 2000b). It was also shown that binding of *SH2D1A* to 2B4 depends on prior association of 2B4 with phosphoinositide 3-kinase (PI3K) (Aoukaty and Tan, 2002).

The Thr-Ile-pTyr-x-x-Val/Ile motif is also present in other members of the CD2 subgroup of the immunoglobulin superfamily (CD229 [Ly-9], CD84) (Li et al., 1999; Nakajima et al., 2000; Tangye et al., 2000a; Sayos et al., 2001) and SF2000 (Fraser et al., 2002), all of which have two such consensus sites in their cytoplasmic tails. Recently it was shown that *SH2D1A* binds to phosphorylated CD229 and CD84 (Sayos et al., 2001; Tangye et al., 2002).

*SH2D1A* also binds to nonphosphorylated SLAM (but not to nonphosphorylated 2B4) at Tyr281 (Sayos et al., 1998; Poy et al., 1999; Morra et al., 2001b; Howie et al., 2002b). Moreover, data derived from an *SH2D1A* crystal structure model suggest that interactions of *SH2D1A* with certain amino-terminal residues in SLAM are likely to further contribute to the high affinity of *SH2D1A* binding to SLAM (Li et al., 1999; Poy et al., 1999; Morra et al., 2001d; Howie et al., 2002b).

*SH2D1A* also binds to a phosphorylated site (tyrosine residue 449) in Dok1 (p62<sup>dok</sup>), a 481–amino acid adaptor protein that associates with p120 Ras-GTPase-activating protein (GAP), Src C-terminal kinase (Csk), and the adaptor protein Nck (Sylla et al., 2000). Furthermore, signaling via the SLAM-*SH2D1A* pathway involves a protein complex that includes SH2 domain–containing inositol phosphatase (SHIP) and the adaptor molecule Dok2. *SH2D1A* also binds to the SH3 domain and the kinase domain of the Src-related protein tyrosine kinase FYN and directly couples FYN to SLAM (Latour et al., 2001, 2003; Chan et al., 2003; Engel et al., 2003; Li et al., 2003b) (Fig. 32.2). Therefore, *SH2D1A* appears to have (at least) dual functional roles by acting both as an adaptor for FYN and an inhibitor to SHIP-2 binding (Li et al., 2003b).

SLAM-*SH2D1A* signaling selectively inhibits in vitro IFN- $\gamma$  production by a SLAM and *SH2D1A* cotransfected murine T cell line (which is normally SLAM<sup>+</sup>/*SH2D1A*<sup>−</sup>; Latour et al., 2001). In contrast, if *SH2D1A*-deficient T cells are similarly activated, IFN- $\gamma$  production is increased compared with that of normal cells (Wu et al., 2001; Howie et al., 2002a). *SH2D1A* is required to attenuate Th1 immune responses in mice (Wu et al., 2001). It has been hypothesized that lack of *SH2D1A* in XLP patients results in the inability to mount an appropriate Th2 response after EBV infection, which leads to an uncontrolled Th1 response (Seemayer et al., 1995). In addition, overexpression of *SH2D1A* has been found to activate the transcription factor NF- $\kappa$ B in vitro (Sylla et al., 2000).

Taken together, *SH2D1A* appears to be a natural inhibitor of SH2 domain–dependent interactions between T and NK cells after immune activation that may affect multiple intracellular signaling pathways.

The role of *SH2D1A* in B cell activation has been investigated even less intensively. *SH2D1A* seems to act in B cells as a regulator of alternative interactions of CD150 with either SHP-2

**Figure 32.2.** A model of FYN activation and recruitment by *SH2D1A*. During formation of the immunological synapse between T cells and antigen-presenting cells, clustering of signaling lymphocytic activation molecule (SLAM) receptors through homophilic binding brings *SH2D1A* and SLAM together. The binding of *SH2D1A* to SLAM promotes association with FYN (SH3 domain and kinase N lobe) and induces its activation. Subsequently, receptor-associated FYN can phosphorylate tyrosine residues in the cytoplasmic tail of the SLAM receptor (adapted from Engel et al., 2003). Alternatively, *SH2D1A* can also recruit already activated FYN (not shown).

or SHIP via the Thr-Ile-pTyr-x-x-Val/Ile motif (Shlapatska et al., 2001).

### *SH2D1A* Gene Mutations in XLP Patients

Various *SH2D1A* gene mutations have been identified in XLP patients, including missense (M1I, M1T, Y7C, H8D, A22P, G27S, S28R, L31P, R32Q, R32T, D33Y, S34G, G39V, C42W, G49V, T53I, Y54C, R55L, R55P, S57P, E67D, E67G, T68I, I84T, F87S, E88P, G93D, Q99P, P101L, V102G), nonsense (R55X, Q58X, W64X, Y76X, Y100X, V102X, R129X), splice site mutations, and micro- and macrodeletions (Coffey et al., 1998; Nichols et al., 1998; Sayos et al., 1998; Brandau et al., 1999; Yin et al., 1999a; Benoit et al., 2000; Gilmour et al., 2000; Honda et al., 2000; Lappalainen et al., 2000; Parolini et al., 2000; Sumegi et al., 2000; Arico et al., 2001; Lewis et al., 2001; Morra et al., 2001a, 2001c; Nakamura et al., 2001; Nistala et al., 2001; Soresina et al., 2002; Halasa et al., 2003; Latour and Veillette, 2003; Hügle et al., 2004; Malbran et al., 2004; Nichols et al., 2005; Pasquier et al., 2005). At present, the R55X mutation has been identified in 20 unrelated XLP patients and seems to be the most prevalent mutation causing XLP (Coffey et al., 1998; Brandau et al., 1999; Lappalainen et al., 2000; Nakajima et al., 2000; Parolini et al., 2000, 2002; Sumegi et al., 2000; Arico et al., 2001; Bottino et al., 2001; Lewis et al., 2001; Morra et al., 2001c; Sumazaki et al., 2001; Hügle et al., 2004). An *SH2D1A* gene mutation registry (*SH2D1A*base) has been established, which is freely accessible through the Internet at [http://www.uta.fi/imt/bioinfo/SH2D1A\\_base/](http://www.uta.fi/imt/bioinfo/SH2D1A_base/) (Lappalainen et al., 2000).

So far, no correlation between *SH2D1A* gene mutations and the clinical phenotype has been found. Identical mutations (for example, the R55X mutation) may manifest different clinical phenotypes even within the same family (Coffey et al., 1998; Sayos et al., 1998; Brandau et al., 1999; Lappalainen et al., 2000; Sumegi et al., 2000; Morra et al., 2001a).

Detectable mutations in the *SH2D1A* gene have been demonstrated in only 50%–70% of patients with the XLP phenotype (Coffey et al., 1998; Nichols et al., 1998; Sayos et al., 1998; Brandau et al., 1999; Sumegi et al., 2000). Therefore, the possi-

bility of a mutation in a *cis*-regulatory element distal from the *SH2D1A* gene or in one of its three introns, or the existence of a second gene in the proximity of the *SH2D1A* gene, which, if mutated, may also predispose for XLP, cannot be excluded.

Morra et al. (2001d) analyzed the effect of missense mutations identified in 10 XLP families on the interaction of *SH2D1A* with its binding proteins. Two sets of mutants were found: (1) those with a marked decrease in protein half-life, and (2) those resulting in structural changes that affect interaction with the SLAM-related cell surface receptors SLAM, Ly-9, 2B4, and CD84 in a distinct fashion. In the latter group, mutations that disrupt the interaction between the hydrophobic cleft of *SH2D1A* and Val in position +3 from the pTyr (Val +3) of its binding motif (e.g., mutant T68I), or mutations interfering with the *SH2D1A* phosphotyrosine pocket (e.g., mutants R32Q and C42W) abrogate *SH2D1A* binding to all four membrane receptors. Surprisingly, a mutation in *SH2D1A* known to interfere with Thr –2 (two amino acids N-terminal to the pTyr of the CD150 [SLAM] binding motif) (mutant T53I) severely impaired the nonphosphotyrosine interaction while preserving unaffected the binding of *SH2D1A* to CD150 (Hwang et al., 2002). Mutant T53I, however, did not bind to Ly-9 (CD229) or 2B4 (CD224), a finding supporting the notion that *SH2D1A* controls several distinct signal transduction pathways in T and NK cells. Furthermore, most *SH2D1A* mutants caused by amino acid substitutions studied thus far—i.e., Y7C, S28R, L31P, R32Q, T53I, Y54C, R55L, E67D, T68I, F87S, G93D, Q99P, P101L, V102G—exhibited significantly reduced binding to the FynT SH3 domain (Li et al., 2003a, 2003b).

*SH2D1A* gene mutations have not been detected in any of 62 cell lines derived from sporadic Burkitt lymphoma or in the peripheral blood of male patients with sporadic Burkitt lymphoma or Hodgkin disease, thus demonstrating that the *SH2D1A* gene does not play an important role in the development of (sporadic) Burkitt lymphoma (Yin et al., 1999b; Parolini et al., 2002).

### Animal Models

#### The XLP SCID-Hu Mouse Model

Severe combined immunodeficient (SCID) mice engrafted with peripheral blood lymphocytes (PBL) from XLP patients as well as from healthy seropositive controls readily developed EBV-induced oligo- or polyclonal lymphoproliferative disease regardless of the immunocompetence of the donors (Purtilo et al., 1991a). These lesions expressed all EBV-latent antigens (EBNA1-6, LMP), regardless of whether the SCID mice had been engrafted with PBL from XLP patients or from healthy controls. Engrafted PBL of both groups also did not differ in their immunoglobulin production (IgG, IgA, and IgM). These findings suggest that the B cells of XLP patients are functionally normal and exhibit no primary defect.

Graft-vs.-host disease (GVHD) developed in 6 of 10 SCID mice engrafted with PBL from five normal donors (EBV seropositive,  $n=2$ ; EBV seronegative,  $n=3$ ), but in none of 9 mice engrafted with PBL from three XLP males (EBV seropositive,  $n=2$ ; EBV seronegative,  $n=1$ ). These findings may be taken as tentative evidence for a primary T cell deficiency in XLP.

#### The *SH2D1A*-Deficient Mouse

To examine the effect of an *SH2D1A* mutation on T cell functions, a mouse with a targeted disruption of the first exon of the *SH2D1A* gene (Wu et al., 2001) or with the T68I *SH2D1A* gene

mutation (Czar et al., 2001; Crotty et al., 2003) was generated by homologous recombination in embryonic stem cells. Mice deficient in *SH2D1A* and wild-type littermates were infected with lymphocytic choriomeningitis virus (LCMV), a virus that elicits strong and well-defined immune responses. In the primary response, dramatically increased numbers of CD8<sup>+</sup> and CD4<sup>+</sup> IFN- $\gamma$ -producing cells were found in the spleen of *SH2D1A*-deficient animals in comparison to wild-type littermates. In the liver of *SH2D1A*-deficient mice, five times more CD8<sup>+</sup>, CD4<sup>+</sup> T cells, and LCMV-specific T cells were detected than in the wild-type mice after infection. IFN- $\gamma$  production by LCMV-infected *SH2D1A*-deficient liver T cells was dramatically higher than that by wild-type liver T cells as measured in an in vitro culture system in the presence of anti-CD3. The increased production of IFN- $\gamma$  by splenic and hepatic T cells was also apparent during a recall response to LCMV. Thus, *SH2D1A*-deficient mice mount more vigorous IFN- $\gamma$ <sup>+</sup> CD8<sup>+</sup> and CD4<sup>+</sup> Th1 responses to infection with LCMV than their wild-type littermates, but their CTL and NK cells responses are intact.

*SH2D1A*-deficient T cells on the Balb/C background produced very low levels of IL-4, IL-10, and IL-13 when activated in vitro by anti-CD3 and anti-CD28 (Wu et al., 2001). The observation of impaired in vitro IL-4 production by *SH2D1A*-deficient CD4<sup>+</sup> T cells was confirmed in vivo during infection with the parasite *Leishmania major* (Wu et al., 2001). In agreement with these results and the well-known critical role played by IL-4 and IL-10 in immunoglobulin heavy-chain isotype switching were the significantly lower levels of total IgE in the *Leishmania major*-infected *SH2D1A*-deficient mice. The aberrant immune responses in *SH2D1A*-deficient mice demonstrate that *SH2D1A* controls several distinct key T signal transduction pathways, which explain part of the underlying principles of the pathogenesis of the XLP.

*SH2D1A* operates as a natural inhibitor of the networking to signal transduction pathways by the cytoplasmic tail of at least five members of the SLAM family. SLAM (CD150), CD84, CD229 (Ly-9), CD244 (2B4), and SF2000, which are expressed on the surface of T cells, NK cells, and antigen-presenting cells, recruit the tyrosine phosphatases SHP-1 or SHP-2 to specific docking sites that are phosphorylated upon activation of T cells or NK cells. The concept of *SH2D1A* as an inhibitor is supported by its high affinity for the binding sites in the cytoplasmic tails of these cell surface receptors as well as by studies of *SH2D1A* missense mutations found in XLP patients. Whereas all four proteins are expressed on the surface of CD8<sup>+</sup> cells, CD4<sup>+</sup> cells lack 2B4 expression. The altered functions of *SH2D1A*-deficient T cells are therefore the sum of the interferences with the individual pathways.

Recently it was shown that *SH2D1A*-deficient mice also have a defect in CD4<sup>+</sup> helper T cells, as these animals generate only a short-lived IgG antibody response after LCMV infection, whereas the production of LCMV-specific, long-lived plasma cells and memory B cells was nearly absent (Crotty et al., 2003). These findings resemble the inability of XLP patients to mount a sustained anti-EBV humoral immune response. However, whereas XLP patients may exhibit deficient isotype switching (dysgammaglobulinemia with high IgM and low IgG), adoptive transfer experiments in *SH2D1A*-deficient mice show normal isotype switching (Crotty et al., 2003). In contrast, in vitro experiments indicate that B cells from *SH2D1A*-deficient mice fail to undergo class switch recombination, suggesting that B cells are directly affected in the absence of SAP (Al-Alem et al., 2006). The studies of *SH2D1A*-deficient mice supports the concept that the small cytoplasmic protein *SH2D1A* negatively interferes with the final

stages of Th1 and CD8<sup>+</sup> cell responses, but provides a positive signal for the development of Th2 cells during an infection.

Yin et al. (2003) generated *SH2D1A*-deficient mice with a partial deletion of intron 1 and exon 2. Infection of these animals with murine gammaherpesvirus-68, which is homologous to human EBV, led to marked tissue damage and hemophagocytosis, similar to findings observed in XLP patients. All 16 *SH2D1A*-deficient mice exhibited hypogammaglobulinemia, which was more pronounced following infection with murine gammaherpesvirus-68.

Recent data indicated that *SH2D1A*-deficient mice, similarly to XLP patients, completely lack NKT cells (Chung et al., 2005; Pasquier et al., 2005; Nichols et al., 2005). The phenotype of *SH2D1A*-deficient mice resembles in some aspects that of Cd1d<sup>-/-</sup> mice and of Fyn<sup>-/-</sup> mice, which both lack NKT cells (Nichols et al., 2005).

A recent study demonstrated that *SH2D1A*-deficient mice are protected from experimentally induced lupus and glomerulonephritis (Hron et al., 2004). They did not develop hypergammaglobulinemia, nor did they produce any autoantibodies (e.g., ANA, anti-DNA). It is not clear at present whether XLP patients are also protected from certain autoimmune diseases such as systemic lupus erythematosus.

### Speculations about the Pathogenesis of X-Linked Lymphoproliferative Disease

The pathognomonic response to EBV infection observed in patients with XLP is characterized by an uncontrolled CD8<sup>+</sup> T cell proliferation leading to parenchymal damage, particularly in the liver and bone marrow. This is likely caused by increased production of IFN- $\gamma$  and the absence of NKT cells. It has been hypothesized that the defect in XLP results from the inability to mount an appropriate Th2 response following EBV infection, leading to an uncontrolled Th1 response. The in vivo and in vitro studies of *SH2D1A*-deficient mice are conceptually in agreement with these aspects of XLP, for they demonstrate that absence of *SH2D1A* causes two distinct T cell defects in mice: (1) hyperproliferation of IFN- $\gamma$ -producing CD8<sup>+</sup> and CD4<sup>+</sup> cells in parallel with excessive IFN- $\gamma$  secretion, and (2) a defect in activation of the IL-4 gene upon T cell triggering, which causes an aberrant Th2 polarization that may lead to abnormal immunoglobulin class switching.

Infection with two LCMV strains, which are unrelated to EBV, induces more vigorous T cell responses in *SH2D1A*-deficient mice than those in wild-type mice. This is consistent with the observations that acquired hypogammaglobulinemia may also occur in EBV-negative XLP patients, possibly because of multiple infections with other viruses. We predict that *SH2D1A*-deficient mice will make a useful tool for dissecting the complex XLP phenotypes and will lead to additional studies to explore further the aberrant immune status of XLP patients. The *SH2D1A* gene knockout mouse model will also permit experiments that aid in our understanding of the fundamental role of a free SH2 domain in regulating T cell activation and terminal differentiation.

### Diagnostic Considerations

#### Diagnosis of X-Linked Lymphoproliferative Disease

The diagnosis of XLP is based on clinical, immunological, and molecular findings and is confirmed by mutation analysis (Table 32.2). Prenatal diagnosis or the evaluation of a heterozygous status in (clinically healthy) women is possible by direct mutation

analysis of the *SH2D1A* gene and/or its RNA or protein expression (Shinozaki et al., 2002; Hügler et al., 2004), or indirectly (in informative families) by RFLP analysis with X chromosomal markers flanking the *SH2D1A* gene proximally and distally (Fig. 32.3) (Mulley et al., 1992; Skare et al., 1992; Schuster et al., 1993, 1994, 1995). In the absence of a potential stem cell donor, prenatal diagnosis of an affected male may raise difficult ethical questions when the affected boy is initially healthy. In sporadic cases, a definite diagnosis of XLP can be verified only by mutation analysis of the *SH2D1A* gene. Because NKT cells are nearly absent in XLP patients, regardless of *SH2D1A* genotype, age, prior exposure to EBV, history of lymphoma or presence of dysgammaglobulinemia (Nichols et al., 2005) the quantification of NKT cells, together with clinical data and family history, may facilitate the diagnosis of XLP.

### Differential Diagnosis

The clinical phenotypes of XLP share similarities with other disorders that need to be excluded. These are discussed below.

Sporadic fatal infectious mononucleosis (SFIM) occurs in approximately 1 in 3000 cases of infectious mononucleosis (Purtilo et al., 1992). The median age of patients is 5.5 years (FIM in XLP: 2.5 years), the male/female ratio is approximately 1:1 (Mroczek et al., 1987b). Presenting signs and symptoms are similar to those seen in XLP patients with fatal mononucleosis. Other XLP phenotypes (dysgammaglobulinemia, lymphoma) are absent. In 25 males with SFIM studied thus far, no mutations within the *SH2D1A* gene have been found (Sumegi et al., 2000).

A non-X-linked syndrome with susceptibility to severe EBV infections can be easily differentiated from XLP by its autosomal inheritance pattern. Common findings in this rare disorder are a decreased NK cell activity and a history of recurrent bacterial infections prior to EBV exposure (Fleisher et al., 1982).

Chronic active EBV (CAEBV) infection involving mostly T or NK cells is characterized by a persistent severe mononucleosis-like illness (lasting for months or years) with additional unusual clinical features such as hypersensitivity to mosquito bites (43%), calcifications in basal ganglia (18%), hydroa vacciniforme (14%), hemophagocytic syndrome (21%), coronary artery aneurisms (21%), and malignant lymphoma (16%) (Kimura et al., 2001). Patients with CAEBV have a high EBV load in their peripheral blood ( $>10^{2.5}$  copies/ $\mu$ g DNA).

**Table 32.2.** Criteria for Diagnosis of X-Linked Lymphoproliferative Disease

#### Definitive Diagnosis of XLP

Male patient with one or more XLP phenotypes plus *SH2D1A* deficiency (i.e., mutations in the *SH2D1A* gene, absent mRNA and/or absent protein expression (Gilmour et al., 2000; Shinozaki et al., 2002; Hügler et al., 2004; Tabata et al., 2005) of the *SH2D1A* gene in lymphocytes)\*

#### Probable Diagnosis of XLP

One or more XLP phenotypes in a male patient plus one or more XLP phenotypes in at least one of his brothers, maternal cousins, uncles, or nephews (*SH2D1A* gene status not known)

#### Diagnosis Suggestive of XLP

One or more XLP phenotypes in a single male family member (*SH2D1A* gene status not known)

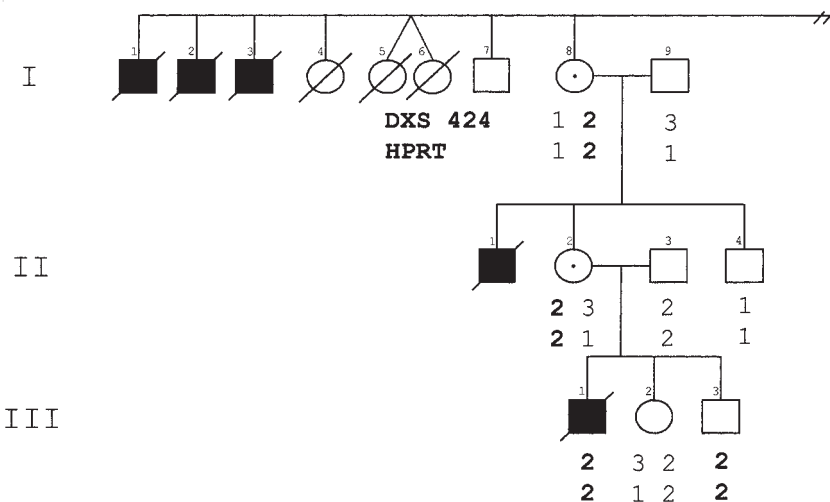

\*Presymptomatic diagnosis of XLP is also definitive in an (initially) healthy male carrying an *SH2D1A* gene mutation, which is known to cause XLP.

Source: Adapted and modified from Sullivan, 1999; Schuster and Kreth, 2000.

EBV infects predominantly T and/or NK cells (Kasahara et al., 2001; Kimura et al., 2001). In 18 male CAEBV patients studied, no mutations of the *SH2D1A* gene were found (Kimura et al., 2001; Sumazaki et al., 2001). One CAEBV patient exhibited a mutated perforin gene (Katano et al., 2004).

Males with X-linked agammaglobulinemia (XLA) have low or absent numbers of B cells, low concentrations of all serum immunoglobulin isotypes, and a severe defect in antibody production leading to recurrent bacterial infections. The molecular defect responsible for XLA is the mutation of a tyrosine kinase (Bruton tyrosine kinase, BTK). Neither any of the XLP phenotypes nor an increased vulnerability to EBV is observed in these patients (see Chapter 21).

X-linked hyper-IgM syndrome (XHIM, CD40 ligand deficiency) is caused by expression of a defective CD40 ligand (*CD40L*, CD154) by activated T lymphocytes due to mutations of the *CD40L* gene, resulting in the inability of B cells to undergo class switch recombination. Affected boys have normal or elevated IgM levels and decreased serum concentrations of IgG, IgE, and IgA. The disease is characterized by severe bacterial and opportunistic infections as well as an increased susceptibility to autoimmunity and neoplasms. Affected males do not exhibit an increased susceptibility to severe EBV infections (see Chapter 19).

**Figure 32.3.** Pedigree of a Spanish XLP family with haplotypes of polymorphic markers DXS424 (proximal to *SH2D1A*) and HPRT (distal to *SH2D1A*). Male subjects I-1 to I-3, II-1, and III-1 (black symbols) suffered and died from fulminant infectious mononucleosis during early infancy. Haplotype 2-2 cosegregated with XLP (Brandau et al., 1999). In the index patient (III-1) but also in his healthy brother a nonsense mutation of the *SH2D1A* gene (Y100X) was identified (Brandau et al., 1999). Subjects I-8 and II-2, but not III-2, were shown to be heterozygous carriers for the Y100X mutation.

X-linked hyper-IgM syndrome associated with hypohydrotic ectodermal dysplasia (XHM-ED, NEMO), a rare disorder, is caused by mutations in the gene that encodes NF- $\kappa$ B essential modulator (*NEMO*, also known as IKK $\gamma$ ), which is required for activation of the transcription factor NF- $\kappa$ B (Doffinger et al., 2001; Jain et al., 2001). B cells from XHM-ED patients are unable to undergo immunoglobulin class-switch recombination, and antigen-presenting cells are unable to synthesize the NF- $\kappa$ B-regulated cytokines IL-12 or TNF- $\alpha$  when stimulated with CD40L (see Chapter 36).

Other genetically determined hyper-IgM syndromes also need to be included in the differential diagnosis of XLP. Mutations in the activation-induced cytidine deaminase (*AICD*) gene causes hyper-IgM syndrome with autosomal recessive inheritance (Revy et al., 2000) (see Chapter 20). Mutations in the gene *CD40*, the natural receptor of CD40L, results in a clinical phenotype similar to CD40L deficiency (Chapter 19). Mutations in the uridine-DNA-glycosylase (*UNG*) gene results in an HIGM phenotype due to abnormal class switch recombination and somatic hypermutation (Imai et al., 2003) (see Chapter 20).

Autoimmune lymphoproliferative syndrome (ALPS), also known as Canale-Smith syndrome, is caused by mutations within the Fas (*CD95*, *TNFRSF6*) or Fas ligand (FasL, *CD95L*, *CD178*, *TNFSF6*) genes (ALPS type I) (Fisher et al., 1995; Rieux-Laucat et al., 1995; Drappa et al., 1996; Le Deist et al., 1996) or within the caspase 10 gene (ALPS type II) (Wang et al., 1999). ALPS is characterized by massive nonmalignant lymphadenopathy, hepatosplenomegaly, autoimmune phenomena, hypergammaglobulinemia, and increased numbers of CD3<sup>+</sup>CD4<sup>+</sup>CD8<sup>−</sup> double-negative lymphocytes. Clinical manifestations occur during early infancy (see Chapter 24). In some patients with an ALPS-like syndrome but with additional immunodeficiency characterized by recurrent sinopulmonary and HSV infections and poor responses to immunization, mutations within the caspase 8 gene have been demonstrated (Chun et al., 2002).

Common variable immunodeficiency (CVID) should also be considered in the differential diagnosis. The characteristic feature of this rather heterogeneous group of patients is a decrease in all or at least two major immunoglobulin isotypes and an impaired antibody response. In the majority of CVID patients B cells are present in normal numbers. However, these cells are unable to differentiate into antibody-producing plasma cells, possibly due to a primary T cell abnormality. The clinical manifestation is similar to that of XLA. In a small subset of CVID patients, mutations in the *ICOS* (Grimbacher et al., 2003) or *TACI* genes (Castigli et al., 2005; Salzer et al., 2005) have been identified. In general, CVID occurs in a sporadic manner. Other than the antibody deficiency, there is little similarity to XLP (see Chapter 23). However, a subset of male XLP patients may present with a CVID-like disease (Gilmour et al., 2000; Morra et al., 2001c; Nistala et al., 2001; Soresina et al., 2002).

Hemophagocytic lymphohistiocytosis (HLH) is a heterogeneous group of disorders characterized by dysregulated activation of T cells and macrophages. Affected children may present with fever, splenomegaly, hepatomegaly, pancytopenia, coagulation abnormalities, neurological abnormalities, and high serum concentrations of IFN- $\gamma$  and TNF- $\alpha$ . Patients with HLH subtype 2 harbor mutations in *PRF1*, the gene encoding perforin (Stepp et al., 1999). Patients with HLH subtype 3 have a mutated Munc13-4 gene (Feldmann et al., 2003). Patients with HLH subtype 4 have a mutated syntaxin 11 gene (Zur Stadt et al., 2005). A few male patients with an HLH-like disease were found to have

mutations in the *SH2D1A* gene (Arico et al., 2001; Halasa et al., 2003).

### Laboratory Findings in XLP Female Carriers

None of the female carriers of the XLP gene studied thus far developed any of the XLP phenotypes. Subtle immunological abnormalities such as hypogammaglobulinemia and elevated IgA and/or IgM have been found in a few carrier females (Sakamoto et al., 1982; Grierson and Purtilo, 1987; Morra et al., 2001c). Forty-five of 56 female carriers (80%) have been shown to exhibit an abnormal serological response to EBV infection (Grierson and Purtilo, 1987).

However, EBV serology alone is not a reliable diagnostic finding in the predictive evaluation of female carriers, since transiently elevated serum antibodies against VCA and EA of the IgM, IgG, or IgA class are also found in normal subjects with a recent primary EBV infection. Carrier females have a random X-chromosome inactivation pattern in their B and T cells (Conley et al., 1990; Nichols et al., 2005). However, X-chromosome inactivation pattern in NKT cells of female XLP carriers is skewed (Nichols et al., 2005).

At present, direct mutation analysis of the *SH2D1A* gene or indirect genotype analysis (in informative families) is the only reliable means to determine if a female at risk is a carrier for XLP or not.

### Treatment and Prognosis

#### Prophylactic Treatment of Males at Risk Prior to Epstein-Barr Virus Infection

There is evidence that maternal EBV-neutralizing antibodies may protect the newborn infant, including XLP males, from primary EBV infection for 4–6 months (Biggar et al., 1978; Mroczek et al., 1987b). Regular intravenous infusions with immunoglobulins rich in EBV-neutralizing antibodies were therefore started in males at risk to prevent or lessen the effects of EBV infection. However, some boys succumbed to fulminant mononucleosis despite this therapy (Okano et al., 1990, 1991; Seemayer et al., 1995). In any case, all EBV-negative XLP males with hypogammaglobulinemia should receive regular immunoglobulin substitutions to prevent severe bacterial or viral infections.

Vaccination against EBV is potentially another strategy to protect males at risk for XLP. Such a vaccine may well be able to induce a solid immunity against natural-occurring EBV infections in immunocompetent subjects. Its use in males at risk for XLP may be dangerous and even contraindicated, however, since it is not known whether this vaccine may be able to trigger an uncontrolled and potentially fatal activation of T cells with disastrous consequences for the patient.

Currently, the only means of preventing EBV- and non-EBV-related complications in later life is early transplantation of allogeneic hematopoietic stem cells (cord blood, bone marrow) (Vowels et al., 1993; Williams et al., 1993; Pracher et al., 1994; Gross et al., 1996; Arkwright et al., 1998; Hoffmann et al., 1998; Ziegner et al., 2001; Lankester et al., 2005). The age of the patient at time of transplantation appears to be critical. Out of eight XLP patients who underwent stem cell transplantation, four boys less than 15 years of age were alive and well for more than 2 years post-transplantation, whereas all four boys older than 15 years of age at the time of transplantation died within 90 days of the

occurrence of complications (Seemayer et al., 1995; Gross et al., 1996). Gene therapy may become an option in the future.

### Treatment of XLP Males During or After Epstein-Barr Virus Infection

During fulminant mononucleosis, treatment attempts with high-dose immunoglobulins, antiviral drugs such as aciclovir, immunosuppressive agents, and IFN- $\alpha$  and IFN- $\gamma$  have been rather disappointing (Okano et al., 1990, 1991).

Etoposide (VP-16), which has been effective in the treatment of lymphoma, leukemia, and hemophagocytic syndromes, has been shown to induce remissions in some XLP males with fulminant mononucleosis, VAHS, or aplastic crisis (Migliorati et al., 1994; Seemayer et al., 1995; Okano and Gross, 1996). One such patient showed rapid improvement of his clinical symptoms of fulminant mononucleosis for a short period after treatment with etoposide. Subsequently, after relapse and clinical deterioration, the boy underwent successful stem cell transplantation following conditioning with etoposide, busulfan, and cyclophosphamide (Pracher et al., 1994). In view of the unfavorable prognosis, a controlled clinical trial with etoposide, with or without stem cell transplantation, in patients with acute exacerbations of XLP is warranted.

Males with XLP who develop hypogammaglobulinemia in response to EBV infection require regular IVIG infusions to prevent recurrent bacterial and viral infections. Despite IVIG therapy, other XLP phenotypes such as aplastic anemia or lymphoma may develop in subsequent years (Purtilo, 1991).

XLP patients suffering from malignant lymphomas may enter remissions of short duration after undergoing standard chemotherapy protocols (Seemayer et al., 1995). However, relapses of the lymphomas are frequent and development of other XLP phenotypes may occur. XLP patients with active EBV infection and lymphoproliferative complications may be successfully treated with anti-CD20 monoclonal antibody (rituximab) in combination with prednisone, acyclovir and IVIG infusions (Malbran et al., 2004; Milone et al., 2006). Eventually, this procedure may also be useful in the treatment of B cell lymphoma in XLP patients.

## DiGeorge Syndrome: A Chromosome 22q11.2 Deletion Syndrome

DEBORAH A. DRISCOLL and KATHLEEN E. SULLIVAN

The association of thymic aplasia with congenital hypoparathyroidism was initially noted by Lobdell in 1959 but wasn't recognized as a syndrome until 1965 when Dr. Angelo DiGeorge described a group of infants with congenital absence of the thymus and parathyroid glands (DiGeorge, 1965). Subsequently, facial dysmorphism and cardiac defects, specifically conotruncal malformations, were included in the spectrum of DiGeorge syndrome (DGS) (Conley et al., 1979). DGS (MIM 188400) is a heterogeneous disorder. However, cytogenetic and molecular studies have shown that deletion of chromosomal region 22q11.2 is the leading cause of DGS. In rare instances, DGS is seen in association with other chromosomal rearrangements, with exposure to teratogens such as retinoic acid, and with maternal diabetes (Lammer and Opitz, 1986; Wilson et al., 1993b).

DGS is a developmental disorder that occurs as a result of abnormal cephalic neural crest cell migration, differentiation, or signaling in the third and fourth pharyngeal arches during the fourth week of embryonic development. Kirby et al. (1983) demonstrated that removal of the premigratory cardiac neural crest cells in the chick embryo results in cardiac outflow tract anomalies similar to those seen in DGS. The cardiac neural crest cells have also been shown to be important in supporting the development of the glandular derivatives of the pharyngeal arches (Kirby and Bockman, 1984). The aortic arch anomalies have been duplicated in transgenic mice with haploinsufficiency due to a deletion of a region of mouse chromosome 16 (*Df1*) that is homologous to human chromosome 22q11.2 and contains the *Tbx1* gene encoding a transcription factor with "T-box" DNA-binding domain (Lindsay et al., 2001; Merscher et al., 2001). Jerome and Papaioannou (2001) produced a mouse knockout with a null mutation of *Tbx1*. The heterozygotes have cardiovascular anomalies seen in DGS, whereas the homozygotes are non-viable but display a DGS phenotype as embryos. In fact, the dose

of T-box1 transcription factor during embryonic development is critical for the phenotypic manifestations (Liao et al., 2004).

Confirming the importance of the human gene *TBX1* in human DGS, a few patients with classical features of DGS have now been identified with point mutations in *TBX1*. Mutations were also identified in patients with less classical manifestations (Yagi et al., 2003). A further consideration is that gene expression in the gene-rich DGS region of 22q11.2 may be influenced by a long-range regulatory element (Botta et al., 2001).

DGS was initially considered a rare sporadic disorder; however, recent studies suggest that the 22q11 deletion, seen in approximately 90% of DGS patients, may occur as frequently as once in 4000–6000 live births, affecting both sexes equally. Furthermore, acknowledgment of the phenotypic overlap with other genetic disorders that share the 22q11.2 deletion such as velocardiofacial syndrome (VCFS, MIM 192430) and conotruncal anomaly face syndrome (CTAFS) has led to further expansion of the phenotype and a better understanding of the immune, endocrine, cognitive, neurologic, and psychiatric problems arising in DGS patients. While most early studies evaluated patients with the classic features of DGS, recent studies have attempted to ascertain all patients with the deletion to better define the clinical spectrum. The immunodeficiency is comparable in all patients with the deletion regardless of the other clinical manifestations (Sullivan et al., 1998). Therefore, we will discuss all patients who carry the deletion under the nomenclature of DGS. It is important to remember that the nomenclature is still evolving, with the term *chromosome 22q11.2 deletion syndrome* being appropriately applied to patients in whom the deletion has been confirmed. DGS is still commonly used for both patients with 22q11.2 deletion and patients with the classical clinical triad of cardiac defects, immunodeficiency, and hypocalcemia, but without a demonstrable deletion. Approximately 10% of patients with

**Table 33.1.** Diagnostic Criteria for DiGeorge Syndrome\*

Diagnostic Category	Description
Definitive	<500 CD3 T cells/mm <sup>3</sup> and two of the three following characteristics: Conotruncal cardiac defect Hypocalcemia requiring therapy for >3 weeks Deletion of chromosome 22q11.2
Probable	<1500 CD3 T cells/mm <sup>3</sup> and deletion of chromosome 22q11.2
Possible	<1500 CD3 T cells/mm <sup>3</sup> and at least one of the following: Cardiac defect Hypocalcemia requiring therapy for >3 weeks Dysmorphic facies or palatal anomaly

\*Source: From the European Society for Immunodeficiencies.

DGS will not have chromosome 22q11.2 deletion, thus the deletion is not absolutely required for the diagnosis of DGS. One scheme for categorizing patients with DGS is given in Table 33.1. However, one problem with this strategy is that patients who have deletion of 22q11.2 but do not have reduced T cell numbers do not receive a separate diagnostic label.

Clinical Features

DiGeorge syndrome has classically been characterized as a triad of clinical features: congenital cardiac defects, immune deficiencies secondary to aplasia or hypoplasia of the thymus, and hypocalcemia due to small or absent parathyroid glands. We now recognize that the phenotypic features seen in patients with DGS are much more variable and extensive than previously recognized (Ryan et al., 1997; McDonald-McGinn et al., 1999; Vantrappen et al., 1999; Botto et al., 2003) (Table 33.2). The acknowledgment of similarities and phenotypic overlap with other disorders, including VCFS and CTAFS, as well as the association of all of these disorders with genetic defects in 22q11 has led to an expanded phenotype that includes palatal and speech abnormalities and cognitive, neurologic, and psychiatric difficulties.

Immune Deficiency

Most DGS patients have a mild to moderate immunodeficiency characterized by impaired production and function of T cells with occasional secondary abnormalities in B cell function (Barrett et al., 1981; Bastian et al., 1989; Mayumi et al., 1989; Schubert and Moss, 1992; Junker and Driscoll, 1995). The most obvious abnormality is the impaired production of T cells. T cell counts are typically in the range of 500 to 1500 cells/mm<sup>3</sup> for the first months of life (Bastian et al., 1989; Junker and Driscoll, 1995). This defect in T cell production is due to an anatomical thymus gland deficiency. Studies have demonstrated that most patients have either a very small anterior mediastinal thymus or small rests of thymic tissue scattered throughout the neck and submandibular areas (Lischner and Huff, 1975; Bale and Sotelo-Avila, 1993). This tissue consists of normal thymic components and is apparently sufficient to support normal T cell maturation. Although decreased numbers of mature T cells are produced, the orderly sequence of maturation appears to be preserved.

The spectrum of immunodeficiency is broad. While the typical patient demonstrates impaired T cell production in the first months of life, some DGS patients have normal or near-normal T cell production, whereas a minority have almost no detectable

**Table 33.2.** Clinical Features of the 22q11 Deletion Syndrome

Conotruncal cardiac defects (49%–83%)
Immune deficiency (80%)
Hypocalcemia (17%–60%)
Palatal abnormalities (69%–100%)
Cleft palate (9%–11%)
Submucous cleft palate (5%–16%)
Velopharyngeal insufficiency (27%–32%)
Feeding and swallowing difficulties (30%)
Dysmorphic facies
Prominent nasal root
Narrow nasal alae with bulbous nasal tip
Hooded eyelids
Protruberant ears
Cup-shaped or thick, overfolded helices
Small mouth
Learning difficulties
Hearing loss (39%)
Renal anomalies (37%)
<i>Less frequent</i>
Thyroid disease
Microcephaly
Short stature
Slender hands and digits
Umbilical hernia
Inguinal hernia
Scoliosis
Skeletal anomalies
Hypospadias
Hematologic abnormalities
Neuropsychiatric disorders

T cell production. In general, the T cell deficit improves during the first year of life, and 35% of DGS patients produce normal numbers of total T cells by the end of the first year of life (Jawad et al., 2001). There is some suggestion that DGS patients with a normal-appearing thymus are unlikely to have substantial persistent immunodeficiency (Bastian et al., 1989). In contrast, complete anatomical absence of a thymus does not preclude the ultimate development of normal immunologic function.

Although all T cell subsets are reduced, CD8 T cells are diminished the most. In early infancy the average CD8 count is approximately 300/mm<sup>3</sup> and the average CD4 count is approximately 850/mm<sup>3</sup> (Bastian et al., 1989; Junker and Driscoll, 1995). In an effort to understand whether peripheral blood T cells in patients with DGS develop aberrantly as a result of insufficient thymic epithelium, patient cells have been stained with markers specific for different stages of thymic maturation (Reinherz et al., 1981; Sirianni et al., 1983a, 1983b; Muller et al., 1989). On the basis of these studies, it appears that T cells use the usual developmental pathways; however, DGS patients are simply not able to produce as many T cells during the first months of life. It is not known why CD8 T cells are more profoundly affected than CD4 T cells.

T cell function is usually grossly normal as measured by responses to T cell mitogens (Barrett et al., 1981; Bastian et al., 1989; Muller et al., 1989; Junker and Driscoll, 1995). However, a small minority of patients have markedly diminished T cell responses. In the past, this distinction has led to confusing nomenclature. Patients with minimal T cell mitogen responses were said to have complete DGS and patients with normal or near-normal T cell mitogen responses were said to have partial DGS. In fact, there is a spectrum of severity for all of the phenotypic features of this disorder. Some of the patients with markedly

impaired T cell function will not improve with time and will require either a bone marrow transplant or thymus transplant whereas others will improve, although improvement becomes less likely after the first few months.

The consequences of T cell deficiency in DGS patients are an increased susceptibility to infections, particularly viral infections, and an increased risk of autoimmune disease. Specifically, parainfluenza, adenovirus, and rotavirus have been shown to cause severe morbidity in DGS patients (Beard et al., 1980; Tuvia et al., 1988; Wood et al., 1988; Gilger et al., 1992). Most viral illnesses are more prolonged in DGS patients with compromised T cell function. It is not known if decreased T cell numbers are an independent risk factor for prolonged viral diseases in the absence of T cell dysfunction. Two studies demonstrated that DGS patients have an impaired T cell repertoire, suggesting that markedly diminished T cell numbers do contribute to infectious morbidity (Pierdominici et al., 2000; Piliero et al., 2004). DGS patients with severely diminished T cells are also at risk from the same opportunistic infections as patients with severe combined immunodeficiency.

Juvenile rheumatoid arthritis, immune-mediated thrombocytopenia (ITP), and autoimmune hemolytic anemia occur with increased incidence in patients with DGS (Pinchas-Hamiel et al., 1994; Duke et al., 2000; Jawad et al., 2001). In addition, individual cases of autoimmune thyroiditis have been described, suggesting that there is a generalized increased frequency of autoimmune disease in DGS patients (Ham Pong et al., 1985). The delayed formation and maturation of T cell regulatory functions might allow for the development and proliferation of autoreactive T cells (Sullivan et al., 2002).

The natural killer (NK) cell compartment often comprises a large fraction of the total peripheral blood lymphocytes. In some cases, this reflects genuine expansion of this cell lineage. NK cell function has been examined in DGS patients and found to correlate poorly with NK cell number or T cell studies (Muller et al., 1989).

In contrast to the quantitative deficiency of T cells, the B cell compartment is typically normal or expanded. The B cells often comprise a larger fraction of the total lymphocyte pool than in normal infants and the absolute numbers of B cells may be expanded as well. Markedly increased B cell numbers may correlate with poorer T cell function (Muller et al., 1989; Jawad et al., 2001). This is thought to be due to aberrant regulation of B cells by the deficient T cells. There is evidence that there is defective T cell suppression of B cell immunoglobulin production in infants with DGS (Durandy et al., 1986) and it is not uncommon for infants with DGS to have hypergammaglobulinemia (Muller et al., 1988). On the other hand, hypogammaglobulinemia, IgA deficiency, and delayed acquisition of appropriate antitetanus and antidiphtheria antibody titers have been described in DGS patients (Mayumi et al., 1989; Junker and Driscoll, 1995; Smith et al., 1998). This is also thought to result from the relative deficiency of appropriate T cell help for immunoglobulin production. A DGS kindred with persistently impaired T cell production, normal T cell function, and defective ability to form some antipolysaccharide antibodies has been described. The occurrence of similar humoral dysfunction in the same kindred suggests that modifier genes may play a significant role in the ultimate level of humoral function. In general, however, it is not possible to predict the level of immunologic function of an affected child on the basis of previously diagnosed siblings or parents. Recognition that T cell dysfunction could alter immunoglobulin production prompted a study of immunoglobulin diversity in DGS patients. The im-

munoglobulin repertoire was normal in a patient with severe T cell deficits as well as in a patient with mild T cell compromise. However, somatic mutation was found to be markedly deficient in the patient with significant T cell dysfunction compared to the more mildly affected patient and normal controls (Haire et al., 1993).

## Other Features

### Congenital abnormalities

The most common cardiovascular malformations include interrupted aortic arch type B (14%–15%), truncus arteriosus (7%–9%), and tetralogy of Fallot (17%–22%). Although neonatal hypocalcemia is not uncommon in DGS, recent studies suggest that patients are at risk for a spectrum of parathyroid gland abnormalities including latent hypoparathyroidism, which may evolve to hypocalcemic hypoparathyroidism during adolescence or early adulthood (Cuneo et al., 1997). One study demonstrated that chromosome 22q11.2 deletions were seen in 10 of 14 neonates with hypocalcemia (Adachi et al., 1998).

Newborns and infants with DGS may have dysmorphic facial features such as widely spaced eyes (hypertelorism); low-set, prominent ears; and micrognathia. Later in childhood, adolescence, and adulthood their facial features become more characteristic of patients with VCFS (Fig. 33.1). The characteristic facial features of VCFS include a long face; a prominent nose with a bulbous nasal tip and narrow alar base; almond-shaped or narrow palpebral fissures; malar flattening; recessed chin; and malformed, prominent ears (Shprintzen et al., 1981). In addition, a spectrum of palatal abnormalities may be seen in DGS, such as cleft palate, submucous cleft palate, velopharyngeal insufficiency (VPI), bifid uvula, and cleft lip with or without cleft palate. Feeding difficulties and gastroesophageal reflux are common and can require tube-feeding or a gastrostomy tube (Eicher et al., 2000). Renal anomalies such as single kidney, multicystic dysplastic kidney, horseshoe kidney, and duplicated collecting system occur in approximately one-third of DGS patients. Hearing loss in one or both ears is not uncommon. Other features seen less frequently include microcephaly, short stature, hypospadias, ocular abnormalities, inguinal and umbilical hernias, hematologic abnormalities, and skeletal anomalies (Ryan et al., 1997; McDonald-McGinn et al., 1999).

### Neurologic abnormalities

Neurologic manifestations may also be seen in DGS. Neural tube defects have been described in three patients (Nickel et al., 1994). Structural brain abnormalities including a small vermis, small posterior fossa, and small cysts adjacent to the anterior horns have been identified by magnetic resonance imaging (MRI); however, these findings did not appear to correlate with developmental, cognitive, or personality disorders (Mitnick et al., 1994). Enlarged Sylvian fissures on MRI have been reported in infants with the 22q11.2 deletion. However, prospective studies will be necessary to determine the significance of these findings (Bingham et al., 1997). Cerebellar atrophy was diagnosed by MRI in a 34-year-old DGS patient with progressive gait difficulties, muscle stiffness, dysarthria, and dysmetria suggestive of a neurodegenerative disorder (Lynch et al., 1995).

Advances in medical and surgical management of newborns and children with DGS have led to increased survival. Hence, prospective evaluations of these children have enabled us to understand the range of cognitive and neuropsychological problems

**Figure 33.1.** Frontal and side views of a 4-month-old male with DiGeorge syndrome and a 22q11.2 deletion. Note the prominent ears, bulbous nasal tip, mild micrognathia, and sloping forehead.

they are at risk to develop. In children of preschool age, developmental delay, mild hypotonia, and language and speech delays, especially for expressive language, are common. Behavioral problems observed include attention deficit-hyperactivity disorder (ADHD), inhibition, and shyness (Goldring-Kushner et al., 1985; Swillen et al., 1997; Gerdes et al., 1999; Solot et al., 2000). Psychoeducational and neurodevelopmental studies of children ages 4–20 with the 22q11 deletion demonstrated full-scale IQ scores in the normal to moderately retarded range, with significantly higher verbal than quantitative IQ scores. Math scores were lower than reading and spelling. These studies are consistent with nonverbal learning disabilities (Moss et al., 1999). Language difficulties persisted in approximately 50% of the children of school age (Solot et al., 2000). Recent studies also suggest an increased frequency of behavioral and psychiatric disorders. ADHD, specific phobias, schizophrenia, anxiety, and depressive disorders have been observed in adolescents and adults with the 22q11 deletion syndrome (Pulver et al., 1994; Sugama et al., 1999). Whether these conditions are primary consequences of 22q11 deletion or secondary to the nonverbal learning disability remains to be determined.

#### Other Disorders Associated with the 22q11 Deletion

In addition to the overlap between DGS and VCFS, there are striking similarities between patients with DGS and those with conotruncal anomaly face syndrome (CTAFS), a disorder predominantly described among the Japanese. CTAFS is characterized by conotruncal cardiac defects in association with a characteristic facial appearance. The facial features include ocular hypertelorism, lateral displacement of the inner canthi, flat nasal bridge, small mouth, narrow palpebral fissures, bloated eyelids, and malformed ears (Kinouchi et al., 1976). Some patients have a history of neonatal tetany, absent or hypoplastic thymus, and partial depression of T cell-mediated immune responses. The finding of 22q11 deletions in CTAFS patients confirmed an earlier suggestion that CTAFS, VCFS, and DGS are the same entity (Burn et al., 1993; Matsuoka et al., 1994).

Recent cytogenetic and linkage studies of patients diagnosed with Opitz/GBBB syndrome, suggest that there is at least one autosomal dominant locus for this disorder on chromosome 22q11 and a second on the X chromosome (Robin et al., 1995a). Opitz/GBBB syndrome (MIM 145410) is characterized by hypospadias, laryngotracheal anomalies, and hypertelorism (Opitz et al., 1965). Patients may have other features including cleft lip and palate, cardiac defects, umbilical and inguinal hernias, cryptorchidism, imperforate anus, and facial dysmorphism such as telecanthus, prominent nasal bridge, or depressed nasal root with anteverted nares. Four patients with Opitz/GBBB syndrome, including a father and son, have 22q11 deletions, which suggests that in some instances deletions within 22q11 are causally related to Opitz/GBBB syndrome (McDonald-McGinn et al., 1995). While there are some phenotypic similarities between these disorders, additional studies will be necessary to determine if Opitz/GBBB syndrome is a genetically distinct disorder from DGS and VCFS.

The DiGeorge anomaly has been observed in several other disorders, including CHARGE association (coloboma, heart defects, atresia of the choanae, retarded growth, genital hypoplasia, ear anomalies), Cayler cardiofacial syndrome, Kallman syndrome, and Noonan syndrome (Lammer and Opitz, 1986; Wilson et al., 1993a; Robin et al., 1995b; Bawle et al., 1998). However, the 22q11 deletion has not been found to be causally related to these disorders in a significant number of cases.

#### Phenotypic Variability of DiGeorge Syndrome and Velocardiofacial Syndrome

Although DGS and VCFS were previously recognized as two distinct disorders, there is significant phenotypic overlap and they share a common etiology; hence, we and others consider deletion-positive DGS and VCFS patients as having the same disorder, the 22q11 deletion syndrome. There is a wide range of phenotypic variability associated with the 22q11 deletion. While some individuals present with classic findings of DGS, others have relatively subtle features such as minor dysmorphic facial features or mild cognitive impairment. Furthermore, the observed

differences between patients with DGS and VCFS probably reflect an ascertainment bias. Newborns with complex congenital cardiac defects associated with hypocalcemia and immune deficiencies are much more likely to be diagnosed with DGS. In contrast, school-age children with palatal abnormalities and speech and learning difficulties are usually diagnosed with VCFS by specialists in cleft palate or craniofacial abnormalities. Prospective studies of newborns and children with conotruncal defects initially believed to be isolated indicate that those patients who have the 22q11 deletion often eventually manifest other features of the syndrome, such as mild facial dysmorphism, velopharyngeal insufficiency, and learning difficulties (McDonald-McGinn et al., 1997). Such studies suggest that all deletion positive patients should receive comprehensive medical evaluations and follow-up as well as neuropsychological and educational assessments.

### Cytogenetic and Molecular Studies

Cytogenetic studies of patients with DGS provided the initial evidence linking chromosome 22 to DGS (reviewed in Greenberg et al., 1988). Early reports of DGS patients with unbalanced translocations resulting in the loss of 22pter to q11 and two patients with interstitial deletions of 22q11 suggested that this region of chromosome 22 was important in the etiology of DGS. Subsequently, restriction fragment length polymorphism (RFLP) analysis and DNA dosage studies demonstrated that cytogenetically normal DGS patients had submicroscopic deletions within 22q11. Delineation of the DiGeorge chromosomal region (DGCR) was initially based on the finding of a consistently deleted region within 22q11 in the first 14 DGS patients described with 22q11 microdeletions (Driscoll et al., 1992a).

The presence of features common to DGS in patients diagnosed with VCFS prompted investigators to study VCFS patients for evidence of a 22q11 deletion. Cytogenetic studies using high-resolution banding techniques detected interstitial deletions (del 22q11.21–q11.23) in 20% of VCFS patients (Driscoll et al., 1992b). Molecular studies with chromosome 22 probes previously shown to be deleted in patients with DGS demonstrated that the majority of individuals with VCFS have similar deletions of 22q11 (Driscoll et al., 1992b, 1993; Kelley et al., 1993). These studies coincided with the increasing utilization of fluorescence in situ hybridization (FISH) for the detection of microdeletions and subtle translocations. FISH of metaphase chromosomes by use of DNA probes from the DGCR led to a dramatic increase in the detection of 22q11 deletions in patients with features of DGS, VCFS, CTAFS, and conotruncal cardiac malformations (Color Plates 33.I and 33.II).

### Mechanism of the 22q11 Deletion

Most DGS patients have a large deletion (3 Mb) within 22q11.2 (Fig. 33.2). Approximately 10%–12% have a smaller deletion nested within the commonly deleted region (Shaikh et al., 2000; Emanuel et al., 2001). A few DGS patients have been identified with deletions outside this region (Rausch et al., 1999; Saitta et al., 1999). Significant progress has been made in our understanding of the mechanism of the 22q11.2 deletion. Numerous DGS-associated translocations within the commonly deleted region and identification of unstable DNA sequences near the recurrent constitutional t(11;22) translocation breakpoints, suggest that 22q11.2 is an unstable region (Kurahashi et al., 2000). The four low copy number repeats (LCRs) near the deletion bound-

aries are associated with aberrant interchromosomal exchanges (Shaikh et al., 2000, 2001; Saitta et al., 2004). Analysis of the sequence of these LCRs indicates that they are large, highly homologous, and complex.

### Gene Identification

At least 40 genes have been identified within the 3 Mb commonly deleted region of 22q11.2. This entire gene-rich region of chromosome 22 has been sequenced and is now available in the public domain (Dunham et al., 1999). On the basis of reports of DGS patients with different nonoverlapping deletions and recent evidence from the mouse, it is possible that more than one gene could contribute to the phenotype. Several of the genes in the commonly deleted region that are in part responsible for some of the phenotypic features in DGS are described in this section.

The most likely single candidate gene for DGS is *TBX1*. The human *TBX1* gene was identified in the commonly deleted region and with rare exceptions is deleted in the majority of DGS patients (Chieffo et al., 1997). *TBX1* is a member of a conserved family of genes that share a “T-box” DNA-binding domain and function as transcription factors involved in the regulation of developmental processes. Animal models strongly suggest a dominant role for TBX1 protein in the DGS phenotype. The recent demonstration of point mutations in *TBX1* leading to the full phenotype of DGS argues strongly for this being the major contributor to the phenotype (Yagi et al., 2003).

Several additional genes described in the common DGS deleted region may also contribute to the phenotype, given their expression patterns and potential role in cardiac and neural crest cell migration and differentiation. In 1995, *DGCR2/LAN/IDD*, a gene expressed in a variety of human adult and fetal tissues, was identified by several investigators (Budarf et al., 1995a; Demczuk et al., 1995; Wadey et al., 1995). This gene encodes a potential adhesion receptor that might mediate specific adhesive interactions between cells resulting in abnormal migration or interaction of the neural crest cells with the branchial arches.

The novel gene *DGCR6* is located in the proximal DGCR and shares homology with the *Drosophila melanogaster* gonadal protein (gdl) and laminin g-1 (*LAMC1*) chain (Demczuk et al., 1996). Although *DGCR6* is present in all adult tissues except placenta, it appears to be most abundant in heart and skeletal muscle. Because of its homology with laminin, which, through its interactions with a receptor plays a role in cell attachment, migration, and tissue organization during embryonic development, it is possible that *DGCR6* may play a role in neural crest cell migration. A goosecoid-like homeobox gene, *GSCL* or *GSC2*, has also been identified within the DGS region (Funke et al., 1997; Gottlieb et al., 1997). *GSCL* is expressed during early human development in the derivatives of the cephalic neural crest cells.

Catechol-*O*-methyltransferase (*COMT*), also within the commonly deleted region (Grossman et al., 1992), is important in the metabolism of catecholamines such as noradrenaline, adrenaline, and dopamine. A polymorphism has been identified in *COMT* (*COMT* 158<sup>met</sup>) that results in decreased enzyme activity and appears to be associated with the development of psychiatric disease, particularly bipolar spectrum disorder, in patients with the 22q11 deletion syndrome (Lachman et al., 1996; Graf et al., 2001). Thus *COMT* defects may play a role in the development of the psychiatric disorders in some DGS patients.

Glycoprotein Ib $\beta$ , encoded by the gene *GP1BB* in 22q11.2, is a component of the major platelet receptor for von Willebrand factor (Budarf et al., 1995b). Defects in this receptor result in

**Figure 33.2.** DiGeorge chromosomal region illustrating the size and location of the 22q11.2 deletions in 200 patients. Deletion size and boundaries (A–D) were determined by fluorescence in situ hybridization (FISH), using as probes cosmids containing the genes and markers listed on the map of 22q11.2. The duplicated blocks of sequence or low copy

repeats, designated A, B, C, D, coincide with observed deletion endpoints in patients. The extent and frequency of the four recurrent deletions are shown as lines below the map. Eighty-seven percent of DGS patients have a 3 Mb deletion extending from A to D. (Modified figure courtesy of B.S. Emanuel.)

a rare autosomal recessive bleeding disorder, Bernard-Soulier syndrome (BSS), which is characterized by excessive bleeding, thrombocytopenia, and very large platelets. A single patient with features of BSS and VCFS with a 22q11 deletion has been described (Budarf et al., 1995b). Haploinsufficiency for this region of chromosome 22 unmasked a mutation in the promoter region of the remaining *GP1BB* allele, resulting in manifestations of BSS (Ludlow et al., 1996). Haploinsufficiency for *GP1BB* is likely to be responsible for the mild thrombocytopenia seen commonly in patients with deletions of 22q11.2 (Lawrence et al., 2003).

### Animal Models

The creation of mouse models has enhanced our understanding of the molecular basis of DGS. Initially, maps and sequence of the region of mouse chromosome 16 that is homologous to the DGS chromosomal region on 22q11 were constructed (Puech et al., 1997; Sutherland et al., 1998; Lund et al., 1999). Targeted mutations of single genes and deletions of the homologous region of 16 have been developed to elucidate the role of individual genes or sets of genes in DGS. Most of the initial attempts failed to recapitulate the DGS phenotype. Eventually, using Cre-loxP chromosome engineering, Lindsay et al. (1999) successfully created a mouse with cardiac defects similar to those seen in DGS. The mice had a 1.2 Mb deletion, designated *Dfl*, of chromosome 16 containing at least 20 genes that are most often deleted in DGS patients. Most of the mice heterozygotes for this deletion were viable; 18%–26% had abnormalities of the fourth aortic arch arteries but no other manifestations of DGS. Subsequently, through chromosome engineering and P1 artificial chromosome transgenesis, these investigators identified *Tbx1* as the gene in the *Dfl* mouse responsible for the cardiac defects (Lindsay et al., 2001). A second group also used the Cre-loxP strategy to generate a slightly larger 1.5 Mb deletion in mouse chromosome 16 that results in conotruncal cardiac anomalies (interrupted aortic arch type B, vascular ring, right aortic arch) and absent parathyroid glands (Merscher et al., 2001). They also used a rescue transgenesis technique and concluded that *Tbx1* was the critical gene for cardiac defects in mice with both deletions. In addition to the cardiac defects, the transgenic mice had a smaller than normal thymus, occasionally with small ectopic thymic lobules, along with a reduced number of CD4 and CD8 cells. However, the parathyroids were normal. Similar to humans, the cardiac

defects in heterozygous *Dfl* mice are not fully penetrant. This mouse model has provided insight into the pathogenesis of the cardiac defects and the basis for reduced penetrance. The aortic arch defects appear to correlate with a delay and occasional failure of the differentiation of vascular smooth muscle from neural crest cell mesenchyme. Migration of the neural crest into the fourth arch and initial formation of the fourth pharyngeal arch arteries proceeds normally in the *Dfl* mice but the affected vessels are impaired in their growth and do not acquire smooth muscle (Lindsay and Baldini, 2001). Many of the heterozygous *Dfl* embryos were capable of overcoming this vascular defect and developed normally. These studies suggest that, contrary to previous beliefs, the cardiac defects in DGS are secondary to delayed growth and responsiveness to developmental signals for remodeling of the vasculature. This finding illustrates how the animal model has altered our understanding of DGS as a developmental disorder.

At the same time, Jerome and Papaioannou (2001) reported on the production of a null mutation in mouse *Tbx1*. The heterozygotes were viable, but in 19%–45% of them, depending on the parental strain of mouse, the fourth aortic arches were absent or reduced in thickness. There were no differences in the weight of the thymus, absolute number of thymocytes, or cell surface markers CD3, CD4, and CD8 in *Tbx1* heterozygote vs. wild-type mice. However, the *Tbx1* homozygous mutants were nonviable. Embryos that were recovered displayed a range of phenotypic findings similar to DGS, including short neck, abnormal facial structure, low-set or abnormally folded ears, single cardiac outflow tract, right aortic arch or a double aortic arch, absent thymus, and absent parathyroids. Other investigators have confirmed the cardiac defects in *Tbx1* mutants (Lindsay et al., 2001; Merscher et al., 2001). In the mouse, a *Tbx1* mutation is sufficient to produce a DGS phenotype. The anomalies in the *Tbx1* knockout mouse model correlate with the expression pattern of *Tbx1* in the embryonic mouse head mesenchyme, pharyngeal arches and pouches, and the otic vesicle. This study provides further evidence that in humans the *TBX1* gene is a key gene in DGS (Jerome and Papaioannou, 2001).

The *Ckrol* mouse mutant developed by Guris et al. (2001) suggests that other genes may contribute to the classical features of DGS. *Crkrl* is highly expressed in the branchial arches during mouse embryogenesis and maps to mouse chromosome 16 outside the *Dfl* deletion. Homozygous mice with a null mutation in

*Crkol* have cardiac defects including double-outlet right ventricle and VSD with an overriding aorta due to abnormal alignment of the outflow tract. Approximately 40% of the mutant embryos also had an abnormal thymus, parathyroid, and thyroid glands, and mild skeletal anomalies of the head. The similarities to DGS suggest that this gene may contribute to the development of at least some of the clinical features.

### Clinical and Laboratory Diagnosis

DGS patients with the 22q11 deletion are ascertained through a variety of medical specialty clinics on the basis of presenting features. Recognition of the 22q11 deletion syndrome is important so that the medical community and schools can meet their diverse needs. Furthermore, identification of a 22q11 deletion enables the clinician to provide the affected patient and his or her family with a more accurate assessment of their recurrence risk. Deletions of 22q11 may be detected in 20%–25% of DGS patients by means of high-resolution cytogenetic analysis (Wilson et al., 1992). However, several studies have clearly shown that FISH of metaphase chromosomes with DNA probes from the DGCR is the most efficient method for detecting 22q11 deletions (Desmaze et al., 1993; Driscoll et al., 1993). Routine cytogenetic analysis continues to be important for the detection of other chromosomal rearrangements, such as translocations, which may involve chromosomes other than 22. Hence, it is recommended that FISH be used as an adjunct to routine cytogenetic analysis for the diagnosis of DGS. At the present time, many commercial and hospital-based laboratories are using FISH with the probes from the DGCR for the clinical and prenatal detection of the 22q11 deletion (Color Plate 33.I). Because of the recent recognition of the DGS phenotype in patients with intragenic single nucleotide mutations in *TBX1* (Yagi et al., 2003), gene sequencing may be considered in patients strongly suspected of having DGS in whom FISH is normal.

### Carrier Detection and Prenatal Diagnosis

The majority of the 22q11 deletions are sporadic events, occurring only in the affected individual. The incidence of familial cases of DGS is approximately 10% (McDonald-McGinn et al., 2001). Hence, it is important to closely examine the parents of an affected child for subtle features, such as mild facial dysmorphism, hypernasal speech, and history of poor school performance, that are suggestive of a 22q11 deletion. Deletion testing of the parents is recommended. A parent or proband with a 22q11 deletion has a 50% chance of transmitting the deletion-bearing chromosome to his or her offspring. Parents with a 22q11 deletion benefit from preconception and antenatal genetic counseling to review their risk of having affected offspring and to discuss their reproductive options, including prenatal testing and preimplantation genetic diagnosis (Iwarsson et al., 1998; Driscoll, 2001).

Antenatal detection of the 22q11 deletion by FISH has been successfully performed on cultured amniocytes and chorionic villi obtained from at-risk pregnancies (Driscoll et al., 1993; Driscoll, 2001). Pregnancies considered at high risk include those of deletion-positive parents or parents with mosaicism for the 22q11 deletion, and those in which ultrasound or echocardiography demonstrates a fetal conotruncal cardiac malformation. Although the recurrence risk for normal parents with a previous affected child is low, parents often request prenatal testing for the deletion to exclude the small possibility of germ-line mosaicism.

Although testing for the deletion is highly accurate, it is impossible to predict the phenotype. The size and extent of the deletion have not shown correlation with the penetrance and severity of features of DGS (Lindsay et al., 1995). There is significant intrafamilial variability and the parental phenotype is not a reliable predictor of outcome for the fetus (McDonald-McGinn et al., 2001). Fetal imaging techniques such as ultrasonography and fetal echocardiography are recommended to evaluate the fetus for the presence of a cleft palate, renal anomaly, or cardiac defect. Subtle congenital anomalies such as a submucous cleft palate and dysmorphic features cannot be appreciated by sonography (Driscoll, 2001).

At the present time, it remains difficult to counsel families with children with nondeleted DGS unless an etiology such as a cytogenetic translocation or maternal diabetes has been identified. These individuals may have intragenic mutation of *TBX1* or a small deletion of chromosome 22 that cannot be detected with the probes currently used by clinical cytogenetic laboratories (Kurahashi et al., 1996; O'Donnell et al., 1997; McQuade et al., 1999; Rauch et al., 1999; Saitta et al., 1999). Currently, screening for smaller deletions within 22q11 and gene mutations is only available on a research basis.

A minority of DGS patients may have other cytogenetic abnormalities such as deletions of the short arm of chromosome 10, and FISH may be used to evaluate these patients for microdeletions of chromosome 10p (Daw et al., 1996; Gottlieb et al., 1998). For now, fetal sonography and echocardiography are the only available prenatal tests that are helpful when evaluating at-risk pregnancies that are not causally related to an abnormality of 22q11 or other recognizable chromosomal abnormality.

### Management and Treatment of the Immunodeficiency

The clinical management of infants and children with DGS depends on their degree of immunocompromise. Most infants with the classic features of DGS are diagnosed in the first weeks of life through their characteristic cardiac anomalies and hypocalcemia, whereas older children may not be recognized until they develop speech and/or learning problems. As soon as the diagnosis of DGS or the 22q11.2 deletion syndrome is established, the individual should have an initial immunologic evaluation. It is important to specifically evaluate immunologic function regardless of the severity of the other phenotypic features. Depending on the age of the child, this could include T and B cell subset analyses, T cell mitogen and antigen responses, immunoglobulin production, and tests of specific antibody formation.

Newborns should be evaluated for T cell production and function by analyzing lymphocyte subsets and responses to mitogens. Very young infants with markedly diminished T cell numbers and function may be followed for a period of time to determine whether the immunodeficiency persists. During this time, they are at risk for opportunistic infections and should receive prophylaxis for *Pneumocystis carinii* pneumonia, reverse isolation, irradiated blood products, and careful monitoring. They should not receive live viral immunizations. Persistence of a SCID-like phenotype requires either a bone marrow or thymus transplant (Markert et al., 1999, 2003) to restore immunologic function. Because both interventions carry significant risk and the immunodeficiency of DGS is developmentally expressed, it seems wise to delay intervention for 1 to 2 months when possible.

Most infants with DGS or a 22q11 deletion will have a mild immunodeficiency with an excellent long-term prognosis. T cell

**Table 33.3.** Suggested Immunologic Evaluations of Newborns and Infants with DiGeorge Syndrome

Humoral function				X*

\*Requires reevaluation if abnormal.

production is usually moderately impaired and T cell mitogen responses are often normal or near normal. Strategies such as PCP prophylaxis and use of killed vaccines for the patient and family contacts may be considered. Most DGS infants will develop normal or near-normal immunologic function over time. However, the first year of life represents a vulnerable time during which they require careful monitoring. Although there are limited data to support specific management strategies, a reasonable approach to minimize risk to the affected infant is to withhold live viral vaccines until T cell function is normal and the child has demonstrated an ability to form functional antibodies. Using the criteria of normal T cell mitogen responses, normal T cell antigen recall responses, a CD8 count of at least 250/mm<sup>3</sup>, and normal antibody responses to diphtheria and tetanus, we and others have not observed any serious side effects with OPV (oral polio vaccine), MMR (measles, mumps, and rubella vaccine), or varicella vaccine administration (Perez et al., 2003; Moylett et al., 2004). The recent widespread use of inactivated poliovirus vaccine (IPV) has limited early infant exposure to live viral vaccines. PCP prophylaxis is required only for extremely low T cell counts. Sequential follow-up studies are important because the pace of immunologic recovery is very unpredictable. Furthermore, there are no laboratory studies or phenotypic markers that predict ultimate immunologic outcome. A typical strategy would be to measure lymphocyte subsets and mitogen responses at the time of diagnosis. If the mitogen responses are normal and the T cell production is moderately impaired, the lymphocyte subsets should be repeated every 4–12 months until they have normalized or stabilized (Table 33.3). At 8–12 months of age, T cell responses to antigen should be evaluated and an analysis of humoral function should be performed. Mitogen and antigen responses should be followed sequentially if abnormal on the first evaluation. More severely affected infants require more careful follow-up, while less severely affected infants may require somewhat less frequent follow-up.

Early management of DGS patients often revolves around their cardiac anomaly, and it may be difficult to adequately assess the patient's immunologic function. Blood transfusions and hemodynamic instability may require that the evaluation be limited or delayed. Although only a minority of patients (<2%) will have severe immunodeficiency, it is prudent to consider the patient as severely immunodeficient until such time as appropriate studies can be done. Because several cases of graft-versus-host disease due to blood transfusions have been recorded in DGS and because early infancy is the most vulnerable time for DGS infants, only irradiated and cytomegalovirus (CMV)-negative blood products should be given (Brouard et al., 1985; Muller et al., 1989; Wintergerst et al., 1989; Washington et al., 1993, 1994).

In older children it is possible to examine immunologic function thoroughly at the first evaluation. Patients with normal or near-normal T cell production, normal T cell mitogen and anti-

gen responses, and a demonstrated ability to form functional antibody do not require special treatment or restrictions. Some patients have persistent mild T cell abnormalities. These patients require individualized management depending on the degree of T cell compromise and the extent to which they develop significant infections. These patients also require follow-up studies because the immunologic changes in DGS can be unpredictable. Most immunologic improvement occurs in the first year of life, but additional T cell function and improved T cell production can occur later. Furthermore, patients with DGS experience thymic involution as they get older and have a decline in peripheral blood T cell counts (Piliero et al., 2004).

In spite of laboratory evidence of normal immunologic function, many DGS patients have recurrent upper respiratory infections due to abnormal palatal anatomy. These patients benefit from the same surgical interventions as other children, and prophylactic antibiotics as adjunct therapy may be considered.

Since the majority of DGS patients will ultimately have normal or near-normal immunologic function, most research efforts have been directed at improved management of the severely affected infants. Bone marrow transplantation from an HLA-matched sibling donor has been efficacious (Goldsobel et al., 1987; Borzy et al., 1989). It may provide sufficient numbers of mature T cells to allow adequate T cell function even in the absence of thymic tissue. Early therapeutic efforts were directed at replacing the missing thymic tissue and used fetal thymic grafts (Thong et al., 1978; Touranine, 1979). Although a minority of these grafts succeeded, the limitations imposed by the use of fetal tissue have compromised their practical application. Recently, success has been reported using partially HLA-matched, discarded postnatal thymic tissue obtained during cardiac surgery grafts (Markert et al., 1995, 1999, 2003, 2004). Four months after placement of a thymic graft, mature functional host T cells were identified in peripheral blood. Antigen-specific T cell responses developed and B cell function normalized. This management strategy appears to offer many advantages over fetal thymus or bone marrow transplantation for severely affected DGS patients, although involution of the thymic graft may be a long-term issue.

### Future Challenges

DGS is characterized by a wide range of congenital malformations, facial dysmorphism, endocrine and immune disorders, cognitive impairment, and neurologic and psychiatric abnormalities. Cytogenetic and molecular studies have contributed greatly to our understanding of the genetic basis of this disorder. These studies have shown that deletions of chromosomal region 22q11 are the leading cause of DGS. More recently, *TBX1* was identified as a major contributor to the phenotype. Other genes within or outside the critical region may mold the phenotypic manifestations. Within the next several years we can expect to have a much clearer understanding of how these genes function and what their roles are in the pathogenesis of the complex and variable phenotype of the 22q11 deletion syndrome in humans.

Prospective studies of DGS patients with 22q11 deletions continue to further delineate the range and severity of the medical, cognitive, and neuropsychological problems for which these patients are at risk. The wide range of phenotypic variability remains poorly understood. Neither the size of the deletion nor the parental origin, a factor in some genetic syndromes because of differences in chromosomal imprinting, appear to explain the penetrance or severity of the phenotype. Murine studies suggest

that genetic background is an important influence on the phenotype. Therefore, we hypothesize that the severity and phenotypic variability in DGS may be due to modifier genes. Genetic studies of potential modifying genes in both humans and animal models may further our understanding of this complex disorder, and eventually lead to more accurate prediction of the outcome and need for specific therapeutics and intervention. In the meantime, we urge clinicians to pursue comprehensive evaluations by a team of medical professionals in genetics, cardiology, immunology, endocrinology, plastic surgery, speech and hearing, and developmental pediatrics who have the expertise in caring for individuals with DGS.

### Acknowledgments

The authors thank B.S. Emanuel, E.H. Zackai, M.L. Budarf, D.M. McDonald-McGinn, and the 22q11 families for their support and collaboration. This work was supported in part by grants from the National Institute of Deafness and Communication Disorders (DC02027), the National Heart, Lung and Blood Institute (HL074731), the General Clinical Research Center (M1-RR00240), and the Wallace Chair of Pediatrics.

## Hyper-IgE Recurrent Infection Syndromes

BODO GRIMBACHER, JENNIFER M. PUCK, and STEVEN M. HOLLAND

Hyper-IgE recurrent infection syndrome (MIM #147060, #243700) is a primary immunodeficiency characterized by recurrent staphylococcal skin abscesses, pneumonias with pneumatocele formation, extreme elevations of serum IgE, eosinophilia, and distinct abnormalities of the connective tissue, skeleton, and dentition (Davis et al., 1966; Buckley et al., 1972; Hill and Quie, 1974; Donabedian and Gallin, 1983a; Belohradsky et al., 1987; Grimbacher et al., 1999a; Erlewyn-Lajeunesse, 2000).

### History

“So went Satan forth from the presence of the Lord, and smote Job with sore boils from the sole of his foot unto his crown.” With this citation from Job II:7, Davis, Schaller, and Wedgewood coined the term *Job syndrome* in 1966 (Davis et al., 1966). They reported two red-haired, fair-skinned girls who had frequent sinopulmonary infections, severe dermatitis, and recurrent staphylococcal skin infections that were remarkable for their lack of surrounding warmth, erythema, or tenderness. The syndrome was further defined and clarified by Buckley et al. (1972), who noted similar infectious problems in two boys with severe dermatitis, distinctive facial appearance, and elevated IgE levels, leading to the term *Buckley syndrome*. Following this report, elevated levels of IgE and a defect in neutrophil chemotaxis were reported in the two girls from the initial report (Hill and Quie, 1974), showing that Job syndrome and Buckley syndrome represented the same condition. To avoid further confusion, the name *hyper-immunoglobulin E recurrent infection syndrome* (HIES) is now widely used. In 1999 a group at the U.S. National Institutes of Health (NIH) undertook to define further the phenotype of HIES. The incidence of 19 clinical features associated with HIES was published, based on a cohort of 30 patients with the disease (Table 34.1) (Grimbacher et al., 1999a).

### Clinical Presentation

The clinical features of HIES include the immune system, the skeleton, and dentition. However, the expressivity of each finding in HIES varies with age and among individuals. Table 34.1 shows the frequency of the 19 most consistent clinical and laboratory findings in HIES.

### Immune System

Eczema, abscesses, pneumonia, mucocutaneous candidiasis, elevated serum IgE, and eosinophilia are the most common features of immunodeficiency and immune dysregulation in HIES patients. Some degree of eczema is present in almost all HIES patients, although persistent moderate to severe eczema is seen in only 80%. A newborn rash occurs in roughly three-quarters of HIES patients (Color Plate 34.I). Eczema with pruritis and lichenification usually appears in the first days to weeks of life (Color Plate 34.II), in a distribution somewhat atypical for atopic dermatitis (involving the posterior auricular areas, back, buttocks, and scalp). Skin infections typically include staphylococcal furunculosis and cellulitis. The abscesses may occur anywhere on the body but are most common around the face and trunk. A “cold” abscess may be either a large fluctuant mass or may feel like a tumor. It is typically neither hot nor tender and is usually not associated with fever or signs of local or generalized inflammation (Erlewyn-Lajeunesse, 2000). In most cases the abscesses are well walled off, filled with pus and almost always grow *Staphylococcus aureus*. Surgical drainage of these lesions is commonly required, and they typically resolve without spreading through the dermis and fascia. Although cold abscesses have been said to be pathognomonic of HIES, they are not essential to the diagnosis. Following institution of almost any prophylactic

**Table 34.1.** Incidence of Clinical Findings Associated with Hyper-IgE Recurrent Infection Syndrome in 30 Patients with Diagnosis of Hyper-IgE Syndrome

Findings Related to Infections and Immune System	%
Moderate to severe eczema	100
Serum IgE >2000 IU/ml	97
Eosinophilia (>2 SD above normal mean)	93
Recurrent ( $\geq 2$ ) pneumonia, X-ray proven	87
Recurrent (>4) skin abscesses	87
Recurrent (>3 per year) upper respiratory infections	84
Mucocutaneous candidiasis	83
Pneumatoceles	77
Newborn rash	74
Other serious infections	52
Lymphoma, other cancer	3
Findings Related to Bones, Teeth, and Connective Tissue	
Characteristic face	83
Retained primary teeth (more than 4)	72
Hyperextensibility of joints	68
Increased nasal width (interalar distance) (>1 SD above normal value for age, race)	65
Scoliosis >10°	63
Recurrent fractures following minor trauma	57
High palate	48
Congenital skeletal anomalies	10

antistaphylococcal antibiotics, recurrent cutaneous abscesses are rare. In some patients abscesses are frequent early in life; but recently, with the institution of prophylactic antibiotics, we have seen mostly impetiginized eczema. In our cohort, 87% of HIES patients had recurrent skin abscesses, and over half had a history of more than four abscesses.

Upper respiratory infections such as sinusitis, bronchitis, otitis media, otitis externa, and mastoiditis are frequent in HIES. Seventy-two percent of patients reported four or more episodes per year. A clinical hallmark of HIES is recurrent pneumonia. The great majority of patients have had at least one bout of pneumonia in their lifetime, but more than half have had three or more. The most common pathogens of acute pneumonia in HIES are *Staphylococcus aureus* and *Haemophilus influenzae*. For reasons still unclear, pneumonias in HIES are frequently complicated. About three-quarters (77%) of HIES patients develop long-term pulmonary complications including bronchiectasis and pneumatoceles (Fig. 34.1). The cycle of infection and lung destruction is further exacerbated by superinfection of the cavities and bronchiectatic lung with *Pseudomonas aeruginosa* and *Aspergillus fumigatus*. Pulmonary infections less commonly seen in HIES include *Pneumocystis jiroveci* (Freeman et al., 2006) and nontuberculous mycobacteria.

Chronic candidiasis of mucosal sites and the nail beds affects 83% of HIES patients, including children (Color Plate 34.III). Although primary invasive fungal infections are relatively uncommon in HIES, cryptococcal infections of the genitourinary tract and colon have been reported (Jacobs et al., 1984; Hutto et al., 1988).

### Skeletal Anomalies

Skeletal and facial abnormalities associated with HIES were recognized in the original reports by Davis et al. (1966) and Buckley et al. (1972). They noted characteristic facies and hyperextensibility of the joints. The facies in HIES are often asymmetric with a prominent forehead and mild prognathism, increased interalar

**Figure 34.1.** Pulmonary complications of hyper-IgE syndrome. (A) Postinflammatory cysts containing aspergillomas. (B) Scoliosis evident in angle of vertebra.

width of the nose, wide-set eyes, thickening of the soft tissue of ears and nose, and a high-arched palate (Borges et al., 1998; Grimbacher et al., 1999a). Although only 83% of HIES patients of all ages in our cohort showed the characteristic facies, the facial features progressively develop and become almost universal by late adolescence (Color Plate 34.IV). Sixty percent have an increased interalar distance (width across the bottom of the nose) and almost half have a high arched palate (Color Plate 34.V, top right). Craniosynostosis has also been reported in a few cases of HIES (Smithwick et al., 1978; Höger et al., 1985; Gahr et al., 1987).

Recurrent pathologic fractures occur in 57% of patients, confirming the multisystem nature of HIES. Fractures occur most commonly in the long bones and ribs (Fig. 34.2A). Although osteopenia is common in HIES and may be cytokine or immune driven (Leung et al., 1988; Cohen-Solal et al., 1995), the fractures that occur are not at the same sites typical of osteoporosis in postmenopausal females. Scoliosis has been seen in 63% of patients: over half had a curvature >15°, and one-third had >20° (Fig 34.2A). Although many cases of scoliosis are idiopathic, diverse contributing factors have been noted, such as leg length discrepancy, prior thoracotomy (e.g., for lung cyst removal), and

**Figure 34.2.** Skeletal manifestations of Job's syndrome. (A) Healed pathologic distal femoral fracture suffered while wading in the ocean. (B) Bone scan showing marked scoliosis.

vertebral body anomalies. Hyperextensibility of the joints was noted in the initial reports and was found in 68% of our patients.

### Dental System

Impaired shedding of primary teeth in HIES patients was only recently recognized and appears to be quite a consistent finding. Reduced resorption of primary tooth roots may lead to prolonged retention of the primary teeth, which in turn prevents the appropriate eruption of the permanent successors (O'Connell et al., 2000). The mechanism underlying this unique developmental abnormality is unknown. In our cohort of HIES patients older than age 6, 72% had delayed shedding of primary teeth (Color Plate 34.V). We currently recommend that, after checking by radiography for the existence and developmental age of the sec-

ondary teeth, children with HIES undergo extraction of retained primary teeth. This procedure is usually followed by normal eruption of the permanent teeth.

### Other Associated Clinical Findings

Several malignancies have been reported in HIES, which suggests that these patients may be at increased risk (Bale et al., 1977; Buckley and Sampson, 1981; Gorin et al., 1989; Einsele et al., 1990; Kowalchuk, 1996; Takimoto et al., 1996; Nester et al., 1998; Huber et al., 1987). In the NIH cohort, two patients developed non-Hodgkin lymphoma and both were successfully treated; another was successfully treated for nodular sclerosing Hodgkin disease. One patient developed metastatic squamous cell carcinoma of the tongue. To date, none of our patients have

**Table 34.2.** Hyper-IgE Syndrome Scoring Sheet

Clinical Findings	Points									
	0	1	2	3	4	5	6	7	8	10
Highest IgE (IU/ml)	<200	200–500			501–1000				1001–2000	>2000
Skin abscesses (total)	None		1–2		3–4				>4	
Pneumonias (X-ray proven, total)	None		1		2		3		>3	
Parenchymal lung abnormalities	Absent						Bronchiectasis		Pneumatocele	
Other serious infection	None				Severe					
Fatal infection	Absent				Present					
Highest eosinophils/ $\mu$ l	<700			700–800			>800			
Newborn rash	Absent				Present					
Eczema (worst stage)	Absent	Mild	Moderate		Severe					
Sinusitis, otitis (no. of times in worst year)	1–2	3	4–6		>6					
Candidiasis	None	Oral, vaginal	Fingernail		Systemic					
Retained primary teeth	None	1	2		3				>3	
Scoliosis, maximum curvature	<10°		10°–14°		15°–20°				>20°	
Fractures with little trauma	None				1–2				>2	
Hyperextensibility	Absent				Present					
Characteristic face	Absent		Mild			Present				
Increased nose width (interalar distance)	<1 SD	1–2 SD		>2 SD						
High palate	Absent		Present							
Congenital anomaly	Absent					Present				
Lymphoma	Absent				Present					

developed systemic lupus erythematosus, another condition previously reported associated with HIES (Schopfer et al., 1983; Leyh et al., 1986; North et al., 1997; Brugnani et al., 1998). Autoimmune vasculitis (Kimata, 1995), dermatomyositis (Min et al., 1999), and membranoproliferative glomerulonephritis (Tanji et al., 1999) have also been reported in HIES but have not occurred in the NIH cohort.

### Diagnostic Criteria

An HIES scoring system (Table 34.2) was developed at the NIH to help estimate the likelihood that a relative of an affected subject might carry an autosomal dominant HIES gene, based on his or her clinical and laboratory phenotype. The scores were shown to be in agreement with the diagnostic opinions of five physicians familiar with HIES who examined the same patients without knowledge of the score. This scoring system was then used to make phenotype assignments for linkage studies (see below). For each clinical finding associated with HIES a point scale was developed. The more specific and more objective findings were assigned higher point scores. This scoring is age sensitive, since older patients are likely to have collected more points. Moreover, some clinical features, such as shedding of primary teeth, cannot be evaluated in very young patients; therefore an age correction is included. In HIES families, an HIES genotype was considered highly likely if the HIES score (based on numbers and severity of HIES characteristics exhibited) exceeded 40 points, and unlikely if the score was less than 20 points. Between 20 and 40 points is an indeterminate zone; patients with these scores may be suspected of having HIES and should be followed over time to gather more conclusive data. We suggest using at least 40 points as a cutoff for a diagnosis of HIES, and more certainty is

afforded if the points are derived from both immune and nonimmune features. Patients with certain conditions such as severe atopic disease may occasionally have very high IgE levels and scores in the HIES range without having HIES. We prefer a multicomponent scoring system for the diagnosis of HIES because no definitive diagnostic laboratory tests, either immunologic or genetic, are currently available.

### Laboratory Findings

The syndrome takes its name from marked polyclonal elevations of IgE in serum. An IgE of >2000 IU/ml often has been used as an arbitrary diagnostic level. However, because IgE levels are very low in utero and climb only after birth in normal infants, infants affected with HIES may not achieve a diagnostic level of 2000 IU/ml early in life. In affected infants the IgE is consistently elevated over the age-adjusted value. For these cases, 10 times the age-appropriate level has been a reasonable guide. IgE levels of >10,000 IU/ml are characteristic of HIES and levels of >50,000 IU/ml have been reported (Buckley and Becker, 1978; Grimbacher et al., 1999a). However, serum IgE levels are not static. Substantial fluctuations in serum IgE concentrations have been noted over time without any obvious change in the clinical status. IgE levels fell below 2000 IU/ml, even close to or into the normal range, in 5 of 30 patients followed at the NIH (Grimbacher et al., 1999a). Therefore, although a high IgE level is part of the diagnostic criteria for HIES, authentic cases may lack this particular feature at some point in their course. The level of serum IgE apparently is not correlated with disease activity or severity. IgE production is thought to be elevated in HIES because of an increased number of B cells making subnormal levels of IgE (Garraud et al., 1999). The driving force for this

abnormality is still unclear, but it is not especially cytokine responsive in vivo (King et al., 1989). IgE catabolism is also impaired in HIES, contributing to the elevation (Dreskin et al., 1987a). In addition to IgE elevation, eosinophilia is seen in >90% of HIES patients. This eosinophilia is at least 2 standard deviations above normal, usually above 700 cells/ $\mu$ l, but it is not correlated with the extent of IgE elevation. The tropism of the elevated IgE in HIES is still unclear. A high proportion of the IgE in HIES binds to *S. aureus* and *C. albicans* (Berger et al., 1980). Similar binding activity was not seen in IgE from other patients infected frequently with *S. aureus*, indicating that this abnormality may be host driven, and not organism driven. Anti-*Staphylococcus aureus* and anti-*Candida albicans* IgE titers have been noted to be raised in HIES, but any relationship to the severity of the disease is not known. Unfortunately, raised antistaphylococcal titers are also seen in atopic patients and are therefore not helpful in the diagnosis of HIES (Walsh et al., 1981).

White blood cell counts are typically in the normal range, but have been reported to range from 1700 to 60,000/ $\mu$ l (Buckley and Becker, 1978; Donabedian and Gallin, 1983a). Chronic leukopenia with borderline neutropenia has been observed in several patients (Donabedian and Gallin, 1983a).

Complement levels have been normal when studied. Elevated levels of urinary histamine have been reported in some patients and correlate with the extent of the eczematoid dermatitis (Dreskin et al., 1987).

### Etiology

The underlying cause of HIES is still unknown. Many studies have focused on the immune aspects of the disease, such as detection of eosinophilia in blood, sputum, and abscesses (Belohradsky et al., 1987; Gahr et al., 1987; Buckley, 1996); defective granulocyte chemotaxis (Buckley et al., 1972; Hill and Quie, 1974; Hill et al., 1974; Van Scoy et al., 1975; Van Epps et al., 1983); abnormal T lymphocyte subsets (Geha et al., 1981; Gahr et al., 1987; Buckley et al., 1991); defective antibody production (Buckley and Becker, 1978; Geha et al., 1981; Dreskin et al., 1985, 1987a); and decreased production of or responsiveness to cytokines such as interleukin-4 (IL-4) and interferon- $\gamma$  (IFN- $\gamma$ ) (King et al., 1989; Vercelli et al., 1990; Paganelli et al., 1991; Rousset et al., 1991; Borges et al., 2000). Originally, HIES was considered to be due to a defect in neutrophil function, because chemotaxis was abnormal at least some of the time in most of the patients (Hill et al., 1974). However, the failure to demonstrate a consistent chemotactic defect, even in the same patient over time, suggested that the chemotactic defects were not central and reproducible aspects of HIES. Even when present, the impaired chemotaxis was not marked in the in vitro assays, compared to syndromes with more profound, primary chemotaxis defects. The 61 kDa protein inhibitor of chemotactic activity described from HIES patients by Donabedian and Gallin (1982, 1983b) is still not completely defined. In summary, no specific immune defect has been found to be present consistently in all patients with HIES.

Several features of HIES have been considered central enough to be of potential etiologic significance. IgE is greatly elevated at most points in the life of patients with HIES (Buckley and Becker, 1978; Donabedian and Gallin, 1983a; Grimbacher et al., 1999a). An infant daughter of a mother with HIES subsequently developed HIES herself and was noted to have elevated cord blood IgE (Dreskin and Gallin, 1987). Since IgE

does not cross the placenta, cord blood elevation reflected endogenous fetal synthesis of IgE and suggests that IgE dysregulation is a primary feature of HIES. Although these findings suggest an important role for extremely elevated IgE in the genesis of HIES, 17% of patients were observed to have IgE levels drop below 2000 IU/ml over long-term follow-up (Grimbacher et al., 1999a), yet retained their increased susceptibility to infection.

The role of IFN in HIES has been investigated because of its participation in IgE responses. IFN- $\gamma$  specifically inhibited the IgE-enhancing activity of a concanavalin-A-stimulated T helper cell line supernatant (Coffman and Carty, 1986) and inhibited the effect of IL-4 on cell expansion and induction of DNA synthesis (Rabin et al., 1986). In HIES patients, there appears to be a reduction in lymphocytes producing either IFN- $\gamma$  or tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ) (DelPrete et al., 1989). However, synthesis of IL-2 and IL-4 appears to be normal. A correlation between elevated in vitro IgE synthesis and diminished IFN- $\gamma$  production in T cells has been reported in HIES patients (DelPrete et al., 1989). Vercelli et al. (1990) did not find in vitro modulation of IgE synthesis by IFN- $\gamma$ , but suggested that T cell-independent mechanisms of IgE regulation were possible.

King et al. (1989) examined effects of IFN- $\gamma$  on HIES peripheral blood mononuclear cell IgE production in vitro and in vivo. They used subcutaneous IFN- $\gamma$  to treat five patients with HIES for 2 to 6 weeks. IFN- $\gamma$  suppressed spontaneous IgE production in vitro and in vivo in most of their patients, as was seen when peripheral blood mononuclear cells were assayed for spontaneous IgE production before and after IFN- $\gamma$  administration. However, serum IgE levels fell in only two of the five patients treated (one received 0.05 mg/m<sup>2</sup>, the other received 0.1 mg/m<sup>2</sup> IFN- $\gamma$ ). After the study, serum IgE levels rebounded to their pretreatment levels in both patients. No patient had any clinical change from the brief course of IFN- $\gamma$  administration.

Garraud et al. (1999) showed that although both IFN- $\gamma$  and IL-12 reduced IgE synthesis, neither cytokine could totally shut it off in HIES cells in vitro. Blocking antibodies to IL-4 or IL-13 reduced in vitro IgE, whereas neutralization of both IL-4 and IL-13 completely suppressed IgE production in cells from subjects with HIES. Interestingly, addition of IL-8 or blockade of IL-6 and TNF- $\alpha$  completely inhibited IgE production in HIES cells in vitro.

Borges et al. (2000) described decreased in vitro IFN- $\gamma$  production in HIES, especially when patient cells were activated with staphylococcal antigen. They postulated that there is a shift toward a T helper-2 type cytokine response, which may result in deficient IFN- $\gamma$  production and promote IL-4, IL-5, IL-13, and, ultimately, IgE production. However, we have not seen decreased IFN- $\gamma$  production in vitro in response to phytohemagglutinin (PHA); if this abnormality exists it may be antigen-specific (D.M. Frucht and S.M. Holland, unpublished observations). Recent studies in patients with sporadic HIES indicated that cytokines and chemokines may be dysregulated in HIES (elevation of IL-12, but decrease of ENA-78, MCP-3, and eotaxin), although it is not clear whether these abnormalities are primary or are secondary to intercurrent infection and inflammation (Chehimi et al., 2001).

Despite the interesting in vitro abnormalities centered around IgE and neutrophil function, the complex multisystem nature of this disease and its effects on skin, bone, teeth, lung, immunity, and infection susceptibility suggest aberrant regulation of some cell or molecular pathway common to all these tissues.

## Genetics

### Autosomal Dominant Hyper-IgE Recurrent Infection Syndrome

Although HIES is thought to be rare, the exact incidence is unknown. Over 200 cases have been published. Although first described in Caucasians with red hair, HIES occurs in all racial and ethnic groups with apparently equal frequency. In one current collected global series there are 68 males and 61 females, suggesting an equal gender distribution in HIES. This is in contrast to earlier reports that suggested a female predominance.

Most pedigrees of multiplex HIES families are consistent with autosomal dominant inheritance (Van Scoy et al., 1975; Blum et al., 1977; Donabedian and Gallin 1983a; Leung und Geha, 1988; Buckley, 1996). Grimbacher et al. (1999a) confirmed autosomal dominant transmission in seven families extending over multiple generations with variable expressivity of the disease phenotype. In a previous collection of HIES families by Grimbacher et al. (1999b), 16 of 19 pedigrees demonstrated parent-to-child transmission, most consistent with dominant inheritance. In six families, transmission from father to son excluded linkage to the X chromosome. Assuming a simple autosomal dominant mode of inheritance, the index patients of the 16 families with apparent dominant transmission had 56 offspring, who would all be at a 50% risk of having HIES. In fact, 29 of them (51%) actually were affected, supporting a Mendelian autosomal dominant trait with high penetrance.

Linkage analysis of a large cohort of 19 multiplex HIES families with 57 affecteds (Grimbacher et al., 1999b) demonstrated linkage to the centromeric region and proximal long arm of chromosome 4. Attention was directed to this region of the genome by a sporadic patient with HIES plus autism and mental retardation, who was found to have a supernumerary marker chromosome derived from a 15–20 cM interstitial deletion from chromosome 4q21 (Grimbacher et al., 1999c). Interestingly, among those 19 families with apparent autosomal dominant transmission of HIES, at least 6 families had an HIES trait that was not linked to chromosome 4, a finding suggesting that at least one additional genetic locus could be responsible for autosomal dominant HIES (AD-HIES). There were no clinical or laboratory features that distinguished HIES linked to chromosome 4 from HIES not linked to 4.

Hershey et al. (1997) identified a polymorphism in the IL-4 receptor (Q576R) linked to atopic eczema and suggested a link to HIES. However, analysis of 25 controls and 20 HIES patients from the NIH cohort showed that Q576R is a polymorphism within the IL-4 receptor unassociated with the HIES phenotype (Grimbacher et al., 1998). Moreover, a pilot linkage study with seven autosomal dominant multiplex families was inconsistent with linkage to the IL-4 receptor locus on chromosome 16 (Grimbacher et al., 1998).

### Autosomal Recessive Hyper-IgE Recurrent Infection Syndrome

In 2004, 13 HIES patients from six consanguineous families with severe recurring infections (pneumonia and abscesses), eczema, high IgE, and eosinophilia were described who fulfilled the criteria for diagnosis of HIES (Renner et al., 2004). Because affected individuals were siblings with consanguineous parents, the mode of inheritance was concluded to be autosomal recessive

(AR-HIES). This cohort of patients with AR-HIES, in addition to the recurrent bacterial infections characteristic of sporadic and dominant HIES (*Staphylococcus aureus*, *Haemophilus influenzae*, *Proteus mirabilis*, *Pseudomonas aeruginosa*, and *Cryptococcus*), also had severe chronic therapy-resistant *Molluscum contagiosum* infections. Furthermore, 7 of 13 patients suffered recurring herpes simplex infections, which caused mouth ulcerations and also keratitis. One patient suffered recurrent *Varicella zoster*. These patients with AR-HIES demonstrate an increased susceptibility to viral infections. A defect in T cells is thus possible in this cohort, especially given the occurrence of recurrent fungal infections in 10 of 13 patients.

Whereas post-pneumonia pneumatocele formation is pathognomonic in dominant or sporadic HIES, no pneumatoceles occurred in patients with AR-HIES, although pneumonia was equally frequent. This observation differentiates the two types of HIES clinically and may be of use as a differential diagnostic parameter. Autoimmune hemolytic anemia was seen in two patients with AR-HIES, and one patient had a pericardial effusion, possibly an indication of autoimmunity. In the AR-HIES cohort, 7 of 13 patients had neurological symptoms, which varied from partial facial paralysis to hemiplegia. Of these patients, four died of neurologic complications, although the etiology is still not clear. AR-HIES patients did not have the skeletal abnormalities, fractures, dental abnormalities, or dysmorphic faces as seen in dominant or sporadic cases of HIES, further differentiating the AR-HIES variant.

All AR-HIES patients had elevated IgE serum levels and eosinophilia. IgE levels were comparable to those in AD-HIES patients. Furthermore, serum levels of the other immunoglobulin isotypes were also raised, indicating a nonspecific stimulation of the humoral response. The eosinophilia was more severe in AR-HIES patients than in AD-HIES patients; values up to 17,500/ $\mu$ l (normal <700) were reached.

Lymphocyte phenotyping of patients with AR-HIES revealed normal lymphocyte subpopulations, including a normal CD4/CD8 ratio. However, in vitro stimulation of lymphocytes by T cell mitogens and the Cowan strain of *S. aureus* strain (SAC), a T cell-independent mitogen, revealed reduced lymphocyte proliferation. This finding indicates that the cellular defect in AR-HIES is qualitative in nature, a hypothesis supported by the occurrence of viral and fungal infections in AR-HIES. In contrast, granulocyte function seems to be normal in AR-HIES.

Linkage analysis of AR-HIES has been complicated by a high mortality rate in early childhood. The only linkage information available thus far is that more than one genetic locus seems to be responsible for this phenotype.

## Hyper-IgE Overlap Syndromes

Interestingly, in rare cases of other defined genetic diseases, the classical triad of HIES with recurrent skin abscesses, recurrent pneumonia, and extreme elevations of IgE is also fulfilled. Antoniadis et al. (1996), reported the coexistence of HIES and Dubowitz syndrome, defined by postnatal growth retardation, microcephaly, and characteristic facial appearance. Boeck et al. (1999) reported the coexistence of pentasomy X and HIES. Boeck et al. (2001) further reported the coexistence of HIES and Saethre-Chotzen syndrome (defined by acrocephalosyndactyly, hypertelorism, and ptosis), caused by mutations in the *TWIST* gene. The relationships of these patients to those discussed above is unknown.

**Table 34.3.** Treatment Alternatives in Hyper-IgE Recurrent Infection Syndromes

<i>Treatment</i>	<i>Number of HIES Patients</i>	<i>Desired Outcome</i>	<i>Results and Remarks</i>	<i>Reference</i>
Cimetidine	8	Reduce eczema	Modest benefit; at least one clinical relapse after discontinuation	Mawhinney et al., 1980; Thompson and Kumararatne, 1989
Interferon- $\gamma$	5	Reduce IgE	IgE reduction in 2/5; rapid rebound after treatment; thrombocytopenia	King et al., 1989
Cyclosporin A	3	Control eczema	Transient benefit; relapse after discontinuation	Wolach et al., 1996; Etzioni et al., 1997
Cromoglycate	1	Reduce inflammation	Benefit	Yokota et al., 1990
Isotretinoin	1	Reduce dermatitis	Improvement in dermatitis	Shuttleworth et al., 1988
I.V. immunoglobulin	8	Reduce infections	Difficult to assess effect	Kimata, 1995; Espanol and Matamoras, personal communication
Plasmapheresis	3?	Control keratoconjunctivitis	Short-lived improvement	Ishikawa et al., 1982; Dau, 1988; Leung et al., 1988

Therefore, HIES is a complex autosomal disorder with several possible genotypes producing a common phenotype of immunodeficiency, eczema, and elevated IgE. Inspection of different pedigrees suggests that HIES may be caused by mutation of a single gene, mutations in different genes in different families (genetic heterogeneity), or deletion of contiguous genes in a short chromosomal region. Because the genetic backgrounds of our patients are diverse and because survival to reproductive age before the advent of antibiotics has previously been unusual, multiple newly arising mutations are expected.

### Treatment

Aggressive skin care and prompt treatment of infections are the main pillars of HIES management. The dermatitis is heavily dependent on ongoing infection, typically with *Staphylococcus aureus*. Therefore, antibiotic treatment is often an essential part of management of HIES eczema, in association with topical moisturizing creams and topical steroids. We have also used topical antiseptic treatments such as bathing in a dilute bleach solution to reduce the bacterial burden in the skin. Skin abscesses are a common complication of HIES and may require incision and drainage. Interestingly, after the introduction of prophylactic antibiotics, skin abscesses are unusual. The role of prophylactic antibiotics has not been rigorously investigated in this setting, but there is general consensus in favor of their use. Most physicians cover *S. aureus* with a semisynthetic penicillin such as dicloxacillin.

The other major recurrent infectious problem in HIES is mucocutaneous candidiasis. This typically manifests as onychomycosis, vaginal candidiasis, and/or thrush. *Candida* rarely disseminates, and these infections are typically highly responsive to oral triazole antifungals. The use of oral antifungals, such as the triazoles, has made an enormous difference in the prevalence and severity of mucocutaneous candidiasis in HIES. Overuse of antibiotics and antifungals is currently discouraged in general practice because of concerns about selection for resistant organisms. However, there is no clear demonstration of increasingly resistant organisms in HIES patients on prolonged prophylactic and suppressive antibiotic therapy, and the benefits of this approach are readily appreciated.

One remarkable feature of HIES is the enormous infectious burden with which patients often present. By the time the patient or parent is aware of illness, there is usually nothing subtle about

the diagnosis. One of the most difficult problems in the management of HIES is that even in the presence of obvious auscultatory and radiographic evidence of pneumonia, patients do not feel unwell and may be unwilling to submit to invasive diagnostic testing or prolonged courses of therapy. In addition, the hesitance of physicians to believe that patients who appear no different from their baseline are really on the verge of collapse is difficult to overcome.

As in most of medicine, the firm establishment of a microbiologic diagnosis cannot be overemphasized. Bronchoscopy may help in both obtaining the specimen and mobilizing secretions. Thick inspissated secretions typically plug ectatic bronchi and are tenacious and difficult to clear. Lung abscesses may require thoracotomy for adequate drainage or resection. However, thoracotomy and lung resection are more difficult in HIES than in other pulmonary infections because of the common failure of remaining HIES lobes to expand and fill the chest cavity. Surgery often results in a need for very prolonged chest tube drainage, thoracoplasty, or pneumonectomy, along with intensive parenteral antibiotic treatment. Therefore, pulmonary surgery in HIES should not be undertaken lightly, and should be performed at a center with experience with the disease where possible.

High-dose intravenous antibiotics for a prolonged course are required for eradication of infection and to prevent bronchopleural fistula formation and bronchiectasis. Empirical acute coverage should consider *S. aureus*, *H. influenzae*, and *S. pneumoniae*. The former two organisms account for the majority of acute infections. One of the typical features of HIES is that following the resolution of acute pneumonias, pulmonary cysts form. These pneumatoceles then serve as the focus for colonization with *Pseudomonas aeruginosa*, *Aspergillus*, and other fungal species. These superinfections are the most difficult aspect of long-term management of HIES. Potential management strategies include prophylactic itraconazole or voriconazole, aerosolized colistin, or aerosolized aminoglycosides.

The role for immune modulators in HIES is unproven (Table 34.3). Levamisole was tried in a double-blind, placebo-controlled trial, and caused an increase in infectious complications in the treatment arm (Donabedian et al., 1982). This is the only published double-blind, placebo-controlled trial of any management intervention in HIES.

It has been previously supposed that since immunodeficiency is a central part of HIES, the underlying defect in HIES must reside in the leukocytes; thus bone marrow transplantation has

been suggestive as a curative treatment. Two cases of bone marrow transplantation in HIES have been reported (Nester et al., 1998; Gennery et al., 2000). The first was a 46-year-old man with HIES who had experienced many pneumonias from childhood onward. Two of his four children were also affected. He developed a B cell lymphoma that was treated with a peripheral stem cell transplant from his HLA-identical sister, preceded by total body irradiation. He was maintained on prednisolone and cyclosporine A post-transplant. Serum IgE fell to normal values following transplant and no infections were reported. However, he died 6 months later from interstitial pneumonitis.

The second patient was a 7-year-old girl who was transplanted in an effort to treat her severe HIES. She received marrow from a matched unrelated donor after cytoreductive therapy. Cyclosporine A was used for prophylaxis of graft-versus-host disease. Engraftment appeared eventually to be complete by study of peripheral blood markers. Initially, the skin lesions cleared, but 4 years after transplant, she developed recurrent staphylococcal and pseudomonal skin infections. Interestingly, the IgE level also returned to pretransplant elevated levels. This result is particularly surprising in view of the reported full engraftment of the B cell compartment.

This case suggests that the features that led to IgE elevation in this patient may have been somatic, and that the features that made her susceptible to infection may not have been confined to the hematopoietic system. The possible somatic components that might lead to this syndrome are unknown; however, this case reinforces the multisystem nature of the disease and suggests that the cardinal IgE elevation and infectious features that have given the syndrome its name may not be intrinsically immune.

### Acknowledgments

We are indebted to all physicians who contributed data and/or DNA from their patients to facilitate better diagnosis and patient management in HIES and eventually unravel the genetic cause of this enigmatic disease. B.G. was a fellow of the Immune Deficiency Foundation in 1999 and was supported by a grant of the Deutsche Forschungsgemeinschaft (GR1617/2).

# Immunodeficiency with Centromere Instability and Facial Anomalies

R. SCOTT HANSEN, CORRY WEEMAES, and CISCA WIJMENGA

Immunodeficiency with centromere instability and facial anomalies (ICF syndrome) (MIM 242860) is a rare autosomal recessive disease characterized by a variable immunodeficiency, mild facial anomalies, and chromosome instability involving the pericentromeric regions of chromosomes 1, 9, and 16. This disease was reported for the first time in the late 1970s by two groups independently (Hultén, 1978; Tiepolo et al., 1978, 1979). The patient described earlier by Østergaard (1973) also appears to have had ICF syndrome, based on the clinical symptoms and chromosomal abnormalities reported. The acronym *ICF* was suggested in accordance with the characteristic features of the syndrome: *I*mmunodeficiency, *C*entromeric instability, and *F*acial anomalies (Maraschio et al., 1988). Only about 30 ICF patients have been described in the literature thus far, but underdiagnosis of the syndrome is quite possible because of phenotypic variability and infrequent chromosome analysis. Here we summarize the common clinical features of this limited set of patients as well as the molecular defects associated with ICF.

## Clinical and Pathological Manifestations

Although ICF patients have been found all over the world, they are particularly concentrated in the Mediterranean area, including Italy (Tiepolo et al., 1979; Maraschio et al., 1988; Gimelli et al., 1993; Franceschini et al., 1995), Turkey (Wijmenga et al., 2000), Algeria (Fasth et al., 1990), and Lebanon (Björck et al., 2000). Inheritance is autosomal recessive and consanguinity has been found in several ICF families (Østergaard, 1973; Fasth et al., 1990; Bauld et al., 1991; Wijmenga et al., 1998; Björck et al., 2000). Males and females appear to be equally affected and present with similar phenotypes.

## Facial Anomalies

Mild facial dysmorphic features are found in most ICF patients (Color Plate 35.I). In 1978, Hultén described a boy with a peculiar facial appearance characterized by bilateral epicanthus and slight protrusion of the right external ear. The patient of Tiepolo et al. had an epicanthus and low nasal bridge (Tiepolo et al., 1978, 1979; Maraschio et al., 1988). Later on, several dysmorphisms were described, namely macroglossia (Fryns et al., 1981), micrognathia (Howard et al., 1985), and hypertelorism (Carpenter et al., 1988). The characteristic features in ICF syndrome that are currently considered part of the phenotype may include a round face with epicanthus, telecanthus, flat nasal bridge, hypertelorism, up-turned nose, macroglossia, micrognathia, and low-set ears. Many of these features become more obvious during childhood. Dysmorphic features are not always present in adult ICF patients. Turleau et al. (1989) noted facial anomalies and macroglossia in an ICF patient immediately after birth, but such characteristic features can be absent at birth. For example, the brother of the patient described by Smeets et al. (1994) did not show dysmorphic features until the age of 1 year when he presented with a round face and telecanthus (Color Plate 35.I).

## Growth and Development

Most ICF patients have normal birth weight, although some patients have been significantly smaller than normal. Growth retardation occurred in some patients because of a failure to thrive following infections or gastrointestinal problems. Most ICF patients have shown a delay in walking as well as in initial speech. In addition, hypotonia was demonstrated in several patients

**Table 35.1.** Summary of Clinical Features

<i>Facial Anomalies</i>
Round face
Epicanthus
Telecanthus
Hypertelorism
Macroglossia
Flat nasal bridge
Micrognathia
Low-set ears
Up-turned nose
<i>Infections</i>
Lower respiratory tract infections
Otitis media
Failure to thrive
Opportunistic infections
Sepsis
<i>Neurological Problems</i>
Hypotonia
Delay in walking
Delay in initial speech
Intelligence: normal, subnormal, mentally retarded
<i>Gastrointestinal Problems</i>
Malabsorption
Ileus, motility disorder
Vomiting

(Carpenter et al., 1988; Schuffenhauer et al., 1995; Petit et al., 1997). Some ICF children need physiotherapy and/or speech therapy to learn to walk or talk.

The intelligence of ICF patients is quite variable. A few patients have been moderately or severely mentally retarded (Tiepolo et al., 1979; Howard et al., 1985; Gimelli et al., 1993; Schuffenhauer et al., 1995). The initial cytogenetic analysis for some of these patients, however, was performed because they presented with mental retardation and dysmorphisms rather than immunodeficiency. Because the cytogenetic abnormalities associated with ICF are characteristic (see below), the number of mentally retarded and/or dysmorphic ICF children may be over-represented because of ascertainment bias. Because many patients succumb to infections at an early age, little is known about sexual development in ICF individuals. Puberty generally appears to be normal in the few cases followed. A pregnancy has been reported, for example, in one adult female patient, although her older affected brother is azoospermic (G. Gimelli, personal communication).

Infections

Infections are a prominent clinical feature in ICF syndrome, especially respiratory tract infections, which occur in nearly all cases (Table 35.1). Pneumonia, most often caused by *Haemophilus influenzae* or *Streptococcus pneumoniae* (Østergaard, 1973; Howard et al., 1985), is a common disease among ICF children. Bacterial sepsis, due to infection with *Klebsiella*, *Pseudomonas*, or *Staphylococcus aureus*, has occurred in several patients. In addition, opportunistic infections such as *Pneumocystis carinii* (Bauld et al., 1991), cytomegalovirus (CMV) (Fasth et al., 1990), and *Candida albicans* (Valkova et al., 1987; Fasth et al., 1990) frequently occur in ICF patients. One English ICF patient developed poliomyelitis after vaccination with an oral polio vaccine (G. Davies, personal

communication). Despite substitution therapy with immunoglobulin, many ICF patients die from infection at a very young age.

Gastrointestinal Problems

Protruding abdomen has been described in several ICF patients (Fryns et al., 1981; Turleau et al., 1989; Smeets et al., 1994). Failure to thrive is common. Many patients suffer from diarrhea (Valkova et al., 1987; Maraschio et al., 1988; Turleau et al., 1989; Fasth et al., 1990; Smeets et al., 1994) and extended, total parenteral feeding was necessary in three children (Turleau et al., 1989; Smeets et al., 1994). Microorganisms such as *Cryptosporidium* or *Giardia lamblia* were not identified in these patients. Malabsorption was reported for several patients (Fryns et al., 1981; Turleau et al., 1989; Smeets et al., 1994; Petit et al., 1997), and villous atrophy has been demonstrated in some patients (Fryns et al., 1981; Carpenter et al., 1988; Turleau et al., 1989).

Laboratory Findings

Immune Function

One of the characteristic abnormalities in the ICF syndrome is immunodeficiency (Table 35.2). Agammaglobulinemia with normal number of B cells is the most common finding in ICF patients. The immune defect is quite variable, ranging from severe immunodeficiency to a nearly normal immune system. Microarray expression analysis of lymphoblastoid cell lines from ICF patients and controls suggests that mutations of *DNMT3B*, the gene responsible for ICF, cause lymphogenesis associated gene dysregulation by indirectly affecting gene expression; this may interfere with normal lymphocyte signaling, maturation and migration (Ehrlich et al., 2001). From the few families known to have more than one ICF patient, it has been suggested that siblings share a similar immunodeficiency phenotype (Fasth et al., 1990; C. Weemaes, unpublished observations). Immunodeficiency has been found in all but one ICF patient, who was reported to have only a slightly decreased number of CD4 cells (Gimelli et al., 1993). The first ICF patient reported (Hultén, 1978) was originally considered to have common variable immunodeficiency (CVID) with low IgG, IgA, and IgM, reduced numbers of T and B cells, and poor lymphocyte transformation with either phytohemagglutinin (PHA) or pokeweed mitogen (PWM). The ICF patient described the same year by Tiepolo et al. (1978, 1979) had IgA and IgE deficiency. Agammaglobulinemia, a decreased percentage of T cells, and low to normal in vitro lymphocyte proliferation to mitogens was found in others (Fryns et al., 1981; Fasth et al., 1990). Additional patients with agammaglobulinemia and normal B and T cells have subsequently been described (Howard et al., 1985; Smeets et al., 1994; Sawyer et al., 1995).

**Table 35.2.** Summary of Immunologic Features

<i>Humoral Immunity</i>
Absent or low levels of one or more of the immunoglobulins IgG, IgA, and IgM
Disturbance in antibody synthesis
<i>Cellular Immunity</i>
Decreased number of CD3, CD4, and CD8 cells
Impaired lymphoproliferation by PHA, PWM, and antigens
PHA, phytohemagglutinin; PWM, pokeweed mitogen.

**Figure 35.1.** Cytogenetic abnormalities in ICF syndrome.

Lymphopenia with or without inverted CD4/CD8 ratio was reported in some individuals (Gimelli et al., 1993; Franceschini et al., 1995; Pezzolo et al., 2002). Hypogammaglobulinemia and abnormal antibody production to vaccinations and absence of isohemagglutinin were found in two boys with ICF (Franceschini et al., 1995). IgM deficiency, failure to produce antibodies to polysaccharide antigens, but a normal response to protein antigens such as tetanus toxoid and diphtheria toxoid was initially observed in a patient with ICF who subsequently was found to have normal IgM levels and normal isohemagglutinin titers; antibodies to *H. influenzae*, however, remained absent (Østergaard, 1973, 1977).

### Cytogenetic Abnormalities

Aberrations of chromosomes 1 and/or 16 involving their heterochromatic pericentromeric blocks can be observed at high frequency in cultures of peripheral blood lymphocytes from ICF patients (Fig. 35.1). These aberrations can be recognized as gaps, breaks, deletions, isochromosomes, multiradial figures, interchanges between pericentromeric regions, and multiradial configurations. Two short arms of chromosomes 1 and 16 are present in all aberrant cells, with a varying number of long arms. These findings suggest that breaks occurred just below the centromere within the heterochromatic region on the proximal long arm (Haas, 1990). Similar aberrations involving chromosome 9 (Tiepolo et al., 1979; Fryns et al., 1981; Valkova et al., 1987) and, rarely, chromosomes 2 (Valkova et al., 1987) and 10 (Turleau et al., 1989) have also been reported.

The overall frequency of ICF cells with chromosomal aberrations increases with culture time (Tiepolo et al., 1979; Maraschio et al., 1988; Smeets et al., 1994), although the opposite has also been reported (Turleau et al., 1989). Moreover, aberrations become more complex with increasing time in culture (Hultén, 1978; Tiepolo et al., 1979; Howard et al., 1985; Smeets et al., 1994). Interphase nuclei consistently show an increased number of micronuclei and/or nuclear protrusions (Fasth et al., 1990; Maraschio et al., 1992). Fluorescence in situ hybridization (FISH) studies have clearly demonstrated that portions of chromosomes 1 and 16 are present in these micronuclei (Maraschio et al., 1992;

Smeets et al., 1994). Cultured peripheral blood lymphocytes always display numerous aberrations, whereas other tissues, such as cultured fibroblasts, Epstein-Barr virus (EBV)-transformed B cells, and bone marrow cells, usually show much fewer, if any, aberrant cells. When aberrations are present in such cells, they are usually reduced in complexity compared to those seen in lymphocytes (Howard et al., 1985; Maraschio et al., 1989; Turleau et al., 1989; Fasth et al., 1990; Gimelli et al., 1993).

### Hypomethylation

Another diagnostic feature of ICF syndrome is hypomethylation of classical satellite repeats. The cytogenetic abnormalities seen in lymphocytes are quite similar to those found in normal cells treated with DNA demethylation agents such as 5-azacytidine (Viegas-Pequignot and Dutrillaux, 1976; Schmid et al., 1984). A defect in DNA methylation in ICF patients was therefore proposed (Maraschio et al., 1988). It has since been demonstrated by Southern blot analysis that the pericentromeric classical satellites involved in the 5-azacytidine-induced abnormalities in normal cells are indeed abnormally hypomethylated in ICF cells (Jeanpierre et al., 1993; Hassan et al., 2001). The pericentromeric satellite regions on chromosomes 1q and 16q are large heterochromatic regions comprised mainly of satellite 2 repeats. The analogous region on chromosome 9q contains a large concentration of satellite 3 repeats. The frequency of CpG dinucleotides at these loci is higher than that for most of the genome and they are normally hypermethylated in somatic cells, as evidenced by their resistance to digestion with methylation-sensitive restriction enzymes such as HpaII and BstBI. In ICF cells, however, these sequences are extensively digested with such enzymes, suggesting extreme undermethylation. These restriction enzyme-based data are largely supported by bisulfite methylation analysis of satellite 2 sequences, although hypomethylation of these sequences is not complete in ICF cells (Hassan et al., 2001).

The methylation status of other regions of the genome has also been examined in ICF cells. Genome-wide methylation is generally unaffected (Ji et al., 1997; Kondo et al., 2000), whereas undermethylation of other heterochromatic regions such as the

CpG islands of the inactive X (Miniou et al., 1994; Bourc'his et al., 1999; Hansen et al., 2000) and certain other CpG-rich repetitive elements (Kondo et al., 2000) is frequently observed.

## Molecular Basis

### Localization of the Defective Gene

Several ICF families have been described with multiple affected siblings, a finding suggesting a strong genetic basis for the syndrome (Valkova et al., 1987). That some of the ICF patients came from consanguineous marriages is consistent with autosomal recessive transmission (Valkova et al., 1987). The extremely rare occurrence of the ICF syndrome and the existence of affected inbred individuals made the localization of the ICF gene a suitable target for homozygosity mapping. This mapping approach is based on the inheritance of two identical copies of the disease locus by the affected inbred child from a common ancestor—i.e., homozygosity by descent (Lander and Botstein, 1987). Wijmenga et al. (1998) performed homozygosity mapping in three consanguineous ICF families: one of Dutch ancestry, and two that were Turkish. The Dutch ICF family included two affected brothers whose parents had common ancestors five generations previously; an initial genome-wide scan of this family was used to find regions that were homozygous and shared between the two affected sibs. Inclusion of the other two consanguineous families confirmed and delimited a 9 cM region on chromosome 20q11–q13 that was homozygous in all four affected inbred individuals (Wijmenga et al., 1998).

The chromosomal localization of the ICF gene to chromosome 20 was the first step in the positional cloning approach. Traditionally, the candidate region had to be narrowed down by analysis of additional ICF families, followed by cloning the region into workable pieces that would allow the isolation of genes and subsequent mutation analysis. A function-based, candidate gene approach, however, has increasingly become more attractive since chromosome-specific sequence data have become available from the Human Genome Project, including those from chromosome 20.

### Identification of *DNMT3B* as the ICF Gene

Although the etiology of ICF syndrome was initially not clear, the hypomethylation observed in ICF patients suggested a role for DNA methylation in this disorder (Jeanpierre et al., 1993). This hypothesis was further substantiated by the observation that the cytogenetic abnormalities in ICF syndrome could be complemented by fusion of ICF cells to normal cells (Schuffenhauer et al., 1995). Cell fusion also led to a partial restoration of the *de novo* methylation of ICF satellite 2 and 3 sequences (Hansen et al., 1999), presumably through the activity of a functional *de novo* DNA methyltransferase from the non-ICF cell. Although there were no *de novo* DNA methyltransferase genes known to exist in the human genome at that time, two DNA methyltransferases (MT3 $\alpha$ , encoded by *Dnmt3a*, and MT3 $\beta$ , encoded by *Dnmt3b*) with *de novo* activity had been identified in the mouse (Okano et al., 1998). Because of the strong evolutionary conservation between humans and mice, it was tempting to speculate that these genes would also exist in the human genome. A search of the raw sequence data from human chromosome 20 for the presence of a DNA methyltransferase gene led to the identification of a gene highly homologous to murine *Dnmt3b*. The *DNMT3B* gene was localized to 20q11 (by FISH and radiation

hybrid mapping) within the 9 cM region to which the ICF gene had been localized previously. Mutations of this gene in ICF patients confirmed that *DNMT3B* was indeed a gene responsible for ICF syndrome (Hansen et al., 1999; Okano et al., 1999a; Xu et al., 1999).

### Gene Structure and Mutational Analysis

The *DNMT3B* gene spans a region of about 50 kb and encodes a transcript of 4.3 kb representing 22 coding exons (Xie et al., 1999). Alternative splicing of the gene leads to at least five isoforms: DNMT3B1, DNMT3B2, DNMT3B3, DNMT3B4, and DNMT3B5 (Hansen et al., 1999; Robertson et al., 1999). DNMT3B expression can be detected in several tissues, but occurs at much higher levels in testis and thymus. The C-terminal region of the protein contains five highly conserved DNA methyltransferase motifs (I, IV, VI, IX, and X) (Xie et al., 1999) and a motif (VIII) with a much weaker similarity (Hansen et al., 1999). Functions for these motifs in the transmethylation reaction, such as cofactor binding, is inferred from crystallography data for other methyltransferases. The N-terminal region of MT3 $\beta$  contains a cysteine-rich domain that shows homology to the zinc finger helicase region found in the ATRX protein (Picketts et al., 1996) that might mediate protein–protein or protein–DNA interactions. Closer to the N terminus of MT3 $\beta$  is a PWWP domain that may also be involved in protein–protein interactions (Stec et al., 2000) but has subsequently been shown to bind DNA (Qiu et al., 2002). Recent reports suggest that DNMT3B binds non-specifically to DNA via the PWWP domain (Chen et al., 2004) and that the PWWP domain is essential for targeting methyltransferase to pericentric heterochromatin in mammalian cells (Chen et al., 2004; Ge et al., 2004).

From the limited number of ICF patients who have been subjected to mutation analysis, 19 different mutations have been discovered in 17 ICF patients from 15 families (Fig. 35.2) (Hansen et al., 1999; Okano et al., 1999a; Xu et al., 1999; Wijmenga et al., 2000; Shirohzu et al., 2002). ICF mutations can be divided into three classes: (1) nonsense mutations that occur early in the transcript, (2) missense and splice site mutations in the methyltransferase catalytic domain, and (3) a missense mutation near the PWWP domain. While the nonsense mutations are not expected to result in protein, the second class of mutations leads to proteins with compromised catalytic activity (Xu et al., 1999; Gowher and Jeltsch, 2002). The missense mutation found within the PWWP domain in a Japanese ICF family (Shirohzu et al., 2002) suggests an important role for this motif in MT3 $\beta$  function. This prediction was confirmed experimentally by demonstrating that the protein with the naturally occurring mutation (S270P), located in the PWWP domain, completely loses its chromatin targeting capacity (Ge et al., 2004). Studies in mice (Okano et al., 1999b) have shown that complete MT3 $\beta$  deficiency is embryonically lethal; such lethality might also apply to humans. Consistent with the retention of some essential MT3 $\beta$  activity in ICF patients, all three predicted null mutations described thus far are accompanied by a missense mutation in the other allele (Xu et al., 1999; Wijmenga et al., 2000). Bisulfite methylation studies of ICF cells also support residual methyltransferase activity for missense mutant enzymes (Hassan et al., 2001). Furthermore, some of the missense mutations have been shown to produce proteins with significant methyltransferase activity *in vitro* (Gowher and Jeltsch, 2002).

Given the rarity of the disease and the finding of consanguinity in some ICF families, the early prediction was that most ICF

**Figure 35.2.** The *DNMT3B* gene and known ICF mutations. (Codon numbers for mutations refer to the largest isoform, 3B1 (genBank accession no. AF156488) (Hansen et al., 1999). Data presented are from Wijmenga et al. (2000), Xu et al. (1999), and Shirohzu et al. (2002).

cases would involve homozygous mutations derived from a limited number of founders. We now know, however, that only 8 of 17 ICF patients had homozygous mutations and that these all differed from each other, thus the majority of *DNMT3B* mutations may have arisen from several unique events. Alternatively, it is possible that the number of gene carriers—and, in turn, the number of potential ICF patients—is much larger than expected; some mutations may be incompatible with life in certain heterozygous combinations, while others may lead to extremely mild phenotypes that have not been connected to the ICF syndrome. Phenotype–genotype relationships have not been determined yet because of the limited set of patients with known mutations, many of which are compound heterozygotes. In addition, phenotypic variability is likely for any given mutation because the corresponding molecular defects are predicted to derive from epigenetic abnormalities that are intrinsically quite variable.

### Genetic Heterogeneity

There are at least six ICF patients in which no *DNMT3B* mutation has been found (Wijmenga et al., 2000). Interestingly, at least two of these ICF2 patients are from consanguineous families but do not show homozygosity for the *DNMT3B* gene region on chromosome 20. This observation raises the intriguing possibility that the ICF syndrome is a genetically heterogeneous disorder in which more than one gene is involved in the disease etiology. It is now clear that the spectrum of hypomethylation defects is different in non-*DNMT3B* ICF cases. Although classical satellites are hypomethylated in both types of ICF, other regions, such as  $\alpha$  satellites (Jiang et al., 2004), are only hypomethylated in ICF2 cases. Hypomethylation of the inactive X is more pronounced in *DNMT3B* cases (R.S. Hansen, unpublished observations). Localization of the ICF2 gene will probably require additional mapping studies. One complication is that non-*DNMT3B* ICF may also be heterogeneous because satellite 2 methylation levels differ among such cases (Hassan et al., 2001; Kubota et al., 2004).

### Functional Aspects of the *DNMT3B* Gene

Genetic information, encoded by DNA sequences, is modulated by “epigenetic modification,” which includes DNA methylation, demethylation, methyl-CpG-recognition, histone modification, and chromatin remodeling (Fitzpatrick and Wilson, 2003; Teitell and Richardson, 2003). Although we know that DNA methylation

plays important roles in vertebrate genome structure and expression, our understanding of how genomic methylation patterns are established and maintained is limited (Colot and Rossignol, 1999). The selective hypomethylation of heterochromatic regions in ICF cells may provide a model to explain these phenomena and guide us to the genes affected by this undermethylation that are involved in the ICF phenotype.

The primary defects leading to phenotypic consequences in ICF are predicted to result from abnormal escape from transcriptional silencing due to lack of methylation by MT3 $\beta$ . Hypomethylation and escape from silencing in ICF cells have been demonstrated for certain genes on the inactive X chromosome (Hansen et al., 2000; Gartler and Hansen, 2002; Tao et al., 2002; Hansen, 2003), the Y chromosome (Hansen et al., 2000), an autosomal repetitive element (Kondo et al., 2000), and an autosomal cancer-testis gene (Tao et al., 2002). In many cases hypomethylation in the promoter region is not sufficient for escape to occur because silencing is maintained by inactive histone modification, unless accompanied by advanced replication (Hansen et al., 2000; Gartler et al., 2004). Although it is not clear how these particular genes could be responsible for the ICF phenotype, it is likely that a similar mechanism is responsible for genes that do play key roles in facial development and the immune system. Abnormal gene regulation could also result from hypomethylation at pericentromeric regions or other repetitive, CpG-rich regions by a mechanism similar to the phenomenon of position-effect variegation found in yeast, *Drosophila*, and mammalian systems (Kleinjan and van Heyningen, 1998; Wakimoto, 1998). Genes of this type would be affected in *cis* because they are within or near repetitive regions that are normally hypermethylated and late replicating. In addition to transcriptional regulation abnormalities, immunoglobulin deficiency in ICF could potentially result from a failure to achieve productive germ-line rearrangements critical to B and T cell development because of hypomethylation within the rearrangement loci (Engler et al., 1993; Mostoslavsky et al., 1998; Whitehurst et al., 2000). This could lead to defective B cell differentiation, lack of memory B cells, and impaired B cell negative selection (Blanco-Betancourt et al., 2004).

In the immune system alone, the list of potential candidate genes for misregulation with ICF-like consequences is quite long (Fitzpatrick and Wilson, 2003; Teitell and Richardson, 2003). One hope for finding key genes involved in ICF is the cDNA microarray approach for large-scale studies of gene expression in normal and ICF cells. Such data may help to identify key pathways affected in ICF that might be targeted for therapeutic intervention. A similar problem exists for understanding the

bases of phenotypic abnormalities associated with Rett syndrome; the gene defective in these patients codes for a protein, MECP2, that recognizes methylated DNA and acts as a transcriptional repressor (Amir et al., 1999).

### Animal Model

Additional evidence that MT3 $\alpha$  and MT3 $\beta$  do, indeed, have de novo methyltransferase activity came from studies in mice in which both genes were inactivated by homologous recombination (Okano et al., 1999a). The expression level of *Dnmt3a* and *Dnmt3b* are extremely high in undifferentiated embryonic stem cells but are rapidly down-regulated after differentiation and found at much lower levels in adult somatic tissues. Both *Dnmt3a* and *Dnmt3b* appear to be essential for mouse development, as the *Dnmt3b*<sup>-/-</sup> mice die before postconception day 11.5 and the *Dnmt3a*<sup>-/-</sup> mice die perinatally. The *Dnmt3a* and *Dnmt3b* genes exhibit some overlapping methylation target sites, but *Dnmt3b* deficiency specifically decreases methylation at pericentromeric minor satellite repeats, similar to the hypomethylation seen in ICF syndrome patients at analogous satellite repeats. Further studies of this model and of future conditional mutations and “knock-in” or transgene ICF mutations should help to elucidate the mechanisms underlying the ICF phenotype.

### Strategies for Diagnosis

Without chromosome studies, most patients with ICF syndrome would be classified as suffering from CVID, according to the World Health Organization (WHO) classification for primary immunodeficiencies. ICF syndrome should be considered, therefore, for all patients with B cell–positive agammaglobulinemia or CVID without a known gene defect, even when facial anomalies are absent. A history of delayed milestones, such as walking and speech, is also suggestive of ICF syndrome. Diagnosis of ICF syndrome can be made by cytogenetic analysis and Southern blot analysis of satellite methylation. Direct confirmation of ICF can be expected to be obtained in about 70% of cases by performing mutation analysis of the *DNMT3B* gene (Wijmenga et al., 2000).

#### Prenatal Diagnosis

Prenatal diagnosis of ICF syndrome by linkage analysis has recently been performed in a Lebanese family that already had an ICF syndrome child. The family structure contained two consanguineous marriages and the proband was found to be homozygous for the ICF gene region. The fetus was heterozygous, and the couple was counseled that there was a more than 90% probability that the fetus would be unaffected, the uncertainty being due to the possibility of genetic heterogeneity (Björck et al., 2000). The couple decided to continue the pregnancy and a healthy boy was born. A homozygous *DNMT3B* mutation was demonstrated in the proband (Wijmenga et al., 2000), thus confirming the prenatal linkage analysis. In the future, the identification of *DNMT3B* mutations in ICF patients through direct mutational analysis will enable more accurate genetic counseling for their families.

### Treatment and Prognosis

Nearly all ICF patients receive regular infusions of immunoglobulins. This treatment reduces the severity and frequency of infec-

tions in most patients. In spite of treatment, however, at least 10 patients have died in infancy or in childhood because of infections (Fryns et al., 1981; Valkova et al., 1987; Fasth et al., 1990; C. Weemaes, unpublished observations). Most of these patients suffered from agammaglobulinemia with some T cell defect, but a patient with only IgA deficiency also died at a young age (11 years) (Tiepolo et al., 1979).

Opportunistic infections with *Pneumocystis carinii* resulting in interstitial pneumonia (PCP), CMV, and *Candida* have been described (Valkova et al., 1987; Fasth et al., 1990; Bauld et al., 1991). Prophylactic use of trimethoprim-sulfamethoxazole to prevent PCP may be indicated, even when a T cell defect has not been demonstrated.

Bone marrow transplantation (BMT) should be considered in patients suffering from infections and failure to thrive. BMT was successful in two ICF patients with agammaglobulinemia (Gennery et al., 2004). The first patient had agammaglobulinemia, recurrent respiratory chest infections, and persistent norovirus diarrhea and poliovirus type 2 excretion associated with failure to thrive. Following partial conditioning with Alemtuzumab, Fludarabine, and Melphalan, she received marrow from an unrelated donor. At 18 months follow-up, the viruses had cleared, her weight had increased from below the first to the 25th percentile, T cell numbers were normal, B cell counts were low, and she remained on IVIG. The second patient presented with agammaglobulinemia and developed persistent diarrhea and intestinal ileus following *Campylobacter* infection at the age of 2 years. He received bone marrow from an HLA-identical sibling after a conditioning regimen consisting of busulfan and cyclophosphamide. He had normal T and B cell reconstitution and produced immunoglobulins 6 months after BMT. He is doing well without infections or intestinal problems. Because B cells are defective in ICF syndrome (Blanco-Betancourt et al., 2004), it is important to consider an extensive conditioning regimen to achieve not only T cell but also B cell reconstitution. Further investigation with mouse models should help to evaluate the efficacy of potential therapies.

### Concluding Remarks

On the basis of our current knowledge, it is likely that a compromised MT3 $\beta$  methyltransferase leads to hypomethylation of specific chromosomal loci, de-heterochromatinization, advanced replication, and transcriptional activation of key genes whose misregulation affects facial and lymphocyte development. Discovery of such genes should further our understanding of the ICF phenotype and of the normal role of MT3 $\beta$  in methylation-dependent transcriptional regulation. Examination of the molecular properties of MT3 $\beta$  and its potential interacting proteins will help explain its apparent specificity for methylating heterochromatic regions and provide candidate genes that might be mutated in non-*DNMT3B*, ICF2 patients. Although the syndrome appears to be quite rare, increased ascertainment may develop as awareness of ICF increases and diagnosis of immunodeficiency includes more cytogenetic and/or methylation studies. Rare or not, the ICF syndrome provides one of the first examples of a human disease whose major defect alters the epigenetic structure and regulation of the genome and thus provides us with an excellent model system for study. Because proper epigenetic regulation is crucial for development and differentiation, explication of the epigenetic alterations in ICF and their functional consequences should have implications for a large spectrum of human disease.

# Immunodeficiencies with Associated Manifestations of Skin, Hair, Teeth, and Skeleton

MARIO ABINUN, ILKKA KAITILA, and JEAN-LAURENT CASANOVA

In several complex syndromes associated with immunodeficiency (reviewed by Ming et al., 1996, 1999), immunological defects are combined with abnormalities of the skin, hair, and teeth. Most of these conditions, such as the Chediak-Higashi syndrome, Griscelli syndrome, Kozart syndrome, Wiskott-Aldrich syndrome, Omenn syndrome, and dyskeratosis congenita, have been reviewed (Ming et al., 1996, 1999; Pignata et al., 2001) and are discussed in other chapters in this book (see Chapters 12, 29, 33–35, 40, and 41). A mutation in the human ortholog of the *nude/whn* gene (Frank et al., 1999; Pignata et al., 2001) has been identified in only one family and thus will not be reviewed here. We will focus on two syndromes associated with skin, hair, dental, and skeletal anomalies: anhidrotic ectodermal dysplasia with immunodeficiency (EDA-ID), and cartilage-hair hypoplasia (CHH).

## Anhidrotic (Hypohidrotic) Ectodermal Dysplasia with Immune Deficiency

### Description and Historical Overview

The main clinical features of anhidrotic (hypohidrotic) ectodermal dysplasia (EDA) include hypo- or anodontia with conical-shaped maxillary incisors, dry skin with hypo- or anhidrosis, and hypo- or atrichosis. In addition, most patients suffer from recurrent but mainly benign respiratory tract infections (Clarke et al., 1987). Historically, the most common immunological abnormality reported in these patients has been dysgammaglobulinaemia with low immunoglobulin (Ig) G and low or elevated IgM levels (Franken, 1966; Davis et al., 1976; Huntley and Ross, 1981; Clarke, et al., 1987). Although some patients have been described with unusually severe infections due to different microorganisms, including pseudomonas and mycobacteria (Frix and Bronson, 1986; Sitton and Reimund, 1992; Smythe et al., 2000), the syn-

drome *immunodeficiency associated with ectodermal dysplasia* was classified only recently as an independent primary immunodeficiency (World Health Organization, 1999). However, without consistent humoral or cellular immune functional defects and no clear mode of inheritance, this syndrome has not always been recognized as an autonomous disorder (Abinun, 1995). For instance, it was still not recognized in the 12th edition of McKusick's *Catalog of Mendelian Inheritance of Man* in 1998.

A small number of male patients with classical features of EDA have been reported with severe, life-threatening infections with pyogenic bacteria such as *Streptococcus pneumoniae* and *Staphylococcus aureus* (Abinun et al., 1996; Schweizer et al., 1999). All had associated specific polysaccharide antibody deficiency, pointing toward the possibility of a distinct recessive X-linked entity resulting in EDA with impaired antibody response to polysaccharides (XL-EDA-ID). The nature of this association is not clear and a transient maturational delay or a persistent selective impaired response to polysaccharide antigens could be the explanation, as had been proposed for children without features of EDA who suffer from recurrent respiratory infections (Rijkers et al., 1993; Sanders et al., 1993). Progressive immunoglobulin deficiency may develop in some of these patients, however, and recently a mutation in *Btk* (Bruton's tyrosine kinase) has been reported as one of the underlying causes (Wood et al., 2001).

Recent progress has been made in our understanding of the molecular basis of the related syndromes of EDA without immune deficiency (ID) (Priolo and Lagana, 2001). Mutations in *EDA*, the gene encoding for ectodysplasin-A (Eda), a transmembrane protein required for development of ectodermal appendages, cause the X-linked form of EDA (MIM \*305100) (Kere et al., 1996; Monreal et al., 1998). This protein is a member of the tumor necrosis factor (TNF) family of proteins (Copley, 1999; Ezer et al., 1999). Both the autosomal dominant (MIM 129490) and

the autosomal recessive (MIM 224900) forms of EDA, by contrast, are caused by mutations in the *EDAR* gene (MIM \*604095) (originally *DL* corresponds to the mouse downless [*dl*] phenotype) on chromosome 2 (Monreal et al., 1999). The protein encoded by this gene acts as a receptor for Eda (EDAR) and is a member of TNF receptor (TNFR) family of proteins, so these two proteins function as receptor and ligand in a common signaling pathway (Kumar et al., 2001).

The breakthrough in our understanding of the association of EDA and immunodeficiency came with the recent description of a surviving male patient from a family affected by X-linked incontinentia pigmenti (IP) (MIM 308300) due to a mutation in the *NEMO* (NF-κB Essential *MOD*ulator) or *IKBG* (Inhibitor of *Kappa* light polypeptide gene enhancer in *B* cells, kinase, *Gamma*) gene (MIM 300248) (Smahi et al., 2000). This gene is essential for intact NF-κB activation, which plays a central role in the inhibition of apoptosis, host defense, and inflammatory responses (Karin and Lin, 2002). The germ-line loss-of-function mutations in *NEMO* are lethal in male fetuses affected by familial IP, an X-linked dominant syndrome. This surviving male, however, and subsequently described male patients (Smahi et al., 2000; Zonana et al., 2000; Aradhya et al., 2001; Doffinger et al., 2001; Jain et al., 2001; Mansour et al., 2001; Dupuis-Girod et al., 2002), have milder *NEMO* mutations that impair but do not abolish NF-κB signaling. Different hypomorphic mutations of *NEMO* cause two distinct XL allelic syndromes of IP: missense mutations in the coding region are associated with the EDA-ID phenotype (MIM 300291), whereas stop codon mutations cause a clinically more severe syndrome that includes features of osteopetrosis and/or lymphoedema (OL-EDA-ID) (MIM 300301). Here we will review the syndromes of XL-EDA-ID and XL-OL-EDA-ID, associated with *NEMO* mutations, excluding other forms of EDA-ID of unknown molecular basis.

Clinical and Pathological Manifestations

The main developmental features are those of EDA, although they are somewhat milder than those in children with “classical” EDA without immunodeficiency, and most patients have normal or sparse scalp hair. Of 33 patients from 23 kindreds reported to date (Table 36.1), 2 unrelated children manifested a more severe phenotype with features including osteopetrosis and lymphedema—i.e., OL-EDA-ID (Smahi et al., 2000; Doffinger et al., 2001; Mansour et al., 2001; Dupuis-Girod et al., 2002). Two related

children from another kindred have been described with EDA-ID and increased bone density (Zonana et al., 2000), a finding suggesting that osteopetrosis could be a variable clinical part of this syndrome. Only in a few of the reported mothers of affected boys in EDA-ID kindreds had variable features of EDA or IP (dry and/or hyperpigmented skin, hypodontia, conical teeth) and elevated IgA levels, whereas mothers of both children with the OL-EDA-ID phenotype showed mild features of IP.

Affected boys suffer in early childhood from unusually severe, life-threatening, and recurrent bacterial infections of the lower respiratory tract, skin and soft tissues, bones, and gastrointestinal tract; meningitis; and septicemia. The causative pathogens have most often been gram-positive bacteria (*Streptococcus pneumoniae*, *Staphylococcus aureus*), followed by gram-negative bacteria (*Pseudomonas* species, *Haemophilus influenzae*) and mycobacteria (Table 36.1). Interestingly, two children had *Pneumocystis jiroveci* infection and two others had severe adenovirus and cytomegalovirus (CMV) infections, which suggest a more profound and combined immunodeficiency. The two children with XL-OL-EDA-ID had a particularly severe phenotype, as they acquired *Mycobacterium* infections in the first year of life and died. A comprehensive description of the clinical features of children with XL-EDA-ID and XL-OL-EDA-ID is not yet available, but an international survey has been undertaken. Data in Table 36.1 are based exclusively on material published by authors cited above.

Laboratory Findings

An international survey has been undertaken to describe the immunologic abnormalities of patients carrying mutations in *NEMO*. Data in Table 36.2 are based on the available literature. B cell abnormalities are the predominant feature of the routine immunologic work-up. Most patients have hypogammaglobulinemia with a low IgG (and IgG2) level in serum, while the levels of other immunoglobulin isotypes (IgA, IgM, and IgE) vary. Occasionally, patients with EDA-ID may have markedly elevated serum IgA levels, possibly as a consequence of recurrent respiratory infections. A number of patients with EDA-ID have been described with elevated serum IgM levels (the hyper-IgM phenotype) (Zonana et al., 2000; Doffinger et al., 2001; Jain et al., 2001). However, despite normal CD40 ligand (CD154) expression on

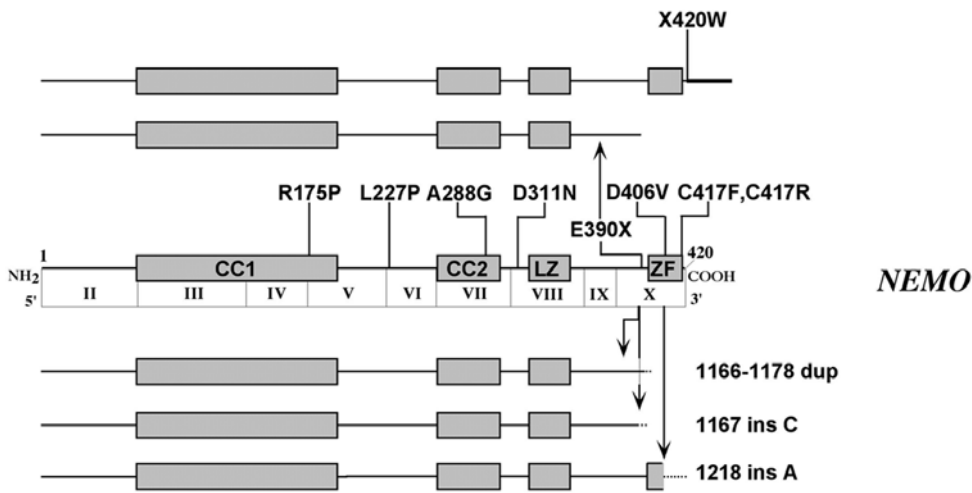

**Table 36.1.** Clinical Features of Anhidrotic Ectodermal Dysplasia with Immune Deficiency

Features of Anhidrotic Ectoderma Dysplasia	Reccurent Severe Bacterial Infections*
Inability to sweat and dry skin	Pneumonia
Delayed dentition and conical teeth	Cellulitis, abscesses
Sparse scalp hair (variable)	Meningitis
Family history of EDA or IP (mothers, variable)	Septicemia
	Gastroenteritis
Other Features	Complications
Osteopetrosis	Bronchiectasis and chronic lung disease
Lymphoedema	Intractable diarrhea and failure to thrive

\*Bacteria include *Streptococcus pneumoniae*, *Staphylococcus aureus*, *Pseudomonas* species, *Haemophilus influenzae*, and mycobacteria.

**Table 36.2.** Laboratory Findings (Routine Immunology Tests) of Anhidrotic Ectodermal Dysplasia with Immune Deficiency

Usually Found
Hypogammaglobulinemia (IgG, IgG2; occasionally IgA, IgM, IgE)
Elevated levels of IgM (often)
Elevated levels of IgA (often)
Absent or low isohemagglutinin titers
Absent or low specific antibody levels to polysaccharide antigens (after naturally occurring <i>S. pneumoniae</i> infection or post-Pneumovax)
Deficient NK cell cytotoxicity (K562 killing) (in some patients)
Normal
Peripheral blood lymphocyte numbers and subpopulations (CD3 <sup>+</sup> , CD3/4 <sup>+</sup> , CD3/8 <sup>+</sup> , CD19 <sup>+</sup> , CD3 <sup>+</sup> /16 <sup>+</sup> /56 <sup>+</sup> )
CD40 ligand expression
T cell function (mitogen- and antigen-induced proliferation)
Neutrophil and complement function
Specific antibody levels to protein antigens
Antibody-dependent cell cytotoxicity (ADCC)

**Figure 36.1.** *NEMO* mutations associated with XL-OL-EDA-ID and XL-EDA-ID. The human *NEMO* protein is shown with the mutations identified in kindreds with EDA-ID and OL-EDA-ID. X420W leads to a predicted 27-amino acid elongated protein. Frameshift insertions, such as 1167insC and 1218insA, cause premature stops. The predicted out-of-frame protein sequence is shown by a dotted line. The structural domains of *NEMO* are indicated: coiled coil (CC1 and CC2), leucine zipper (LZ), and zinc finger (ZF).

their activated T cells and CD40 expression on B cells, their B cells were not able to proliferate (Doffinger et al., 2001), express surface CD27, or up-regulate CD54 expression when stimulated with trimeric CD40 ligand (Jain et al., 2001). They were capable of IgE production and expression of CD23 (Doffinger et al., 2001). These experiments show that some but not all CD40-mediated signals are *NEMO*-dependent in B cells. B cells have kept an intrinsic ability to switch in response to CD40L, but impairment of proliferation and activation results in a hyper-IgM-like phenotype in some patients. The impaired antibody response to polysaccharide antigens, with low specific antibodies after infection caused by *S. pneumoniae* or post immunization with polyvalent pneumococcal polysaccharide vaccine, and low isohemagglutinin titers are the most consistent laboratory features (Table 36.2).

In contrast to these B cell abnormalities, patients with XL-EDA-ID and XL-OL-EDA-ID have normal T cell proliferation to mitogens and antigens. Recently, three new patients with XL-EDA-ID and deficient CD40 signaling were described with deficient natural killer (NK) cell cytotoxicity (deficient K562 killing); however, their peripheral blood NK cell numbers and antibody-dependent cell cytotoxicity (ADCC) were normal (Orange et al., 2002).

### Molecular Basis

Because not all investigated families with the X-linked form of EDA have mutations of *EDA* and no immunodeficiency has been seen in most families with known *EDA* mutations (Monreal et al., 1998), different mechanisms may be involved in development of skin and the immune system to be involved in. Indeed, the importance of NF- $\kappa$ B activation has been shown to be linked with the EDA/EDAR pathway. Whereas EDAR binds the EDA-1 isoform of the ectodysplasin receptor protein, an X-linked form of the receptor (XEDAR; MIM \*300276) binds EDA-2 isoform and causes activation of NF- $\kappa$ B through binding of TNF receptor-associated factor-6 (TRAF6) (Yan et al., 2000). Final evidence of the role of NF- $\kappa$ B activation in the pathogenesis of this syndrome was shown when the International Incontinentia Pigmenti Consortium (IIPC) demonstrated that loss-of function mutations in *NEMO* cause X-linked dominant IP and that the most common one (~80% of new mutations) is a genomic rearrangement resulting in deletion of part of the gene (exons 4–10). The conse-

quence is loss of *NEMO* (IKBKG) function (vide infra) and lack of NF- $\kappa$ B activation (Aradhya and Nelson, 2001; Courtois et al., 2001). These features in turn result in extreme susceptibility to apoptosis and lead to embryonic death in males. The clinical features and extremely skewed X inactivation seen in females with IP are also explained by these deficiencies (Smahi et al., 2000). The finding of another, different mutation of *NEMO* affecting the stop codon in a surviving male (Table 36.1 and Fig. 36.1) raised the question of whether this milder phenotype is the result of partial loss of *NEMO* function.

Indeed, several groups have subsequently reported different mutations in both previously described (Sitton and Reimund, 1992; Abinun et al., 1996; Schweizer et al., 1999; Doffinger et al., 2001) and newly diagnosed patients (Zonana et al., 2000; Aradhya et al., 2001; Doffinger et al., 2001; Jain et al., 2001) with association of EDA and immunodeficiency (Table 36.1). Both the original patient (Doffinger et al., 2001; Smahi et al., 2000; Mansour et al., 2001), now diagnosed as allelic OL-EDA-ID phenotype rather than IP, and another unrelated patient (Doffinger et al., 2001; Dupuis-Girod et al., 2002) had the hypomorphic X420W stop codon mutation. Sequence analysis in four families (Zonana et al., 2000) revealed mutations in exon 10 (MIM 300248.0007-300248.0010) affecting the C terminus of the *NEMO* protein, a domain believed to connect the I $\kappa$ B kinase (IKK) signaling complex to upstream activators. In this group, two boys from the same kindred had features of subclinical osteopetrosis, but not lymphedema, associated with EDA-ID. The frameshift mutation in exon 10 at codon 390 (1167–1168insC) resulted in a premature stop at codon 394. However, another described patient with the same mutation had no features of osteopetrosis (Doffinger et al., 2001). The nonsense mutation at codon 391 (E391X), resulting in truncated protein and 1218insA frameshift mutation, both in exon 10, as well as the previous two mutations, leads to prevention of translation (Doffinger et al., 2001) or deletion (Zonana et al., 2000) of the *NEMO* C-terminal zinc-finger domain. A number of other missense mutations have been reported (Doffinger et al., 2001; Orange et al., 2002), but the vast majority occurred in exon 10 and almost half of these affect cysteine 417, a key residue of the C-terminal zinc-finger domain of *NEMO* (Zonana et al., 2000; Doffinger et al., 2001).

Similar mutations C417R and N406V in the putative zinc-finger motif of *NEMO*, a potentially shared intracellular signaling component for DL (EDAR) and CD40L, were reported in

two patients with the hyper-IgM phenotype (the XHM-ED syndrome) (Jain et al., 2001). Two families with atypical IP type II were reported with duplications of 13 bp at a cytosine tract in exon 10 and intron 3 to exon 6 (Aradhya et al., 2001; Nishikomori et al., 2004). These duplication mutations allowed males to survive and affected females to have random or slightly skewed X inactivation. These findings suggest that these hypomorphic mutations are not deleterious enough to cause lethality in cells with an active mutant X chromosome and are consistent with the survival to term of affected males in these families. Rather than VOIMIE syndrome (Vascular anomalies, Osteopetrosis, Immune dysfunction in Males with IP or ED), as suggested by Aradhya and Nelson (2001), we propose that XHM-ED and atypical IP type II be designated *XL-EDA-ID*, as they are all caused by hypomorphic mutations in the coding region of *NEMO*. In males, there is a correlation between the type of *NEMO* mutation and the clinical phenotype, since loss-of-function mutations cause IP and stop-codon hypomorphic mutations found in two patients cause the allelic *XL-OL-EDA-ID* syndrome. Whether there is a further form of correlation between specific *NEMO* coding region hypomorphic mutations and cellular and clinical phenotypes is currently being investigated (Puel et al., 2006).

### Functional Aspects of the Protein, and Pathophysiology

Activation of NF- $\kappa$ B (i.e., nuclear translocation) requires the phosphorylation of inhibitors of NF- $\kappa$ B (such as I $\kappa$ B- $\alpha$ ), which are constitutively bound to NF- $\kappa$ B and retain the complex in the cytoplasm. NEMO interacts with the  $\alpha$  and  $\beta$  subunits of a complex kinase, known as I $\kappa$ B kinase (IKK), and is required for activation of the kinase complex in response to extracellular or intracellular stimuli (Rothwarf et al., 1998; Yamaoka et al., 1998). NEMO (IKK- $\gamma$  or I $\kappa$ BKG, inhibitor of  $\kappa$ B kinase- $\gamma$ ) is the essential regulatory subunit of IKK required for NF- $\kappa$ B activation and resistance to TNF-induced apoptosis, and it is central to many immune and inflammatory pathways. Its absence results in a complete inhibition of NF- $\kappa$ B activation. Whether different mutations in *NEMO* have a different impact on NF- $\kappa$ B activation in response to certain stimuli remains to be determined. A structure–function characterization of *NEMO* may be facilitated by the investigation of patients with *XL-EDA-ID*.

What mechanisms underlie the developmental clinical features of patients with *XL-EDA-ID* and *XL-OL-EDA-ID*? NEMO-dependent NF- $\kappa$ B activation has been shown to be an essential step in the developmental pathway engaged by ectodysplasin and its receptor (Yan et al., 2000; Doffinger et al., 2001; Kumar et al., 2001). The mild clinical features of EDA and the overlap in phenotype with IP seen in these patients are probably accounted for by residual EDAR signaling. NF- $\kappa$ B has a role in endothelial cell survival, and a role for NEMO in capillary architecture is supported by the fact that retinal vascular abnormalities are an important complication in affected females with IP (Mansour et al., 2001). Most patients with EDA-ID do not manifest retinal vessel abnormalities, but an occasional patient has been described with hematopoietic or vascular development problems (Roberts et al., 1998; Aradhya et al., 2001). The vascular anomalies in the *OL-EDA-ID* phenotype (Mansour et al., 2001; Dupuis-Giroud et al., 2002) show a resemblance to primary lymphedema, an autosomal dominant developmental disorder caused by mutations of vascular endothelial growth factor receptor-3 (VEGFR-3) (Karkkainen et al., 2000). These anomalies are very likely due to disruption of the signaling between VEGFR-3 and NF- $\kappa$ B

mediated via NEMO. NF- $\kappa$ B-mediated signaling is important in the differentiation and function of osteoclasts (Franzoso et al., 1997), and mice deficient in the receptor activator of NF- $\kappa$ B (RANK) suffer from severe osteopetrosis due to a block in osteoclast differentiation (Dougall et al., 1999). Osteopetrosis in the *OL-EDA-ID* phenotype is therefore probably due to impaired RANK signaling. Residual NF- $\kappa$ B signaling may vary and account for the milder phenotype seen in some *EDA-ID* patients.

What accounts for the infectious diseases seen in the patients? In-depth investigations following the identification of *NEMO* mutations have shown impaired cellular responses of peripheral blood lymphocytes to lipopolysaccharide (LPS), interleukin-1 $\beta$  (IL-1 $\beta$ ), IL-18, TNF- $\alpha$ , and CD40 ligand in *OL-EDA-ID* patients bearing the X420W mutation (Doffinger et al., 2001). NEMO-dependent NF- $\kappa$ B activation is important to the signaling pathways downstream of Toll receptors (Tlr) (O'Neill and Dinarello, 2000). These germ-line–encoded receptors recognize conserved molecular patterns shared by large groups of microorganisms and have a crucial role in inducing an appropriate inflammatory and antimicrobial process (Janeway and Medzhitov, 2002). LPS/Tlr-4 mediated signaling was impaired in one of these patients, a finding suggesting that impaired recognition of pathogens, rather than of antigen, appears to be an important immunopathogenic mechanism (Doffinger et al., 2001). These patients exhibit very poor inflammatory response, both clinically and biologically, because of impaired cellular responses to proinflammatory cytokines (IL-1 $\beta$ , IL-18, TNF- $\alpha$ ) (Doffinger et al., 2001). An impaired response to LPS and partially impaired CD40 signaling could explain the susceptibility of these patients to infections with gram-negative bacteria and PCP, respectively (Doffinger et al., 2001). Infections by gram-positive bacteria may result from impaired responses to IL-1 $\beta$ , IL-18, or other NF- $\kappa$ B-dependent signaling pathways (Doffinger et al., 2001). It is known that *S. pneumoniae* activates NF- $\kappa$ B mainly but not exclusively through Tlr-2 mediated signaling (Yoshimura et al., 1999). The occurrence of severe mycobacterial disease in these patients is not due to the impairment of essential antimicrobial pathways mediated by IL-12 and IFN- $\gamma$  (Underhill et al., 1999). However, it could be due to impaired IL-1 $\beta$ - and IL-18-dependent induction of IFN- $\gamma$ , impaired cellular responses to IFN- $\gamma$ -inducible TNF- $\alpha$ , or to impaired signaling through Tlr-2 or Tlr-4 (Doffinger et al., 2001). *M. tuberculosis* activates NF- $\kappa$ B through Tlr-2 and Tlr-4 (Means et al., 1999) and induces TNF- $\alpha$  by a Tlr-2 dependent pathway (Underhill et al., 1999).

The immunological pathways in patients with *XL-EDA-ID* have not been investigated, and the pathogenesis of their susceptibility to bacterial infections is unknown. These patients suffer almost exclusively from gram-positive, gram-negative, and acid-fast bacterial infection. The links between hypomorphic mutations in the *NEMO* coding region, impaired NF- $\kappa$ B activation, the various stimuli that trigger NF- $\kappa$ B, the various immune cell subsets, the genes induced by NF- $\kappa$ B, and these bacterial infections remain to be established. In any case, NEMO-dependent NF- $\kappa$ B activation seems to be particularly important for the control of extracellular and intracellular bacteria, even though the association of more severe mutations of NEMO (such as X420W) with fungal disease suggests that the role of NF- $\kappa$ B in host defense may be broader (Uzel, 2005).

### Mutation Analysis and Strategies for Diagnosis

Many boys with “classical” EDA have problems as infants with feeding and episodes of fevers associated with respiratory

infections, mainly pneumonia, along with high reported mortality at 30% (Clarke et al., 1987). Although a number of these patients will remain susceptible to recurrent upper respiratory infections, bouts of fever, eczema, and asthma or chronic obstructive airway disease believed to be related to the abnormal mucosa of the gastrointestinal and respiratory tracts, most of these patients are unlikely to fall seriously ill. In contrast, boys with EDA-ID suffer from recurrent, severe, life-threatening infections caused mainly by encapsulated bacteria and, particularly in those with the OL-EDA-ID phenotype, mycobacteria. As mentioned above, they manifest less obvious clinical features of EDA (Table 36.1).

Laboratory investigations will reveal different types of dysgammaglobulinemia, but the most striking finding is failure to respond by specific antibody synthesis to either naturally occurring infection or to immunization with *S. pneumoniae* polysaccharide (Table 36.2). Boys in whom the diagnosis of XL-EDA-ID is suspected on the basis of infections and/or impaired humoral immunity should be tested for NF- $\kappa$ B activation with fibroblast cell lines and stimuli such as IL-1 $\beta$  and TNF- $\alpha$ . If there is impaired NF- $\kappa$ B activation, *NEMO* mutations can be sought by sequence analysis.

#### Mode of Inheritance, Carrier Detection, and Prenatal Diagnosis

XL-EDA-ID is inherited as an X-linked recessive trait; It has thus been assumed that only males have EDA-ID. However, a female patient with features of EDA-ID and a heterozygous hypomorphic *NEMO* mutation has been reported (Kosaki et al., 2001), widening further the phenotypic spectrum of this gene mutation in females and opening the question of the type of genetic counseling these families should be given. The clinical status of mothers and sisters of males with EDA-ID, who are heterozygotes for such coding region *NEMO* mutations, have never been carefully analyzed. An international survey is in progress to address this important question.

Females who are carriers of stop codon mutations (and male patients with XL-OL-EDA-ID) may show variable features of IP, such as dry and hyperpigmented skin, hypodontia, and conical teeth, and some will have elevated serum IgA levels (Smahi et al., 2000; Zonana et al., 2000; Aradhya et al., 2001; Doffinger et al., 2001; Jain et al., 2001; Mansour et al., 2001; Dupuis-Girod et al., 2002). Interestingly, some female carriers are reported to have random or only slightly skewed X inactivation, which suggests that these hypomorphic (milder) *NEMO* mutations may not cause lethality in cells with an active mutant X chromosome (Aradhya et al., 2001). In contrast, loss-of-function *NEMO* mutation results in extreme susceptibility to apoptosis leading to embryonic death in males and extremely skewed X inactivation in females (Smahi et al., 2000). It is also important to note that the same mutation causing OL-EDA-ID in hemizygous males may cause IP in heterozygous females (Mansour et al., 2001; Dupuis-Girod et al., 2002). It turns out that the two mothers carrying X420W had mild IP, but it is unpredictable whether this will be the case in all affected females in a kindred. Although very rare and unique, cases of fully manifesting females with X-linked recessive disorders have been reported (Kosaki et al., 2001). Hence, genetic counseling regarding the status of a female baby should remain cautious at this time.

As with other single-gene mutations, presuming the mutation in the affected family is known, there are possibilities for prenatal diagnosis (Roberts et al., 1998). Given the severity of XL-

OL-EDA-ID and, to a lesser extent, of XL-EDA-ID, a prenatal diagnosis in males can probably be offered to the family irrespective of the type of *NEMO* mutation. In females, a prenatal diagnosis may be offered to families in which OL-EDA-ID, but not EDA-ID, is diagnosed.

#### Treatment and Prognosis

The two children with OL-EDA-ID died in their second year of life of overwhelming mycobacterial disease after they had experienced a variety of fungal and bacterial infections. Bone marrow transplantation was attempted in one patient, who died 2 weeks after transplant of massive hepatic veno-occlusive disease (Dupuis-Girod et al., 2002).

EDA-ID is also a syndrome of severe immunodeficiency with significant morbidity and mortality. Recurrent infections lead to repeated hospitalizations and cause serious complications, such as bronchiectasis, chronic lung disease, intractable diarrhea, and failure to thrive (Table 36.1). The mortality is as high at 50% in childhood; at least 15 of 33 reported patients from 23 kindreds died at ages ranging from birth to 17 years (Smahi et al., 2000; Smythe et al., 2000; Zonana et al., 2000; Aradhya et al., 2001; Doffinger et al., 2001; Jain et al., 2001; Kosaki et al., 2001; Mansour et al., 2001; Dupuis-Girod et al., 2002; Orange et al., 2002). Four of these children died with disseminated mycobacterial infections.

As with other humoral immunodeficiencies with specific antibody production failure, regular intravenous immunoglobulin (IVIG) substitution is the mainstay of treatment. However, even though the majority of patients were on regular IVIG after the diagnosis was established, this treatment was not always protective against recurrent infections by *S. pneumoniae* and development of bronchiectasis. This finding, together with the increased susceptibility of patients to infections caused by gram-negative bacteria and mycobacteria, may suggest existence of additional immunological defects. Antibiotic prophylaxis should be determined on a case-by-case basis, as there is significant clinical heterogeneity between patients. As a rule, live vaccines such as BCG should be avoided.

#### Animal Models

There are no mouse models of hypomorphic *NEMO* mutations. In *NEMO*-deficient mouse models for IP (Makris et al., 2000; Schmidt-Supprian et al., 2000), as in human males bearing loss-of-function *NEMO* mutations (Smahi et al., 2000), the pro-apoptotic effects of TNF result in embryonic lethality in males. In heterozygous females, the skewing of X-inactivation in blood results from progressive apoptotic elimination of cells bearing mutated *NEMO* on the active X chromosome. Female mice heterozygous for *NEMO* mutations exhibit a severe but self-limiting dermatopathy, or *genodermatosis* and transient growth retardation (Makris et al., 2000; Schmidt-Supprian et al., 2000), traits almost identical to the human X-linked *genodermatosis* IP caused by loss-of-function *NEMO* mutations (Smahi et al., 2000). In contrast to humans, these mice exhibit increased apoptosis in both thymus and spleen (Rudolph et al., 2000).

#### Concluding Remarks and Future Challenges

XL-EDA-ID and XL-OL-EDA-ID are severe immunodeficiencies and developmental defects caused by hypomorphic mutations in *NEMO*. The milder developmental and immunological

phenotype of EDA-ID, compared with that of OL-EDA-ID, is probably due to higher levels of residual NF-κB signaling, at least in certain tissues at certain developmental stages. Abnormal immunity in the OL-EDA-ID phenotype results from impaired cellular responses to at least LPS, IL-1β, IL-18, TNF-α, and CD154, whereas the immunological signaling pathways affected in patients with EDA-ID phenotype remain to be determined. Patients with EDA-ID show phenotypic heterogeneity, as some have overwhelming clinical diseases caused by several microorganisms whereas others seem to be susceptible to a limited number of species. Encapsulated bacteria are the leading pathogens in EDA-ID and all patients tested have impaired antibody response to polysaccharide antigens, with low specific antibodies to *S. pneumoniae* and low isohemagglutinin titers. A detailed comparison of the cellular and clinical phenotypes of patients with known genotypes is required to better define the genotype–phenotype correlation and to further improve our understanding of the pathophysiology of EDA-ID. Finally, it will be important to unravel the molecular basis of other forms of EDA-ID that are not associated with mutations in *NEMO*.

Cartilage-Hair Hypoplasia

Description and Historical Review

Cartilage-hair hypoplasia (CHH), or metaphyseal chondrodysplasia, McKusick type (MIM 250250), is an autosomal recessive form of skeletal dysplasia in which immunodeficiency is a constant feature (McKusick et al., 1965). There are more than 250 genetic human diseases of the skeleton or osteochondrodysplasias. The metaphyseal chondrodysplasias constitute a subgroup of bone dysplasias with eight distinct and well-defined disorders in the recent international classification (Hall, 2002). The molecular defects have been detected in four metaphyseal dysplasias: Schmid type (OMIM 156500), Jansen type (OMIM 156400), adenosine deaminase (ADA) deficiency (SCID) (OMIM 102700), and, recently, CHH and a third metaphyseal dysplasia associated with hematopoietic abnormalities, Shwachman-Diamond syndrome (OMIM 260400). The association of immunodeficiency and/or aplastic anemia with growth failure and other skeletal disease has been observed relatively often (Hong, 1989). Well-defined examples are Schimke immunoosseous dysplasia (OMIM 242900) and Nijmegen breakage syndrome (OMIM 251260) (see Chapter 30).

CHH shows a high incidence among the Amish in the United States and among the Finns in Europe. Families with affected offspring have also been observed in most Caucasian and Asian populations, whereas there are no reports from black populations (Makitie et al., 1998, 2000b). CHH is a pleiotropic condition, as indicated in the original description and confirmed in investigations on the Finnish patients (McKusick et al., 1965; Makitie and Kaitila, 1993; Makitie et al., 1995). In the original description on CHH, McKusick and coworkers observed an increased propensity to infections, caused by viruses in particular. Since then the defective immunity in CHH has been repeatedly confirmed by clinical and laboratory studies (Makitie et al., 1998, 2000b). The disease-causing gene, *RMRP*, has recently been identified following a positional cloning approach, and a number of mutations have been found (Makitie et al., 1992a, 2000b, 2001c). However, the pathogenic mechanisms of the pleiotropic features, including the immunodeficiency syndrome, have remained elusive.

Table 36.3. Phenotypic Findings in Cartilage-Hair Hypoplasia

Finding	Frequency (%)
Disproportionately short limbed-short stature	100
Short fingers and toes	100
Increased lumbar lordosis	85
Marked	20
Moderate	65
Extension limitation in the elbow joints	92
>25°	28
5–25°	64
Laxity in finger joints and knees	95

Clinical and Pathological Manifestations

Nonimmunological features

The clinical phenotypic findings and their frequencies in CHH are listed in Table 36.3 (see also Color Plate 36.1). The pleiotropic features include growth failure (Makitie and Kaitila, 1993; Makitie et al., 1995), hair hypoplasia (Makitie and Kaitila, 1993; Makitie et al., 1995), refractory anemia in childhood (Makitie et al., 1992b), intestinal neurocristopathy or Hirschsprung disease (HD) (Makitie et al., 2001a), and risk of malignancies (Makitie et al., 1999) (Table 36.4). Recently, defective spermatogenesis was added to the features (Makitie et al., 2001c).

Table 36.4. Pleiotropic Features in Cartilage-Hair Hypoplasia

Feature	Frequency (%)
Short stature, –4 SD or <5th percentile	100
Hair hypoplasia	93
Immunodeficiency	56
Propensity to infections	56
In vitro immunodeficiency	88
Hypoplastic childhood anemia	79
Gastrointestinal dysfunction	18
Hirschsprung disease	9
Defective spermatogenesis	100
Metaphyseal chondrodysplasia on childhood skeletal radiographs	100
Overall risk of malignancies (SIR)	6.9
Non-Hodgkin lymphoma	90
Basal cell carcinoma	35

SIR, standardized incidence ratio.

Source: Modified from Makitie and Kaitila (1993) and Makitie et al. (1999, 2001b).

The marked disproportionately short-limbed, short stature is due to metaphyseal dysplasia (Makitie and Kaitila, 1993; Makitie et al., 1995). The CHH-specific growth curves based on Finnish patients indicated a progressive retardation of growth, with mean birth length of 45.8 cm (range, 38–50 cm) for boys and 44.9 cm (range, 38–51 cm) for girls. The median height was 131.2 cm (range, 110.7–158 cm) for adult males and 122.5 cm (range, 103.7–137.4 cm) for females, which was  $-7.9$  SD for the Finnish normal males and females (Makitie et al., 1992; I. Kaitila, unpublished observations). In spite of normal or slightly delayed pubertal development, there was no pubertal growth spurt in boys and girls. The relative weight was around 20% less for both girls and boys. However, there is a substantial risk for being overweight after puberty in both genders (Makitie et al., 1992a).

The radiographic skeletal abnormalities are short and thick tubular bones with splaying and irregular metaphyseal border of the growth plate (Fig. 36.2). The costochondral junctions are similarly splayed and irregular, whereas the vertebrae are normal or slightly tall. These findings develop and are diagnostic by the age of 6 to 9 months. In adults the spine and skull are about normal, whereas the tubular bones of the extremities remain short and thick but are otherwise unspecific (Makitie and Kaitila, 1993; Makitie et al., 1995).

The characteristic hair hypoplasia in CHH presents as fair, thin, and sparse hair growth from the newborn. However, there is

a marked variation and individuals with normal hair have been observed (Table 36.3) (Verloes et al., 1990; Makitie and Kaitila, 1993; Makitie et al., 1995; Bonafe et al., 2002).

Gastrointestinal problems, such as intestinal neurocristopathy or neuronal dysplasia of the intestine, are common in CHH. In a recent study, congenital HD was found in 13 of 147 Finnish patients with CHH (9%), all of whom had an overall severe form (Makitie et al., 2001a). Eight patients had the classic form with rectosigmoid involvement, two had long-segment colonic disease, and three had total colonic aganglionosis. Six of the patients had episodes of enterocolitis, two with colonic perforations prior to the first surgery. Eleven patients had postoperative enterocolitis and some died of enterocolitis-related septicemia. The bacterial etiology was nonspecific with *Clostridium difficile* mentioned (I. Kaitila, unpublished data).

In another recent study, defective quantitative and qualitative spermatogenesis was observed in all 11 patients studied (Makitie et al., 2001c), although whether this finding was associated with male infertility was not studied.

Defective erythropoiesis in early childhood presenting as hypoplastic anemia is a common feature in CHH and was found in 54 of 74 Finnish patients (73%). Three children died of anemia and four additional patients were treated with repeated erythrocyte transfusions at up to 2–3 years of age. Macrocytosis often remained into adulthood (Makitie et al., 1992b, 2000a). In a study of colony formation of myeloid lineages from blood and bone marrow in vitro, all patients with CHH showed defective erythroid and granulocyte-macrophage colony formation, which was not caused by a decreased number of progenitors (Juvonen et al., 1995). Anemia is related to body growth and to the insulin-like growth factor system (Makitie et al., 2000a).

#### Immunodeficiency

In the original description of CHH there was an increased propensity to infections, including viral diseases (McKusick et al., 1965). A peculiar feature was that varicella occasionally resulted in a prolonged and severe disease with hemorrhagic vesicles, high fever, and even fatality. Since then a number of patients with chronic, severe, and even fatal infections due to viruses, bacteria, and fungi have been reported (Lux et al., 1970; Saulsbury et al., 1975; Steele et al., 1976; Polmar and Pierce, 1986; Hong, 1989; Castigli et al., 1995; Berthet et al., 1996). A classical presentation is that of a child with a history of recurrent respiratory infections and chronic diarrhea from 6 months of age. She had multiple episodes of sepsis caused by *Klebsiella pneumoniae*, *Streptococcus fecalis*, and *Staphylococcus epidermidis* and had stool cultures positive for *Clostridium difficile*, rotavirus, and adenovirus. She also had recurrent vesicular eruptions due to varicella and needed continuous acyclovir therapy (Castigli et al., 1995). Such severe clinical presentations reflect impaired cellular immunity and are rare; however, most CHH patients do relatively well and have only mild impairment of humoral immunity (Makitie et al., 1998, 2000b). Trojak et al. (1981) studied 18 CHH patients with no history of infections and found consistent defective immunity by laboratory studies. In a recent retrospective questionnaire study of 35 Finnish patients, the parents reported 31% increased respiratory and other infection rates during the preceding year for their CHH children, compared to rates for the unaffected siblings (Makitie et al., 1998, 2000b). Chronic progressive lung disease, such as bronchitis and bronchiectasis, was the cause of death in three adolescents (I. Kaitila, personal experience). Thrombocytopenia and autoimmune hemolytic anemia have also been reported as an association with

**Figure 36.2.** Radiograph of the lower extremities of a 6-years 9-months-old child with cartilage-hair hypoplasia. The tubular bones are short and thick, and there is remarkable generalized splaying and irregularities at the metaphyses.

CHH (Ashby and Evans, 1986; Berthet et al., 1996; Matsumoto et al., 2000; authors' personal experience).

Children with CHH have usually been vaccinated with routine regimens with BCG, diphtheria, tetanus, polio, and mumps, etc. without reported complications (I. Kaitila, personal experience). However, two patients developed severe disease following live poliovirus vaccine (Saulsbury et al., 1975; Ashby and Evans, 1986).

#### Variability

There is some variability of adult height, from <100 cm up to 158 cm (Makitie and Kaitila, 1993; I. Kaitila, personal observations). Most patients present with marked hair hypoplasia. However, there are case reports describing normal hair (Verloes et al., 1990; Bonafe et al., 2002), and among the Finnish patients 7% had normal hair and only 55% severe hair hypoplasia (Makitie and Kaitila, 1993). The clinical presentation of the immunodeficiency syndrome itself varies from lethal septicemic infections in early childhood to no infection in adults (Makitie et al., 1998; Makitie 2000b). In a recent study the mortality in CHH was increased, mainly but not exclusively because of defective immunity in childhood. The major causes of mortality in adulthood have been chronic pulmonary infections related to the immunodeficiency, and lymphomas (Makitie et al., 1999, 2001; I. Kaitila, personal experience). As a result, the variability of the clinical outcome in CHH is quite extensive, ranging from lethality in the newborn period to normal life span. The global morbidity also varies from case to case.

#### Laboratory Findings

McKusick and coworkers demonstrated in 1970 that two Amish patients had mild to moderate lymphopenia, decreased delayed hypersensitivity, and impaired leukocyte responses to mitogens whereas the immunoglobulin concentrations and antibody synthesis were normal (Lux et al., 1970). Similar results were subsequently confirmed in other Amish patients (Trojak et al., 1981; Pierce and Polmar, 1982; Pierce et al., 1983; Polmar and Pierce, 1986). The proportions of the major T lymphocyte subpopulations were normal. The results of allogeneic stimulations indicated an intrinsic T cell defect, whereas antigen-presenting cells were not affected. Furthermore, they showed that the IL-2 production by CHH lymphocytes was reduced, but exogenous IL-2 did not correct the defect in proliferation (Pierce and Polmar, 1982; Pierce et al., 1983; Polmar and Pierce, 1986). The NK cell activity was normal or even above normal. There was an impaired proliferation of B lymphocytes in response to stimulation in vitro, despite the lack of detectable antibody deficiency.

In studying the Finnish CHH patients we also found depressed or absent delayed skin hypersensitivity reactions and decreased lymphocyte proliferative responses to mitogens in vitro (Ranki et al., 1978; Virolainen et al., 1978). The absolute lymphocyte count was about half that of normal controls. Again, the serum immunoglobulin concentrations and antibody synthesis were normal. In the Finnish patients, a reduction of 50% in CD4<sup>+</sup> cell count and a reduction of 30% in CD4<sup>+</sup>/CD8<sup>+</sup> cell ratio have been reported. The B lymphocyte count was usually normal, whereas the NK cell count was often elevated (Makitie et al., 1998). Unexpectedly, we found that one-third of the Finnish CHH patients also had partially defective humoral immunity presenting as isolated IgA and IgG subclass deficiencies (Makitie et al., 2000b).

Other patients have also been investigated to determine the immunological basis of infections in CHH. The decreased prolifera-

tive response of T cells to phytohemagglutinin (PHA) could not be restored by addition of rIL-2 (Kooijman et al., 1997). On the basis of increased expression of Fas (CD95), CD95L, and Bax, and decreased expression of Bcl-2 and inhibitor of apoptosis protein (IAP) in both CD4<sup>+</sup> and CD8<sup>+</sup> cells, it has been suggested that the lymphopenia might be due to increased apoptosis of these cells (Yel et al., 1999). In another study, the levels of mRNA encoding c-myc, IL-2R $\alpha$ , IL-2, and IFN- $\gamma$  were decreased in the stimulated CHH lymphocytes, whereas those of other early activation gene products, such as c-fos and c-jun, were not impaired, findings suggesting a lymphocyte intracellular signaling defect (Castigli et al., 1995). One child with CHH had severe combined immunodeficiency (SCID) with severe T lymphopenia but normal numbers of B cells (Berthet et al., 1996).

#### Molecular Basis

On the basis of molecular linkage studies on Finnish multiplex CHH families, the disease-causing gene was mapped to 9p12 in 1993, and the homogeneity of the condition was confirmed in the Finnish and Amish populations by haplotype analyses of the nearby molecular markers (Sulisalo et al., 1993, 1994, 1995b). The location was refined by disequilibrium analysis; finally, the mutated gene, *RMRP*, was detected through physical mapping and sequencing (Ridanpää et al., 2001). Several dozen *RMRP* mutations have been detected (Fig. 36.3A) (Makitie et al., 2000b, 2001c; Bonafé et al., 2005).

Three types of mutations of *RMRP* are associated with CHH (Fig. 36.3A,B). Most are base substitutions, insertions, or short duplications that alter conserved nucleotide sequences in the transcribed region. The second set of mutations consists of insertions or duplications in the promoter region between the TATA box and the site of initiation of transcription. The third set includes insertions and duplications in the 5' end of the transcribed region. All patients with insertion or duplication in the promoter region on one allele carry a mutation in the transcribed region on their second allele. This finding suggests that if two allelic mutations in the promoter region would have a lethal outcome.

Recently, we have shown that the most common CHH-causing mutation is 70A > G, found in 92% of Finnish CHH patients and probably all Amish patients. The same mutation accounts for 48% of the mutations among patients from other parts of Europe, North and South America, the Near East, and Australia (Makitie et al., 2000b). In the non-Finnish families the same major mutation segregates with the same major haplotype as in most of the Finnish families. Thus all the chromosomes with the 70A > G mutation probably arose from a solitary founder many thousand years ago. A minor common mutation, 262G > T, accounts for 7% of the Finnish patients, always in compound heterozygosity with the 70A > G mutation. Compound heterozygosity for the 70A > G mutation and for a private mutation was also common in the non-Finnish, non-Amish patients, and several patients presented as homozygotes for a private mutation in *RMRP* gene (Makitie et al., 2000b). The sites for the different types of mutation in the transcribed region are evolutionarily conserved (Schmitt et al., 1993; Sbisà et al., 1996; Shadel et al., 2000).

#### Functional Aspects of the Gene Product

The human *RMRP* gene encodes the 267 bp RNA molecule of the RNase MRP complex, which consists of protein components and the RNA molecule. Thus, exceptional to most of the known disease-associated genes, the *RMRP* is an untranslated gene. It is

**Figure 36.3** (A) *RMRP* gene mutations in cartilage-hair hypoplasia. There are three duplications and one insertion, and 15 base pair substitutions in the transcript, which is only 267 base pairs in length. Between the TATA box and the initiation site of the transcription—i.e., in the promoter—there are five duplications and one insertion of varying length. A, adenine; C, cytosine; G, guanine; T, thymidine (B) Schematic presentation of the RNA molecule encoded by *RMRP*. Base pair substitutions and the sites of duplications are indicated by arrows. A, adenine; C, cytosine; G, guanine; U, uridine.

found in mammals, *C. elegans*, yeast, and bacteria (van Eenennaam et al., 2000). The RNase MRP is a ribonucleoprotein endoribonuclease involved in the processing of precursor ribosomal RNA and in priming of the RNA for mitochondrial DNA replication. It has been suggested that the RNase MRP also carries other important biological functions, such as control of cell proliferation (Clayton, 2001). In situ hybridization experiments have indicated the presence of RNase MRP in both mitochondria and nucleoli, the majority being localized to the latter. The central region of the RNA molecule is important for its mitochondrial localization, whereas the 5'-terminal region is required for nucleolar localization, which suggests that these domains determine the transportation to these subcellular compartments. In yeast, the RNase MRP cleaves the pre-rRNA to two forms of 5.8S rRNA, the long and short forms. Experimental mutations in yeast RNase MRP RNA result in lethal, temperature-conditional lethal and nutrient preferential, and altered growth phenotypes; the growth defect was proportional to the severity of the 5.8S rRNA processing phenotype (Shadel et al., 2000). The pathogenetic mechanisms of the *RMRP* mutations in human health and disease are still unknown.

### Mutation Analysis

DNA samples are screened for insertions and deletions in the promoter region by use of two polymerase chain reaction (PCR) primers, RM3IF 5'-CTTAGAAAGTTATGCCCCGAAAAC-3' and RM3IR 5'-GAAAGGGGAGGAACAGAGTC-3', for amplification, and 5% Sequagel (National Diagnostics) gels for separation. In case of changes in the length, this region is amplified with RM3F 5'-GGCCAGACCATATTTGCATAAG-3' and RM3R 5'-CGGACTTTGGAGTGGGAAG-3' primers and then sequenced.

The major mutation (70A > G) is amplified with PCR primers RM70F 5'-GTGCTGAAGGCCTGTATCCT-3' and RM70R 5'-CTAGGGGAGCTGACGGATG-3'. Single-strand conformation polymorphism (SSCP) analyses are performed in 0.7×MDE (FMC BioProducts) gels at room temperature using 5W overnight. For sequencing of the whole RNA coding region of *RMRP*, PCR primers RMF 5'-CCAACTTTCTCACCCTAACCA-3' and RMR 5'-AAGGCCAAGAACAGCGTAAA-3' are used. The 3' region can be separately amplified for sequencing with RM4F 5'-AGAGAGTGCCACGTGCATAC-3' and RM4R 5'-CTTCATAGCAAGGCCAAGAAC-3'. All PAGE and SSCP gels are detected through silver staining (Ridanpää et al., 2001).

### Strategies for Diagnosis

The diagnosis of CHH is based on the clinical phenotype, family history and radiographic phenotypes; it can be confirmed by mutation analysis of the *RMRP* gene. The clinical variability in CHH is marked but well analyzed (Makitie and Kaitila, 1993; Makitie et al., 1995; Ridanpää et al., 2001). However, with the detection of the defective *RMRP* gene, enlarged phenotypic variation has emerged. The essential features are short birth length for gestational age, and delayed growth in height ranging from -3 to -8 SD of the mean in the population and for the patient's gender. The extremities are usually disproportionately short. With the exception of elbow joints, the hyperextensibility of the joints is marked. The lower extremities are often curved, and the lumbar lordosis is increased. The physical handicap is usually a minor problem, and patients do not have early osteoarthritis.

Most patients have sparse, thin, fair hair. About one-third present with hypoplastic anemia in infancy and early childhood,

and erythrocyte macrocytosis may prevail throughout their lives. Lymphopenia is common, hypogammaglobulinemia with low IgA and/or low IgG2 is relatively rare, and SCID is exceedingly rare. Immunodeficiency in CHH is often associated with chronic sinusitis and respiratory disease. A minority of the patients present with chronic constipation, and newborns occasionally have HD.

A consistent diagnostic feature is the generalized metaphyseal irregularity of the tubular bones on childhood skeletal radiographs. The characteristic radiographic features cannot be observed in the newborn, but they do develop by the age of 6 to 9 months. Detection of mutations in the *RMRP* gene will confirm the suspected diagnosis.

### Mode of Inheritance, Carrier Detection, and Prenatal Diagnosis

The mode of inheritance is autosomal recessive. Thus, it is typical to find one or more affected siblings whose healthy carrier parents may be consanguineous. Two epidemiological studies have indicated a lower than expected number of affected siblings (McKusick et al., 1965; Makitie et al., 1992a). Two cases of maternal isodisomy were observed among approximately 100 Finnish families (Sulisalo et al., 1997).

Carrier detection is feasible for individuals at risk for affected offspring through direct mutation analysis. For prenatal diagnosis, the fetal ultrasound in the first and second trimester should be regarded as unreliable, and it should be replaced by molecular studies for the *RMRP* gene on either chorionic biopsy material or amniotic fluid cells taken at the tenth week or later of pregnancy (Sulisalo et al., 1995a).

### Treatment and Prognosis

For patients with CHH, the standardized mortality ratio is 9.3 compared to normal parents and healthy siblings, according to Finnish population figures. This increased mortality is confined to young age-groups and associated with defective immunity (Makitie et al., 2001b). The standardized incidence ratio for overall cancer is also higher, at 6.9, the main cancer type being non-Hodgkin lymphoma, with a ratio of 90 (Makitie et al., 1999).

Most patients with CHH present with a relatively mild phenotype; however, careful annual follow-up for growth and psychomotor development is indicated. Hypoplastic anemia must be carefully evaluated and patients should be followed with appropriate hematological studies. Regular erythrocyte transfusions may be needed during the first 2 to 3 years of life. Autoimmune hemolytic anaemia is probably rare and may or may not respond to prednisone treatment (Ashby and Evans, 1986). Erythropoietin treatment has been shown to be ineffective (I. Kaitila, personal experience). Bone marrow transplantation (BMT) has cured the immunodeficiency and autoimmune hemolytic anemia but not the skeletal disease: a 16-month-old child with unusually severe CHH and SCID had a complete reconstitution of cellular immunity at 4 months and humoral immunity at 15 months after BMT from an HLA-identical sister (Berthet et al., 1996).

Children with CHH should not be vaccinated with live or attenuated bacteria or viruses. Antibiotic and antiviral treatment of infections, as well as prophylactic antibiotics, should be recommended on a case-by-case basis. The HD of the newborn requires immediate operative treatment. Rarely, long-segment intestinal neurocristopathy occurs that is associated with severe functional (constipation or diarrhea) and inflammatory bowel disease and thus major nutritional problems (Makitie et al., 2001a). The

skeletal growth failure cannot be corrected with growth-hormone or other hormonal therapy (I. Kaitila, personal experience). The only effective means to achieve more height is bone-lengthening procedures of the lower extremities. However, this treatment has been associated with a variety of complications (I. Kaitila, unpublished observations).

### Animal Models

There are presently no animal models for CHH.

### Concluding Remarks and Future Challenges

Pleiotropic, autosomal recessive CHH is caused by mutations in an untranslated gene, *RMRP*, which encodes the RNA component of an endoribonuclease, RNase MRP. There is no observed genotype–phenotype correlation between the mutations and clinical manifestations, which vary from a lethal, infantile condition of severe growth failure, immunodeficiency, hypoplastic anemia, and HD to a mild condition with disproportionately short stature with normal life span. Until now, immunological studies have confirmed complex and variable deficiencies in both cell-mediated and humoral immunity. The pathogenetic mechanisms involved are still unknown. Future research should be directed toward understanding the mechanisms of suppressed cellular differentiation and proliferation as a result of the mutated *RMRP* gene in multiple human tissues and organs, and in other organisms, including bacteria, yeast, fish, amphibians, and mammals.

## Chronic Granulomatous Disease

DIRK ROOS, TACO W. KUIJPERS, and JOHN T. CURNUTTE

Chronic granulomatous disease (CGD) is an uncommon congenital immunodeficiency seen in approximately 1 in 250,000 individuals. It is caused by a profound defect in a burst of oxygen consumption that normally accompanies phagocytosis in all myeloid cells (neutrophils, eosinophils, monocytes, and macrophages). This “respiratory burst” involves the catalytic conversion of molecular oxygen to the oxygen free-radical superoxide ( $O_2^-$ ), which in turn gives rise to hydrogen peroxide ( $H_2O_2$ ), hypochlorous acid ( $HOCl$ ), and hydroxyl radical ( $\bullet OH$ ). These oxygen derivatives play a critical role in the killing of pathogenic bacteria and fungi. As a result of the failure to activate the respiratory burst in their phagocytes, the majority of CGD patients suffer from severe recurrent infections, the most common of which are pneumonia, lymphadenitis, cutaneous and hepatic abscesses, osteomyelitis, and septicemia. These severe infections usually become apparent during the first year of life and are caused predominantly by *Staphylococcus aureus*, *Aspergillus* species, enteric gram-negative bacteria, *Serratia marcescens*, and *Burkholderia* (*Pseudomonas*) *cepacia*. In addition, CGD patients have diffuse granulomas (presumably caused by microbes) that can become sufficiently large to cause obstructive or painful symptoms in the esophagus, stomach, biliary system, ureters, or urinary bladder.

While all CGD patients share the severe defect in the respiratory burst, there is substantial heterogeneity in the molecular mechanisms responsible. The enzyme that catalyzes the respiratory burst, NADPH oxidase, consists of at least four subunits (designated *phox* for *phagocyte oxidase*): gp91<sup>phox</sup> and p22<sup>phox</sup> (the two membrane-bound subunits of a low-potential flavocytochrome *b*, termed flavocytochrome *b*<sub>558</sub>, that is the redox center of the oxidase) as well as two cytosolic oxidase components, p47<sup>phox</sup> and p67<sup>phox</sup>. CGD is caused by a defect in any one of these four components. Mutations in the gp91<sup>phox</sup> gene (*CYBB* on chromosome Xp21.1) cause the X-linked recessive form of

the disease that affects about 70% of all CGD patients. As expected from the genetics, the overwhelming majority of X-linked patients are males. The remaining 30% of cases are inherited in an autosomal recessive manner in which males and females are equally affected. These patients have mutations in the genes encoding p47<sup>phox</sup> (*NCF1* on chromosome 7q11.23; about 25% of cases), p67<sup>phox</sup> (*NCF2* on chromosome 1q25; about 2% of cases), or p22<sup>phox</sup> (*CYBA* on chromosome 16q24; about 3% of cases). Deletions, insertions, splice site defects, nonsense mutations, missense mutations, and, in rare cases, regulatory mutations have been identified in the four types of CGD at the molecular genetic level. With the exception of p47<sup>phox</sup>-deficient patients, who are usually homozygous for a GT deletion at the beginning of exon 2 in *NCF1*, most CGD patients have mutations unique to their families. The diversity of these mutations and the multiple genes affected provide an explanation for the genetic, biochemical, and clinical heterogeneity of CGD.

In two separate reports in 1957, Landing and Shirkey as well as Good and colleagues described a new syndrome of recurrent bacterial infections in male children that were associated with pigmented lipid-laden histiocytes in visceral organs, diffuse granulomas, and normal immunoglobulin levels (Berendes et al., 1957; Landing and Shirkey, 1957). The syndrome was originally referred to as “fatal granulomatous disease of childhood,” because most patients succumbed to death at early ages from severe infections that responded poorly to even the most aggressive therapy (Berendes et al., 1957; Bridges et al., 1959). Over the ensuing several decades, the prognosis for children afflicted with this rare disorder has steadily improved because of an increasing understanding of its molecular and clinical features. Fatal granulomatous disease is now known by its more upbeat appellation, *chronic granulomatous disease* (CGD). What is remarkable about the early reports on CGD is the extent to which the clinical

and genetic observations in a relatively small number of patients have held true; since then over 2000 additional patients have been identified and, in numerous cases, reported in the literature.

Because the most striking hallmark of the early cases of CGD was unresolved bacterial and fungal infections, investigators were drawn to study the function of granulocytes from these patients. Indeed, patient neutrophils demonstrated markedly abnormal killing of organisms such as *S. aureus* and *Escherichia coli* in in vitro assays (Quie et al., 1967). This defect was not due to an immunoglobulin or complement deficiency in patient serum, nor to an abnormality in neutrophil chemotaxis, ingestion, or degranulation. (Patient neutrophils also contained normal levels of lysosomal proteins and degradative enzymes.) The first clue to the underlying molecular defect came in 1959 in a seminal report by Sbarra and Karnovsky. It had been known since 1933 that neutrophils substantially increase their consumption of oxygen concomitant with phagocytosis of microbes (Baldrige and Gerard, 1933), and it had been assumed that this was due to increased energy metabolism. Sbarra and Karnovsky demonstrated, however, that the oxygen was not used for mitochondrial respiration but was instead utilized for the production of potentially microbicidal molecules such as hydrogen peroxide. This set the stage for the report in 1967 that CGD neutrophils did not undergo this respiratory burst when bacteria were ingested (Holmes et al., 1967). A subsequent report in 1973 identified the oxygen radical, superoxide ( $O_2^-$ ), as the initial product formed from the oxygen consumed in the respiratory burst and the precursor of the other microbicidal oxygen derivatives (Babior et al., 1973). CGD neutrophils were found not to generate superoxide (Curnutte et al., 1974). The absence of the respiratory burst and its various products (such as superoxide and hydrogen peroxide) was then used as the defining characteristic of CGD and remains the cornerstone for its diagnosis today. Interestingly, one of the earliest assays used to measure respiratory burst activity in phagocytes, the nitroblue tetrazolium (NBT) test, is still one of the most widely used tests for detecting CGD (Baehner and Nathan, 1968).

The NBT test also proved to be a powerful tool in defining the genetics of CGD. When used to stain neutrophils adherent to a microscope slide, the NBT "slide" test revealed that many of the mothers of affected males had two populations of cells: one that underwent a respiratory burst and stained positive, and another that failed to stain with the dye and therefore resembled the defective cells in the patient. While this finding indicated that CGD could be inherited in an X-linked recessive fashion, an autosomal recessive mode of inheritance was also suggested by pedigrees with females suffering from a nearly identical syndrome of recurrent infections and absent respiratory burst but normal respiratory burst in neutrophils from patients' mothers (Azimi et al., 1968; Quie et al., 1968). It was hypothesized that X-linked CGD involved a defect in the enzyme that catalyzed the respiratory burst whereas the autosomal form was due to defects in other aspects of phagocyte metabolism (such as glutathione peroxidase activity) that indirectly affected the respiratory burst (Holmes et al., 1970).

Before this confusing genetic picture could be clarified, it was first necessary for the field to identify the enzyme responsible for the respiratory burst. A debate raged for over a decade as to whether the "respiratory burst oxidase" was a soluble NADH oxidase or a membrane-bound NADPH oxidase (Rossi, 1986; Curnutte and Babior, 1987). Finally, the ability of the two candidate enzymes to produce superoxide was used as one of the defining properties of the respiratory burst oxidase, and it eventually became clear that NADPH oxidase was the enzyme responsible for

the burst in human neutrophils (Curnutte et al., 1975). An additional important breakthrough occurred in 1978 when Segal and colleagues found that a low-potential cytochrome *b* was undetectable in the neutrophils from four CGD patients (Segal et al., 1978). A multicenter European study of the prevalence of cytochrome *b* deficiency in a group of 27 CGD patients revealed that the cytochrome was undetectable in all 19 males who had X-linked CGD whereas it was present in normal levels in all 8 patients (7 females and 1 male) who appeared to have autosomal recessive inheritance (Segal et al., 1983). It thus appeared that cytochrome *b* (termed cytochrome  $b_{-245}$  or  $b_{558}$  to reflect its  $-245$  mV midpoint potential or its 558 nm absorption peak, respectively) was an important component of NADPH oxidase and that X-linked CGD could be explained by its deficiency. The defect in autosomal recessive CGD remained unknown, and the picture was complicated by the identification of patients with this form of the disease who had undetectable levels of cytochrome  $b_{558}$  (Weening et al., 1985b). Thus, at least three distinct forms of CGD appeared to exist: X-linked, cytochrome *b*-negative ( $X^0$ ); autosomal recessive, cytochrome *b*-positive ( $A^+$ ); and autosomal recessive, cytochrome *b*-negative ( $A^0$ ). That these three types of CGD are genetically distinct was conclusively demonstrated by complementation studies in which monocytes from pairs of these three groups of patients were fused with each other to form heterokaryons. Complementation (measured as acquisition of NBT staining) was observed in the  $X^0/A^0$ ,  $X^0/A^+$ , and  $A^0/A^+$  fusions, indicating three distinct complementation groups in CGD (Hamers et al., 1984; Weening et al., 1985b).

One of the other major breakthroughs in unraveling the mystery of the genetic heterogeneity of CGD was the discovery in several laboratories of a cell-free system for activating NADPH oxidase (Bromberg and Pick, 1984; Heyneman and Vercauteren, 1984; Curnutte, 1985; McPhail et al., 1985). Studies with this system revealed that both the plasma membrane and cytosol fractions were required for oxidase activity. In both the X-linked and autosomal recessive forms of cytochrome  $b_{558}$  deficiency, it was the membrane fraction that was defective in the cell-free system (Curnutte, 1985; Curnutte et al., 1987) whereas in the autosomal recessive, cytochrome  $b_{558}$ -positive patients the cytosol was devoid of activity (Curnutte et al., 1988). The identities of the missing or defective proteins came to light in parallel with these findings through the convergence of several lines of investigation. First, Orkin and colleagues identified the gene affected in X-linked CGD, without knowledge of its protein product, through restriction fragment length polymorphism (RFLP) studies that localized the gene to Xp21 and the study of two patients with X-linked CGD who had small interstitial deletions within this region of the X chromosome (Baehner et al., 1986; Royer-Pokora et al., 1986). Second, Jesaitis, Parkos, and colleagues (Parkos et al., 1987) and Segal (1987) found that cytochrome  $b_{558}$  is a heterodimer composed of a heavily glycosylated 91 kDa subunit (termed  $\beta$ ) and a nonglycosylated 22 kDa component (termed  $\alpha$ ). The 91 kDa subunit was found to be identical with the product of the X-CGD gene identified by Orkin et al. (termed *CYBB*) (Dinauer et al., 1987; Teahan et al., 1987) whereas the  $\alpha$  subunit gene (termed *CYBA*) was localized to chromosome 16q24 and found to be defective in autosomal recessive, cytochrome  $b_{558}$ -negative patients (Parkos et al., 1988; Dinauer et al., 1990). Finally, selected pairs of defective cytosols from patients with autosomal recessive, cytochrome  $b_{558}$ -positive CGD were found to complement each other in the cell-free activation system and restore near normal activity (Nunoi et al., 1988; Curnutte et al., 1989). Two cytosolic complementation groups were

thus defined by this method, and the deficient proteins were identified as two novel myeloid-specific polypeptides—one that was 47 kDa in mass and the other that was 67 kDa (Nunoi et al., 1988; Volpp et al., 1988; Leto et al., 1990). In one major cooperative study, the 47 kDa protein was undetectable in 22 of 25 CGD patients with defective cytosols whereas the 67 kDa polypeptide was absent in the remaining three patients (Clark et al., 1989). The gene encoding the 47 kDa component (termed *NCF1*) maps to 7q11.23 and the 67 kDa gene (termed *NCF2*) localizes to 1q25, findings consistent with the autosomal recessive mode of inheritance for each of these deficiencies in CGD (Francke et al., 1990).

A CGD-like syndrome caused by a defect in the activation mechanism of the NADPH oxidase (Rac2 deficiency) or by a shortage of substrate supply for the oxidase (glucose 6-phosphate dehydrogenase [G6PD] deficiency) has to be considered for differential diagnosis.

### Clinical and Pathological Manifestations

Given the key role the products of the respiratory burst play in host defense, it is not surprising that patients with CGD suffer from a variety of recurrent bacterial and fungal infections. These infections occur most commonly in those organs in contact with the outside world—the lungs, gastrointestinal tract, and skin, as well as the lymph nodes that drain these structures. Because of both contiguous and hematogenous spread of infection, a wide range of other organs can be affected, most notably the liver, bones, kidneys, and brain. In approximately two-thirds of patients, the first symptoms of CGD appear during the first year of life in the form of infections (lymphadenitis, pneumonia, rectal abscesses, and osteomyelitis), dermatitis (sometimes seen at birth), and gastro-

intestinal complications (vomiting secondary to granulomatous obstruction of the gastric antrum; intermittent bloody diarrhea due to CGD colitis) (Johnston and Newman, 1977). On physical exam, CGD infants are often underweight and anemic, particularly the X-linked males. It is worth noting that this clinical picture can be quite variable, with some infants suffering from several or more of these complications whereas others appear far less ill. In some cases, the presenting symptoms of CGD can be mistaken for pyloric stenosis, food or milk allergy, or iron-deficiency anemia. In general, infants with X-linked CGD tend to present earlier and with more dramatic symptoms than infants with the autosomal recessive forms of the disease, especially p47<sup>phox</sup> deficiency (Weening et al., 1985a; Margolis et al., 1990; Gallin et al., 1991; Winkelstein et al., 2000). In a small but noteworthy subset of patients, the diagnosis of CGD is not made until the teenage or adult years because of the mildness of the symptoms (Liese et al., 1996). The underlying reasons for this somewhat surprising clinical variability will be discussed below.

The full spectrum of CGD is summarized in Table 37.1. Despite the rarity of CGD, a number of investigators have either reviewed or assembled large series of patients from the United States, Europe, and Japan (Johnston and Newman, 1977; Cohen et al., 1981; Gallin et al., 1983; Hitzig and Seger, 1983; Tauber et al., 1983; Hayakawa et al., 1985; Forrest et al., 1988; Mouy et al., 1989; Winkelstein et al., 2000). The approximately 750 patients represented by these studies provide a striking picture of the multiple manifestations of the disease. As shown in Table 37.1, *Staphylococcus aureus*, *Aspergillus* species, enteric gram-negative bacteria (including *Serratia marcescens* and various *Salmonella* species), and *Burkholderia cepacia* (previously termed *Pseudomonas cepacia*) are the most frequently encountered pathogens. Most CGD pathogens share the property of containing

**Table 37.1.** Infections, Chronic Conditions, and Organisms Associated with Chronic Granulomatous Disease\*

<i>Infections</i>	<i>Percent of Infections</i>	<i>Condition</i>	<i>Percent of Cases</i>	<i>Infecting Organisms</i>	<i>Percent of Isolates</i>
Pneumonia	70–80	Lymphadenopathy	98	<i>Staphylococcus aureus</i>	30–50

Meningitis	<5	Esophagitis	<10	<i>Pneumocystis carinii</i>	<1
		Gastric antral narrowing	<10	<i>Mycobacterium fortuitum</i>	<1
		Granulomatous ileocolitis	<10	<i>Chromobacterium violaceum</i>	<1
		Granulomatous cystitis	<10	<i>Chromobacterium violaceum</i>	<1
		Glomerulonephritis	<10	<i>Francisella philomiragia</i>	<1
		Discoid lupus erythematosus	<10	<i>Torulopsis glabrata</i>	<1

\*The relative frequencies of different types of infection in CGD are estimated from data pooled from several large series of patients in the United States, Europe, and Japan (Johnston and Newman, 1977; Cohen et al., 1981; Gallin et al., 1983; Hitzig and Seger, 1983; Tauber et al., 1983; Hayakawa et al., 1985; Forrest et al., 1988; Mouy et al., 1989; Winkelstein et al., 2000). These series encompass approximately 550 CGD patients after accounting for overlap between reports. The list of infecting organisms is also arranged according to data in these reports and is not paired with the entries in the first column.

<sup>†</sup>These infections are most frequently seen at the time of presentation.

<sup>‡</sup>In some instances, the incidence is estimated from the 100 cases of CGD followed at Scripps Clinic (unpublished data).

Reproduced with permission (Curnutte, 1992).

**Figure 37.1.** Chest X-ray of a male patient with chronic granulomatous disease (CGD) and fatal *Aspergillus* infection.

catalase; as such, they are unable to “lend” hydrogen peroxide generated metabolically within the microbes to the peroxide-starved CGD phagocytes. For catalase-negative organisms, the CGD phagocytes use bacteria-generated peroxide (once converted to hypochlorous acid by neutrophil myeloperoxidase) to kill the microbes (Mandell and Hook, 1969). Catalase production may thus be a microbial pathogenicity factor in CGD. However, this view has been questioned (Chang et al., 1998; Messina et al., 2002).

Pneumonia is the most common type of infection encountered in CGD in all age groups and is typically caused by *Staphylococcus aureus*, *Aspergillus* species, *Burkholderia cepacia*, and enteric gram-negative bacteria (Fig. 37.1). In cases where the pneumonia is already severe or where the patient fails to respond promptly to the empiric regimen, more invasive approaches are warranted to establish the diagnosis, such as bronchoscopy, needle biopsy, and open lung biopsy. Rarer pathogens requiring special types of treatment (for example, *Nocardia* infections) are usually only identified by this more aggressive approach. One of the more problematic pulmonary pathogens is *B. cepacia* (and the closely related organisms *B. gladioli*, *B. mallei*, *B. pseudomallei*, and *B. pickettii*). These bacteria are unusually virulent in CGD patients and have come to be identified as one of the predominant causes of fatal pneumonias in these patients (Speert et al., 1994). Contributing to this mortality is the fact that many strains of *Burkholderia* are not adequately treated with the antibiotics used for the empiric treatment of CGD infections because most are resistant to aminoglycosides and many strains are resistant to cef-

tazidime. Moreover, cultures from patients infected with *Burkholderia* often grow slowly. The virulence of these organisms is compounded by their ubiquitous presence in the environment. *Aspergillus* and other fungal infections of the lung also pose difficult challenges because they typically require prolonged treatment (4–6 months). If possible, it is important to determine the source of the *Aspergillus* in the patient’s environment so that the risk of reexposure can be minimized.

Cutaneous abscesses and lymphadenitis represent the next most common types of infection in CGD and are typically caused by *S. aureus* followed by various gram-negative organisms, including *B. cepacia* and *Serratia marcescens* (Color Plate 37.I). These infections may respond slowly to antimicrobial therapy and require incision and drainage for resolution. Recurrent impetigo, frequently in the perinasal area and caused by *S. aureus*, usually requires prolonged courses of oral antibiotics to clear. Hepatic (and perihepatic) abscesses are also quite common in CGD and are typically caused by *S. aureus*. Patients usually present with fever, malaise, and weight loss. Liver function laboratory tests are often normal. Resolution may require surgical drainage or excision of the lesion as well as several months of parenteral antibiotics. Osteomyelitis is another important infection in CGD and can arise from hematogenous spread of organisms (*S. aureus*, *Salmonella* spp., *Serratia marcescens*) or contiguous invasion of bone, typically seen with *Aspergillus* pneumonia spreading to the ribs or vertebral bodies. Perirectal abscesses are also common in CGD patients and once formed can persist for years despite aggressive antimicrobial therapy and fastidious local care. Other important but less commonly seen infections in CGD are summarized in Table 37.1.

Not all encounters with microorganisms in CGD result in overt pyogenic infections, as stalemates may develop between the pathogen and the patient’s leukocytes. In these cases, chronic inflammatory cell reactions consisting of lymphocytes and histiocytes develop, which can then organize to form granulomas, one of the hallmarks of CGD. As discussed above and noted in Table 37.1, esophageal and gastric granulomas can cause dysphagia, stomach pain, and even recurrent vomiting if they partially block the pylorus (Renner et al., 1991; Danziger et al., 1993). Similarly, granulomas in the urinary bladder can present with dysuria, decreased urine volume, and penile pain (Aliabadi et al., 1989; Walther et al., 1992). Hydronephrosis can develop if these lesions are in the vicinity of the ureters and do not resolve. Another important type of chronic inflammation in CGD is a form of inflammatory bowel disease that closely resembles Crohn’s disease and affects approximately 10% of patients. While the colon is typically involved, the ileum and other parts of the gastrointestinal tract can be affected. The symptoms can range from mild diarrhea to a debilitating syndrome of bloody diarrhea and malabsorption that can necessitate a colectomy (Ament and Ochs, 1973). Other types of chronic inflammation include gingivitis, chorioretinitis, glomerulonephritis, and destructive white matter lesions in the brain (Table 37.1) (Martyn et al., 1972; Frifelt et al., 1985; Hadfield et al., 1991). In rare cases, patients may develop either discoid or (even more rarely) systemic lupus erythematosus (Sillevis Smitt et al., 1990a; Manzi et al., 1991).

Patients with CGD can suffer from a variety of other chronic complications outlined in Table 37.1. One of the more striking is short stature, seen most commonly in X-linked males, in which the children grow at or below the fifth percentile until adolescence, when some catch-up growth can occur. Lymphadenopathy, hepatosplenomegaly, and eczematoid dermatitis are also

common features of CGD and are most frequently encountered in infants and children. Children with CGD are typically anemic with hemoglobin levels in the 8–10 g/dl range with microcytic erythrocyte indices. The anemia is most likely due to the chronic disease state and, not surprisingly, responds poorly to iron therapy. Interestingly, this anemia tends to spontaneously resolve near the end of the first decade of life. A few X-linked CGD patients have McLeod syndrome, a mild hemolytic anemia characterized by acanthocytosis and weak Kell antigens (Marsh and Redman, 1987). This anemia is caused by a deletion in the X chromosome that affects both the gene for gp91<sup>phox</sup> (*CYBB*) and the nearby *Xk* gene that encodes a 37 kDa erythrocyte membrane protein necessary for expression of Kell antigens.

Carriers of CGD, whether of the X-linked form or any of the three autosomal recessive forms, are usually asymptomatic, with three important exceptions. First, roughly half of X-linked carriers have either recurrent stomatitis or moderately severe gingivitis or both. Second, in a small percentage of X-linked carriers, there can be an unusually high degree of inactivation of the normal X chromosome in their myeloid cells. If the circulating neutrophil population is skewed to the point that fewer than 10% of the cells function, then the carrier has an increased risk of infection (usually mild) (Mills et al., 1980; Curnutte et al., 1992). Third, approximately one-quarter of X-linked carriers develop discoid lupus erythematosus characterized by discoid skin lesions on the face, shoulders, arms, and upper chest and back that can be induced or exacerbated by sun exposure. This syndrome typically becomes apparent in the second decade of life, can range from mild (common) to fairly intense, and does not appear to progress to systemic lupus erythematosus either clinically or serologically (Schaller, 1972; Brandrup et al., 1981; Sillevs Smitt et al., 1990b; Manzi et al., 1991; Yeaman et al., 1992). Severe cases usually respond well to hydroxychloroquine. Discoid lupus erythematosus has not been associated with the carrier state in any of the autosomal recessive forms of CGD. The underlying mechanism responsible for discoid lupus in X-linked CGD carriers is not known, although it has been hypothesized that autoantibodies to antigens from incompletely destroyed microbes (derived from the defective subpopulation of neutrophils) may be responsible (Manzi et al., 1991).

### Composition, Activation, and Function of the NADPH Oxidase

#### Composition of the NADPH Oxidase

The phagocyte NADPH oxidase consists of a membrane-bound catalytic subunit and a number of activity-regulating components that reside in the cytosol of resting phagocytes but translocate to the membrane upon cell activation (Fig. 37.2). In this way, the activity of this potent enzyme is restricted to the time when and the site where it is needed. The membrane-bound catalytic subunit is the flavohemeprotein gp91<sup>phox</sup>, which is stabilized in a 1:1 complex with the transmembrane p22<sup>phox</sup> protein (Table 37.2) (Huang et al., 1995; Wallach and Segal, 1996). The complex together is called flavocytochrome *b*<sub>558</sub>. The N-terminal half of gp91<sup>phox</sup> contains six hydrophobic regions that may serve as membrane-spanning domains and three N-linked glycosylation sites (Wallach and Segal, 1997) (Fig. 37.3). This part of gp91<sup>phox</sup> contains two heme moieties, each located between two histidines in transmembrane domains of the protein (Fig. 37.3) (Cross et al., 1995; Finegold et al., 1996; Yu et al., 1998). The location of the heme binding domain has been deduced from sequence homology

**Figure 37.2.** Activation of the NADPH oxidase. The membrane-bound NADPH-oxidase components gp91<sup>phox</sup> and p22<sup>phox</sup> and the small GTP-binding protein Rap1A are located in resting neutrophils in the membranes of specific granules and secretory vesicles. During cell activation (e.g., after binding of opsonized microorganisms to surface receptors on the neutrophils), these organelles fuse with the plasma membrane, thus leading to up-regulation of the expression of these components on the neutrophil surface, especially in plasma membrane areas surrounding phagocytosed material (phagosomes). Concomitantly, the cytosolic NADPH-oxidase components p40<sup>phox</sup>, p47<sup>phox</sup>, and p67<sup>phox</sup> translocate to the cytochrome *b*<sub>558</sub> subunits (gp91<sup>phox</sup> and p22<sup>phox</sup>) and induce a conformational change in gp91<sup>phox</sup> that allows NADPH to bind to gp91<sup>phox</sup> and donate its electrons to the FAD moiety in this subunit. The cytosolic small GTP-binding proteins Rac1 (in macrophages) and Rac2 (in neutrophils) regulate the translocation process by binding to p67<sup>phox</sup>, to gp91<sup>phox</sup>, and to the plasma membrane.

between the N-terminal half of gp91<sup>phox</sup> and the FRE1 protein of the iron reductase in *Saccharomyces cerevisiae* (Finegold et al., 1996). This part of gp91<sup>phox</sup> also appears to be involved in the interaction with p22<sup>phox</sup>. The C-terminal part of gp91<sup>phox</sup> is hydrophilic, probably cytosolic, and contains one FAD group. The location of the putative FAD binding domain has been deduced from sequence homology between the C-terminal half of gp91<sup>phox</sup> and the ferridoxin NADP reductase flavoenzyme family (Rotrosen et al., 1992; Segal et al., 1992; Sumimoto et al., 1992; Leusen et al., 2000). In a similar way, the position of the putative NADPH binding domain has been mapped on gp91<sup>phox</sup> (Fig. 37.3). Like gp91<sup>phox</sup>, the N-terminal half of p22<sup>phox</sup> contains hydrophobic helices that may be transmembrane domains, and the C-terminal half is more hydrophilic.

The cytosolic NADPH oxidase components p47<sup>phox</sup> and p67<sup>phox</sup> each contain two src homology region 3 (SH3) motifs, known to interact with proline-rich regions in the same or in other proteins (Table 37.2). Both of these cytosolic components also contain at least one such proline-rich region. The SH3–proline interactions may be involved both in keeping p47<sup>phox</sup> and p67<sup>phox</sup> in an inactive conformation in resting cells (by mutual interaction) and activating the NADPH oxidase enzyme by promoting interactions between the cytosolic components and flavocytochrome *b*<sub>558</sub> (De Mendez et al., 1994; Finan et al., 1994; Leto et al., 1994; Leusen et al., 1994a, 1994b, 1995; Sumimoto et al., 1994). The p67<sup>phox</sup> protein also contains four tetratricopeptide (TTP) regions in its C terminus, which form binding regions for the small GTPases Rac1 or Rac2; this constitutes another activation mechanism of the phagocyte NADPH oxidase

(Nisimoto et al., 1997; Koga et al., 1999). A third cytosolic component, called p40<sup>phox</sup>, with N-terminal homology to p47<sup>phox</sup> and one SH3 domain resembling that of p67<sup>phox</sup>, is possibly involved in stabilization of the p47<sup>phox</sup>/p67<sup>phox</sup> complex in resting cells and in facilitating membrane recruitment of this complex during oxidase activation (Table 37.2) (Fuchs et al., 1995; Kuribayashi et al., 2002). Both p47<sup>phox</sup> and p40<sup>phox</sup> contain a so-called PX (phox homology) region that can bind to phosphatidyl phosphoinositides in the plasma membrane as yet another interaction to stabilize the active NADPH oxidase complex (Ellson et al., 2001; Kanai et al., 2001). P40<sup>phox</sup> also contains in its C terminus an octicos peptide repeat (OPR), also

called PC (Phox Cdc24p) domain, which is involved in binding to a so-called PB1 (Phox and Bem-1) domain in p67<sup>phox</sup> (Ponting, 1996; Nakamura et al., 1998; Ito et al., 2001). The regions within the cytoplasmic oxidase components that interact with each other or with flavocytochrome *b*<sub>558</sub> are partially known from studying natural mutations (Dinauer et al., 1991; Leusen et al., 1994a, 1994b; 2000; Leto et al., 1994; Sumimoto et al., 1994). More detailed information in this respect has been gained from analyzing peptides in the two-hybrid system (Fuchs et al., 1995) or in a phage display system (DeLeo et al., 1995a, 1995b), or from peptide walking (Joseph and Pick, 1995; Morozov et al., 1998).

**Figure 37.3.** Schematic picture of gp91<sup>phox</sup> and X91<sup>+</sup> CGD mutations. The hydrophobic regions of gp91<sup>phox</sup> that may serve as membrane-spanning domains are shown as cylinders, while the asparagines that are *N*-glycosylated are indicated by the codon number and a carbohydrate tree. The heme-binding histidines are located in the third and fifth trans-

membrane regions. The putative FAD and NADPH binding regions are also indicated, as are the mutations that lead to the X91<sup>+</sup> phenotype of CGD. The loop of 20 amino acids that covers the cleft of the NADPH binding region in resting cells is indicated in the lower right corner of the picture.

### Activation of the NADPH Oxidase

It is possible to construct a provisional model for the mechanism of NADPH oxidase activation based on a synthesis of multiple reports. In the inactive state of the enzyme in quiescent phagocytes, the flavohemeprotein gp91<sup>phox</sup> is inaccessible for its substrate NADPH because a stretch of 20 amino acids (residues 484–504) lies over the nucleotide-binding cleft (Fig. 37.4) (Taylor et al., 1993). Interaction of p47<sup>phox</sup> and p67<sup>phox</sup> with flavocytochrome *b*<sub>558</sub> results in movement of this 20-amino acid loop and hence provides NADPH with access to its binding site in gp91<sup>phox</sup>. Some evidence suggests that binding of p67<sup>phox</sup> to flavocytochrome *b*<sub>558</sub> suffices for electron flow from NADPH via FAD and the heme groups to oxygen, thus generating superoxide; the function of p47<sup>phox</sup> may be to tighten the binding of the cytosolic oxidase components to the assembled oxidase complex (Freeman et al., 1996; Koshkin et al., 1996). One of the heme groups is probably attached to histidine-115, located in the middle of an H-X-X-X-H-X-X-X-H motif that may be involved in proton translocation for charge compensation of superoxide release outside the cells or in the phagosomes (Henderson, 1998; Henderson and Meech, 1999). Whether the hemes participate in this proton conductance is not known. However, the concept of gp91<sup>phox</sup> itself acting as a proton channel is contradicted by the findings of DeCoursey (2003).

The translocation of the cytosolic NADPH oxidase components to the flavocytochrome is initiated by serine phosphorylation of p47<sup>phox</sup> (and of p67<sup>phox</sup> and p40<sup>phox</sup>) during phagocyte activation (Segal et al., 1985; Okamura et al., 1988; Bolscher et al., 1989; Dusi and Rossi, 1993; Bouin et al., 1998; Forbes et al., 1999). This phosphorylation may cause exposure of SH3 and proline-rich domains in these proteins that are inaccessible in the p40<sup>phox</sup>/p47<sup>phox</sup>/p67<sup>phox</sup> complex in the cytosol of resting cells (Leto et al., 1994; Fuchs et al., 1995). One proline-rich re-

gion in p22<sup>phox</sup> involved in binding an SH3 region in p47<sup>phox</sup> has been identified from the mutation in this proline-rich region in a CGD patient (Leto et al., 1994; Leusen et al., 1994a; Sumimoto et al., 1994). The phosphorylation of several serines in p47<sup>phox</sup> appears to be critical for the translocation of this protein and for the activation of the NADPH oxidase (Faust et al., 1995; Johnson et al., 1998; Price et al., 2002b). In addition, phosphorylation of p22<sup>phox</sup> also correlates with NADPH oxidase activation (Regier et al., 2000). It is not yet known which protein kinases are responsible for the phosphorylation of these oxidase components, nor how these kinases are activated. Possibly, protein kinase C  $\beta$  plays an important role in this respect (El Benna et al., 1996; Korchak et al., 1998; Reeves et al., 1999). Positioning of the cytosolic oxidase components in the membrane is facilitated by the formation of phosphatidylinositol (PtdIns) species phosphorylated at the inositol-3 position in the membrane by phosphoinositide-3-OH kinase [PI(3)K] during neutrophil activation. The PX domain of p40<sup>phox</sup> binds to PtdIns(3)P and the PX domain of p47<sup>phox</sup> binds to PtdIns(3,4)P<sub>2</sub> (Kanai et al., 2001). Charge interactions between gp91<sup>phox</sup> and the cytosolic components may play a role in the formation of the oxidase complex, because several substitutions of amino acids in gp91<sup>phox</sup> for amino acids with a different charge lead to stable expression of mutant gp91<sup>phox</sup> molecules that no longer support translocation of cytosolic components (Leusen et al., 1994b, 2000). The proper positioning and stabilization of the oxidase complex may also depend on binding of the cytosolic components to cytoskeletal proteins, such as coronin, actin, moesin, and the calcium-binding protein S100A8/A9 (Grogan et al., 1997; Tamura et al., 2000; Wientjes et al., 2001; Doussi re et al., 2002). In addition, the myeloid-related proteins MRP8 and MRP14 appear to be involved in the conformational change induced in gp91<sup>phox</sup> during phagocyte activation, in synergy with p47<sup>phox</sup> and p67<sup>phox</sup> (Berthier et al., 2003). Finally, cPLA2-generated arachidonic

**Figure 37.4.** Three-dimensional model of the C-terminal, cytosolic part of gp91<sup>phox</sup>. This figure shows a model of the cytosolic portion of gp91<sup>phox</sup> based on that for spinach ferridoxin NADP reductase (Karplus et al., 1991), as described by Taylor et al. (1993). The figure was kindly provided by Dr. Nicholas Keep from Prof. Segal's group (London, U.K.). The protein is shown in the activated, NADPH-bound state. The 20-amino acid coil covering the cleft over the NADPH binding region in the active protein is now drawn aside (on top of the picture). In this coil, the position of Asp-500 is indicated. Cys-369 is located in another protein loop exposed to the cytosol, but Gly-408 is buried in the protein between these two loops. Mutations Asp500Gly, Cys369Arg, and Gly408Glu lead to the X91<sup>+</sup> CGD phenotype with defective translocation of cytosolic NADPH oxidase components.

acid is an essential cofactor in NADPH oxidase activation in intact or permeabilized cells, but the mechanism of this phenomenon is unknown (Dana et al., 1998).

Several low-molecular weight GTP-binding proteins are involved in the NADPH oxidase activation (Table 37.3) (Knaus et al., 1991; Abo et al., 1991). One of these is p21rac, of which two subtypes exist in phagocytes—Rac1 (mainly in macrophages) and Rac2 (mainly in neutrophils) (Dusi et al., 1995). During neutrophil activation, these GTP-binding proteins change from an inactive, GDP-bound state into an active, GTP-bound state, a process that is regulated by guanine-nucleotide exchange factors (GEFs) and GTPase-activating proteins (GAPs). Two Rac-activating GEFs have been identified in phagocytes: P-Rex1 and Vav1. P-Rex1 is synergistically activated by PtdIns(3,4,5)P<sub>3</sub> and the  $\beta\gamma$  subunits of trimeric G proteins associated with seven-span membrane receptors (Welch et al., 2002). This indicates that P-Rex1 in neutrophils is under direct control of ligand binding to these receptors, but this was proven only for C5a. Vav1 is activated by tyrosine phosphorylation in its acidic region, a process downstream of receptor-linked tyrosine kinases. Vav1 appears to activate Rac1 and Rac2 in phagocytes in response to formyl-methionyl-leucyl-phenylalanine (fMLP), C5a, IgG complexes, lipopolysaccharide (LPS), or Ca<sup>2+</sup> ionophore, but not to interleukin-8 (IL-8) or leukotriene B<sub>4</sub> (LTB<sub>4</sub>) (Price et al., 2002a; Vilhardt et al., 2002; Kim et al., 2003; Zhao et al., 2003). Several GAPs are known in these cells, both in the cytosol and in the membrane (Geiszt et al., 2001). By inactivating Rac, these proteins may be involved in termination of the respiratory burst

(Szaszi et al., 1999). The inactive form of Rac is kept in a complex with Rho GDP-dissociation inhibitor (RhoGDI), which shields the geranylgeranyl moiety of Rac (Abo et al., 1991; Mizuno et al., 1992; Kwong et al., 1993). The activated, GTP-bound Rac, liberated from RhoGDI, binds to p67<sup>phox</sup> and associates with its fatty-acid tail into the phospholipids of the plasma membrane (Diekmann et al., 1994). However, p47<sup>phox</sup> and p67<sup>phox</sup> are drawn to the membrane and can form a complex with the flavocytochrome independent of the translocation of Rac (Heyworth et al., 1994; Dorseuil et al., 1995; Zhao et al., 2003). Probably, Rac also interacts with gp91<sup>phox</sup> itself, to facilitate electron flux through this protein (Diebold and Bokoch, 2001). Another low-molecular weight GTP-binding protein called Rap1A is associated with flavocytochrome b<sub>558</sub> in the membrane (Table 37.3) (Quinn et al., 1992). This association is decreased upon protein kinase A-mediated phosphorylation of Rap1A, which suggests that Rap1A may modulate NADPH oxidase activity in response to agents that elevate cAMP in the cells (Bokoch et al., 1991).

### Function of the NADPH Oxidase

It is clear that the functional defects of CGD phagocytes result from the inability of these cells to generate superoxide, hydrogen peroxide, hypochlorous acid, and other products derived from superoxide. However, the bactericidal potency of superoxide and hydrogen peroxide is low, and cells with myeloperoxidase deficiency, which are unable to generate hypochlorous acid, show almost normal bactericidal activity. By contrast, CGD cells incubated with bacteria together with beads covered with glucose oxidase, which generate hydrogen peroxide in the presence of glucose, show clearly improved killing of the bacteria (Johnston and Baehner, 1970). Similar results have been obtained with liposomes filled with glucose oxidase (Gerber et al., 2001). This would indicate that the reactive oxygen compounds themselves are the prime bactericidal agents. An alternative hypothesis has been formulated by the group of Segal (Reeves et al., 2002). These investigators found that mice deficient in leukocyte elastase and cathepsin G have a similar defect in bacterial killing to that of gp91<sup>phox</sup> knockout mice. They also found that these proteases are liberated from their carbohydrate matrix in the granules by cations, and that this process takes place in neutrophil phagosomes containing ingested bacteria because of an influx of potassium. This influx is induced together with the influx of protons by the accumulation of superoxide, with its negative charge, generated in the phagosomes. In CGD phagocytes, this process does not take place, resulting in decreased protease activity in these organelles and hence decreased bacterial killing. Recently, the potassium channel involved was identified as a large-conductance Ca<sup>2+</sup>-activated K<sup>+</sup> channel (Ahluwalia et al., 2004). However, the idea expressed in this article, that the K<sup>+</sup> influx into the phagosome is responsible for most or all of the charge compensation needed to neutralize the superoxide generated in this compartment, has met strong criticism (DeCoursey, 2004). In addition, recent evidence from the group of Ligeti indicates that both direct and indirect bactericidal activity of the reactive oxygen species play an important role in the antimicrobial defense of phagocytes (Rada et al., 2004).

Another hallmark of CGD is the occurrence of diffuse granulomas. Some recent articles indicate that this too may be caused by the failure of the leukocyte NADPH oxidase in these patients to generate reactive oxygen species, in particular H<sub>2</sub>O<sub>2</sub> (Hampton et al., 2002; Kobayashi et al., 2004). Phagocytosis of bacteria by

neutrophils leads to externalization of phosphatidylserine (PS) in the plasma membrane and to other apoptosis-related changes in these cells (Kobayashi et al., 2003), and this PS exposure labels these cells for removal by macrophages. Both PS exposure and uptake by macrophages appear to be dependent on the formation of hydrogen peroxide by the neutrophils (Hampton et al., 2002). Thus, clearance of stimulated neutrophils might be delayed in CGD, a concept that was proven in gp91<sup>phox</sup> knockout mice. This defect may well relate to the formation of granulomas in CGD patients. Gene expression profiling has shown that CGD neutrophils have constitutively up-regulated expression of genes encoding mediators of inflammation and host defense. In contrast, during phagocytosis-induced apoptosis, CGD neutrophils did not display increased Bax expression, as do normal neutrophils (Kobayashi et al., 2004). Thus, granuloma formation in CGD patients may reflect increased proinflammatory activity and defective apoptosis of CGD neutrophils. This aberrant gene expression profile may be a direct effect of diminished reactive oxygen species (ROS) production or ROS-sensitive gene expression. Also, the diminished production of anti-inflammatory mediators by CGD neutrophils and macrophages during phagocytosis of bacteria or apoptotic cells (Brown et al., 2003) may contribute to the persistence of inflammation in CGD.

### Nonphagocyte NADPH Oxidases

Recently, several homologues of gp91<sup>phox</sup> have been identified in cells other than phagocytes. These homologues have conserved the overall structure of six transmembrane domains with four heme-coordinating histidines in the N-terminal part of the mole-

cule, followed by a cytosolic C-terminus that contains highly conserved binding sites for FAD and NADPH. In a new nomenclature, these proteins are now called Nox (NADPH oxidase) proteins, including gp91<sup>phox</sup> (Nox2). Mox1 (or Nox1) mRNA is expressed in colon, uterus, and vascular smooth muscle cells (Suh et al., 1999). Reactive oxygen species produced by this enzyme seem to be generated intracellularly, in contrast to the situation with the phagocyte NADPH oxidase. Overexpression of Nox1 results in increased cell growth, suggesting a role for these oxygen species in signal transduction for cell growth regulation. Another gp91<sup>phox</sup> homologue, called Renox or Nox4, has been detected by in situ RNA hybridization and immunohistochemistry in the renal cortex, predominantly in proximal convoluted tubule epithelial cells (Geiszt et al., 2000; Shiose et al., 2001). It has been suggested that Nox4 may participate in the oxygen-sensing mechanism that regulates the production of erythropoietin. Transfection of Nox4 into 3T3 fibroblasts resulted in enhanced superoxide production; however, these modified cells displayed substantially diminished cell growth. Nox 3 is highly expressed in the inner ear, especially in the vestibular and cochlear sensory epithelia, but its function there is unknown. Nox5 is distinguished from the other family members by its longer N terminus, which contains four EF hand Ca<sup>2+</sup>-binding motifs. It is found in B and T lymphocytes. Some of these alternative NADPH oxidases, in particular Nox1, Nox 3, and Nox4, may interact with specific cytosolic partners for activity regulation and localization—i.e. with the recently discovered alternative members of the p47 and p67 protein families (Bánfi et al., 2003; Geiszt et al., 2003; Takeya et al., 2003).

Finally, two similar homologues have been discovered that are characterized by an N-terminal extension containing a peroxidase

homology domain, a calmodulin-like calcium-binding motif, and an additional transmembrane domain (De Deken et al., 2000). RNA for these proteins, called ThOX-1 and ThOX-2 (or Duox1 and Duox2), is expressed specifically in the thyroid gland, at the apical membrane of the thyrocytes. Duox2, and perhaps also Duox1, is involved in the iodination of the thyroid hormone, because nonsense mutations in the gene for Duox2 have been identified in patients with congenital hypothyroidism (Moreno et al., 2002).

### Molecular Basis

Deficiency of the phagocyte NADPH oxidase, as seen in CGD, can be the result of any of a number of defects. First, one of the structural components of the enzyme can be deficient, which is the case when mutations occur in the genes encoding gp91<sup>phox</sup>, p22<sup>phox</sup>, p47<sup>phox</sup>, or p67<sup>phox</sup>. Mutations in the gene for p40<sup>phox</sup> have not been described. Together, mutations in these four genes account for the overwhelming majority of CGD cases, with defects in the X chromosome–encoded gp91<sup>phox</sup> found in about 70% of the cases and in p47<sup>phox</sup> in about 25%. Defects in p22<sup>phox</sup> or p67<sup>phox</sup> are rare. Even more rare are defects in the activation process of the NADPH oxidase. In particular, one patient has been described with a mutation in Rac2, leading to CGD-like symptoms in combination with defects in chemotaxis and in degranulation (Ambruso et al., 2000; Williams et al., 2000). This finding indicates that Rac2 is involved not only in the activation of superoxide production but also in the activation of other neutrophil functions. Finally, defects may occur in the process that provides the cell with the substrate for the oxidase, i.e., NADPH. This compound is generated in phagocytes for the largest part in the hexose monophosphate pathway, in the successive G6PD and the 6-phosphogluconate dehydrogenase (6PGD) reactions. Occasionally, patients are found with a deficiency of G6PD in not only the erythrocytes but also the leukocytes (Baehner et al., 1972; Gray et al., 1973; Roos et al., 1999). These patients suffer from a mild form of CGD.

The *CYBB* gene for gp91<sup>phox</sup> has a size of 30 kb, with 13 exons (Table 37.2). It is located on the X chromosome, at Xp21.1. Its promoter region has been clarified in some detail. In transgenic mice, 450 bp of the 5′ flanking region of *CYBB* suffices for expression of reporter genes in a subset of mononuclear phagocytes, but not in all myelomonocytic cells (Skalnik et al., 1991a). The same investigators have identified a repressor region around the CCAAT box motif at about 160 and 170 bp 5′ from the *CYBB* initiation codon (Skalnik et al., 1991b) and a high-mobility group (HMG) chromosomal protein binding to the same region and supposedly acting as a transcriptional activator (Skalnik and Neufeld, 1992). Another transcription factor involved in *CYBB* activity regulation is YY1, which binds at five places within the first 412 bp of its promoter region (Jacobsen and Skalnik, 1999). Six CGD families are known with mutations in the promoter region of *CYBB* that interfere with binding of Elf-1 and PU.1 (Newburger et al., 1994; Woodman et al., 1995; Suzuki et al., 1998; Voo and Skalnik, 1999; Weening et al., 2000; Stasia et al., 2003). In addition, the transcription of *CYBB* and *NCF1* is enhanced by interferon- $\gamma$  (IFN- $\gamma$ ) (Casatella et al., 1990; Weening et al., 1996).

The *CYBA* gene for p22<sup>phox</sup> has a size of 8.5 kb, with six exons (Table 37.2). It is located on chromosome 16, at 16q24. Its promoter region has been partly characterized (Moreno et al., 2003). The *NCF1* gene for p47<sup>phox</sup> has a size of 15 kb, with 11 exons, and the *NCF2* gene for p67<sup>phox</sup> measures 40 kb, with 16 exons (Table 37.2). These genes are located on chromosomes

7 and 1, respectively, at 7q11.23 and 1q25. Finally, the *NCF4* gene for p40<sup>phox</sup> has a size of 18 kb, with 10 exons, and is located on chromosome 22, at 22q13.1. Detailed information on the promoter regions of these *NCF* genes has been collected (Li et al., 1997, 1999, 2001, 2002). In none of the NADPH oxidase genes do the exon organizations coincide with the various functional regions of the proteins they encode.

The *RAC2* gene is located on chromosome 22, at 22q13. It has a size of 18 kb, with at least seven exons. The promoter region of this gene has not yet been studied in detail. The Rac2 protein has a molecular weight of 22,000 and consists of 192 amino acids. The *G6PD* gene is located on the X chromosome, at Xq28. It has a size of 18 kb, with 13 exons. The first exon is not translated. Comparison of the promoter region of *G6PD* with 10 other housekeeping enzyme genes confirmed the presence of common features. In particular, in eight of these genes in which a TATA box was present, a conserved region of 25 bp is found immediately downstream. The G6PD protein has a molecular weight of 58,000 and consists of 531 amino acids. By binding NADP<sup>+</sup>, the protein forms catalytically active dimers.

### Laboratory Findings

#### Diagnosis

As mentioned above, CGD is caused by dysfunction of the NADPH oxidase enzyme in phagocytic leukocytes (neutrophils, eosinophils, monocytes, and macrophages). This enzyme generates superoxide, the one-electron reduction product of molecular oxygen. Superoxide is subsequently converted into hydrogen peroxide, either spontaneously or catalyzed by superoxide dismutase. Hydrogen peroxide is further metabolized through the action of myeloperoxidase into hypochlorous acid and other microbicidal metabolites. In CGD, the activated phagocytes fail to generate superoxide and as a result also fail to generate the other reactive oxygen products. As a consequence, phagocytosed microorganisms are less efficiently killed by CGD leukocytes.

Patients suspected of suffering from CGD can therefore be diagnosed by the inability of their blood phagocytes to kill catalase-positive bacteria (e.g., *Staphylococcus aureus* or *Escherichia coli*) in vitro or by their inability to generate reactive oxygen species. The respiratory burst can be measured by oxygen consumption (with an oxygen electrode), by superoxide generation (reduction of ferricytochrome *c* or nitroblue tetrazolium), or by hydrogen peroxide production (oxidation of homovanillic acid or Amplex red). Chemiluminescence with luminol or lucigenin is often used as a very sensitive test of NADPH oxidase activity. Flow-cytometric detection of this activity combines the advantage of sensitivity with the possibility of using nonpurified leukocyte suspensions rapidly derived from whole blood. One such assay, using dihydrorhodamine-1,2,3 (DHR) as the fluorescent detector of hydrogen peroxide production, has proven to be highly reliable and sensitive, even on blood that is 24–48 hours old. This assay has therefore replaced superoxide measurements and the NBT slide test as the primary screening assay for CGD in many laboratories (Emmendorffer et al., 1994; van Pelt et al., 1996; Vowells et al., 1996).

#### Chronic Granulomatous Disease Subgroup Identification

Because the NADPH oxidase is composed of multiple subunits, four of which may be affected by mutations leading to CGD (see

above, Table 37.2), further differentiation of the diagnosis is needed before mutation analysis can be performed. CGD subgroup investigation starts with immunoblot analysis of neutrophil fractions or intracellular staining in permeabilized neutrophils with antibodies against these four NADPH oxidase components. In cases where one of the cytosolic components (p47<sup>phox</sup> or p67<sup>phox</sup>) is missing, one can be confident that the gene carrying the mutation has been identified. However, if one of the membrane-bound components (gp91<sup>phox</sup> or p22<sup>phox</sup>) is missing, the other is always undetectable as well (Parkos et al., 1989; Verhoeven et al., 1989), because the subunits stabilize each other for full maturation and expression (Porter et al., 1994; Yu et al., 1997). In that case, distinction can usually be made by searching for a mosaic pattern of NADPH oxidase activity or gp91<sup>phox</sup>/p22<sup>phox</sup> expression in the neutrophils of female relatives of the patient, because the gene for gp91<sup>phox</sup> is located on the X chromosome. Convenient assays for this purpose are the NBT slide test, which scores the NADPH oxidase activity per cell on a semiquantitative basis (Meerhof and Roos, 1986), or the DHR flow-cytometric assay (Roesler et al., 1991; Vowells et al., 1996). Alternatively, one can perform flow cytometry to detect gp91<sup>phox</sup>/p22<sup>phox</sup> on the neutrophil surface with certain anti-flavocytochrome *b*<sub>558</sub> antibodies (Mizuno et al., 1988). However, it must be kept in mind that up to one-third of all X-linked defects may arise from new mutations in germ-line cells and will therefore not always be present in the somatic cells from the mother. Thus failure to define the mother as an X-linked carrier does not disprove the X-linked origin of the disease.

If all four subunits of the NADPH oxidase are detectable, even though the activity of this enzyme is absent or strongly decreased, the possibility of so-called (+) variants must be considered (Table 37.4). These are caused by mutations in any of the four subunits that leave the protein expression intact but destroy the enzymatic activity of the assembled oxidase complex. In that case, a cell-free oxidase assay may be used to distinguish a defect in a cytosolic component (p47<sup>phox</sup> or p67<sup>phox</sup>) from a defect in a membrane-bound component (gp91<sup>phox</sup> or p22<sup>phox</sup>). For this assay, neutrophil membranes from the patient are mixed with neutrophil cytosol from a healthy donor (or vice versa), incubated with NADPH, and activated with an amphiphilic agent (low concentrations of sodium dodecyl sulfate [SDS] or arachidonic acid). The resulting oxidase activity can be measured by superoxide formation or oxygen consumption and used to localize the defect to either the cytosol or membrane fraction (Curnutte et al., 1987). Identification of the mutated gene that causes the defect in NADPH oxidase activity can also be made if transfection of the patient's Epstein Barr virus (EBV)-transformed B lymphocytes with retroviral vectors that contain the wild-type cDNA restores this activity (Malech et al., 1997).

Patients with variant forms of X-linked CGD are characterized by a partial loss of gp91<sup>phox</sup> expression and a proportional loss of NADPH oxidase activity (so-called X<sup>-</sup> variants) (Table 37.4). For an exact idea of gp91<sup>phox</sup> expression, it can be useful to measure the heme content of flavocytochrome *b*<sub>558</sub> (Cross and Curnutte, 1995).

Finally, some patients with CGD-like symptoms are known with defects in either G6PD or Rac2. The first type can easily be recognized by measuring the activity of the G6PD enzyme in the red blood cells and confirming the diagnosis by repeating the assay with a leukocyte preparation (Roos et al., 1999; Van Bruggen et al., 2002). Moreover, one will usually find a mosaic of normally and faintly stained cells in the NBT slide test or DHR assay with purified neutrophils of the mother, because the G6PD

**Table 37.4.** Mutations in *CYBB* (gp91<sup>phox</sup>)

	No. of Kindreds	Frequency (%)	Phenotype*
Deletions	92	22.1	X91 <sup>0</sup>
Insertions	38	9.1	X91 <sup>0</sup>
Splice site mutations	81	19.5	X91 <sup>0</sup>
Missense mutations	103	24.8	X91 <sup>0</sup> , X91 <sup>-</sup> , X91 <sup>+</sup>
Nonsense mutations	102	24.5	X91 <sup>0</sup>

\*In this nomenclature, the first letter (X) represents the mode of inheritance, while the number (91) indicates the phox component that is genetically affected. The superscript symbols indicate whether the level of protein of the affected component is undetectable (<sup>0</sup>), diminished (<sup>-</sup>), or normal (<sup>+</sup>) as measured by immunoblot analysis.

Data from a multicenter database (Vihinen et al., 2001).

gene is localized on the X chromosome. Rac2 deficiency can be recognized by the defect in NADPH oxidase activity in combination with defects in chemotaxis toward complement fragment C5a, IL-8, fMLP, LTB<sub>4</sub>, and platelet-activating factor (PAF). A defect in the release of proteins from the azurophilic granules but not from the specific granules or secretory vesicles is also apparent (Roos et al., 1993; Ambruso et al., 2000). The Rac2 deficiency can only be diagnosed with certainty when the oxidase activity in the cell-free assay is restored by addition of purified Rac.

### Carrier Detection

Carrier detection of X-CGD is usually performed by searching for a mosaic pattern of oxidase-positive and -negative neutrophils in the NBT slide test, in the DHR flow-cytometric assay, or in a flow-cytometric assay of gp91<sup>phox</sup>/p22<sup>phox</sup> protein expression. However, because of the random process of X chromosome inactivation, X-CGD carriers may show a near-normal or a near-pathological pattern in these tests. Once the family-specific mutation is known, it is more reliable to perform carrier detection at the DNA level. This is best performed by polymerase chain reaction (PCR) amplification of the relevant region of genomic DNA, followed by sequencing or allele-specific restriction enzyme analysis. Alternatively, single-strand conformation polymorphism (SSCP) can be informative if the mutation leads to an abnormal band pattern. If the mutation involves a large deletion, simple RFLP analysis of genomic DNA may reveal the carriers.

Carriers of autosomal (A) CGD subtypes are difficult to detect. The NADPH oxidase activity of phagocytes from obligate carriers (parents of patients) is normal unless phorbol-myristate acetate is used to activate these cells (Verhoeven et al., 1988; de Boer et al., 1994). However, this is a rather insensitive assay, and it has not been tested with A22 CGD carriers. Also, the expression of p47<sup>phox</sup> and p67<sup>phox</sup> proteins appears normal in obligate carriers of A47 and A67 CGD, respectively. Hence, detection of carriers of autosomal CGD is much better performed at the DNA level. Unfortunately, for A47 CGD, this is difficult (see Mutation Analysis).

### Mutation Analysis

#### Mutation Analysis in X-Linked Chronic Granulomatous Disease

In our laboratories, the mutations in more than 400 families with X-CGD (MIM 306400) have been characterized (Hopkins et al., 1992; Roos et al., 1996a, 1996b; Rae et al., 1998; Cross et al.,

2000; Heyworth et al., 2001). In addition, about 100 X-CGD mutations have been identified and some of these have been published by other investigators; updates of all mutations known to us can be found in Heyworth et al. (2001) and at the Internet address <http://www.uta.fi/imt/bioinfo/CYBBbase/>. The results show that CGD is a very heterogeneous disease, not only clinically and cell biologically but also at the molecular level, even within one subgroup. All possible mutations, except gene conversions, have been found in the *CYBB* gene. These different categories will be briefly mentioned, followed by a more detailed description of a few mutations that have given us insight into the structure–function relation of gp91<sup>phox</sup>.

Deletions and/or insertions in *CYBB* are encountered in about 31% of all X-CGD patients; single nucleotide substitutions are seen in the remaining 69%. This last category can be subdivided into splice site mutations leading to aberrant mRNA processing (19%), missense mutations causing single amino acid substitutions (25%), and nonsense mutations inducing premature termination of protein synthesis (25%) (Heyworth, Roos in: Vihinen et al., 2001). Table 37.4 provides an overview.

Deletions range in size from about 5,000,000 to one single nucleotide. When the deletions are very large, not only the *CYBB* gene is affected but neighboring genes as well. Such patients suffer from other clinical syndromes in addition to CGD—for example, Duchenne muscular dystrophy, retinitis pigmentosa, and, as mentioned above, McLeod syndrome (a mild hemolytic anemia with decreased levels of Kell erythrocyte antigens due to defects in the K<sup>x</sup> system). In two families, affected brothers were detected who each carried different deletions in their *CYBB* genes (de Boer et al., 1998). Only in one patient has an in-frame partial exon deletion been reported to lead to expression of the truncated (inactive) gp91<sup>phox</sup> protein (Schapiro et al., 1991).

Insertions in *CYBB* are usually small in size and, like small deletions, may be caused by slipped mispairing at the DNA replication fork. A few larger tandem duplications of 24, 31, and 40 base pairs, respectively, have been detected, apparently due to unequal crossing-over during meiosis or misalignment during DNA repair (Rabbani et al., 1993; Bu-Ghanim et al., 1995; Roos et al., unpublished findings). Several combinations of small deletions and insertions have been found (Ariga et al., 1995; Rae et al., 1998; Heyworth et al., 2001; Roos et al., unpublished findings), in one of them predicting substitution of three amino acids by four others near the C terminus of gp91<sup>phox</sup> (Azuma et al., 1995). This mutation leads to a stable mutant protein and thus to the X91<sup>+</sup> CGD phenotype. The lack of oxidase activity in this patient may be due to decreased binding of NADPH to flavocytochrome *b*<sub>558</sub>, because the mutation is in the putative NADPH binding region of gp91<sup>phox</sup>, but this possibility was not investigated. Finally, two large fragments of LINE-1 transposable elements have recently been identified within *CYBB*. The first one is a 1 kb fragment within intron 5, causing a complicated pattern of misspliced mRNA (Meischl et al., 2000). The second is a 2.1 kb fragment within exon 4, causing a frameshift (Brouha et al., 2002). In both families, the insertion was a recent event because it was not found in the somatic cell DNA from the patients' mothers. The 2.1 kb fragment was identified as part of an active LINE-1 element on chromosome 2 of the patient's mother.

Single nucleotide substitutions at exon–intron boundaries lead to aberrations in mRNA splicing, usually causing skipping of an entire exon. However, this phenomenon was proven in only about half of the cases (in the other half, only genomic DNA was investigated). The percentage of splice site mutations found in CGD is similar to that found in other diseases (Krawczak et al., 1992).

Single nucleotide changes in the middle of exon 6 and in the middle of introns 5 and 6 have created new splice sites, causing a partial exon deletion or insertions, respectively, in the mRNA (de Boer et al., 1992a; Noack et al., 1999, 2001a).

Missense and nonsense mutations constitute the most frequently encountered cause of many genetic diseases. A hot spot for such mutations is the CpG sequence, especially in the CGA codon for arginine, leading to the stop codon TGA. Nonsense mutations in *CYBB* affect the level of mRNA for gp91<sup>phox</sup> to a variable degree but have not been seen in CGD to produce stable truncated proteins. Similarly, deletions, insertions, and splice site mutations in general also lead to the X91<sup>0</sup> phenotype (no gp91<sup>phox</sup> protein expression, no NADPH oxidase activity). In contrast, missense mutations do not influence the level of mRNA and may give rise to any of three phenotypes. Single amino acid replacements due to missense mutations can lead to intrinsically unstable gp91<sup>phox</sup> or to gp91<sup>phox</sup> unable to be stabilized by interaction with p22<sup>phox</sup> (X91<sup>0</sup> phenotype), to partial deficiencies in this respect (X91<sup>−</sup> phenotype: decreased expression, decreased oxidase activity), or to stable but inactive gp91<sup>phox</sup> (X91<sup>+</sup> phenotype) (Table 37.4). Small in-frame deletions and a few splice site mutations with residual normal mRNA splicing have also been found associated with the X91<sup>−</sup> phenotype.

The X91<sup>+</sup> mutations can be very informative for our understanding of the properties of the different domains in gp91<sup>phox</sup>. At present, 13 X91<sup>+</sup> patients are known with missense mutations in *CYBB*. (Two additional X91<sup>+</sup> patients carry deletions that remove 5 or 10 amino acids while another has a 3–amino acid deletion/4–amino acid insertion.) Four X91<sup>+</sup> patients have amino acid substitutions in the N-terminal half of gp91<sup>phox</sup> (Fig. 37.3). The first one is an Ala57Glu substitution; this mutant protein has not been studied in detail (Ariga et al., 1993). The other three are Arg54 substitutions; one of these (Arg54Ser) has been studied in detail. This substitution affects the function of one of the heme groups in flavocytochrome *b*<sub>558</sub>, as evidenced by a slight shift in the optical absorbance and a decrease in the midpoint potential (Cross et al., 1995). Superoxide production was completely inhibited and both heme groups were nonfunctional, suggesting that the electron flow from FAD to oxygen requires sequential involvement of the two heme groups (Cross et al., 1995; Cross and Curnutte, 1995). The investigators speculate that Arg54 may interact with one of the propionate side chains of a heme group.

The other X91<sup>+</sup> patients have amino acid substitutions in the C-terminal half of gp91<sup>phox</sup> (Fig. 37.3). In four of these, the translocation of p47<sup>phox</sup> and p67<sup>phox</sup> to cytochrome *b*<sub>558</sub> upon neutrophil activation was found to be strongly diminished (Leusen et al., 1994b, 2000). This was seen with Cys369Arg, Gly408Glu, Asp500Gly, and Glu568Lys, residues located (respectively) in a loop between the putative FAD and NADPH binding regions, on the edge of the NADPH binding region, in the 20–amino acid loop over the NADPH cleft, and in the extreme C-terminal region of the gp91<sup>phox</sup> protein. Apparently, not only the loop over the NADPH cleft is of importance as a docking site for the cytosolic oxidase components, but other regions surrounding this area as well (Fig. 37.4). All together, these results provide strong support of the three-dimensional model of the C-terminal half of gp91<sup>phox</sup> as constructed by Taylor et al. (1993). Support for the putative NADPH binding region of gp91<sup>phox</sup> comes from the decreased binding of NADPH observed in a mutant gp91<sup>phox</sup> containing a Pro415His substitution, a residue believed to be part of the NADPH binding domain (Segal et al., 1992).

Some X91<sup>−</sup> mutations have also proven to be informative. Tsuda et al. (1998) have described a patient with a His101Tyr

mutation, causing 90% loss of gp91<sup>phox</sup> protein expression but total loss of heme incorporation. This indicates that His101 of gp91<sup>phox</sup> may be involved in heme binding, in accordance with the prediction based on the FRE1 protein (Finegold et al., 1996) and with the need of heme incorporation for maturation and stability of the gp91<sup>phox</sup>/p22<sup>phox</sup> complex (Yu et al., 1997). A mutation of His338Tyr led to about 80% decreased heme levels but almost complete loss of FAD incorporation, in accordance with the His-Pro-Phe-Thr 338-341 motif being involved in FAD binding (Yoshida et al., 1998). This is probably also the explanation for the loss of activity in an X91<sup>+</sup> CGD patient with a Thr341Lys mutation in gp91<sup>phox</sup> (Leusen et al., 2000).

Finally, four different single nucleotide substitutions have been identified in the 5' promoter region of *CYBB* (Newburger et al., 1994; Woodman et al., 1995; Suzuki et al., 1998; Weening et al., 2000; Stasia et al., 2003). Mutations at -52 and -53 were found to be located in a binding element for the nuclear transcription factor PU.1 and to suppress the binding of PU.1 and the subsequent promoter activity. Remarkably, these mutations abolished NADPH oxidase activity in the neutrophils, monocytes, and transformed B lymphocytes of the patients, but not in their eosinophils (Suzuki et al., 1998). This finding probably explains the mild clinical phenotype of these patients (Weening et al., 2000). Apparently, eosinophils have an additional *CYBB* activation mechanism, which has been identified as the eosinophil-specific transcription factor GATA-1 (Yang et al., 2000). The patients with mutations at -55 and -57 had small subsets of neutrophils (approximately 5%) with normal NADPH oxidase activity. These mutations strongly reduced the association of Elf-1 and PU.1 and also reduced the ability of these factors to *trans*-activate the promoter (Voo and Skalnik, 1999). The investigators speculate that different DNA binding proteins are used in different neutrophil subsets for the initiation, enhancement, and repression of *CYBB* transcription.

On the basis of a multicenter review of the mutations identified in 416 X-linked CGD kindreds (Heyworth, Roos, in Vihinen et al., 2001), 69% of them are family-specific. Only four polymorphisms in *CYBB* have been detected to date, two of which predict an amino acid substitution, thus pointing to an extreme sensitivity of this protein for mutations (Heyworth et al., 2001).

### Mutation Analysis in Autosomal Chronic Granulomatous Disease

The number of well-characterized mutations in autosomal CGD is much lower than that in X-linked CGD, owing to the lower incidence of these forms of the disease. Thirty-three A22 families, about 100 A47 families, and 23 A67 families have been investigated in this respect. The results indicate that the molecular genetic basis of A22 and A67 CGD is as heterogeneous as that of X91 CGD, but A47 CGD is much more homogeneous in origin.

In the 33 A22 CGD families with mutations of p22<sup>phox</sup> (MIM 233690), 27 different mutations have been found in the 66 alleles, including deletions, insertions, splice site mutations, nonsense, and missense mutations (for a detailed overview see Cross et al., 2000, and the Internet address <http://www.uta.fi/imt/bioinfo/CYBAbase/>). In 26 families, the patients carried homozygous deficiencies; in 7 families, the patients were compound heterozygotes. Ten mutations were found in more than one unrelated family, with a hot spot of a missense mutation at 354C → A, changing the AGC codon for Ser118 into the AGA codon for Arg, in three families (six alleles). Only seven polymorphisms

are known in the p22<sup>phox</sup> protein. Thus, small changes in the composition of this protein appear to lead to intrinsic instability and/or instability due to decreased interaction with gp91<sup>phox</sup>. Only one A22<sup>+</sup> patient has been found, with a Pro156Glu substitution (Dinauer et al., 1991). Pro156 is in a proline-rich region of p22<sup>phox</sup> that serves as a binding region for an SH3 domain in p47<sup>phox</sup>. Apparently, the Pro156Glu substitution destroys the interaction between these proteins and hence the activation of the NADPH oxidase (Leto et al., 1994; Leusen et al., 1994a; Sumimoto et al., 1994). This substitution is the first recognized mutation that disturbs an SH3-proline interaction and leads to a genetic disease.

The mutations that cause A47 CGD have long puzzled investigators. In more than 100 unrelated patients with p47<sup>phox</sup> deficiency (MIM 233700), a dinucleotide deletion has been found at a GTGT tandem repeat corresponding to the first four bases of exon 2 in the *NCF1* gene (Casimir et al., 1991; Volpp and Lin, 1993; Iwata et al., 1994; Roos et al., 1996a; Roesler et al., 2000; Noack et al., 2001b; Vazquez et al., 2001). In all but 13 of these reported families, the GT deletion appeared to be homozygous. In these 13 exceptions, 9 patients were heterozygotes for the GT deletion and one additional mutation, and 4 had mutations other than ΔGT on both alleles of *NCF1*. Of these last four patients, three were homozygotes for a mutation and one was a compound heterozygote. For an overview of these mutations see Cross et al. (2000) and the Internet address <http://www.uta.fi/imt/bioinfo/NCF1base/>. The spectrum of these non-ΔGT mutations is as diverse as that in the other CGD genes (Noack et al., 2001b; de Boer et al., 2002; Roos et al., unpublished findings). Obviously, the ΔGT-bearing allele of *NCF1* is the most common CGD-causing allele in the population, carried by approximately 1 in 500 individuals. The reason for this predominance is that most normal individuals have on each chromosome 7 two p47<sup>phox</sup> pseudogenes, which colocalize with the functional *NCF1* gene to 7q11.23. These pseudogenes are >99% homologous to *NCF1* but carry the GT deletion, which renders them inactive because the predicted protein from these pseudogenes contains a premature stopcodon. Recombination events between *NCF1* and the pseudogenes lead to the incorporation of ΔGT into *NCF1*, and thus to CGD (Goerlach et al., 1997; Roesler et al., 2000; Vazquez et al., 2001). To date, only one polymorphism has been recognized in *NCF1*, but the identification of these variations is complicated by the presence of the pseudogenes. All mutations in *NCF1* identified thus far lead to absence of p47<sup>phox</sup> protein.

Unfortunately, this complicated genetic background of A47 CGD renders reliable carrier testing difficult, because normal individuals appear to be "heterozygous" for the GT deletion by virtue of containing the pseudogenes. Allele-specific PCR amplification can be used to solve this problem but is not easily applicable (Noack et al., 2001b). A screening method for the GT deletion with the restriction enzyme *DraIII*, which cuts only the GTGT-containing sequence, distinguishes homozygous GT deletion patients from healthy donors (no reaction with patients, 33% reaction with healthy donors), but it is too insensitive to discriminate between a normal individual and either an A47 patient who is a compound heterozygote for the GT deletion or a carrier for the GT deletion. Recently, a gene-scan method has been developed for determining the relative number of *NCF1* and pseudogenes in genomic DNA. With this test, patients and carriers with the GT deletion can be distinguished from normal individuals and from each other (Dekker et al., 2001). However, it is not yet clear whether the compound protein with the GTGT sequence from *NCF1* followed by the 3' sequence of the pseudogenes is

expressed and has oxidase-promoting activity (Heyworth et al., 2002). In all A47 CGD patients analyzed thus far, the mRNA levels for p47<sup>phox</sup> were normal, but the amount of p47<sup>phox</sup> protein in each was undetectable. Thus, only A47<sup>0</sup> patients have been identified to date.

In the 23 characterized A67 CGD families with abnormal p67<sup>phox</sup> (MIM 233710), the patients carry 22 different (and 2 unidentified) mutations among the 46 total alleles affected. These include missense mutations, splice site mutations, nonsense mutations, a dinucleotide insertion, and a variety of deletions ranging from one nucleotide to 11–13 kb (for a detailed review see Cross et al., 2000, and the Internet address <http://www.uta.fi/imt/bioinfo/NCF2base/>). In 16 families, the patients are homozygous for one mutation, in 7 they are compound heterozygotes. Four mutations were found in more than one unrelated family, with a hot spot of a gt → at splice site mutation at the start of intron 4 in four families. Twelve polymorphisms in *NCF2* are known (including the 5' untranslated region), six of which predict amino acid substitutions. In some of the A67 CGD patients, the level of mRNA for p67<sup>phox</sup> is normal, but in most the p67<sup>phox</sup> protein is undetectable. However, in one of the patients, with a trinucleotide deletion (170–172) on one allele (the other allele carried a large deletion), about half the normal amount of protein was found. In this patient, the mutation predicts an in-frame deletion of Lys58 from the protein and apparently results in the expression of a nonfunctional p67<sup>phox</sup> that fails to translocate to the plasma membrane because of the inability of this protein to bind Rac (Leusen et al., 1996). Hence, A67<sup>+</sup> patients may exist.

### Mutation Analysis in Rac2 Deficiency

Rac2 deficiency has been described in one patient only (MIM 602049) (Ambruso et al., 2000; Williams et al., 2000), although the cellular deficiencies exactly match those described in another patient with neutrophil defects of unknown etiology (Roos et al., 1993). The patient with proven Rac2 deficiency suffered from severe bacterial infections and poor wound healing, symptoms that, together with late separation of the umbilical stump, leukocytosis, and absence of pus in infected areas, also observed in the patient, are reminiscent of leukocyte adhesion deficiency (LAD). Indeed, neutrophil studies indicated a defect in chemotaxis toward C5a, fMLP, and IL-8, but in contrast to LAD1, normal expression of  $\beta_2$  integrins (CD18) on the leukocytes (see Chapter 38). Moreover, despite a normal content of enzymes of the azurophilic granules, strongly decreased release of these enzymes after neutrophil activation with either fMLP or phorbol myristate acetate (PMA) was found. In contrast, the release of lactoferrin from the specific granules induced by these agents was normal. Neutrophil polarization and actin polymerization in response to fMLP was also deficient, as was transient adhesion to the L-selectin ligand GlyCAM-1 and stable adhesion to fibronectin. Finally, the neutrophils from this patient failed to respond with superoxide production after activation with fMLP or C5a, but responded normally with PMA. Thus, this syndrome combined defects seen in LAD with those observed in CGD and in addition included defects in degranulation and actin-dependent functions. However, in contrast to CGD, the NADPH oxidase defect was selective for certain stimuli. A common defect in intracellular signaling for activation of the various neutrophil functions seemed plausible. Indeed, in the cell-free NADPH oxidase assay, the defect was localized in the cytosol fraction, and the activity was restored by addition of recombinant, GTP-activated Rac1, which

can substitute for Rac2 in this assay system. A possible defect in Rac2 activity was corroborated by half-normal expression of this protein in the patient's neutrophils. Mutation analysis of the patient's Rac2 gene showed a heterozygous 169G → A transition, predicting a substitution of Asp57 for Asn. This Asp57 is in a conserved D-X-X-G motif involved in GTP binding to Ras GTPases. Recombinant Rac2<sup>D57N</sup> bound GDP normally but failed to bind GTP.

The involvement of Rac2 in multiple neutrophil functions had already been deduced from studies with Rac2 knockout mice (Roberts et al., 1999). However, in these studies it was shown that both Rac2 alleles had to be disrupted for defects to become apparent. The fact that the patient was heterozygous for the Rac2 mutation and expressed both normal and mutant mRNA for Rac2 but nevertheless exhibited strong neutrophil defects indicates that Rac2<sup>D57N</sup> has a dominant negative effect on the function of wild-type Rac2. This was proven in the cell-free NADPH oxidase assay with recombinant proteins (Ambruso et al., 2000) and in normal human bone marrow cells transduced with Rac2<sup>D57N</sup> or patient bone marrow cells transduced with wild-type Rac2 (Williams et al., 2000). The mechanism of this dominant negative effect of Rac2<sup>D57N</sup> was clarified by Gu et al. (2001), who found that Rac2<sup>D57N</sup> binds the guanine nucleotide exchange factor (GEF) TrioN normally, but that this binding had no effect on the exchange of GDP for GTP, in contrast to the increased exchange seen with wild-type Rac2. These results suggest that Rac2<sup>D57N</sup> sequesters GEFs in neutrophils by binding these factors but, because of the impaired binding of GTP, do not release these factors, resulting in decreased turnover rates of Rac2 and possibly other Rho-like GTPases that use these GEFs.

### Mutation Analysis in Glucose-6-Phosphate Dehydrogenase Deficiency

Deficiency of G6PD is one of the most common genetic defects in humans (MIM 305900), probably because of the protection of G6PD-deficient erythrocytes against proliferation of malaria parasites. The clinical expression of G6PD deficiency varies from mild hemolytic anemia induced by infections or drugs (World Health Organization [WHO] class 3) to chronic nonspherocytic hemolytic anemia with attacks of severe anemia induced by infections and drugs (WHO class 1). The clinical symptoms are often restricted to the erythrocytes, for several reasons. One is that G6PD and the next enzyme in the hexose monophosphate pathway (6-PGD) catalyze the only NADPH-generating reactions in cells that lack mitochondria, i.e., erythrocytes. These cells need NADPH for protection against oxidative stress. Other reasons for G6PD deficiency effects in erythrocytes are the long survival time of these cells in the circulation and their lack of protein synthesis. G6PD mutant enzymes often have decreased protein stability, causing a decline in enzyme activity, especially in long-living cells that cannot generate new proteins. A total lack of G6PD activity is probably incompatible with life, because mutations in G6PD concern missense mutations or small in-frame deletions, but not frameshift mutations, gross deletions, or nonsense mutations (with one exception near the end of the protein) (Beutler et al., 1996).

Occasionally, patients with G6PD deficiency have been described with a decreased neutrophil respiratory burst after activation with opsonized particles, as well as an increased susceptibility of patients to bacterial or fungal infections (Baehner et al., 1972; Cooper et al., 1972; Gray et al., 1973; Vives Corrons et al., 1982; Mamlok et al., 1987; Roos et al., 1999; Van Bruggen et al.,

2002). In general, the G6PD activity in these cells needs to be below 5% of normal for such impairment to occur (Baehner et al., 1972). This situation might arise if mutations in G6PD severely decrease the enzyme activity even in newly synthesized protein. To date, information about mutations that give rise to these CGD-like symptoms is restricted to a few families. In one of these, we found replacement of Pro172 by Ser, leading to a thermolabile variant G6PD with about 15% of normal activity (Roos et al., 1999). Interestingly, the only patient in the family was a female, with somatic cells that contained only the mutant mRNA. This phenomenon was explained by the failure of paternal X chromosome inactivation, a trend in the female line in this family. Recently, we analyzed two additional families with mild CGD and G6PD deficiency. Both were found to carry a triplet nucleotide deletion that predicted deletion of Leu61 from the protein. G6PD protein expression and enzyme activity in all blood cells were extremely low, being detectable only in actively dividing lymphocytes (Van Bruggen et al., 2002).

### Phenotype-Genotype Correlation

In general, the A22 and A67 subgroups of CGD appear to be as severe as X91<sup>0</sup> CGD. Clinical comparisons between X-CGD and A47 CGD patients have been made by several investigators, with the general contention that X-CGD patients follow a more severe clinical course than that of A47 CGD patients (Weening et al., 1985a; Margolis et al., 1990; Gallin et al., 1991; Winkelstein et al., 2000). The milder disease course may be due to residual superoxide or hydrogen peroxide formation by p47<sup>phox</sup>-deficient neutrophils (Bemiller et al., 1991; Cross et al., 1994; Cross and Curnutte, 1995).

It might be expected that patients with the X91<sup>-</sup> phenotype, with 3%–30% of residual NADPH oxidase activity in their phagocytes (Roos et al., 1992), would follow a more benign clinical course than that of patients with the X91<sup>0</sup> or X91<sup>+</sup> phenotype. This generally appears to be the case, but it is not universally true (Roos et al., 1992). Female carriers of X-CGD mutations may occasionally present with clinical manifestations of the disease similar to those of hemizygous patients. In general, this concerns only carriers with less than 10% of normal phagocytes (Roos et al., 1996a), but healthy carriers with less than 10% of normal phagocytes are also known (Roos et al., 1986).

Functional polymorphisms in the oxygen-independent antimicrobial systems or other host defense elements play an important role in this respect. Foster et al. (1998) have found that in a cohort of 129 clinically well-defined CGD patients (104 X-linked, 25 autosomal recessive), an increased risk for abnormal granulomatous or inflammatory processes leading to gastrointestinal or urogenital complications was strongly associated with a polymorphism in the promoter region of myeloperoxidase that increases transcriptional activity and with the NA2 allele of the Fcγ receptor IIIb, which reacts less efficiently with IgG<sub>1</sub>-opsonized microorganisms than does the NA1 allotype. Autoimmune and rheumatologic disorders were seen more frequently in CGD patients with variant alleles of mannose-binding lectin and Fcγ receptor IIa.

Another disease-modifying gene in CGD may be nitric oxide (NO) synthase-2, which catalyzes the production of NO radicals and subsequently formed reactive nitrogen intermediates. Recent data reveal an important functional difference between CGD and either normal or myeloperoxidase (MPO)-deficient neutrophils in their ability to metabolize NO (Clark et al., 2002). This difference may have bearing on the formation of granulomas in CGD

patients, but not in normal or MPO-deficient individuals. In addition, the presence of cation transporters, such as Nramp1, may exacerbate the effects of these toxic nitrogen intermediates on invading microbes. The question as to how oxidative and nonoxidative mechanisms cooperate in intraphagosomal killing has recently been addressed by the work of Reeves et al. (2002), who found that charge compensation for superoxide generation not only leads to potassium influx, thus liberating proteases from the proteoglycan matrix in the azurophil granules that have fused with the phagosome, but also to increased pH needed for optimal functioning of these proteases. While some of these antimicrobial systems may operate independently, the combination of their activities is synergistic in the successful containment of the invading pathogens. Such gene modifiers may explain the variability in the infectious burden in CGD. Also the prevalence of specific pathogens in certain patients, such as *Nocardia* or atypical mycobacterial strains, may depend on these nonoxidative systems (Weening et al., 2000; Winkelstein et al., 2000; Dorman et al., 2002). In addition, weak nonoxidative defense systems may allow also catalase-negative microorganisms to infect CGD patients. Finally, this variability of non-oxidative defense systems may explain the beneficial effects of rhIFN-γ in vivo in CGD patients (see below), despite its lack of effect on NADPH oxidase activity; many of the nonoxidative systems are activated and modulated by microbial products and a series of temporally expressed cytokines such as IFN-γ.

### Prenatal Diagnosis

Prenatal diagnosis of CGD can be performed by analysis of the NADPH oxidase activity of fetal blood neutrophils (Newburger et al., 1979), but fetal blood sampling cannot be undertaken before 16–18 weeks of gestation. Instead, analysis of DNA from amniotic fluid cells or chorionic villi now provides an earlier and more reliable diagnosis for families at risk. In cases where the family-specific mutation is known, this analysis can be performed as indicated above. Between our laboratories and that of Heyworth and Cross at Scripps, we have analyzed more than 80 pregnancies at risk for X-CGD of the fetus (de Boer et al., 1992b). In all cases, the fetal origin of the DNA was checked in a genetic center with markers for X and Y chromosomes. The sequence of the fetal PCR product was always compared on one gel with that of the indicator patient in the family, the mother of the fetus, and a healthy control individual. The same strategy can be used for prenatal diagnosis of other CGD subtypes, although this may be more complicated if the parents carry different mutations. Recently, we have performed prenatal diagnosis in two families with a p67<sup>phox</sup>-deficient CGD patient and in two families with p47<sup>phox</sup>-deficient CGD patients. In the latter two families, the deficiency proved to be due to mutations other than the GT deletion at the start of exon 2 in *NCF1*, which was proven by sequencing of *NCF1*-specific PCR products (de Boer et al., 2002).

In cases where the family-specific mutations are not known, different methods must be applied. Partial or complete gene deletions can be recognized by RFLP analysis of genomic DNA, but more subtle abnormalities require the use of allele-specific markers. Within the *CYBB* gene, two *NsiI*-specific RFLPs have been detected (Battat and Francke, 1989; Mühlebach et al., 1990; Pelham et al., 1990), as well as several highly polymorphic (GT/AC)<sub>n</sub> repeats (Hardwick et al., 1993; Gorlin, 1998) and single-nucleotide polymorphisms (Heyworth et al., 2001). Within the *NCF2* gene, a *HindIII*-specific RFLP exists (Kenney et al.,

1993); single-nucleotide polymorphisms in the *CYBA*, *NCF1*, and *NCF2* genes are listed in Cross et al. (2000). These markers offer a more than 50% reliable method for prenatal diagnosis of CGD.

### Animal Models, Comparison with Human Disease

Natural animal models of CGD are not known. However, Din-aucr's group succeeded in constructing a mouse model of X-linked CGD through *Cybb* gene targeting of murine embryonic stem cells (Pollock et al., 1995). With a similar technique, p47<sup>phox</sup> knockout mice have been constructed (Jackson et al., 1995; Reeves et al., 2002). Such models are of great value for testing the safety and efficacy of correction of the genetic defect by gene transfer technologies (see Future Directions, below). In addition, the clinical differences between the various subgroups of CGD and new therapeutic strategies are studied in detail with these models. By comparison with elastase knockout mice, cathepsin-G knockout mice, and elastase/cathepsin-G double-knockout mice, the importance of the oxidative and nonoxidative microbicidal mechanisms can be studied in vivo (Tkalcovic et al., 2000). The mice deficient in NADPH oxidase components have also been used to study the involvement of this enzyme system in oxygen sensing, blood pressure regulation, and pathogenesis of atherosclerosis (Archer et al., 1999; Fu et al., 2000; Hsieh et al., 2000; Kirk et al., 2000; O'Kelly et al., 2000; Wang et al., 2001; Brandes et al., 2002). For instance, a gp91<sup>phox</sup>-containing NADPH oxidase seems to play an important role in the development of angiotensin II-induced cardiac hypertrophy, independent of changes in blood pressure (Bendall et al., 2002). However, a role for one or more of the classical phox proteins in human vascular disease cannot be deduced from the clinical symptoms of CGD patients thus far. Finally, the Rac2 knockout mouse has been used to study the role of this signal transduction protein in the activation of the various neutrophil functions (Roberts et al., 1999).

### Treatment Options

The prognosis for patients with CGD has dramatically improved since the disorder was first described in the 1950s as fatal granulomatous disease. The grim prognosis in these earlier times was borne out in retrospective epidemiological studies. In one such review of 31 patients followed between 1964 and 1989, actuarial analysis shows 50% survival through the third decade of life (Finn et al., 1990). In another retrospective study of 48 patients followed between 1969 and 1985 in Paris, the survival rate was 50% at 10 years of age with substantially fewer deaths thereafter (Mouy et al., 1989). This latter point is noteworthy in that CGD patients of all genetic types appear to suffer from fewer serious infections after they reach adolescence. While there are no large recent series examining the impact of newer treatment approaches on prognosis, there is a general consensus that a majority of patients should survive well into their adult years, particularly those individuals with CGD caused by p47<sup>phox</sup> deficiency. One important factor in the improving prognosis for CGD patients is the emergence of several centers in the world that have concentrated on the study and care of scores of patients with CGD (e.g., the National Institutes of Health, Scripps Clinic/Stanford University, the Pediatric Clinics of the Universities of Amsterdam, Munich, and Zürich). Many insights have been gained from the coordi-

nated treatment of these large groups of patients, and this information has been widely disseminated through the literature and through personal communications.

The cornerstones of treatment of CGD are as follows: (1) prevention of infections through immunizations and avoidance of certain sources of pathogens; (2) use of prophylactic trimethoprim-sulfamethoxazole or dicloxacillin; (3) use of prophylactic recombinant human interferon- $\gamma$  (rhIFN- $\gamma$ ); (4) early and aggressive use of parenteral antibiotics; and (5) surgical drainage or resection of recalcitrant infections. Of these five components, the most important is early intervention in infections before they have the potential to overwhelm the compromised immune system of the CGD patient.

There are multiple ways in which CGD patients can minimize their risk of infection. They should receive all routine immunizations (including live-virus vaccines) on schedule as well as influenza vaccine yearly. Lacerations and skin abrasions should be promptly washed with soap and water and rinsed with an antiseptic agent such as 2% hydrogen peroxide or a Betadine solution. The risk of developing perirectal abscesses can be lessened by careful attention to hygiene, avoidance of constipation, and frequent soaking in warm, soapy baths. The frequency of pulmonary infections can be reduced by refraining from smoking, not using bedside humidifiers, and avoiding sources of *Aspergillus* spores (e.g., hay, straw, mulch, decaying plant material, rotting wood/sawdust, and compost piles). Professional dental cleaning, flossing, and antibacterial mouthwashes can help prevent gingivitis and periodontitis.

Chronic prophylaxis with trimethoprim-sulfamethoxazole (5 mg/kg per day of trimethoprim given orally in one or two doses up to a maximum dose of 160 mg trimethoprim per day) can decrease the number of bacterial infections in CGD patients—by more than half in one series of 36 patients (Margolis et al., 1990). Similar conclusions were reached in a review of 48 European patients (Mouy et al., 1989). In sulfa-allergic patients, dicloxacillin can be used (25–50 mg/kg per day), although there is less documentation of the efficacy of this antibiotic in the prophylactic setting. At one point, there was concern that the sustained use of prophylactic antibiotics could lead to an increased risk of fungal infections. Fortunately, the data do not warrant this concern (Margolis et al., 1990). The effectiveness of antifungal prophylaxis is far less clear. Itraconazole, a newer orally active triazole antifungal antibiotic, has been reported to be an effective prophylactic agent in one study (Mouy et al., 1994). The long-term safety of this drug, however, has not been fully investigated in the CGD setting.

The efficacy of rIFN- $\gamma$  as a prophylactic agent in CGD was evaluated in a phase III multicenter, double-blind, randomized, placebo-controlled study involving 128 patients. The results, published in 1991, showed a 70% reduction in the risk of developing a serious infection in the rIFN- $\gamma$ -treated group compared to placebo (Gallin et al., 1991). This benefit is maintained in patients treated for longer periods of time, as reported in two phase IV studies (Bemiller et al., 1995; Weening et al., 1995). Side effects are generally minimal, even with prolonged therapy, and are mainly mild headaches and low-grade fevers within a few hours after administration. The recommended dose is 0.05 mg/m<sup>2</sup> given subcutaneously three times per week. (For infants <0.5 m<sup>2</sup>, the recommended dose is 0.0015 mg/kg given subcutaneously three times per week.) The significant clinical improvements in the phase III patients were not accompanied by improvements in superoxide production, a finding confirmed in subsequent studies

(Mühlebach et al., 1992; Woodman et al., 1992; Davis et al., 1995). It now appears that rIFN- $\gamma$  augments host defense in the vast majority of CGD patients, regardless of genetic subtype, by means other than reversing the respiratory burst defect.

One of the most serious errors in the management of CGD patients is the failure to treat potentially serious infections promptly with appropriate parenteral antibiotics and to continue therapy long enough to eradicate them. Once bacterial and fungal infections become well established and gain the upper hand in a CGD patient, even the best-chosen antibiotics may be relatively ineffective. Therefore, early intervention can be of critical importance. It is usually necessary to begin antibiotic therapy empirically before culture results are available; in these cases, the antibiotics should be chosen to provide strong coverage for *S. aureus* and gram-negative bacteria, including *B. cepacia* (e.g., a combination of nafcillin and ceftazidime). If the infection fails to respond within 24–48 hours, then more aggressive diagnostic procedures should be instituted to identify the responsible microorganism. Additional empirical changes in antibiotic coverage may be warranted, such as adding high-dose intravenous trimethoprim-sulfamethoxazole to cover ceftazidime-resistant *B. cepacia*. If fungus is identified or strongly suspected, amphotericin B is the drug of choice. *Aspergillus* infections of the lung and bone are the most common fungal infections and require 5–6 months of treatment, 2–3 months of which should be given on a daily basis before switching to alternate-day therapy. Amphotericin B treatment should be continued even longer if necessary depending on radiographic, clinical, and culture data (and the return of the erythrocyte sedimentation rate to its “normal” baseline for the patient). Once it is discontinued, most patients should be treated for at least several years with oral itraconazole to prevent recurrence or reactivation of the fungal infection. Caspofungin, a new echinocandin antifungal, has now been approved by the U.S. Food and Drug Administration for the treatment of invasive *Aspergillus* infections in patients unresponsive or unable to receive amphotericin B. New triazole antifungals for intravenous and oral use, itraconazole and voriconazole, have already shown promise in clinical trials in patients with refractory fungal infections. Fungal infection may progress under amphotericin B therapy in CGD, despite the addition of rIFN- $\gamma$ , filgrastim, and transfusions with donor granulocytes. Early treatment with additional intravenous antifungals and surgical resection of infected tissues must be given (Jabado et al., 1998; Van 't Hek et al., 1998; Walsh et al., 2002).

Surgery plays an important role in the management of CGD patients. As noted above, surgical drainage (and sometimes excision) of infected lymph nodes and abscesses involving the liver, skin, rectum, kidney, and brain is often necessary for healing, particularly for the visceral abscesses. In cases of highly aggressive fungal or bacterial infections that fail to respond to the medical and surgical approaches outlined above, granulocyte transfusions may be helpful.

Special caution must be exercised in CGD patients regarding transfusions, whether they be granulocytes, erythrocytes, or platelets. Some CGD patients have McLeod syndrome, as discussed earlier. Since the K<sup>x</sup> protein is absent and other Kell antigens are only weakly expressed on the erythrocytes of these patients, they will become quickly sensitized to the Kell antigens that are ubiquitous in the population if they are not transfused with K<sup>x</sup>-negative McLeod blood products. Unless the molecular genetic basis of a patient's CGD is known not to involve a deletion of the Xp21.1 region, erythrocyte antigen phenotyping

should be done prior to a CGD patient's first blood product transfusion.

Clinically significant or symptomatic complications of granuloma formation are best treated with corticosteroids, as these lesions respond quickly to relatively low doses of these agents (e.g., 0.5–1.0 mg/kg per day of prednisone) (Chin et al., 1987; Danziger et al., 1993). It is usually necessary to treat the granulomas for a few weeks before tapering the steroid dose to prevent a rapid relapse. Corticosteroid therapy (topical or by mouth) may also be required to control the symptoms of CGD inflammatory bowel disease. In general, however, corticosteroid therapy in CGD patients should be avoided whenever possible to minimize the inevitable immunosuppression caused by these agents.

Bone marrow transplantation in CGD (see Chapter 47) can be curative and has been successfully employed in several cases (Fischer et al., 1986; Kamani et al., 1988; Ho et al., 1996). However, the overall results have been mixed, as failure to engraft has been a major problem, at least in the earlier transplants. It appears that newer conditioning regimens employing higher doses of busulphan to achieve adequate myeloid suppression may have overcome this problem (Ho et al., 1996; Seger et al., 2002). A recent European study reports the outcome of 27 transplanted CGD patients in the period 1985–2000. Most of these were children, and most received a myeloablative busulphan-based regimen and had unmodified marrow allografts from HLA-identical sibling donors. After myeloablative conditioning all patients (23) were fully engrafted with donor cells, whereas after myelosuppressive regimens only 2 of 4 patients were engrafted (Seger et al., 2002). This latter result recalls a similar observation in the United States (Horwitz et al., 2001). In the European study, severe graft vs. host disease, exacerbation of infection during aplasia, and an inflammatory flare were seen in the subgroup of nine patients with preexisting infection. Overall survival was 85%, with 96% cured of CGD. Survival was excellent in patients without infection at the moment of transplantation. Preexisting infections and inflammatory lesions cleared in all engrafted survivors.

The future will indicate when and whether gene therapy offers the best cure (see below), but until that time the alternative of myeloablative conditioning followed by transplantation of unmodified hematopoietic stem cells is a valid option for children with CGD having an HLA-identical donor. The decision should be made early during childhood, preventing the hazards of severe disease or an ominous course during the procedure of bone marrow transplantation. Although secondary malignancies due to bone marrow conditioning will not be the biggest fear, cyclophosphamide-related infertility still has a dominant effect. Prognostic indicators such as disease-modifying genes associated with a severe course of CGD (see genotype phenotype correlation section) may be helpful in making relevant treatment decisions.

## Future Directions

The improvement in the prognosis for patients with CGD over the past 10–15 years is remarkable. Patients diagnosed in infancy and treated with prophylactic antibiotics and rIFN- $\gamma$  before a relentless cycle of serious infections begins have a fairly optimistic future. It is clear, however, that the prophylactic and therapeutic approaches currently employed are still imperfect, as even these very young, optimally treated children can develop disastrous infections and die. Moreover, all of the treatments developed to date (with the exception of bone marrow transplantation) are

only supportive, not curative, and demand a lifetime of diligence and compliance. While further refinements in the medical and surgical management of CGD are likely in the years to come, the ultimate goal is the development of curative approaches for this immunodeficiency. Attention has appropriately been directed toward gene replacement therapy (see Chapter 48). Partial correction of the oxidase defect has been achieved in vitro by transduction of CD34-positive peripheral blood or bone marrow progenitor cells from patients with each of the four types of CGD, using retroviral vectors containing the correct cDNA for the missing NADPH oxidase component (Sekhsaria et al., 1993; Li et al., 1994; Porter et al., 1996; Weil et al., 1997). Substantial reconstitution of oxidase activity was also achieved in granulocyte/monocyte bone marrow progenitors from an X-CGD gp91<sup>phox</sup> knockout mouse using a retroviral vector system (Ding et al., 1996). This approach has been extended to the treatment of gene knockout CGD mice lacking either gp91<sup>phox</sup> or p47<sup>phox</sup> in which bone marrow progenitors were treated ex vivo and then transplanted into irradiated syngeneic CGD mice (Björgvinsdóttir et al., 1997; Mardiney et al., 1997). In both cases, the recipient mice showed increased resistance to bacterial or fungal infection. Levels and duration of expression of the transfected oxidase subunits have been sufficiently large to justify the initiation of early clinical trials for these two forms of CGD (Malech et al., 1997).

The results have been disappointing. In five p47<sup>phox</sup>-deficient CGD patients, the fraction of gene-corrected neutrophils in the circulation was never more than 0.05%, and corrected cells were no longer detectable after 6 months (Malech et al., 1997). Similar results were obtained in two X-CGD patients (Malech, 1999). Several problems are evident: the corrected bone marrow cells have no growth advantage over the uncorrected cells (so bone marrow conditioning may be necessary); the corrected gene may be silenced because of its linkage to an unnatural promoter (so vectors may be needed with the capacity to contain the original promoter sequence); and the retroviral vectors used integrate only in dividing cells, thus precluding correction of uncommitted stem cells (so lentiviral vectors are needed). Indeed, new viral vectors are now being tested, such as those that after insertion excise proviral sequences not required for gene expression (Grez and von Melchner, 1998), vectors that contain a selectable marker gene in addition to the disease-correcting gene (Grez et al., 2000; Sadat et al., 2003; Sugimoto et al., 2003), and lentivirus-based vectors (Demaison et al., 2002; Roesler et al., 2002; Scherr et al., 2002). A highly encouraging clinical trial with a monocistronic gp91<sup>phox</sup> retroviral vector was reported during the 2004 European Society for Immune Deficiency (ESID) meetings (by G.M. Ott for the groups of M. Grez and R. Seger). Both patients were conditioned with liposomal busulfan before reinfusion of the transduced (40%–45% transduction efficiency) granulocyte colony-stimulating factor (G-CSF)-mobilized CD34<sup>+</sup> cells. A significant fraction of gene marked cells has been detected in peripheral blood of both patients since day +21. The patients have clinically improved: in one patient, a chronic liver abscess resolved, the other achieved resolution of a fungal lung infection. In addition, a new mouse model for testing the effects of gene therapy has been developed. When CD34<sup>+</sup> peripheral blood stem cells from X-CGD patients were injected into NOD/SCID mice, these animals produced X-CGD neutrophils, which were corrected by pretreatment of the CD34<sup>+</sup> cells with self-inactivating lentivector encoding gp91<sup>phox</sup> (Roesler et al., 2002). Impressive improvement of gene therapy in this mouse model was achieved by infusion of peripheral blood CD34<sup>+</sup> stem cells from X-CGD patients transduced ex vivo with a retroviral vector (the same that

was used in the treatment of X-CGD patients [Malech, 1999] and A470 CGD patients [Malech et al., 1997]) that expressed not only the missing gp91<sup>phox</sup> protein but also the feline endogenous virus (RD114) envelope. This envelope binds to neutral amino acid transporter (RDR), which is highly expressed on human CD34<sup>+</sup>CD38<sup>−</sup> hematopoietic stem cells (Brenner et al., 2003). Further improvement of gene therapy may perhaps be expected from targeted gene therapy in which a mutated gene can be repaired in vivo (Kren et al., 1998; Strauss, 1998). This would overcome the danger of unintentionally activating genes by the random insertion of viral vectors into the genome, which can induce malignant growth in the recipient cells (Hacein-Bey-Abina et al., 2003).

While these are early days in the field of gene therapy, there is some room for optimism in the case of CGD. The study of patients with variant forms of X-linked CGD has revealed that levels of oxidase activity as low as 3%–5% in all of the myeloid cells may be associated with a mild clinical phenotype. In addition, insights derived from X-linked CGD carriers indicate that as few as 5% fully functioning neutrophils can provide substantial protection against infection. It is thus clear that full correction of 100% of the circulating neutrophils in CGD patients will not be required to have an impact on the immune deficit. Even if corrected cells are only transiently generated, there is the potential for substantial benefits for CGD patients, as this therapeutic approach could be used to help treat stubborn, recalcitrant infections.

#### Acknowledgments

D.R. and T.W.K. thank Jan Dekker, Martin de Boer, Elsbeth van Koppen, Ron Weening, and Rob van Zwieten for their experimental and clinical investigations, and the Netherlands Foundation for Preventive Medicine (Praeventiefonds) and the CGD Research Trust (U.K.) for financial support.

## Cell Adhesion and Leukocyte Adhesion Defects

AMOS ETZIONI and JOHN M. HARLAN

Leukocyte trafficking from bloodstream to tissue is important for the continuous surveillance for foreign antigens and for rapid leukocyte accumulation at sites of inflammatory response or tissue injury. Leukocyte emigration to sites of inflammation is a dynamic process, involving multiple steps in an adhesion cascade. These steps must be precisely orchestrated to ensure a rapid response with only minimal damage to healthy tissue (Carlos and Harlan, 1994; Springer, 1994; von Andrian and Mackay, 2000). Leukocyte interaction with vascular endothelial cells is a pivotal event in the inflammatory response and is mediated by several families of leukocyte and endothelial adhesion molecules, including the integrins, the selectins, and members of the immunoglobulin gene superfamily (IgSF). Each is involved in a different phase of leukocyte adherence to and migration across the endothelium, and the synchronization of their surface expression and activation is crucial for the leukocyte trafficking.

While the importance of leukocyte movement toward sites of inflammation was well recognized more than a century ago, the molecular basis of leukocyte emigration from the bloodstream through the endothelium was only recently elucidated. The integrin family and several integrin ligands of the IgSF were described in the 1980s, whereas the selectins and their carbohydrate counterstructures were discovered in the 1990s. Several years after reporting the structure of the leukocyte integrin molecule, a genetic defect in the subunit of the molecule (ITGB2) was discovered. The resultant syndrome, now called leukocyte adhesion defect type I (LAD I; MIM 116920), has been described in more than 200 children and is characterized by delayed separation of the umbilical cord, recurrent soft tissue infections, chronic periodontitis, marked leukocytosis, and a high mortality rate at an early age. Currently, the only definite therapy is bone marrow transplantation. In vivo and in vitro studies have shown a marked defect in neutrophil motility.

In 1992 a second defect, LAD II (MIM 266265), was discovered in two children and was found to be due to a defect in the synthesis of selectin ligands (Frydman et al., 1992). Although several adhesive functions of LAD II leukocytes are markedly impaired in vitro, the clinical course with respect to infectious complications is milder than that in LAD I. However, patients with LAD II present with other abnormal features, such as growth and mental retardation, which are related to the primary defect in fucose metabolism and are not observed in LAD I.

Recently, a third rare LAD syndrome has been described (Alon et al., 2003; Alon and Etzioni, 2003). Patients with LAD III suffer from severe recurrent infections, similar to LAD I, but also have a bleeding tendency. Although integrin expression is normal and its structure is intact, a defect in integrin activation is the primary abnormality in LAD III.

In this chapter we will briefly review the various adhesion molecules involved in leukocyte–endothelial interactions and then focus on the clinical consequences of defects in these molecules.

### Adhesion Molecules

#### Leukocyte Integrins

*Integrins* are transmembrane cell surface proteins that bind externally to matrix and membrane proteins and internally to cytoskeletal proteins and thereby communicate extracellular signals (Hynes, 1992). Each integrin consists of noncovalently linked, heterodimeric  $\alpha$  and  $\beta$  subunits. Each subunit is composed of a large extracellular domain (1000 to 1150 amino acids for the  $\alpha$  subunit and 700 to 740 for the  $\beta$  subunit), a single transmembrane domain of about 20 amino acids, and a short cytoplasmic domain of 40 to 50 amino acids (Humphries, 2000). The crystal

structure of the integrin  $\alpha$ -subunits containing a  $\beta$ -propeller domain has been described and elegant models of the domain structure of the other regions have been proposed (Springer, 1997). Specificity of receptor binding to various ligands appears to depend primarily on the extracellular portion of the  $\alpha$  subunit, although both subunits are required for functional activity of the receptor.

Integrins have been arranged in subfamilies according to the  $\beta$  subunits, and each  $\beta$  subunit may have from 1 to 10 different  $\alpha$  subunits associated with it. To date, there are 19  $\alpha$ - and 8  $\beta$ -subunit genes identified in mammals, encoding polypeptides that combine to form up to 25 receptors. Within this large family of integrin receptors only four members have been clearly shown to be significantly involved in leukocyte adhesion to endothelium.

Two belong to the  $\beta_2$  subfamily and one each to the  $\beta_1$  and the  $\beta_7$  subfamilies.

### $\beta_2$ Integrins

This subfamily comprises four heterodimeric glycoproteins with a common  $\beta$ -subunit, designated  $\beta_2$  (CD18) (Table 38.1). The first three heterodimers identified were lymphocyte function-associated antigen-1 (LFA-1), macrophage antigen-1 (Mac-1), and p150, 95; their  $\alpha$  subunits are designated  $\alpha_L$  (CD11a),  $\alpha_M$  (CD11b), and  $\alpha_X$  (CD11c), respectively. A fourth heterodimer,  $\alpha_D\beta_2$ , was subsequently identified. The  $\alpha_L$ ,  $\alpha_M$ ,  $\alpha_X$ ,  $\alpha_D$ , and  $\beta_2$  polypeptides are initially assembled in the cytoplasm, and only then is the complete  $\beta_2$  heterodimer expressed extracellularly. Both subunits are required for expression on the plasma membrane; if the

**Table 38.1.** Adhesion Molecules Involved in Leukocyte–Endothelial Interactions

<i>Name</i>	<i>Distribution</i>	<i>Mediators (Induced by; Activated by)</i>	<i>Counterstructure(s)</i>	<i>Function(s)</i>
<i>Integrins</i>				
LFA-1 ( $\alpha_L\beta_2$ , CD11a/CD18)	All leukocytes	Constitutively expressed; activated by crosslinking of other surface receptors, chemokines	ICAM-1, 2	Leukocyte firm adhesion and transmigration
Mac-1 ( $\alpha_M\beta_2$ , CD11b/CD18)	Neutrophils, monocytes, natural killer cells, eosinophils	Constitutively expressed; activated by cytokines, chemokines, chemoattractants	ICAM-1	Phagocyte firm adhesion and transmigration
$\alpha_4\beta_7$	Lymphocytes, eosinophils, natural killer cells	Constitutively expressed; activated by chemokines	MAdCAM-1, VCAM-1, fibronectin	Leukocyte rolling and firm adhesion
VLA-4 ( $\alpha_4\beta_1$ , CD49d/CD29)	All leukocytes except neutrophils	Constitutively expressed; activated by crosslinking of other surface receptors, chemokines, chemoattractants	VCAM-1, fibronectin	Leukocyte rolling, firm adhesion, and migration
<i>Ig Superfamily</i>				
ICAM-1 (CD54)	Endothelial cells, lymphocytes, other cell types	Constitutively expressed; upregulated by IL-1, LPS, TNF, IFN- $\gamma$	LFA-1, Mac-1	Leukocyte firm adhesion and transmigration
ICAM-2 (CD102)	Endothelial cells, leukocytes	Constitutively expressed	LFA-1	Leukocyte firm adhesion
VCAM-1 (CD106)	Endothelial cells, other cell types	Induced by TNF IL-1, LPS, etc.	VLA-4, $\alpha_4\beta_7$	Leukocyte rolling and firm adhesion
PECAM-1 (CD31)	Leukocytes, endothelial cells, platelets	Constitutively expressed	PECAM-1	Transmigration
MAdCAM-1	Mucosal HEV	Constitutively expressed	$\alpha_4\beta_7$ , L-Selectin	Leukocyte rolling and firm adhesion
<i>Selectins</i>				
E-selectin (CD62E)	Endothelial cells	Induced by TNF, IL-1, LPS, etc.	Sialylated, fucosylated structures (e.g., SLeX) expressed on PSGL-1, ESL-1, other glycoproteins	Leukocyte rolling
P-selectin (CD62P)	Endothelial cells, platelets	Induced by histamine, thrombin, etc.	Sialylated, fucosylated, sulfated structures on PSGL-1	Leukocyte rolling
L-selectin (CD62L)	Most leukocytes	Constitutively expressed; shed by diverse activating agents	Sialylated, fucosylated (and often sulfated) structures expressed on CD34, MAdCAM-1, GlyCAM-1, PSGL-1, and other glycoproteins	Leukocyte rolling

ESL-1, E-selectin ligand-1; HEV, high endothelial venule; ICAM, intercellular adhesion molecule; IL-1, interleukin-1; LFA-1, lymphocyte function-associated antigen-1; LPS, lipopolysaccharide; Mac-1, macrophage antigen-1; MAdCAM-1, mucosal addressin cell adhesion molecule-1; PECAM-1, platelet-endothelial cell adhesion molecule-1; PSGL-1, P-selectin glycoprotein ligand-1; SLeX, sialyl Lewis X; TNF, tumor necrosis factor; VCAM-1, vascular cell adhesion molecule-1; VLA, very late antigen.

$\beta_2$  subunit is absent,  $\alpha_L$ ,  $\alpha_M$ , and  $\alpha_X$  are not detected on the cell surface, even if the synthesis of the  $\alpha$  subunits is normal (Springer et al., 1984).

$\beta_2$  integrin expression is restricted to leukocytes, but among subsets of leukocytes the distribution of the CD11/CD18 heterodimers differs. LFA-1 ( $\alpha_L\beta_2$ , CD11a/CD18) is expressed by all leukocytes. Mac-1 ( $\alpha_M\beta_2$ , CD11b/CD18) and p150, 95 ( $\alpha_X\beta_2$ , CD11c/CD18) are expressed primarily by myeloid cells, although they are also expressed by some lymphocytes and natural killer (NK) cells.  $\alpha_D\beta_2$  (CD11d/CD18) is expressed at moderate levels on myelomonocytic cell lines and subsets of peripheral blood leukocytes. Leukocyte adhesion to endothelium involves primarily LFA-1 and Mac-1. Importantly, the  $\beta_2$  integrins participate in many adhesion-related functions in addition to adherence to endothelium, such as phagocytosis, killing of bacteria, antibody-dependent cell-mediated cytotoxicity, and homotypic and heterotypic aggregation.

An important characteristic of the leukocyte  $\beta_2$  integrins is that under baseline conditions they exist in a relatively inactive conformation, rendering the leukocyte nonadhesive. One of the key events in leukocyte adhesion to endothelium is the activation and deactivation of these integrins at the appropriate time and place. Activation of leukocytes by a variety of mediators (e.g., for phagocytes C5a, platelet-activating factor, leukotriene B<sub>4</sub>, or interleukin-8) results in a transient increase in adhesion by CD11/CD18-dependent mechanisms. This increased adhesiveness occurs through qualitative changes, involving transformation of LFA-1 and Mac-1 from a low- to high-affinity state and clustering of receptors, which increases avidity. In phagocytes, there is also concurrent up-regulation of the surface expression of Mac-1 and p150, 95 (Carlos and Harlan, 1994).  $\beta_2$  integrins mediate leukocyte adhesion to endothelium through binding to their ligands, members of the IgSF that are expressed on most cells, and this  $\beta_2$  integrin-dependent adhesion promotes leukocyte interactions with all cells in the body, particularly during inflammatory conditions. Aside from its role in leukocyte adhesion, CD11/CD18 binding to its ligands may also induce intracellular signals. Thus ligand binding could affect cellular functions such as apoptosis, cytotoxicity, proliferation, and cytokine production (Lub et al., 1995).

#### $\alpha_4$ Integrins

$\beta_1$  or very late antigen (VLA) integrins comprise the largest subfamily (Table 38.1). Most are receptors for extracellular matrix proteins, including fibronectin, collagen, and laminin. One member of this subfamily,  $\alpha_4\beta_1$  (VLA-4; CD49d/CD29), has been shown to be involved in lymphocyte, eosinophil, basophil, NK cell, and monocyte adhesion to the CS-1 fragment of fibronectin and to the cytokine-induced endothelial cell surface protein, vascular cell adhesion molecule-1 (VCAM-1). Because circulating human neutrophils do not normally express significant levels of VLA-4, they do not normally use this pathway to adhere to activated endothelium.

The  $\alpha_4\beta_7$  integrin is expressed on lymphocytes and eosinophils and functions as the homing receptor that binds to the mucosal vascular addressin cell adhesion molecule (MAdCAM-1) and, to a lesser extent, to VCAM-1 or fibronectin (Table 38.1).

### Immunoglobulin Superfamily

#### Intercellular adhesion molecules

The intercellular adhesion molecules (ICAMs), of which five have been identified, were originally defined functionally as

LFA-1 ligands (Springer, 1994) (Table 38.1). Only ICAM-1 and ICAM-2 are expressed on endothelium and participate in leukocyte adhesion to endothelium. The gene for ICAM-1 is located on chromosome 19. The molecule has five Ig-like domains, with a short hinge region separating the third and fourth Ig-like domain (Diamond et al., 1991). ICAM-1 is a ligand for both LFA-1 and Mac-1. The binding sites in ICAM-1 for the two integrins are distinct; LFA-1 binds to domains 1 and 2 and Mac-1 binds to domain 3. Human ICAM-2 is a single-copy gene located on chromosome 17. It has only two extracellular Ig-like domains, and the binding site for LFA-1 is located in these domains (Staunton et al., 1989). The other  $\beta_2$  integrins do not bind ICAM-2.

ICAM-1 is expressed only at low levels on some endothelial cells, but it is dramatically up-regulated by lipopolysaccharides (LPS), interleukin-1 (IL-1), and tumor necrosis factor (TNF). This increased expression of ICAM-1 peaks at 4–6 hours and persists for days with continued exposure to cytokines. ICAM-2 expression, in contrast, is expressed constitutively, and is not regulated by cytokines.

#### Vascular cell adhesion molecule-1

VCAM-1 also belongs to the IgSF. A single VCAM-1 gene gives rise through alternative splicing to distinct isoforms that differ in the number of integrin binding sites (Pepinsky et al., 1992). In humans the predominant isoform contains seven Ig-like domains with binding sites for the integrin VLA-4 located within the first and fourth domains (Table 38.1). VCAM-1 is induced by cytokines on endothelial cells with a time course similar to that of ICAM-1.

#### Mucosal addressin cell adhesion molecule-1

MAdCAM-1 is a member of the IgSF that has a mucin-like domain, which functions as a ligand for L-selectin, as well as an Ig-like domain(s) that serves as a ligand for the  $\alpha_4\beta_7$  integrin (Briskin et al., 1993). MAdCAM-1 may serve as a bridge between selectin- and  $\beta_2$  integrin-dependent events (Bargatze et al., 1995).

#### Platelet-Endothelial cell adhesion molecule-1

Platelet-endothelial cell adhesion molecule-1 (PECAM-1; CD31) is a member of the IgSF that is expressed at low levels on most leukocytes and platelets but at high levels in endothelial cells where it is localized to intercellular junctions. PECAM-1 is involved in phagocyte transendothelial migration, primarily in migration through the subendothelial basement membrane (Duncan et al., 1999).

### Selectins

This family of adhesion molecules was discovered in 1989, when the cDNA sequences for three distinct cell surface glycoproteins found on endothelium (E-selectin, CD62E), platelets (P-selectin, CD62P), and leukocytes (L-selectin, CD62L) were reported (Bevilacqua and Nelson, 1993). These molecules were initially designated ELAM-1; PADGEM or GMP-140; and MEL-14 or LECAM-1, respectively. The genes for the selectins are closely linked on chromosome 1, reflecting their common evolutionary origin. All three members have common structural features, most prominently an N-terminal lectin-like domain that is central to the carbohydrate binding properties of all three selectins (Kansas, 1996). The lectin domain is followed by a domain homologous to the epidermal growth factor (EGF) and then by a discrete number of domains similar to those found in certain complement binding proteins. The term *selectin* was proposed to highlight the

amino-terminal lectin domain and to indicate the selective function and expression of these molecules.

All three selectins are involved in the recruitment of leukocytes to sites of tissue injury, but there are fundamental differences in their distribution, activation, and mode of expression (Tedder et al., 1995). For example, while all three selectins take part in the first step of the adhesion cascade, the rolling phase (vide infra), E-selectin participates somewhat later in the recruitment process (Ley and Tedder, 1995).

#### E-selectin

E-selectin is restricted to endothelial cells and its expression is induced when the cells are activated by LPS, IL-1, TNF, and other stimuli (Table 38.1). These substances activate the transcription and translation of E-selectin, resulting in peak cell surface expression at 4–6 hours, decreasing to near basal levels by 24 hours (Cotran et al., 1986). Although E-selectin expression in vitro is typically transient, it is expressed chronically in certain inflammatory conditions.

#### P-selectin

P-selectin is expressed on platelets as well as on endothelial cells (Table 38.1). Its expression does not necessarily require *de novo* synthesis because it is stored in the granules in platelets and in secretory granules (Weibel-Palade bodies) in endothelial cells. Thus, within minutes of activation of either cell type by thrombin or histamine, P-selectin is rapidly redistributed to the surface of the cells. Its expression in vitro is typically very short-lived—up to 15 minutes. However, studies in vivo suggest that endothelial P-selectin may also be regulated at the level of protein synthesis, providing a mechanism for more prolonged expression (Gotsch et al., 1994).

#### L-selectin

In contrast to the E- and P-selectins, L-selectin is not expressed on quiescent or activated endothelial cells but rather is constitutively expressed on leukocytes (Table 38.1). Although originally described as a lymphocyte homing receptor, it was subsequently shown to be expressed on most other leukocytes (Lewinsohn et al., 1987). After a transient increase of this selectin during activation, it is shed rapidly because of proteolytic cleavage near the membrane insertion. Cleavage of L-selectin may serve to limit further leukocyte recruitment at inflammatory sites.

#### Selectin ligands

Studies of the molecular basis of selectin adhesion have focused mainly on carbohydrate recognition by the lectin domains. Identification of the physiological ligands for the selectins has been challenging because, like many lectins, the selectins can bind a variety of carbohydrate structures in vitro (Kansas, 1996). These ligands are carbohydrate groups typically found as terminal structures on one or more glycoproteins and/or glycolipids. The EGF domain as well as the lectin domain contributes to selectin binding to glycoconjugates.

One major selectin ligand is a member of a class of sialylated and fucosylated tetrasaccharides related to the sialylated Lewis X blood group (SLeX, CD15s). SLeX is usually expressed at high levels on neutrophils and monocytes, whereas most peripheral lymphocytes express SLeX only after activation. Both the sialic acid and the fucose moieties are critical for efficient binding. Monoclonal antibodies against SLeX block the binding of neutrophils to activated endothelial cells. Cell lines that do not express this structure show no binding, but after induction of SLeX by transfection of appropriate fucosyltransferases, binding

is observed. Furthermore, infusion of SLeX blocks leukocyte rolling along inflamed venules (Asako et al., 1994). Although the detailed carbohydrate structures for the various physiological selectin ligands are not fully characterized, carbohydrate recognition is clearly critical for selectin-mediated adhesion.

While the selectins bind weakly to small sialylated, fucosylated oligosaccharides, they appear to bind with much higher avidity to carbohydrate determinants on a limited number of glycoproteins. L-selectin binds at least three different heavily glycosylated mucin-like proteins: GlyCAM-1X, CD34X, and MAdCAM-1. P-selectin and, to a lesser extent, E-selectin have been reported to selectively bind P-selectin glycoprotein ligand-1 (PSGL-1), which is expressed on most leukocytes (Sako et al., 1993). A monoclonal antibody specific for PSGL-1 completely inhibited P-selectin-mediated rolling of leukocytes under a range of physiologic shear stress (Moore et al., 1995).

### The Adhesion Cascade

The migration of leukocytes from the bloodstream to the tissue occurs in several distinct steps (Butcher, 1991) (Fig. 38.1). First, under conditions of flow, loose adhesion to the vessel wall, primarily in postcapillary venules, causes the leukocytes to roll on the endothelium. This transient and reversible step is a prerequisite for the next stage, the activation of leukocytes. This is followed by firm adhesion, i.e., sticking, after which migration occurs. Each of these steps involves different adhesion molecules and can be differentially regulated.

#### Selectin-Mediated Rolling

Leukocytes in the circulation must resist shear forces to arrest along the vascular endothelium. Under normal conditions, leukocytes move rapidly in the laminar flow stream of blood and do not adhere to the endothelium. However, with activation of the

**Figure 38.1.** The adhesion cascade and leukocyte adhesion deficiency (LAD) syndromes. Under conditions of flow at sites of inflammation, normal leukocytes first roll along the venular wall via selectin–carbohydrate interactions. Following integrin activation by local chemoattractants or chemokines, the rolling cells then adhere firmly via binding of leukocyte integrins to endothelial immunoglobulin gene superfamily (IgSF) ligands. Subsequently, the adherent leukocytes diapedese between endothelial cells utilizing PECAM-1 and integrin–IgSF ligand interactions. Defects in selectin-mediated rolling or integrin-mediated sticking impair emigration. In LAD I, neutrophils deficient in  $\beta_2$  integrin are able to roll along the endothelium but are unable to adhere firmly to transmigrate. In LAD II, neutrophils deficient in fucosylated carbohydrate ligands for selectins are unable to roll and thus cannot adhere and transmigrate.

endothelium due to local trauma or inflammation, leukocytes immediately begin to roll along the venular wall. This phenomenon of leukocyte rolling was observed for more than a century, but its molecular basis was delineated only recently. Several studies showed that although CD18 monoclonal antibodies block sticking, they do not prevent rolling (Arfors et al., 1987). Monoclonal antibodies to selectins, however, markedly reduced the rolling process in vivo and in vitro (Olofsson et al., 1994). Moreover, rolling is much diminished in both P- and L-selectin-deficient mice (Mayadas et al., 1993; Ley and Tedder, 1995). The endothelial selectins will bind to the leukocytes through their carbohydrate ligands. Patients who lack SLeX molecules and other fucosylated selectin ligands show defective in vivo rolling (von Andrian et al., 1993). The presentation of SLeX to E- and P-selectins may be partially mediated by L-selectin, which is expressed on microvilli of the leukocytes (von Andrian et al., 1995). L-selectin itself recognizes sialylated, fucosylated, counterstructures on glycoproteins such as CD34 on high endothelial venules (Baumhater et al., 1993) and as yet poorly characterized ligands on systemic vasculature (Spertini et al., 1991). The rolling phase is transient in part because L-selectin is shed quickly from the leukocytes and P-selectin on endothelial cells is internalized.

Activation of Integrins

The initial rolling interaction of leukocytes with endothelium is reversible unless the leukocytes are activated and become firmly adherent. Binding to the selectins tethers the leukocytes, exposing them to stimuli in the local microenvironment (Zimmerman et al., 1992). Chemoattractants released from endothelium or cells in the surrounding tissue can rapidly trigger the leukocyte integrins to proceed to activation-dependent sticking and arrest. The leukocyte chemoattractants include classical chemoattractants, such as C5a and leukotriene B4, and chemokines, which bind to the apical surface of endothelial cells (Mackay, 2001). The importance of chemotactic agents in mediating firm adhesion was illustrated in experiments using the flow chamber model. In this model leukocyte rolling stops immediately after a small amount of a chemotactic agent is added and the cells then start to spread (Lawrence and Springer, 1991). Increased adhesive capacity is mediated primarily through qualitative changes in integrin receptor affinity or avidity, although in phagocytes a rapid increase in surface expression of Mac-1 also occurs through translocation of  $\alpha_M\beta_2$  heterodimers from cytoplasmic granules to the plasma membrane.

Adhesion and Transendothelial Migration  
Via Integrins and Immunoglobulin  
Superfamily Ligands

Activation of integrins results in increased binding to their Ig-like ligands on the endothelial cells. This ensures that adhesion is firm enough to withstand the continuous shear forces in the blood vessels. Monoclonal antibodies to both integrins and their IgSF ligands block the firm adhesion of leukocytes to endothelial cells. The final event, the transendothelial migration of the leukocytes to the site of inflammation, is in part dependent on integrin-IgSF interactions and can be blocked by monoclonal antibodies to these molecules. Another member of the endothelial IgSF, PECAM-1, was found to be important mainly in migration of phagocytes through the subendothelial basement membrane (Duncan et al., 1999).

Adhesion Molecule Deficiency Syndromes

Perhaps the best way to appreciate the in vivo importance of leukocyte and endothelial adhesion molecules in humans is to examine those rare “experiments of nature” in which a genetically determined defect in an adhesion molecule is associated with disease. Two such syndromes have been recognized (Table 38.2). In the first LAD syndrome (LAD I), the  $\beta_2$ -integrin family is deficient, whereas in the second, LAD II, the fucosylated carbohydrate ligands for selectins are absent (Etzioni, 1996). Most recently, a third leukocyte adhesion deficiency, LAD III, has been identified (Alon et al., 2003; Alon and Etzioni, 2003).

Leukocyte Adhesion Deficiency Type I

Before 1980, several reports documented a group of patients with recurrent bacterial and fungal infections, defective leukocyte motility and phagocytosis, impaired wound healing, and delayed separation of the umbilical cord (Boxer et al., 1974; Gallin et al., 1978; Hayward et al., 1979). In 1980, a seminal study suggested a possible molecular basis for this emerging syndrome (Crowley et al., 1980). Crowley and colleagues reported the absence of a high-molecular weight neutrophil membrane glycoprotein in a young boy with an inherited defect in neutrophil adhesion. This abnormality was manifested in vitro by failure to spread on surfaces and impaired chemotaxis. In 1982 the association of this syndrome with a missing membrane glycoprotein was confirmed in two other patients (Bowen et al., 1982).

At the same time as this clinical syndrome was being characterized, in separate studies other investigators were identifying a new leukocyte membrane glycoprotein complex involved in multiple adhesion-related functions. Mac-1 and LFA-1 were identified in 1979 and 1981, respectively (Anderson et al., 1995). A third complex belonging to this family, p150, 95, was described several years later. A relationship between the inherited defect of neutrophil adhesion and these glycoproteins was suggested by the fact that monoclonal antibodies to the  $\alpha$  or  $\beta$  chains of this complex induced in vitro defects in chemotaxis and phagocytosis

Table 38.2. Leukocyte Adhesion Deficiency Syndromes

Features	LAD I	LAD II	LAD III

similar to those observed in affected patients. Indeed, in 1984, using specific monoclonal antibodies, multiple groups reported that leukocytes of patients with this syndrome were deficient in both the common subunit as well as in the various subunits (Schwartz and Harlan, 1991). These findings led to the proposal that the primary defect in this syndrome is related to the  $\beta_2$  subunit and that biosynthesis of the  $\beta_2$  subunit is necessary for surface expression of the  $\alpha$  subunits (Springer, 1985).

While many names had previously been given to this syndrome, in the interest of brevity and comprehensiveness, the term *leukocyte adhesion deficiency* (LAD) was proposed in 1987 (Anderson and Springer, 1987). LAD I is inherited in an autosomal recessive manner with heterozygotes exhibiting no significant clinical manifestations. More than 200 patients with this defect have now been described (Etzioni, 1999).

#### Clinical and pathologic manifestations

The prominent clinical feature of these patients is recurrent bacterial infections, primarily localized to skin and mucosal surfaces. These infections are indolent and necrotic and tend to recur. Sites of infection often progressively enlarge, and they may lead to systemic spread of the bacteria. Infections are usually apparent from birth onward, and a common presenting infection is omphalitis with delayed separation of the umbilical cord (Color Plate 38.I). The most frequently encountered bacteria are *Staphylococcus aureus* and gram-negative enteric organisms, but fungal infections are also common. The absence of pus formation at the sites of infection is one of the hallmarks of LAD I. Severe gingivitis and periodontitis are major features among all patients who survive infancy. Impaired healing of traumatic or surgical wounds is also characteristic of this syndrome.

The recurrent infections observed in affected patients result from a profound impairment of leukocyte mobilization into extravascular site of inflammation. Skin windows yield few, if any, leukocytes, and biopsies of infected tissues demonstrate inflammation totally devoid of neutrophils. These findings are particularly striking considering that marked peripheral blood leukocytosis (5 to 20 times normal values) is consistently observed during infections. Transfusions of normal leukocytes resulted in the appearance of donor cells in the skin of one LAD I patient (Bowen et al., 1982), indicating that the defect is intrinsic to the leukocyte. In contrast to the difficulties experienced in defense against bacterial and fungal microorganisms, LAD I patients do not exhibit a marked increase in susceptibility to viral infections.

The severity of clinical infectious complications among patients with LAD I appears to be directly related to the degree of CD18 deficiency. Two phenotypes, designated *severe deficiency* and *moderate deficiency*, have been defined (Fischer et al., 1988). Patients with less than 1% of the normal surface expression exhibited a severe form of disease with earlier, more frequent, and more serious episodes of infection, often leading to death in infancy, whereas patients with some surface expression of CD18 (2.5%–10%) manifested a moderate to mild phenotype with fewer serious infectious episodes and survival into adulthood.

The hallmark pathological finding in LAD I is the complete absence of neutrophils in sites of infection. The necrotic areas are devoid of pus. While this finding is typical for many tissues, in the lung, neutrophil migration to the site of infection may be normal and a normal inflammatory response has been observed (Hawkins et al., 1992). Lymphoid tissue is also severely depleted of lymphocytes, indicating a role for LFA-1 in lymphocyte homing.

#### Laboratory findings

The defective migration of neutrophils from patients with LAD I has been observed in studies in vivo as well as in vitro (Bowen et al., 1982; Schwartz and Harlan, 1991; Harlan, 1993). Neutrophils failed to mobilize to skin sites in the in vivo Rebuck skin-window test. In vitro studies demonstrated a marked defect in random migration as well as chemotaxis to various chemoattractant substances. Adhesion and transmigration through endothelial cells were found to be severely impaired (Harlan et al., 1985). With the use of an intravital microscopy assay it was found that fluorescein-labeled neutrophils from a LAD I boy rolled normally on inflamed rabbit venules, a finding suggesting that they were capable of initiating adhesive interactions with inflamed endothelial cells (von Andrian et al., 1993). However, these cells failed to perform activation-dependent,  $\beta_2$  integrin-mediated adhesion steps and did not stick or emigrate when challenged with a chemotactic stimulus (Fig. 38.1).

Patients with LAD I exhibit mild to moderate neutrophilia in the absence of overt infection. Marked granulocytosis with neutrophil counts in peripheral blood reaching levels of up to 100,000/ $\mu$ l occurs during acute infections. Defects in other myeloid functions are also observed. Binding and phagocytosis of iC3b-opsonized particles is also deficient, in agreement with the function of Mac-1 as complement receptor 3 (CR3). Abnormalities of neutrophil-mediated, antibody-dependent cellular cytotoxicity have been reported in several patients (Kohl et al., 1986).

A wide variety of in vitro abnormalities of lymphocyte function have also been described in LAD I, but their in vivo relevance remains unclear. Although no humoral immune deficiency has been described in most of the patients, an impaired primary and secondary antibody response to a T-dependent neoantigen was found (Ochs et al., 1993).

#### Functional aspects

The CD11/CD18 integrin receptor is expressed on all normal leukocytes, and CD11/CD18 plays an important role in multiple leukocyte functions. However, the predominant clinical manifestation of LAD I—i.e., markedly impaired phagocyte emigration in response to pyogenic infections—can be attributed to the reduced adhesion to endothelium and impaired transendothelial migration observed in CD18-deficient neutrophils of patients with this syndrome.

#### Molecular basis

Early on, several lines of evidence supported an autosomal recessive pattern of inheritance. Equal numbers of male and female patients were described, and family studies showed heterozygous male and female carriers who expressed 50% of the normal amount of the  $\beta_2$ -integrin molecules on their neutrophils. Furthermore, a frequent history of consanguineous marriages strongly supported the concept that LAD I is inherited as an autosomal trait (Anderson et al., 1995). Early studies showed that patients with this disorder were uniformly deficient in the expression of all three leukocyte integrins (Mac-1, LFA-1, p150, 95), suggesting that the primary defect was in the common  $\beta_2$  subunit, which is encoded by a gene located at the tip of the long arm of chromosome 21q22.3 (Solomon et al., 1988). To date, none of the reported affected individuals has demonstrated a selective deficiency of a single  $\beta_2$ -integrin heterodimer. Normal B cell lines synthesize  $\alpha_L$  and  $\beta_2$  precursors, which associate in the cytoplasm and then are transported to the cell surface as an  $\alpha_L\beta_2$  heterodimer. In contrast, lymphoblasts of patients with LAD I

synthesize only normal  $\alpha_L$  subunit precursor, but it is never expressed on the cell surface and is apparently degraded in the absence of a normal  $\beta_2$  subunit (Springer et al., 1984).

Heterogeneity among LAD I patients was first described with respect to the extent of  $\beta_2$ -integrin deficiency on the leukocyte surface as shown by flow cytometry. As previously discussed, the severity of the clinical features and the magnitude of the functional deficits observed are directly related to the degree of CD18 deficiency, but the underlying molecular basis for this heterogeneity remained largely undefined until the  $\beta_2$ -subunit gene (*ITGB2*) was cloned (Kishimoto et al., 1987).

Subsequently, several LAD I variants were reported in which there was a defect in  $\beta_2$ -integrin adhesive functions despite normal surface expression of CD18. A child with classical LAD I features with normal surface expression of CD18 was reported (Hogg et al., 1999) in whom a mutation in CD18 led to a non-functional molecule. Another child with a moderately severe form of LAD I was found to have a novel point mutation in CD18, leading to the expression of dysfunctional  $\beta_2$  integrin (Mathew et al., 2000).

#### Mutation analysis

The molecular basis for CD18 deficiency varies (Vihinen et al., 2001). In some cases it is due to the lack of or diminished expression of CD18 mRNA. In other cases there is expression of mRNA or protein precursors of aberrant size with both larger and smaller CD18 subunits. In still other cases LAD I results from a failure to process normal-sized protein precursors to the mature normal product (Wright et al., 1995). Analysis at the gene level has revealed a degree of heterogeneity, which reflects this diversity. A number of point mutations have been reported, some of which lead to the biosynthesis of defective proteins with single amino acid substitutions, while others lead to splicing defects, resulting in the production of truncated and unstable proteins (Kishimoto et al., 1987). In one kindred a 90-nucleotide deletion in the CD18 mRNA produced an in-frame deletion of a 30-amino acid region. Analysis of the genomic DNA showed this 90 bp region to be encoded by a single exon (exon 9) (Kishimoto et al., 1989). The 30-amino acid deletion is located in a 241-amino acid region of the extracellular domain of the CD18 molecule that is highly conserved in evolution. Notably, a high percentage of CD18 mutations identified in LAD I are contained in this highly conserved segment (Kishimoto et al., 1989) (Fig. 38.2). Domains within this segment are presumably required for association and biosynthesis of precursors and may represent critical contact sites between the  $\alpha$ -subunit and  $\beta$ -subunit precursors.

Mutation analysis of other severe and moderate LAD I phenotypes has defined point mutations in the coding region of the

CD18 subunit mRNA. In one case, a normal-sized  $\beta_2$ -subunit precursor was present in the cytoplasm but was not expressed on the cell surface membrane. The mutations were found again in the same highly conserved extracellular domain (Sligh et al., 1992). Several splicing defects resulting in the production of abnormal proteins were reported. Other mutations were found in exons 7 and 13 (Back et al., 1992). Homozygosity for the mutation was described in some cases, whereas in others compound heterozygosity was observed. Thus far over 20 different mutations have been described (Fig. 38.2). In many cases no molecular analysis has been performed.

Thus, LAD I can be caused by a number of distinct mutational events, all resulting in the failure to produce a functional leukocyte  $\beta_2$  subunit. In most cases a point mutation, small insertions, or deletions in the *CD18* (*ITGB2*) gene have been reported, although an infant with LAD I and gross abnormality in chromosome 21, representing a deletion of q22.1–3, has been described (Rivera-Matos et al., 1995).

#### Strategy for diagnosis

In any infant male or female with recurrent soft tissue infections and a very high leukocyte count, the diagnosis of LAD I should be considered. The diagnosis is even more suggestive if a history of delayed separation of the umbilical cord is present. To confirm the diagnosis, absence of the  $\alpha$  and  $\beta$  subunits of the  $\beta_2$ -integrin complex must be demonstrated. This can be accomplished with the use of the appropriate CD11 and CD18 monoclonal antibodies and flow cytometry. Sequence analysis to define the exact molecular defect in the  $\beta_2$  subunit is a further option. In rare cases functional assays must be performed to diagnose a LAD I variant.

#### Carrier detection and prenatal diagnosis

LAD I carriers have 40%–60% of normal CD18 and lack clinical symptoms. Sequence analysis shows one normal and one abnormal gene.

Because leukocytes express CD18 on their surface at 20 weeks of gestation, cordocentesis performed at this age can establish a prenatal diagnosis (Weening et al., 1991). In families in whom the exact molecular defect has been previously identified, an earlier prenatal diagnosis is possible by chorionic biopsy and mutation analysis.

#### Treatment and prognosis

Patients with the moderate LAD I phenotype usually respond to conservative therapy and the prompt use of antibiotics during acute infectious episodes. Prophylactic antibiotics may reduce the risk of infections. A trial of interferon- $\gamma$  (IFN- $\gamma$ ), which can

**Figure 38.2.** Representative mutations in the  $\beta_2$ -integrin subunit that have been identified in patients with LAD I syndrome.

enhance transcription of the  $\beta_2$  subunit, was found to be ineffective in a single LAD I patient studied (Weening et al., 1992). Transfusion of granulocytes immediately after harvest by leukopheresis has been found to be useful in selected cases of infections that otherwise could not be controlled. Although granulocyte transfusions may be life saving, their use is limited because of difficulties in supply of daily donors and immune reactions to the allogeneic leukocytes.

At present, the only corrective treatment that should be offered to all cases with the severe phenotype is bone marrow transplantation (Le Deist et al., 1989; Thomas et al., 1995). The absence of host LFA-1 may be advantageous in these transplants because graft rejection appears to be in part dependent on the CD18 complex. Indeed, a higher rate of successful engraftment of transplants, even with only partially compatible HLA matching, was reported in patients with LAD I than that for patients with other forms of primary immunodeficiency syndromes (Fischer et al., 1994).

The introduction of a normal  $\beta_2$ -subunit gene (*ITGB2*) into hematopoietic stem cells has the potential to cure children with LAD I (Bauer and Hickstein, 2000). Retroviral-mediated transduction of the *CD18* gene was shown to reconstitute a functional CD11a/CD18 in lymphoblastoid cell lines derived from patients with LAD I (Back et al., 1990; Wilson et al., 1990; Krauss et al., 1991), and transduction of murine bone marrow cells with CD18 retroviral vector resulted in gene expression in a variable percentage of neutrophils at 2 weeks post-transduction (Wilson et al., 1993). Retroviral-mediated transfer of the *CD18* gene into primary LAD I bone marrow cells has also been reported (Yorifuji et al., 1993; Bauer et al., 1998). Expression of CD18 in a low percentage of neutrophils in two LAD I patients undergoing gene therapy without conditioning was observed (Bauer et al., 1998). With the future development of gene therapy techniques that allow efficient gene transfer into hematopoietic stem cells, severely deficient LAD I patients may be ideal candidates for this procedure.

## Leukocyte Adhesion Deficiency Type II

LAD II syndrome results from a general defect in fucose metabolism, causing the absence of SLeX and other fucosylated ligands for the selectins. LAD II was first described in two unrelated Palestinian boys, each the offspring of consanguineous parents (Frydman et al., 1992). Subsequently, two additional unrelated Palestinian children and one Turkish child (Etzioni and Tonetti, 2000b) and a child of Brazilian origin whose parents were consanguineous (Hidalgo et al., 2003) have been reported, for a total of five LAD II patients.

### Clinical and pathologic manifestations

Affected children are born after uneventful pregnancies with normal height and weight. No delay in the separation of the umbilical cord has been observed. Patients with LAD II have severe mental retardation, short stature, a distinctive facial appearance, and the rare Bombay (hh) blood phenotype (Table 38.2). They develop recurrent episodes of bacterial infections early in life, mainly pneumonia, periodontitis, otitis media, and localized cellulitis. Mild to moderate skin infections without obvious pus have also been observed. The infections are generally not life threatening and are usually treated in the outpatient clinic (Etzioni et al., 1998). Interestingly, after the age of 3 years, the frequency of infections decreases and the children no longer need prophylactic antibiotics.

At an older age their main infectious problem is severe periodontitis, which is also observed in patients with LAD I. During times of infections the neutrophil count increases up to 150,000/ $\mu$ l. It is of interest to note that from the first days of life there is marked neutrophilia, ranging between 25,000 and 30,000/ $\mu$ l, even when patients are free of infections.

Overall, the infections in LAD II appear to be comparable to the moderate rather than the severe phenotype of LAD I. It is possible that the ability of LAD II neutrophils to adhere and transmigrate via  $\beta_2$  integrin under conditions of reduced shear forces (von Andrian et al., 1993) may permit some neutrophils to emigrate to sites of severe inflammation where flow may be impaired, thereby allowing some level of neutrophil defense against bacterial infections.

As is observed in LAD I, at the site of infection there is no pus formation, and there is a striking absence of neutrophils in the lesions. Lymphocytic infiltration, by contrast, is clearly present (see below).

### Laboratory findings

The clinical picture of skin infections, pneumonia, and periodontitis associated with a very high blood neutrophil count initially suggested a neutrophil defect as the cause of this syndrome. Subsequently it was found that although the opsonophagocytic activity was normal, a marked defect in neutrophil motility was present in all LAD II patients (Etzioni et al., 1992). Both random migration and directed migration toward chemotactic factors were markedly decreased (10% of normal).

Furthermore, homotypic aggregation of patient neutrophils was found to be defective (Etzioni, 1994). These observations suggested that the problem was a defect in neutrophil adherence to surfaces; therefore, the possibility of a defect in adhesion molecules was investigated. Indeed, while patients' and their parents' neutrophils exhibited normal levels of integrin subunits, LAD II neutrophils were found to be deficient in expression of the SLeX antigen (Etzioni et al., 1992). In contrast to LAD I neutrophils, which failed to flatten and spread on phorbol ester-treated glass coverslips, the majority of LAD II neutrophils flattened and spread extensively in a pseudopod formation (Phillips et al., 1995). Interestingly, a small percentage of the LAD II cells exhibited an intermediate appearance and retained a more spherical shape. The poor migration toward chemoattractants in an under-agarose assay and the defective homotypic neutrophil adhesion could not be readily explained by the biochemical deficiency of SLeX and suggested a more global defect in cell activation or adhesion. Nevertheless, LAD II neutrophils could be activated normally with up-regulation of various adhesion molecules (Phillips et al., 1995).

### Functional aspects

To examine further the significance of the fucosylation defect, both in vitro and in vivo functions of LAD II neutrophils were assessed. Neutrophils isolated from peripheral blood of one LAD II patient failed to bind to purified platelet-derived P-selectin and recombinant E-selectin in vitro (Phillips et al., 1995). To determine the effect of SLeX deficiency on neutrophil-endothelial interactions, neutrophil adherence to IL-1-, TNF-, histamine-, and phorbol ester-activated human umbilical vein endothelial cells was examined. No adhesion of LAD II neutrophils was observed when the endothelial cells were activated with IL-1 $\beta$  (Fig. 38.3) or TNF- $\alpha$ , both potent inducers of E-selectin, whereas normal neutrophils bound avidly. Similarly, endothelial cells activated

LAD II Neutrophil Adhesion to Endothelial Cells

**Figure 38.3.** Selectin-dependent adhesion of LAD II neutrophils in vitro is impaired in LAD II syndrome. Purified neutrophils from a normal donor (open columns) or the LAD II patient (filled columns) were incubated for 5 minutes on human umbilical vein endothelial cell monolayers that had been treated with control medium or with recombinant human IL-1. In some wells neutrophil CD18 was activated by addition of phorbol myristate acetate (PMA). An anti-CD18 monoclonal antibody or an anti-E-selectin monoclonal antibody was added to some wells during incubation. The plates were washed and neutrophil adherence was quantitated by spectrophotometric analysis of the neutrophil-specific enzyme myeloperoxidase (Etzioni et al., 1992; Phillips et al., 1995).

by histamine to express P-selectin bound normal neutrophils but not LAD II neutrophils. By contrast, normal adhesion to endothelial cells was observed after activation with phorbol myristate acetate (PMA), an activating stimulus for  $\beta_2$  integrins (Fig. 38.3). Furthermore, LAD II neutrophil migration across endothelial monolayers in response to f-Met-Leu-Phe (fMLP), a CD11/CD18-dependent function, was comparable to that of normal neutrophils (Phillips et al., 1995).

Rolling, the first step in neutrophil recruitment to the site of inflammation, is mediated primarily by the binding of the selectins to their fucosylated glycoconjugate ligands. Through intravital microscopy, the in vivo behavior of fluorescein-labeled neutrophils from a normal donor and from LAD I and LAD II patients was investigated during their passage through the inflamed microcirculation of rabbit mesentery (von Andrian et al., 1993). The rolling fraction of normal donor neutrophils in this assay was approximately 30%, and LAD I neutrophils behaved similarly. In contrast, LAD II neutrophils rolled poorly and failed to emigrate (Fig. 38.1). Their rolling fraction was only 5% (Fig. 38.4), and most of the cells that did interact with endothelial cells had a higher rolling velocity, rolled only over short distances, and frequently detached from the vessel wall. This marked inability to interact with inflamed vasculature was observed only in the presence of intravascular shear force: when the mesenteric blood flow was temporarily stopped and LAD II cells were injected into the nonperfused microvasculature, it was observed that numerous LAD II cells became stuck and did not detach when the blood flow was subsequently restored. These experiments indicate that the defect in LAD II is due to a shear-dependent inability of neutrophils to roll and slow down in inflamed venules and is not due to a dysfunction of the later shear-independent steps in the adhesion cascade.

To examine in vivo chemotaxis, the response of patient neutrophils to cutaneous inflammation was assessed by both skin-

LAD I and LAD II Neutrophil Rolling in Inflamed Rabbit Mesenteric Vessel

**Figure 38.4.** Selectin-dependent rolling of neutrophils in vivo is reduced in LAD II syndrome. Quantitation of neutrophil rolling from control subjects and patients with LAD I and LAD II was assessed in inflamed mesenteric venules in rabbits. Samples of fluorescent neutrophils were injected into the terminal mesentery artery blood stream 4 to 6 hours after intraperitoneal injection of IL-1. Cells passing through venules in the downstream segment were made visible by stroboscopic epi-illumination and were recorded on videotape. Tapes were analyzed for assessment of neutrophil rolling behavior. The rolling fraction was determined as the percentage of rolling neutrophils in the total flux of fluorescent cells passing a venule during an injection (Arbones et al., 1994). A total of 10 venules was analyzed, 5 vessels for each neutrophil sample in each rabbit. Means  $\pm$  SD are shown (von Andrian et al., 1993). Reproduced from the *Journal of Clinical Investigation* 1993; 191:2893–2897, by copyright permission of the American Society for Clinical Investigation.

chamber and skin-window techniques. Neutrophil emigration was markedly diminished in both tests, the values being approximately 1.5% and 6% of normal in the skin-window and skin-chamber tests, respectively (Price et al., 1994). Monocyte migration to the skin-window site was reduced to a similar degree. Notably, neutrophils from a patient with LAD I, studied concurrently, showed the same magnitude of defect in these assays.

Adhesion molecules are known to participate in the immune reaction of T lymphocytes (Springer, 1995) and, as noted above, some lymphocyte functions are defective in LAD I (Beatty et al., 1984; Fischer et al., 1988; Ochs et al., 1993). In contrast, LAD II patients show a normal proportion and absolute numbers of T lymphocyte subpopulations. They also exhibit normal proliferative responses to various mitogens, normal NK cell activity, and normal immunoglobulin levels. Furthermore, in contrast to patients with LAD I, antibody production in response to immunization with bacteriophage OX174 was found to be normal with appropriate switching from IgM to IgG (Price et al., 1994). However, delayed cutaneous hypersensitivity reactions were not observed upon intradermal injection of various antigens. This apparent anergy may be due to absence of the skin homing T cell antigen, CLA, which contains fucose in its structure (Picker, 1994). Therefore, the in vivo immune response to keyhole limpet hemocyanin (KLH) was investigated. Normal KLH-specific in vitro T cell proliferation and normal in vivo anti-KLH antibody titers were found, indicating normal T and B cell function and collaboration. However, skin testing with KLH failed to elicit a positive reaction (rubor, calor, edema) (Kuijpers et al., 1997a). A biopsy of the site of intradermal KLH injection revealed that the number and phenotype (CD3<sup>+</sup>) of infiltrating lymphocytes were identical to those of a positive control (except for the lack of CLA staining in the LAD II biopsy). Up-regulation of various

**Figure 38.5.** LAD II is a congenital disorder of glycosylation. GDP-1-fucose is synthesized in the cytosol and must be transported into the Golgi apparatus where fucosyl transferases are located. In the Golgi, fu-

ceryl transferases add fucose to macromolecules. In LAD II, deficiency of the GDP-fucose transporter prevents fucosylation of membrane glycoproteins and glycolipids.

endothelial adhesion molecules was similar in the patient and control. The discrepancy between the almost normal histological findings and the absence of an intradermal reaction remains unexplained. Rather than mediating trafficking, CLA may be important in activating T cells to induce the inflammatory reaction and to initiate the classical signs of delayed-type hypersensitivity reaction in the skin.

#### Molecular basis

Because the first two LAD II patients identified were the offspring of first-degree relatives and the parents were clinically unaffected, autosomal recessive inheritance was assumed (Frydman et al., 1992). In addition to being of the Bombay phenotype (absence of the H antigen), the cells of LAD II patients were found to lack Lewis a and b antigens and the patients were nonsecretors. Therefore, the biochemical abnormality in LAD II is a general defect in fucosylation of macromolecules (Fig. 38.5). The three unique blood phenotypes (Bombay, Lewis a and b) have in common a lack of fucosylation of glycoconjugates. Because at least four different fucosyltransferases would have to be affected to produce negativity for SLeX, H, Lewis, and secretor and the genes in these molecules are not physically linked in the human genome (loci include chromosomes 11, 19p, and 19q), LAD II cannot result from abnormal fucosyltransferase(s). Furthermore, LAD II patients possess normal activity of  $\alpha$ -2-fucosyltransferase (Shechter et al., 1995), which is needed for H antigen and is defective in individuals who carry the rare Bombay blood phenotype but do not have LAD II. These findings suggest that the primary defect in LAD II must instead be a general defect in fucose production.

After the observation was made that the defect in the Palestinian patients may affect the de novo GDP-1-fucose biosynthesis pathway (Karsan et al., 1998), the two enzymes involved in this pathway, GMD and FX protein, were assessed and found to be normal, without a mutation in cDNA isolated from LAD II patients. Subsequently, the Turkish child with LAD II was found to have decreased GDP-1-fucose transport into the Golgi vesicles (Lubke et al., 1999). Similar studies were performed in the Palestinian patients and indeed, the same general defect in fucose transport to the Golgi vesicles was found. Still, marked kinetic differences were observed between the Turkish and the Palestinian patients (Sturla et al., 2001). This finding may explain

the different response to fucose supplementation in the Turkish and the Arab children (see below). Recently, through use of the complementation cloning technique, the human gene encoding the fucose transporter was found to be located on chromosome 11 (Lubke et al., 2001). The Turkish child was homozygous for a mutation at amino acid 147, in which arginine is changed to cysteine (Lubke et al., 2001; Luhn et al., 2001), whereas the two Palestinian patients examined had a homozygous mutation in amino acid 308, in which threonine is changed to arginine (Lubke et al., 2001). Both mutations are located in highly conserved transmembrane domains. The Brazilian patient has a homozygous single nucleotide deletion (588delG) resulting in frameshift and premature stop codon 34 residuals after the mutation (Hidalgo et al., 2003). LAD II is thus one of the congenital disorders of glycosylation (CDG) and is classified as CDG-IIc (Lubke et al., 2001). Although only three unique mutations (in five affected patients) have been described thus far, there seems to be a genotype-phenotype correlation (Etzioni et al., 2002). Recently it was found that in some mutations the transporter is located in the Golgi apparatus, but it is nonfunctional, while in others the transporter cannot be localized to the Golgi (Helmus et al., 2006).

#### Strategies for diagnosis

LAD II is a very rare syndrome, described originally in four Palestinian children from two apparently unrelated families, one child from a Turkish family, and subsequently in a Brazilian child. Because the clinical phenotype is very striking, the diagnosis can be made based on the presence of recurrent, albeit mild, infections, marked leukocytosis, and the Bombay blood group, in association with mental and growth retardation.

Analysis of peripheral blood leukocytes by flow cytometry with an anti-CD15s monoclonal antibody will demonstrate the absence of SLeX expression. To confirm the diagnosis, sequence analysis of the gene encoding the GDP-fucose transporter is required.

#### Carrier detection and prenatal diagnosis

Prenatal diagnosis was carried out successfully through use of a cord blood sample obtained from a female fetus of one of the affected families. Because of the presence of the Bombay blood phenotype the pregnancy was aborted (Frydman et al., 1996).

Having cloned the gene causing LAD II, carrier detection is possible, and prenatal diagnosis can be performed earlier with chorionic villus samples for DNA analysis.

#### Treatment and prognosis

Each of the LAD II patients described to date suffered from recurrent episodes of infections that responded well to antibiotics. No serious consequences were observed, and prophylactic treatment was never considered in the Palestinian patients, whereas the Turkish child was placed on prophylactic antibiotics. A chronic problem for all patients has been periodontitis, a condition that is especially difficult to treat in children with severe mental retardation (Etzioni et al., 1998). The oldest LAD II patient is now 14 years old, has severe psychomotor retardation, but only mild infectious problems.

Because of the proposed defect in fucose production, supplemental administration of fucose through either addition to the diet or intravenous infusion has been suggested. Indeed, fucose supplementation caused dramatic improvement in the condition of the Turkish child (Marquardt et al., 1999). A marked decrease in leukocyte count with improved neutrophil adhesion was noted. Furthermore, improvement in developmental delay was observed and no episodes of infections occurred during fucose therapy. However, the same protocol produced no improvement in laboratory data or clinical features in two Palestinian children (Etzioni and Tonetti, 2000a). This difference may be due to the genetic defect in the Turkish child, which leads to decreased affinity of the transporter for fucose. An increase in cytosolic concentration of fucose would be expected to overcome, at least in part, the defect in fucose transport.

#### Leukocyte Adhesion Deficiency Type III

Recently, a rare, autosomal recessive LAD syndrome that is distinct from LAD I and LAD II has been reported (Alon et al., 2003; Alon and Etzioni, 2003). Although leukocyte integrin expression and intrinsic adhesion to endothelial integrin ligands have been found to be normal in LAD III, in situ activation of all major leukocyte integrins, including LFA-1, Mac-1, and VLA-4, by endothelial-displayed chemokines or chemoattractants is severely impaired in patient-derived lymphocytes and neutrophils. Whereas the rolling of LAD III leukocytes on endothelial surfaces is normal, they fail to arrest on endothelial integrin ligands in response to endothelial-displayed chemokines. G protein-coupled receptor (GPCR) signaling appears to be normal and the ability of leukocytes to migrate toward a chemotactic gradient is not impaired. The key defect in this syndrome has been attributed to a genetic loss of integrin activation by rapid chemoattractant-stimulated GPCR signaling (Alon et al., 2003). This novel LAD shows striking similarities to three cases previously referred to as LAD I variants (Kuijpers et al., 1997b; Harris et al., 2001; McDowall et al., 2003). All four cases had similar clinical symptoms, characterized by severe recurrent infections, a bleeding tendency, and marked leukocytosis (Table 38.2). In all cases tested, integrin expression and structure were intact with a defect in integrin activation by physiological stimuli. Because LAD I leukocytes have defects in integrin expression or structure, it was proposed that this group of integrin activation disorders be designated *LAD III* (Alon and Etzioni, 2003; Kinashi et al., 2004). The term *LAD I variant*, which was ascribed to this unique syndrome, is inaccurate because this syndrome does not evolve from structural defects in leukocyte or platelet integrins.

In all of the LAD III cases studied, defects in GPCR-mediated integrin activation are accompanied by variable defects

in activation of leukocyte integrins by non-GPCR-mediated signals. A growing body of evidence implicates the Ras-related GTPase Rap-1 as a key regulator of integrin activation by multiple stimuli (Caron, 2003). Rap-1 is also implicated in the activation of platelet and megakaryocyte GpIIb/IIIa integrin, which is defective in LAD III (Eto et al., 2002). It is thus highly attractive to hypothesize that at least some of the LAD III cases have either a direct or an indirect defect in the activation of integrins in leukocytes and platelets by Rap-1. Although lymphocytes from two patients expressed normal levels of Rap-1 (Kinashi et al., 2003; McDowall et al., 2003), in one case studied an abnormal pattern of Rap-1 activation was observed (Kinashi et al., 2004). However, the ubiquitous expression of Rap-1 in most tissues and its highly diverse functions in nonhematopoietic cells (Bos et al., 2001) make it unlikely that Rap-1 is structurally mutated in any of the LAD III cases. It is more likely that a hematopoietic-restricted effector of Rap-1 or a specific hematopoietic adaptor that links this GTPase to cytoskeletal partners involved in integrin activation is functionally defective in patients with LAD III syndrome.

#### E-selectin deficiency

Recently, another potentially inherited defect in the selectin system was described in a child with moderate neutropenia and severe recurrent infections (DeLisser et al., 1999). There was markedly reduced expression of E-selectin on blood vessels of inflamed tissue with increased levels of circulating soluble E-selectin, suggesting increased cleavage of surface E-selectin. Notably, the E-selectin gene sequence was normal.

### Animals Models

#### CD18-Deficient Dogs and Cattle

A spontaneous mutation in the gene coding for the  $\beta_2$  single integrin has been described in both dogs (Giger et al., 1987) and cattle (Shuster et al., 1992). Canine LAD (CLAD) occurs in Irish setters and results from a single missense mutation in the *CD18* gene, resulting in a change from cysteine to serine at amino acid 36 (Kijas et al., 1999). In bovine LAD (BLAD) there is also a point mutation (Asp128Gly) in the *CD18* gene. Animals homozygous for this mutation exhibited persistent neutrophilia and suffered from recurrent infections associated with poor growth performance. The carrier frequency of the defective gene among Holstein cattle has been approximately 15% in bulls and 6% in cows (Shuster et al., 1992).

#### CD18-Deficient Mice

Multiple mice with targeted disruption of one or more leukocyte and endothelial adhesion molecules have been generated (Etzioni et al., 1999). Of particular interest are those knockouts that most closely mimic LAD I or LAD II.

Mutant mice lineages with complete deficiency of CD18 have defects similar to the severe clinical phenotype of LAD I (Mizgerd et al., 1997; Scharffetter-Kochanek et al., 1998). As in LAD I, these animals exhibit marked neutrophilia (11- to 30-fold increase over wild type). The granulocytosis observed in the CD18-deficient mice was due mainly to continuous stimulation of the bone marrow as a consequence of the defective antimicrobial functions leading to infections (Horwitz et al., 2001). Similar to LAD I, there was almost no emigration of neutrophils in the CD18-null animals into sites of inflammation in the skin. In contrast, the CD18-deficient mice exhibited comparable num-

bers of neutrophils in lavage fluid from inflamed peritoneum and increased emigration into inflamed lung when compared with wild type. The lack of neutrophil emigration to the skin with normal emigration to the lungs was also described in one patient with the severe phenotype of LAD I (Hawkins et al., 1992). The persistence of neutrophil emigration into the inflamed peritoneum in the CD18 animals may result from the marked increase in circulating neutrophils in the CD18-deficient animals. Because the number of emigrating neutrophils is in part dependent on the number of circulating neutrophils, the observation that the same absolute numbers of neutrophils emigrate in the CD18 animals as in the wild-type mice may reflect a significant inhibition. However, limited studies in one LAD I patient showed an absence of neutrophils in infected peritoneum (Hawkins et al., 1992). This discrepancy may reflect a biological difference between mice and humans, a sampling effect (peritoneal fluid in mice vs. tissue in humans), or a difference in the duration of the inflammatory response (4 hours in mice vs. days in the patient).

### Selectin-Deficient Mice

The defective GDP-fucose transporter gene responsible for LAD II has only recently been identified, and studies of mice with targeted disruption of this gene have not been reported. Although the genetic deficiency in LAD II has no direct effect on the selectin genes themselves, the resulting defect in fucose metabolism produces a deficiency of fucosylated leukocyte ligands for endothelial E- and P-selectins. The endothelium in LAD II patients likely also exhibits reduced expression of fucosylated leukocyte L-selectin ligands (Karsan et al., 1998). Thus, with respect to leukocyte adhesion, LAD II patients are the human equivalent of mice with combined knockout of E-, P-, and L-selectin genes or mice with knockout of the genes that direct biosynthesis of fucose-containing selectin ligands.

Mice deficient in E- and P-selectin (E/P) and mice deficient in E-, P-, and L-selectin (E/P/L) show leukocytosis, dramatic reduction in leukocyte rolling, markedly reduced emigration into inflamed peritoneum, and increased susceptibility to mucocutaneous infections (Bullard et al., 1996; Frenette et al., 1996; Jung and Ley, 1999; Robinson et al., 1999). In contrast to the E/P- or E/P/L-deficient mice, the two older LAD II patients have had no increase in systemic infections, and the few episodes of localized infection have responded to conventional treatment as in any immunocompetent child. The phenotype of the multiple selectin-deficient animals thus appears to be much more severe than that observed in LAD II, perhaps reflecting differences between humans and mice in susceptibility to mucocutaneous infections. However, the possibility that nonfucosylated ligands participate in selectin interactions *in vivo* has not been completely excluded. If this were the case, then the absence of fucosylated ligands in LAD II would not impact all E-, P-, and L-selectin-dependent functions, whereas the selectin-null mice would be severely affected (Etzioni et al., 1999).

Mice deficient in biosynthesis of SLe<sup>x</sup> have also been generated. The gene encoding  $\alpha(1,3)$  fucosyltransferase Fuc-TVII, an enzyme that controls synthesis of SLe<sup>x</sup>, was knocked out in mice, resulting in a phenotype reminiscent of the human LAD II, with defective adhesion and marked leukocytosis (Maly et al., 1996). The same phenotype was observed in mice deficient in core 2  $\beta(1-6)$  N-acetylglucosaminyltransferase, which is also important in the synthesis of SLe<sup>x</sup> (Ellies et al., 1998). However, neither murine models showed any gross abnormalities, confirming that the growth and mental retardation in LAD II is most

likely due to the general defect in fucose metabolism and not to the adhesion deficiency.

### Conclusion

The crucial role of the  $\beta_2$ -integrin subfamily in leukocyte emigration was convincingly demonstrated after LAD I was discovered. Patients with this disorder suffer from life-threatening bacterial infections. In its severe form, death usually occurs in early childhood unless bone marrow transplantation is performed.

The LAD II disorder clarifies the role of the selectin receptors and their fucosylated ligands such as SLe<sup>x</sup>. *In vitro* as well as *in vivo* studies establish that this family of adhesion molecules is essential for neutrophil rolling, the first step in neutrophil emigration through the blood vessel. Clinically, patients with LAD II suffer from a less severe form of disease, resembling the moderate phenotype of LAD I. This may be due in part to the ability of LAD II neutrophils to emigrate when blood flow rate is reduced and to the observed normal T and B lymphocyte function in LAD II as opposed to that in LAD I. The molecular defect responsible for LAD III is not yet known, but experimental evidence points toward a defect in integrin activation, resulting in severe recurrent infections, a bleeding tendency, and marked leukocytosis.

## Cyclic and Congenital Neutropenia Due to Defects in Neutrophil Elastase

DAVID C. DALE and ANDREW G. APRIKYAN

Severe neutropenia predisposes patients to recurrent bacterial infections (Boxer and Dale, 2002). These infections are usually caused by organisms that are resident on body surfaces—i.e., staphylococci, streptococci, and enteric organisms. In general, the susceptibility is inversely related to the neutrophil count. Infections of two general types occur: superficial infections of the skin and oropharyngeal areas and more serious infections involving the lung and gastrointestinal tract, which may be complicated by sepsis. In general, these infections are poorly responsive to antibiotics. Both cyclic and congenital neutropenias are now effectively treated with the hematopoietic growth factor, granulocyte colony-stimulating factor (G-CSF). Recent studies have shown that both of these diseases are attributable to mutations in the gene for neutrophil elastase, a protease made and packaged in the primary granules of neutrophils early in their differentiation from the hematopoietic stem cells.

### Cyclic Neutropenia

Cyclic neutropenia (MIM 162800) was first described in 1910 in a child with recurrent mouth ulcers (Leale, 1910). The oscillations of blood neutrophils were reported again for this same patient in 1932, a finding illustrating the extremely consistent pattern of oscillations of blood counts characteristic for this disorder (Rutledge et al., 1930). In 1949, Reiman described a parent and child with cyclic neutropenia (Reiman and de Berardinis, 1949) and Morley later described five families with occurrence of disease in a classic autosomal dominant pattern (Morley et al., 1967). The estimated disease frequency is approximately 1 case per million population and most cases have occurred among Caucasians.

### Clinical Features

The classic manifestations of cyclic neutropenia are oscillations of neutrophils and monocytes with a 21-day periodicity (Dale et al., 2002). At the nadir, neutrophils are usually less than  $0.2 \times 10^9/l$ , for 3 to 5 days, after which they rise rapidly to levels near the lower limits of normal, about  $2 \times 10^9/l$ . Neutrophil counts then remain at this approximate level for several days until neutropenia recurs (Fig. 39.1). Blood monocytes oscillate reciprocally with the peak levels occurring during the neutropenic period. Monocyte counts generally cycle from normal to above-normal levels. In many patients there are also detectable oscillations of reticulocytes and platelets and, in some cases, oscillations of other cells, such as eosinophils and lymphocytes. The term *cyclic hematopoiesis* is sometimes used because of the oscillations in so many blood cells (Guerry et al., 1973; Brandt et al., 1975). In some patients with strictly regular oscillations in childhood, quite commonly the oscillations become much less obvious in adulthood. Family studies also show that not all family members affected by this disease have easily detected neutrophil oscillations (Haurie et al., 1998). There also are rare cases of acquired cyclic neutropenia, in which patients are well throughout childhood with normal blood counts but have characteristic 21-day oscillations of their neutrophil counts later in life. Other periodicities, ranging from 15 to 35 days, have been reported in rare instances.

Serial bone marrow examinations done at 2 to 4 day intervals show waves of hematopoietic activity (Guerry et al., 1973; Brandt et al., 1975). At times, the marrow has only promyelocytes and some myelocytes in the neutrophil series, with a total absence of more mature neutrophil precursors. A few days later, when blood neutrophils have recovered, there is often a large proportion of

**Figure 39.1.** Serial blood cell counts in a patient with cyclic neutropenia.

mature neutrophils in the marrow. Electron-microscopic studies done during the cycle show cytoplasmic blebbing and nuclear condensation in neutrophils and their precursors at all phases of the cycle (Parmley et al., 1984; Aprikyan et al., 2001). Macrophages are laden with cellular debris (Aprikyan et al., 2001). Flow-cytometric analyses of myeloid progenitor cells demonstrate increased numbers of annexin V–staining cells. These findings suggest that the primary cellular abnormality in cyclic neutropenia is selective apoptotic death of neutrophil precursors with their removal by marrow macrophages (Aprikyan et al., 2001).

As a consequence of the recurrent severe neutropenia, patients usually have recurrent fever at 3-week intervals (Bar-Joseph et al., 1997; Wright et al., 1981). During neutropenia, patients may develop deep, painful aphthous ulcers, cervical adenopathy, pharyngitis, sinusitis, and cellulitis. Perirectal cellulitis is particularly common. Deep tissue abscesses occur less often. Abdominal pain and signs of peritonitis are alarm signals for the development of sepsis, often clostridial in origin, which may be fatal.

#### Pathophysiological, Molecular, and Genetic Studies

For many years, the cyclic oscillations in marrow cells and proliferative activity have been interpreted as suggesting that cyclic neutropenia occurs because of regular interruptions in neutrophil production (Wright et al., 1981). This concept was supported by investigations using tritiated thymidine administered in vivo at different phases of the cycle (Guerry et al., 1973). At the time of onset of neutropenia, very little of the injected thymidine is incorporated into neutrophils. During the proliferative phase, when neutrophils are abundant, normal incorporation occurs. Studies with radioisotopically labeled neutrophils show that the blood half-life of the mature neutrophils is normal, indicating that neutropenia is not attributable to a defect in the survival of the mature cells (Guerry et al., 1973). In vitro studies of colony-forming cells have shown that early precursors are present at all stages in the

cycle, but the number of these cells measured as colony-forming unit (CFU)-C/ $10^3$  nucleated marrow cells oscillated with the same periodicity as that of the blood counts (Migliaccio et al., 1990). Recent studies have demonstrated marked differences in the formation of various types of CFU-C from CD34<sup>+</sup> marrow cells. High proliferative potential cell colonies (HPPC) appear to form normally, but more differentiated colonies—i.e., colony-forming units—granulocyte macrophage (CFU-GM)—are severely decreased (Aprikyan et al., 2001). These studies suggest that as the precursors mature, they lose their proliferative potential. These data, together with the electron-microscopic and annexin V studies, indicate that increased cell loss by apoptosis early in neutrophil development is the cellular basis for the cyclic neutropenia (Aprikyan et al., 2000b).

Linkage analysis studies of a series of 13 families with autosomal dominant cyclic neutropenia localized the genetic defect for this disorder to chromosome 19p13.3 (Horwitz et al., 1999). In this region of chromosome 19, there are three genes for well-characterized proteases found in neutrophil granules: protease 3, cathepsin G, and neutrophil elastase (ELA-2). Sequencing of these genes revealed that all patients with cyclic neutropenia have mutations in the gene for ELA2, occurring predominantly in exon 5, or at the junction of exon 4 and intron 4 (Fig. 39.2) (Horwitz et al., 1999; Aprikyan et al., 2000a; Dale et al., 2001). The presently favored hypothesis postulates that the mutations in one allele of the ELA2 gene result in a gain of function or an aberrant function of the product of this mutant gene that triggers the death of the developing cells at the promyelocyte stage (Dale et al., 2001). Studies are in progress to confirm this hypothesis and define its precise cellular mechanisms.

In 1978, Mackey hypothesized that oscillations in the hematopoietic system originate with abnormalities of hematopoietic stem cells. He developed a mathematical model in which oscillations of peripheral blood cells were attributable to irreversible loss of cells from an early proliferative compartment. In this model, the pattern of the peripheral counts varies according to the rate of early cell loss and the strength of the feedback signal from the periphery; this signal is presumed to be a specific or a combination of several hematopoietic growth factors (Haurie et al., 1999). Although other hypotheses have been advanced to explain cycling (von Schulthess and Mazer, 1982; Dunn, 1983; Wichmann et al., 1998), the recent data on accelerated apoptosis due to mutations in the gene for neutrophil elastase are most consistent with the Mackey hypothesis.

#### Treatment Responses

Recombinant human G-CSF is a very effective treatment for cyclic neutropenia, usually administered subcutaneously at doses of 2–3  $\mu\text{g/kg}$  on a daily or alternate-day basis (Dale et al., 2003). This therapy increases the amplitude of oscillations of blood neutrophils and other cells and shortens the oscillations from 21 days to about 14 days, with a reduction in the duration of severe neutropenia, from 3–5 days to usually 1 day or less (Lund et al., 1967). With this shortening of neutropenia, the recurrent fevers, mouth ulcers, and other manifestations of the disease are eliminated or ameliorated substantially. Studies of marrow precursors show that treatment with G-CSF improves the survival properties of isolated CD34<sup>+</sup> cells (Aprikyan et al., 2001). The clinical improvement on G-CSF appears to be due to both increase in survival and proliferative activity of the marrow precursor cells.

**Figure 39.2.** Mutations in the neutrophil elastase gene (*ELA-2*) and cyclic and congenital neutropenia.

### Severe Congenital Neutropenia

In 1956, Kostmann described severe congenital neutropenia (MIM 202700), or congenital agranulocytosis, in a large kindred in northern Sweden as an autosomal recessive disorder. These patients had extremely low neutrophil counts and usually died of severe infections in early childhood. Typically, there are no other congenital abnormalities in this disorder. A number of patients with this syndrome have been identified with a familial pattern suggesting autosomal dominant inheritance, although most are sporadic cases. Cases of both congenital and cyclic neutropenia in the same family have also been recognized. The estimated frequency of congenital neutropenia is probably one to three cases per million population. Severe neutropenia is also associated with other congenital disorders, including Schwachman-Diamond syndrome, cartilage-hair hypoplasia syndrome (see Chapter 36), Gricelli syndrome (Chapter 41), Barth syndrome, X-linked agammaglobulinemia (Chapter 21), the X-linked hyper-IgM syndrome (Chapter 19), and the Wiskott-Aldrich syndrome associated with mutations affecting the Cdc42 binding domain (Chapter 31). The term *severe congenital neutropenia* is generally reserved, however, for patients with selective neutropenia of the Kostmann type.

### Clinical Features

Serial blood counts usually reveal that untreated patients have blood neutrophil counts of less than  $0.2 \times 10^9/\text{L}$ . Carefully collected serial counts examined mathematically may show oscillatory patterns (Haurie et al., 1999; Bellanne-Chantelot et al., 2004). Characteristically, there is a marked monocytosis with levels often two to four times that of normal (Dale et al., 2000). Most patients have anemia and mild thrombocytosis attributable to chronic inflammation. Marrow examinations show the pres-

ence of early precursor cells but very few mature cells beyond the promyelocyte stage, or “promyelocytic arrest.” As in cyclic neutropenia, electron-microscopic studies often show evidence of accelerated apoptosis in neutrophil precursors and cellular debris in marrow macrophages.

Patients with severe congenital neutropenia frequently have fever and abscesses in the subcutaneous tissues, liver, and lungs. Sinusitis, otitis, pharyngitis, and other infections are quite common, although sepsis occurs relatively infrequently. Children often grow and develop slowly, ultimately resulting in short stature in many cases.

### Pathophysiological, Molecular, and Genetic Studies

In vitro marrow culture studies of colony-forming cells generally have shown that very few colonies are formed from precursor cells, even with the addition of a rich mix of colony-stimulating factors (Nakamura et al., 2000). The colonies that form are also small and appear to degenerate rapidly. CFU-C assays of isolated precursors show reduced formation of primitive precursors, the HPPC colonies, but formation of more mature colonies (CFU-GM, early and late) is even more severely decreased. Flow-cytometric analysis of the cycle for CD34<sup>+</sup> cells suggests a block in the G<sub>0</sub>/G<sub>1</sub> transition to S phase in congenital but not cyclic neutropenia (Aprikyan et al., 2003; Debatin, 2003). Annexin V staining shows that a high proportion of CD34<sup>+</sup> precursors are in an apoptotic state (Debatin, 2003). An elevated degree of apoptosis was observed in the bone marrow of patients with congenital neutropenia and a selective decrease in B cell lymphoma-2 (Bcl-2) expression was seen in myeloid progenitor cells. In vitro apoptosis of bone marrow derived progenitor cells was increased, and mitochondrial release of cytochrome C was detected in CD34<sup>+</sup> and CD33<sup>+</sup> progenitors from neutropenic patients, but not in

controls, suggesting a role for mitochondria-dependent apoptosis in the pathogenesis of Kostmann syndrome (Carlsson et al., 2004). Accelerated apoptosis of differentiating but not of proliferating cells was observed in vitro using the HL-60 promyelocytic cell line retrovirally transduced with the naturally occurring G185R neutrophil elastase mutant that is associated with severe congenital neutropenia (Massullo et al., 2005).

Because some patients with congenital neutropenia may have oscillations in their blood counts, a series of patients was examined for mutations of the gene for neutrophil elastase, based on the presumption that a molecular mechanism similar to that in patients with cyclic neutropenia could be the mechanism (Dale et al., 2000). This study reported that more than 80% of patients had mutations in the *ELA-2* gene, with a greater diversity of mutations than that observed in patients with cyclic neutropenia (Fig. 39.2). Molecular modeling suggests that these mutations result in structural changes of the molecule remote from the active site of the enzyme and supports the idea that the mutations cause abnormalities in the packaging or storage of the enzyme in the primary neutrophil granules (Dale et al., 2000). Further studies are ongoing to examine this hypothesis and define more precisely the molecular mechanisms that connect mutations of neutrophil elastase and accelerated apoptosis of precursor cells observed in these patients.

### Treatment and Complications

Severe congenital neutropenia responds to treatment with G-CSF, usually in doses of 5 to 10 µg/kg per day given subcutaneously; the dosage of G-CSF required to elevate neutrophils to  $>1.0 \times 10^9/l$  varies substantially from patient to patient, but for individual patients the same dosage is effective for very long periods (Dale et al., 1993). More than 90% of patients respond to this therapy. With increases in neutrophils there is uniformly a reduction in infection-related events. With treatment, patients' elevated platelet counts decline toward normal and hematocrit levels gradually increase to normal. Other growth factors, such as granulocyte-macrophage colony-stimulating factor, are not of proven benefit for treatment of this condition. Patients with severe congenital neutropenia that are refractory to G-CSF treatment may have mutations of the G-CSF receptor (Druhan et al., 2005).

Before the availability of the hematopoietic growth factors, it was known that some patients with congenital neutropenia developed leukemia (Gilman et al., 1970; Rosen and Kang, 1979). Over the past decade, the Severe Chronic Neutropenia International Registry has accumulated data on more than 300 patients with congenital neutropenia. These data show that there is at least a 10% risk for evolution of severe congenital neutropenia to leukemia for patients treated with G-CSF (Freedman and Alter, 2002). Development of leukemia is often associated with acquired chromosomal abnormalities (most frequently monosomy 7) and mutations of the *Ras* oncogene and the gene for the G-CSF receptor. Sequential studies have suggested that these occur in a stepwise fashion and that evolution occurs slowly, usually over many months (Ancliff et al., 2003). Most but not all patients evolving to leukemia have preexisting mutations in the gene for neutrophil elastase (Freedman and Alter, 2002; Bellanne-Chantelot et al., 2004). It is now hypothesized that the neutrophil elastase gene mutations result in accelerated proliferative activity of very primitive precursors, which is the primary predisposing factor for the molecular events that lead to leukemia (Dale et al., 2001). It is not known if treatment with G-CSF contributes to this predisposition.

### Animal Models

Collie dogs with a distinctive gray coat color can have autosomal recessive cyclic neutropenia that has many features of the human disease (Lund et al., 1967). In these dogs, the cycle length is approximately 13 days and involves all hematopoietic elements (Dale et al., 1972). Dogs respond to treatment with lithium (an agent that stimulates endogenous G-CSF production) (Hammond and Dale, 1980), daily injections of endotoxin (which also elevates production of endogenous G-CSF), and exogenous canine G-CSF (Hammond et al., 1979). Treatment, however, does not affect the coat color of these dogs. Canine cyclic neutropenia is attributable to mutations in the  $\beta$  subunit of adaptor protein complex 3 (AP3) that direct localizations of enzymes to the granules of neutrophils (Benson et al., 2003). This canine model suggests that the molecular basis of hereditary neutropenia involves the mistrafficking of neutrophil elastase and that an intact AP3 recognizes neutrophil elastase as a cargo protein (Horwitz et al., 2004).

Mouse models with knockouts of the gene for G-CSF (Lieschke et al., 1994) and its receptor (Liu et al., 1997) have been developed in an attempt to better understand the relationship between mutations in the G-CSF receptor and predisposition to the development of leukemia. Mice with homozygous deletions of the gene for neutrophil elastase or with knock-in mutations are not neutropenic (Belaouaj et al., 1998). Studies are ongoing to determine if specific mutations in the neutrophil elastase gene may result in murine neutropenia or the risk of leukemia.

## Chediak-Higashi Syndrome

RICHARD A. SPRITZ

Chediak-Higashi syndrome (CHS; MIM #214500) is a frequently fatal autosomal recessive genetic disorder characterized clinically by hypopigmentation or albinism, severe immunologic deficiency, mild bleeding tendency, neurologic abnormalities, and early death from a lymphoma-like syndrome, the so-called “accelerated phase” of the disorder. Striking abnormally large granules and even giant organelles are seen in peripheral blood leukocytes and many other cell types (Spritz, 1998; Shiflett et al., 2002; Ward et al., 2002). First reported by Beguez-Cesar (1943), a Cuban pediatrician, CHS was further described by Steinbrinck (1948), Chediak (1952), and Higashi (1954), the latter two of whose names then came to be associated with the disorder (Sato, 1955; Donohue and Bain, 1957). The incidence of CHS has been reported as 3 per 15,500 hospital admissions (Moran and Estevez, 1969), although the true frequency of the disorder appears to be far lower. CHS is very rare in almost all populations, although a cluster of cases has been described in a genetic isolate in Tachira State, high in the Venezuelan Andes (Ramirez-Duque et al., 1982).

Disorders similar to human CHS occur in many mammalian species, including mink (Leader et al., 1963; Padgett et al., 1964), cattle (Padgett et al., 1964), cats (Kramer et al., 1977), foxes (Nes et al., 1983, 1985), rats (Nishimura et al., 1989), and even killer whales (Taylor and Farrell, 1973)—could Moby Dick, the Great White Whale, have had CHS? Most important, though, is the beige (*bg*) mouse (Lutzner et al., 1966), which has been extensively studied as an animal model of human CHS. In recent years human CHS (Barbosa et al., 1996; Nagle et al., 1996), mouse beige (Barbosa et al., 1996; Perou et al., 1996b), rat beige (Mori et al., 1999), and cattle CHS (Kunieda et al., 1999; Yamakuchi et al., 2000) have all been found to result from mutations in the *LYST* gene (MIM \*606897, also termed *CHS1*),

which encodes a novel protein of unknown function that appears to play a key role in organellar protein trafficking.

### Clinical and Pathologic Manifestations

Dermatologic manifestations of CHS (Color Plate 40.I) range from mild pigmentary dilution of the skin and hair to severe hypopigmentation comparable to tyrosinase-positive oculocutaneous albinism (Pierini and Abulafia, 1958; Stegmaier and Schneider, 1965) with concomitant photophobia, nystagmus, and reduced visual acuity (Rescigno and Dinowitz, 2001) (Table 40.1). Patients generally have lighter hair than that of their unaffected family members, as illustrated in the Caucasian and the Japanese patients in Color Plate 40.I, frequently with an usual sheen. Hyperpigmentation in sun-exposed areas has been noted in several cases.

Immunologic and hematologic manifestations of CHS include neutropenia and lack of natural killer (NK) cell function, resulting in recurrent, sometimes fatal cutaneous and systemic pyogenic infections, most typically with staphylococci and streptococci. There is a mild bleeding diathesis, due to storage pool deficiency of platelets (Boxer et al., 1977; Buchanan and Handin, 1977), characterized clinically principally by bruisability, although hemorrhages may become severe during the accelerated phase of CHS. Hepatosplenomegaly and pancytopenia are frequently present.

Neurologic manifestations are frequent, including seizures, mental deficiency or progressive intellectual decline, cranial nerve palsies, and progressive peripheral neuropathy with tremor, muscle weakness, stiffness, clumsiness, abnormal gait, and foot drop (Lockman et al., 1967; Misra et al., 1991; Uyama et al., 1994).

**Table 40.1.** Clinical Findings in Chediak-Higashi Syndrome

<i>System</i>	<i>Clinical Findings</i>
Integument	Pigmentary dilution in skin and hair; may resemble oculocutaneous albinism
Ocular	Variably present reduced iris pigmentation, photophobia, decreased visual acuity, nystagmus, strabismus, macular hypoplasia
Neurologic	Seizures, mental deficiency, cranial nerve palsies, tremor; progressive peripheral neuropathy with muscle weakness (particularly lower extremities), clumsiness, foot drop, abnormal gait, decreased deep tendon reflexes
Hematologic	Bleeding diathesis, bruisability
Immunologic	Frequent pyogenic infections (staphylococcal and streptococcal); routine childhood immunizations are well tolerated
Accelerated phase (85% of patients)	Fever, jaundice, hepatosplenomegaly, lymphadenopathy, bleeding, gingivitis, pseudomembranous sloughing of buccal mucosa

About 85% of patients progress to an accelerated phase, characterized by an enigmatic lymphoproliferative syndrome, with generalized lymphohistiocytic infiltrates, fever, jaundice, hepatosplenomegaly, lymphadenopathy, pancytopenia, and bleeding (Page et al., 1962; Dent et al., 1966; Argyle et al., 1982; Rubin et al., 1985). Though somewhat resembling lymphoma, the accelerated phase of CHS does not appear to be a true malignancy (Dent et al., 1966) but more closely resembles familial erythrophagocytic lymphohistiocytosis and the virus-associated hemophagocytic syndrome (Spritz, 1985). There is widespread belief that the accelerated phase of CHS is caused by active Epstein-Barr virus (EBV) infection (Rubin et al., 1985; Okano and Gross, 2000), although there is little actual evidence that this is the case.

Many children with CHS die during the first decade of life from pyogenic infections, hemorrhage, or complications of the accelerated phase of the disorder. Nevertheless, 10% to 15% of patients have a relatively mild early clinical course and may survive to adulthood with few or even no severe infections and no sign of the accelerated phase. Some of these patients have chronic periodontal (Delcourt-Debruyne et al., 2000; Shibutani et al., 2000) and dermatologic infections, and most eventually develop progressively severe peripheral neuropathy and other neurologic manifestations that may become debilitating and even fatal (Misra et al., 1991; Uyama et al., 1994; Hauser et al., 2000). Many of these patients with the clinically milder adolescent or adult forms of CHS appear to have mutations of the *LYST* gene that allow some residual function of the CHS1 polypeptide (Karim et al., 2002).

The ultrastructural hallmark of CHS is giant organelles— inclusion bodies, lysosomes, and melanosomes (Color Plate 40.IIA). Giant inclusion bodies occur in virtually all granulated cells, and histochemical and electron-micrographic studies of these structures have indicated that they are derived from lysosomes in many cell types (White, 1966; Windhorst et al., 1966; Lockman et al., 1967; Jones et al., 1992; Burkhardt et al., 1993) and from secretory granules in others. CHS melanocytes are characterized by giant melanosomes (Windhorst et al., 1966; Zelickson et al., 1967; Bedoya, 1971). It seems likely that CHS, like Hermansky-Pudlak syndrome in humans and a number of other mutants of mice, involves a common step required for the

biogenesis, structure, or function of a variety of intracellular organelles—lysosomes, melanosomes, and some secretory granules (Windhorst et al., 1966)—and recent findings suggest that these disorders involve pathways of organellar protein trafficking shared among these otherwise quite different organelles (Spritz, 1999; Huizing et al., 2000; Starcevic et al., 2002).

The clinical presentation of CHS is sufficiently variable that the only invariant finding is the observation of giant intracellular granules, raising the question of whether all cases truly represent the same entity. The age at first diagnosis of 67 reported cases of CHS has ranged from 4 weeks to 39 years, with a mean of 5.6 years but with wide variation. The diagnosis is first suspected for many patients by the juxtaposition of significant hypopigmentation with the occurrence of frequent or even fatal pyogenic infections, or on the basis of a similarly affected sibling in whom the diagnosis had been made previously. However, in some patients the diagnosis of CHS may be considered only after observation of giant intracellular granules as an incidental finding on a peripheral blood smear. In general, the clinical presentations and clinical course of CHS tend to be similar among affected siblings, especially when the parents are consanguineous, or among patients in an inbred population (Ramirez-Duque et al., 1982; Leal et al., 1985). In particular, the clinically milder adolescent and adult forms of CHS, with slowly progressive or indolent clinical course with no accelerated phase and prolonged survival, tends to “breed true” within sibships, although even this is not always the case. Whereas much of the clinical heterogeneity among patients with CHS appears to result from a diversity of mutations in the *LYST* gene, resulting in an apparent genotype–phenotype correlation (Karim et al., 2002), it is likely that epistatic factors, perhaps even the involvement of other genes besides *LYST*, may also play some role.

### Laboratory Findings

The classic laboratory finding in CHS (Table 40.2) is giant granules in all cells of the leukocytic series in peripheral blood and bone marrow (Donohue and Bain, 1957; White, 1966) (Color Plate 40.IIA). Those in neutrophils, eosinophils, and basophils are irregularly shaped, blue to slate gray, and PAS positive (Blume and Wolff, 1972), whereas lymphocytes typically contain at most one round or ovoid azurophilic giant granule. Platelets may also contain abnormal giant granules. Red blood cells generally appear normal. The bone marrow is usually normocellular, although granulocytic cells are extensively vacuolated, with PAS-positive, acid phosphatase–positive inclusions, occasional giant vacuoles, and abnormal granules (Blume et al., 1968; Blume and Wolff, 1972). In fact, enlarged cytoplasmic granules are found in all granulated cells, including granulocytes, lymphocytes, monocytes, erythroid precursors, histiocytes, mast cells, platelets, melanocytes, Schwann cells, neurons, renal tubular epithelium, and fibroblasts, and appear to represent structurally abnormal but histologically normal granular elements (Page et al., 1962; Kritzer et al., 1964; Windhorst et al., 1968; Kjeldsen et al., 1998).

The accelerated phase of CHS is characterized by diffuse lymphohistiocytic infiltrates of many tissues (Color Plate 40.IIB), particularly the bone marrow, spleen, lymph nodes, liver, and lungs. Erythrophagocytosis may be a prominent feature of the infiltrate. Hematologic analysis during the accelerated phase typically shows pancytopenia.

There are a variety of immunologic abnormalities in CHS, perhaps most importantly virtually absent NK and T cell cytotoxicity (Haliotis et al., 1980; Klein et al., 1980; Roder et al., 1980). The

**Table 40.2.** Laboratory Findings in Chediak-Higashi Syndrome

System	Laboratory Findings
Integument	Giant granules in skin fibroblasts; giant immature melanosomes in skin and hair melanocytes; large clumped melanin granules and vacuolization in skin histiocytes, endothelial cells, fibroblasts
Ocular	Visual evoked potentials showing misrouting characteristic of albinism; giant melanosomes in optic cup and neural crest–derived melanocytes
Neurologic	Diffuse brain and spinal cord atrophy seen by cranial imaging (CT and MRI scans); markedly delayed nerve conduction; variable neurogenic changes by electromyography; giant granules in Schwann cells and muscle cells
Hematologic	Giant azurophilic, PAS-positive granular inclusions in leukocytes of peripheral blood; red cells and platelets usually do not, but may also contain inclusions; giant cytoplasmic inclusions in all granulated cells of bone marrow; cells frequently vacuolated
Immunologic	Decreased neutrophil and monocyte migration and chemotaxis; normal leukocyte phagocytosis, but delayed intracellular killing; absent NK cell and reduced antibody-dependent cellular cytotoxicity; normal B and T cell functions
Other	Giant granules in cells of many tissues
Accelerated phase	Generalized lymphohistiocytic infiltrates, pancytopenia, erythrophagocytosis

NK cell number appears to be normal, and NK cells bind their targets normally, but there is defective effector function (Katz et al., 1982). NK T cell cytotoxicity appears normal (Bannai et al., 2000). Loss of T cell cytotoxicity appears to result from inability to secrete cytolytic proteins stored in the giant granules, perhaps the result of defective secretion of these granules due to abnormal vesicular membrane fusion (Baetz et al., 1995; Stinchcombe et al., 2000). Antibody-dependent cellular cytotoxicity is also reduced (Merino et al., 1983), and the proportion of T cells bearing  $\gamma\delta$  T cell receptor antigens is increased (Holcombe et al., 1990). Neutrophil and monocyte migration and chemotactic responses are diminished (Clark and Kimball, 1971; Wolff et al., 1972; Yamazaki et al., 1985), perhaps due to mechanical impediment by giant granules (Clawson et al., 1978) or a primary defect in chemotactic response (Wilkinson, 1993). Nevertheless, leukocyte phagocytosis is normal (Root et al., 1972; Wolff et al., 1972), although intracellular killing of various microorganisms is de-

layed (Clark and Kimball, 1971; Root et al., 1972; Gallin et al., 1979). These chemotactic and cell-killing defects are improved in vitro by agents that increase cyclic GMP (Boxer et al., 1976; Oliver, 1976; Rister and Haneke, 1980), although effects in vivo are less clear. Defective cell surface expression of CTLA-4 after T cell activation may contribute to the lymphoproliferative accelerated phase of CHS (Barrat et al., 1999). B lymphocyte functions are usually entirely normal (Blume and Wolff, 1972; Deprez et al., 1978; Prieur et al., 1978; Klein et al., 1980; Merino et al., 1983), and routine childhood immunizations are well tolerated by patients with CHS.

Light and electron microscopy of skin (Stegmaier and Schneider, 1965; Windhorst et al., 1966, 1968; Zelickson et al., 1967; Bedoya, 1971; Deprez et al., 1978; Fukai et al., 1993; Zhao et al., 1994) and ocular (Valenzuela and Morningstar, 1981) melanocytes has shown giant, abnormal melanosomes, with an aberrant maturation pathway. Apparent inappropriate fusion of premelanosomes with lysosomes results in their premature destruction, likely accounting for the pigmentary dilution and oculocutaneous albinism in CHS.

Cranial computed tomography (CT) and magnetic resonance imaging (MRI) show diffuse atrophy of the brain and spinal cord (Ballard et al., 1994; Uyama et al., 1994). Electrophysiologic studies show markedly impaired transmission of action potentials along nerve fibers, but electromyography is either normal or shows only neurogenic changes (Lockman et al., 1967; Blume and Wolff, 1972; Uyama et al., 1994). Histochemistry and electron microscopy of peripheral nerve tissue shows characteristic giant granules in Schwann cells (Lockman et al., 1967; Blume and Wolff, 1972; Uyama et al., 1994) and in muscle shows neurogenic atrophy with unusual acid phosphatase–positive granules and autophagic vacuoles (Uchino et al., 1993).

**Molecular Basis**

The critical clues to identification of the *LYST* gene came from studies of the beige mouse. It was long thought that mouse beige might be homologous to human CHS (Lutzner et al., 1966; Windhorst and Padgett, 1973), and this hypothesis was supported by the failure of fusion of human CHS and beige mouse fibroblasts to complement the lysosomal structural defects (Perou and Kaplan, 1993). Further evidence of homology between mouse beige and human CHS came from gene mapping studies; the mouse *bg* gene is located on chromosome 13 (Holcombe et al., 1987, 1991; Jenkins et al., 1991), and the human *LYST* gene mapped to the homologous segment of chromosome 1q42–q43

**Figure 40.1.** Molecular architecture of human 3801–amino acid CHS polypeptide. Amino acid residue numbers are indicated on the scale above the diagram. Positions of identified pathologic *LYST* gene mutations are indicated by diamonds (frameshifts), triangles (nonsense mutations), and filled circles (missense substitutions) (Barbosa et al., 1996; Nagle et al., 1996; Karim et al., 1997, 2002; Certain et al., 1999). Open

circle indicates a common nonpathologic polymorphic amino acid substitution. Horizontal hatched columns, hydrophobic motifs analogous to HEAT and ARM repeats; filled black area, BEACH domain; diagonal hatched columns, WD40 repeats (after Nagle et al., 1996). The GenBank accession number for the human *LYST* cDNA sequence is U67615.

(Barrat et al., 1996; Fukai et al., 1996). The mouse *bg* gene was positionally cloned (Barbosa et al., 1996; Perou et al., 1996a, 1996b) and a mouse *bg* probe was then used to isolate the homologous human *LYST* gene (Nagle et al., 1996). Subsequent analyses of the human *LYST* gene in patients with CHS quickly demonstrated obvious pathologic mutations (Barbosa et al., 1996; Nagle et al., 1996) (Fig. 40.1), formally proving that the mouse beige and human CHS phenotypes are homologous.

The human *LYST* gene is enormous, consisting of 55 exons spanning more than 222 kb in chromosome 1q42 (Karim et al., 2002). The *LYST* cDNA is also enormous, 13.5 kb (Nagle et al., 1996), corresponding closely to a ~12 kb mRNA observed on Northern blot analysis of many tissues (Barbosa et al., 1996; Perou et al., 1996b). Several other minor mRNAs result from alternative splicing of *LYST* pre-mRNA, although it is not clear that the corresponding related proteins are of functional significance in vivo.

### Functional Aspects

The human CHS polypeptide consists of 3801 amino acids with a molecular mass of 429,153 kDa (Fig. 40.1). The CHS protein does not have extensive sequence homology to any other known proteins, although CHS contains several peptide motifs: a number of so-called "ARM" (ARMadillo; Peifer et al., 1994) and "HEAT" (Huntingtin, EF3, PP2A regulatory A subunit, TOR1; Andrade and Bork, 1995) repeats, and seven consecutive WD40 (Trp [W]-Asp [D]-X<sub>40</sub>; Neer et al., 1994) motifs near the carboxyl terminus. One particularly interesting region of the human CHS protein shares extensive sequence homology with various anonymous proteins of many different species; thus, this region of sequence homology probably corresponds to a functional domain, named *BEACH* (BEige And Chediak-Higashi; Nagle et al., 1996). Crystal structure analysis of the BEACH domain from neurobeachin, a BEACH domain protein that is otherwise unrelated to CHS, indicates that the BEACH domain assumes a novel and unusual protein fold and may mediate certain protein-protein interactions (Jogl et al., 2002).

The only protein known to contain helical HEAT and ARM motifs, C-terminal consecutive WD40 motifs, and a globular  $\alpha/\beta$  domain in an arrangement similar to that of CHS is a yeast serine/threonine protein kinase, Vps15. Vps15 is a component of a membrane-associated protein complex that regulates intracellular trafficking of proteins to the yeast vacuole (Stack et al., 1993), one of more than 40 different Vps proteins involved in this process (Klionsky and Emr, 1990; Herman et al., 1991). Although Vps15 is not a direct homologue of CHS, the vacuolar protein-trafficking defects in yeast *Vps* mutants are similar to the defects of vesicular protein trafficking to and from the lysosome and late endosome and aberrant compartmentalization of lysosomal and granular enzymes in both human CHS (Zhao et al., 1994) and mouse beige (Brandt et al., 1975; Swank and Brandt, 1978). Recently, similar findings have come from the unicellular slime mold, *Dictyostelium*, whose genome contains BEACH protein genes (Wang et al., 2002), at least two of which, *LvsA* and *LvsB*, are involved in lysosomal protein trafficking (Cornillon et al., 2002). Indeed, null mutants of *LvsB* displayed enlarged vesicles, abnormal trafficking lysosomal enzymes, and other subcellular abnormalities very similar to those in human CHS (Harris et al., 2002).

The specific cell biological defect in CHS is not yet known. Lysosomes and melanosomes tend to be distributed in the perinuclear region, rather than more widely distributed throughout the

cytoplasm, suggesting a defect in maturation of these organelles. Defective endosomal sorting of major histocompatibility complex (MHC) class II molecules and subcellular ultrastructural abnormalities suggests that CHS may involve a defect of sorting endosomal resident proteins into late multivesicular endosomes (Faigle et al., 1998). Tchnernev and coworkers (2002) demonstrated that the CHS protein interacts with components of the t-SNARE complex, which plays a key role in vesicle docking and fusion. These findings suggest that CHS might help mediate intracellular membrane fusion.

### Mutation Analysis

Because of the very large size of the *LYST* gene and the large number of exons, molecular diagnostic testing for *LYST* mutations is currently available only on a research basis. At least 26 different pathologic mutations of the *LYST* gene have been reported in patients with CHS (Fig. 40.1) (Barbosa et al., 1996; Nagle et al., 1996; Karim et al., 1997, 2002; Certain et al., 2000). These mutations, shown in Figure 40.1, are instructive, as there appears to be a rough genotype-phenotype correlation. The great majority are nonsense mutations and frameshifts, predicted to result in functionally null alleles (Karim et al., 1997). Indeed, all patients with severe childhood CHS have these types of null mutations, although in some such cases it has not been possible to identify mutations of the *LYST* gene at all, which suggests that these cases might result from mutations in genes other than *LYST* (Karim et al., 2002). Surprisingly, some patients with relatively mild clinical courses have had *LYST* nonsense or frameshift mutations (Nagle et al., 1996; Certain et al., 2000; Karim et al., 2002), and in some instances both mild and severe cases of CHS have occurred in the same family (Certain et al., 2000). Clearly, factors other than *LYST* mutations alone may play roles in determining the ultimate clinical phenotype. Nevertheless, one important genotype-phenotype correlation has emerged. Only four patients have been described with *LYST* missense mutations resulting in amino acid substitutions (Karim et al., 2002). Two of these, with homozygous missense substitutions, had mild, adult-onset CHS. Two other patients, both compound heterozygotes for one missense mutant *LYST* allele and one null-mutant allele, had relatively mild disease, intermediate in severity between childhood and adult CHS, termed *adolescent CHS*. Overall, it appears that most although not all patients with null-mutant *LYST* alleles manifest a clinically severe course, whereas many or all patients with missense mutant alleles manifest a relatively mild clinical course. Thus, molecular diagnosis of *LYST* mutations may provide a useful prognostic indicator in counseling parents of young children with CHS.

One particularly interesting patient has been reported with a homozygous nonsense mutation of *LYST*. The patient's mother was found to be a carrier of this mutation, whereas no mutation of the gene was found in the father. Nonpaternity was excluded by analysis of microsatellite markers on chromosome 1, which instead demonstrated maternal uniparental isodisomy for the entire chromosome 1 (Dufourcq-Lagelouse et al., 1999).

### Strategies for Diagnosis

The diagnosis of CHS must be considered in any child with hypopigmentation and abnormal susceptibility to infection, especially if accompanied by neurologic abnormalities or signs of the accelerated phase, such as hepatosplenomegaly, jaundice, and bleeding tendency. Histologic demonstration of giant azurophilic

cytoplasmic inclusions, readily seen by routine microscopic examination of granulocytes on a peripheral blood smear (Color Plate 40.IIA), provides strong support for the diagnosis of CHS. Molecular confirmation can be provided by mutation analysis of the *LYST* gene in patient DNA, although this is not yet routinely available. Moreover, in at least some patients with clinically typical CHS, the disorder may not result from mutations in *LYST* but rather at an as yet unidentified locus (Karim et al., 2002).

### Carrier Detection and Prenatal Diagnosis

Prenatal diagnosis of CHS has been accomplished in a number of cases by fetal blood sampling and demonstration of enlarged lysosomes and granules in polymorphonuclear leukocytes (Diukman et al., 1992; Durandy et al., 1993) and by light and electron microscopic demonstration of giant melanosomes in fetal hair shafts (Durandy et al., 1993). Retrospective studies have shown that lysosomes were also enlarged in cultured amniotic fluid cells and chorionic villus cells (Diukman et al., 1992), indicating that these cells might also be used for prenatal diagnosis of CHS.

Molecular analysis of the *LYST* gene permits direct mutation-based carrier detection and prenatal diagnosis in families with defined *LYST* gene mutations, although application of this technique has not yet been reported. While the demonstration of pathologic mutations in the *LYST* gene may be considered diagnostic, molecular diagnosis of CHS may be complicated by the fact that some cases of typical CHS may result from mutations in other genes (Karim et al., 2002). In particular, locus heterogeneity for CHS would greatly complicate any attempt to perform carrier detection and prenatal diagnosis by genetic linkage analysis alone in families in which pathologic *LYST* gene mutations have not been identified.

### Treatment and Prognosis

The prognosis for long-term survival in CHS is relatively poor, with many patients not surviving the first decade. In a retrospective analysis of 56 reported patients with CHS, Blume and Wolff (1972) found that 66% had died, at a mean age of 3.1 years, usually from pyogenic infection, hemorrhage, or complications of the accelerated phase. Nevertheless, these data predated treatment by bone marrow transplantation, which has proved successful in many cases of CHS and can significantly improve survival and longevity.

There is no specific treatment for CHS. Diagnosis and treatment of infections and management of hemostasis are of great importance, following standard approaches. However, treatment during the accelerated phase is a particular problem. Chemotherapy can be of limited transient benefit during the accelerated phase (Bejaoui et al., 1989), but relapses are typical and bone marrow transplantation is eventually required in most cases (Kazmierowski et al., 1975; Virelizier et al., 1982; Filipovich et al., 1992; Haddad et al., 1995). In families in which no sibling donor is available, transplantation using an HLA-matched unrelated donor has proved successful (Liang et al., 2000). While immunologic reconstitution regularly accompanies successful bone marrow transplantation, this treatment does not alter the hypopigmentation of CHS. Similarly, long-term follow-up indicates that the development and progression of neurological symptoms is unfortunately not arrested by bone marrow transplantation.

Bone marrow transplantation does result in cure of the accelerated phase and of the immunologic defect, even in patients in whom transplantation results only in mixed hematopoietic chimerism (Haddad et al., 1995; Mottonen et al., 1995; Trigg and Schugar, 2001). A similar immunologic improvement with only mixed chimerism following bone marrow transplantation also occurs in familial hemophagocytic lymphohistiocytosis (Landman-Parker et al., 1993), which the accelerated phase of CHS somewhat resembles. Because the 429 kDa CHS polypeptide does not appear to be a soluble, circulating factor, functions supplied by even a relatively small fraction of donor cells are apparently sufficient to reconstitute the immune system and suppress or prevent the accelerated phase. These findings raise the intriguing prospect of relatively facile gene or stem cell therapy for CHS, since apparently even a small fraction of genetically corrected cells, derived from the patients themselves, might provide beneficial effects of significant degree.

As discussed above, 10%–15% of patients with CHS manifest the clinically milder adolescent and adult forms of the disease, surviving to over 30 years of age with few infections and requiring only minimal treatment. Granulocyte colony-stimulating factor (G-CSF) may be useful in managing acute infections in such patients (Baldus et al., 1999). Most of these patients eventually develop peripheral neuropathy or more severe neurologic symptoms. Treatment with oral prednisolone has proved helpful in treating the neuropathy in at least one case (Fukuda et al., 2000), a result suggesting that neurological deterioration in CHS might stem at least in part from chronic inflammation.

### Animal Models

As mentioned above, disorders similar to human CHS have been described in many mammalian species, including mink (Leader et al., 1963; Padgett et al., 1964), cattle (Padgett et al., 1964), cats (Kramer et al., 1977), foxes (Nes et al., 1983, 1985), killer whales (Taylor and Farrell, 1973), rats (Nishimura et al., 1989; Ozaki et al., 1994), and mice (Lutzner et al., 1966). Of these models, the beige mouse is by far the most important. The mouse *beige* locus consists of a series of at least seven mutant alleles of the mouse *Lyst* gene homologue on chromosome 13 (Holcombe et al., 1987, 1991), three of which have been characterized in molecular terms (Barbosa et al., 1996; Nagle et al., 1996). The phenotype of the beige mouse corresponds to human CHS in virtually all respects, including diluted coat and eye pigmentation, reduced chemotactic and bacteriocidal activity of granulocytes (Gallin et al., 1974), greatly reduced NK cell function (Roder, 1979), deficient cytotoxic T cell and antibody-dependent cytotoxic responses (Saxena et al., 1982; Carlson et al., 1984), increased susceptibility to bacterial infections, enlarged melanosomes in pigment cells, enlarged lysosomes in many cell types (Oliver and Essner, 1973; Windhorst and Padgett, 1973), and platelet storage pool deficiency (Novak et al., 1984). Growth of syngeneic tumor cells is greater in beige mutant mice than in normal littermates, a phenomenon thought to result from deficient NK cell function (Karre et al., 1980; Talmadge et al., 1980), although beige mice ordinarily do not develop either tumors or signs of an accelerated phase, perhaps simply because mice do not live long enough. Like CHS, beige mice exhibit aberrant compartmentalization of lysosomal and granular enzymes (Brandt et al., 1975; Swank and Brandt, 1978; Holcombe et al., 1994).

Beige rats (Nishimura et al., 1989; Ozaki et al., 1998) and CHS cattle (Padgett et al., 1964; Ogawa et al., 1997; Shiraishi

et al., 2002a, 2002b) also exhibit mutant phenotypes very similar to those of beige mice and humans with CHS. Like human CHS, both beige rats (Mori et al., 1999) and CHS cattle (Kunieda et al., 1999; Yamakuchi et al., 2000) have pathologic mutations in their respective *LYST* gene homologues. The many other animal CHS models have not been studied nearly as extensively, and none have yet been defined in molecular detail.

### Concluding Remarks and Future Challenges

The past few years have seen great progress in understanding the molecular basis of the Chediak-Higashi and Griscelli syndromes. Similarly, there has been considerable progress in treatment, largely brought about by improved management of patients undergoing bone marrow transplantation. Nevertheless, considerable challenges remain in the diagnosis and treatment of patients with these disorders. Even though the genes are now known and numerous gene mutations associated with these diseases have been described, the rarity of these mutations and the large sizes and genomic complexity of these genes renders DNA-based diagnosis technically difficult and generally unavailable. As the result, improved molecular understanding has generally not yet been translated into improved diagnosis of these disorders. Likewise, discovery of the causal genes for these diseases has not yet resulted even in solid understanding of the cell biological or biochemical mechanisms of disease pathogenesis. The remarkably large sizes of the *LYST* cDNA and CHS protein, for example, make systematic laboratory investigation of CHS pathogenesis exceedingly difficult. Accordingly, the very substantial advances in understanding these disorders at the molecular level remain to be translated into meaningful advances in patient management and new approaches to treatment. The challenge for the future is to achieve these goals.

## Inherited Hemophagocytic Syndromes

GENEVIÈVE DE SAINT BASILE

Several hereditary disorders of the immune system are characterized by the occurrence of a similar T lymphocyte and macrophage activation syndrome, also called hemophagocytic lymphohistiocytosis (HLH) syndrome or accelerated phase of the disease, which is generally fatal in the absence of treatment. Hemophagocytic syndrome is characterized by lymphoid organ and extranodal infiltration by polyclonal activated T cells and activated macrophages that phagocytose blood cells (Table 41.1). HLH is in most cases triggered by a viral infection, especially of the herpes group (Epstein-Barr virus [EBV], cytomegalovirus [CMV]). Four inherited disorders have been identified that lead to HLH syndrome (Dufourcq-Lagelouse et al., 1999b): the familial hemophagocytic lymphohistiocytosis (FHL) (MIM 267700), the Griscelli syndrome (GS) (MIM 214450), the Chediak-Higashi syndrome (CHS) (MIM 214500), and the X-linked lymphoproliferative syndrome (X-LP) (MIM 308240). Only FHL and GS will be discussed in this chapter, the two other disorders being addressed in other chapters (Chapters 19 and 31). The primary causes of HLH should be distinguished from lymphohistiocytic proliferation with hemophagocytosis, which develops secondary to severe infections in an immunocompromised host, or during the course of malignancies.

### Familial Hemophagocytic Lymphohistiocytosis

Familial hemophagocytic lymphohistiocytosis is inherited as an autosomal recessive disease, with an incidence estimated at 0.12 per 100,000 per year, or 1 in 50,000 live births (Henter et al., 1991c). FHL was first reported by Farquhar and Claireaux in 1952 in two siblings as a rapidly fatal disease, which they termed *familial hemophagocytic reticulosis*. Both infants developed fever, diarrhea, vomiting, and irritability at the age of 9 weeks,

with enlargement of liver and spleen and pancytopenia. A remarkably widespread histiocytic infiltration in lymph nodes, spleen, liver, and kidney, with active phagocytosis mainly of the red cells, was revealed on autopsy. The term *hemophagocytosis* chosen by Farquhar and Claireaux underscores the importance of this feature in the diagnosis of this disease. *Reticulosis* was further modified to *lymphohistiocytosis* when the origin of the involved cells became better understood. Since 1952, many additional cases have been reported in various ethnic groups and from all continents (Arico et al., 1996).

Because secondary causes can lead to similar clinical and biological features, establishing the diagnosis of FHL remains a difficult task in families with a single affected case. Interestingly enough, however, almost all children with familial disease appear to have low or absent natural killer (NK) cell activity during the entire course of their disease (Arico et al., 1996; Egeler et al., 1996; Sullivan et al., 1998). In 1999, by means of homozygosity mapping, two loci for FHL were disclosed—on 9q21 (FHL1) (Ohadi et al., 1999) and 10q21 (FHL2) (Dufourcq-Lagelouse et al., 1999a). The mutation in the gene encoding perforin, at FHL2, was shown to cause FHL in about one-third of familial cases (Stepp et al., 1999; Goransdotter Ericson et al., 2001). More recently, a third locus was identified on 17q25 (FHL3) and mutation in a gene encoding hMunc13-4 was shown to account for a second third of FHL cases (Feldmann et al., 2003). This now makes feasible detection of presymptomatic affected patients as well as prenatal diagnosis in families in which FHL results from a perforin or hMunc13-4 deficiency. Several groups are working worldwide toward identification of the gene located on chromosome 9 region and on the other causative genes suggested by genetic heterogeneity studies (Dufourcq-Lagelouse et al., 1999b; Ohadi et al., 1999; G. de Saint Basile, unpublished data).

**Table 41.1.** Clinical and Biological Features of Hematophagocytic Lymphohistiocytosis Syndrome

<i>Clinical Manifestations</i>	<i>Biological Manifestations</i>
High fever	Cytopenia
Edema	Hypofibrinogenemia
Hepatomegaly	Hypertriglyceridemia
Splenomegaly	Elevated liver enzymes
Icterus, skin rash	Cerebrospinal fluid pleocytosis
Neurologic symptoms	Low natural killer cell activity
	Presence of activated T lymphocytes and macrophages infiltrating various organs Hemophagocytosis by activated macrophages

### Clinical Phenotypes and Pathologic Manifestations of Familial Hemophagocytic Lymphohistiocytosis

Most patients develop the disease very early in life, within the first half year of life in two-thirds of the patients. A short period of normal development and absence of symptoms after birth is typical. In rare cases onset occurs earlier, *in utero* or at birth (Lipton et al., 2004). In contrast, familial forms have been reported with a later onset (Janka, 1983; Arico et al., 1996; Henter et al., 1998). Several studies suggest that within a family, a tendency toward a similar age at onset is observed.

The symptoms may vary widely. In nearly all patients, high fever, frequently undulant and protracted, is the first sign in association with hepatomegaly and splenomegaly. Pallor, anorexia, vomiting, and irritability are often noted. Transient uncharacteristic skin rash and moderate lymph node enlargement may occasionally be observed. Signs of central nervous system (CNS) involvement may be pronounced and early, but more commonly they develop later during disease progression. Neurological symptoms consist mostly of seizure, hypotonia, or hypertonia, ataxia, hemiplegia, or nonspecific signs of increased intracranial pressure. Nonspecific findings such as jaundice, edema, and failure to thrive as well as purpura and bleeding resulting from thrombocytopenia may be associated (Table 41.1).

### Pathologic Features

The major histologic finding is infiltration of the various organs by a nonmalignant activated lymphocyte population, mainly of the CD8<sup>+</sup> T cell phenotype, associated with macrophage/histiocyte cell infiltration (Farquhar and Claireaux, 1952; Janka, 1983; Henter et al., 1991a; Favara, 1992). The infiltrating lymphocytes and macrophages are most prominent in the interstitial and perivascular spaces of the organs. Active hemophagocytosis of red blood cells and occasionally of platelets or leukocytes is a frequent feature, although not constant. All the organs may be infiltrated, predominantly the spleen, liver, bone marrow, lymph nodes, and CNS (Filipovich, 1997; Haddad et al., 1997; Henter and Nennesmo, 1997).

When examined at an early stage, the white pulp of the spleen is often reduced in size and depleted of lymphocytes, whereas the red pulp is expanded as a result of the mononuclear cell infiltration. In the liver, portal tracts are the place of moderate to extensive lymphocytic infiltration; in the lymph nodes, sinuses are frequently involved and dilated (Henter et al., 1998). Hemophagocytic cells are predominantly found in the T cell areas, frequently depleted of lymphocytes in the later stages of the disease.

CNS infiltration begins generally in the meninges, then perivascular changes occur, leading to diffuse infiltration of the tissue and multifocal necrosis at a later stage.

### Laboratory Findings

#### Hematology

Viral infection, principally of the herpes group, can be identified at onset of the disease. However, in many cases viral, bacteriologic, and serologic investigations fail to implicate a known infectious agent.

At onset of the disease, most patients present with anemia, thrombocytopenia, and, to a lesser degree, neutropenia. Leukopenia at first presentation is less frequent and an initial leukocytosis is reported in 15% of patients. Nearly all patients become severely pancytopenic during disease progression.

In the cerebrospinal fluid, moderate pleocytosis ( $5\text{--}50 \times 10^6/\text{L}$ ), consisting mostly of lymphocytes and occasionally monocytes as well as an increased protein level, is observed in about half of the patients early in the course of the disease (Janka, 1983; Arico et al., 1996; Haddad et al., 1997). However, spinal fluid may be normal even in children with encephalitis. Hyperdense areas, atrophy, and brain edema may be found by magnetic resonance (MR) imaging or computed tomography (CT) scan, particularly later during the prolonged course of the disease.

#### Chemistry

Signs of liver dysfunction or cytolysis are constant findings and include hypertriglyceridemia, hyperbilirubinemia, elevated serum transaminases, elevated ferritin, hyponatremia, and hypoproteinemia. Coagulation abnormalities are common during active disease, particularly hypofibrinogenemia.

#### Immunologic findings

Before onset of the disease, patients with FHL have normal numbers of T and B lymphocytes. The proliferative response of peripheral blood lymphocytes to phytohemagglutinin (PHA) and antigen is normal. However, markedly decreased NK cell activity and decreased T cell cytotoxic activity have been observed in many patients with FHL, a function that does not normalize during remission phase, in contrast to the decrease in cytotoxic activity of NK cells in patients with secondary HLH (Arico et al., 1996; Egeler et al., 1996; Janka et al., 1998; Sullivan et al., 1998). When observed, this decrease in cytotoxic activity may help in differentiation between these two diagnoses. Suppressed NK cytotoxic activity has also been reported in first-degree relatives (Sullivan et al., 1998). Activated CD8<sup>+</sup> T cells and, to a lesser extent, CD4<sup>+</sup> T cells are observed in FHL patients during the course of an active hemophagocytic syndrome. T cell count may be transiently increased but then decreased, as with the other hematopoietic lineages. High levels of soluble CD8 and CD25 molecules as well as hypercytokinemia with elevated serum levels of inflammatory cytokines, such as tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ), interferon- $\gamma$  (IFN- $\gamma$ ), and interleukins IL-1 and IL-6, are striking features of FHL and reflect the T lymphocyte and macrophage activation (Henter et al., 1991b) (Table 41.2).

### Molecular Basis of Familial Hemophagocytic Lymphohistiocytosis

Studies based on linkage analysis in several consanguineous and/or multiplex families with FHL identified three FHL loci, on

**Table 41.2.** T Lymphocyte and Macrophage Activation Markers During Hematophagocytic Lymphohistiocytosis Syndrome

High serum level of IFN- $\gamma$ secretion	

chromosome 9q21.3–22 (FHL1) (Ohadi et al., 1999), 10q21–22 (FHL2) (Dufourcq-Lagelouse et al., 1999a), and 17q25 (FHL3) (Feldmann et al., 2003). Investigators have also found evidence for additional genetic heterogeneity (Graham et al., 2000; Goransdotter Ericson et al., 2001; G. de Saint Basile, unpublished data). On chromosome 9 q21–22, a 7.8 cM region between markers D9S1867 and D9S1790 was identified by homozygosity mapping in four inbred FHL families of Pakistani descent, although not all FHL cases in Pakistani families segregate with this locus (Feldmann et al., 2003). It is not known whether this genetic form is associated with lymphocyte cytotoxic defect.

FHL2, located on 10q21–22, results from mutation in the gene encoding perforin (PRF1) (Stepp et al., 1999), an important effector of cellular cytotoxicity. The perforin gene comprises three exons, of which only exons 2 and 3 are translated, encoding for the 555-amino acid polypeptide (Lichtenheld and Podack, 1989). Perforin defect accounts for approximately one-third of FHL cases (Stepp et al., 1999; Goransdotter Ericson et al., 2001). Patients whose disease is associated with FHL3 locus have typical features of FHL that are indistinguishable from those of patients with the perforin defect (FHL2) (Feldmann et al., 2003). However, impairment of lymphocyte cytotoxic function in these patients occurs independently of perforin, which is normally expressed in lymphocytes. FHL3 is associated with mutations in the gene *UnC13D* encoding for hMunc13-4, a member of the Munc13-UNC13 family (Feldmann et al., 2003). This gene contains 32 exons that encode a 123 kDa protein. Two calcium binding (C2) domains separated by long sequences containing two Munc13-homology domains (MHD1 and MHD2) structurally characterize hMunc13-4. The other causes of FHL remain unidentified.

Functional Aspects

Perforin and hMunc13-4 are two critical effectors of the granule-dependent cytotoxic pathway of lymphocytes. This process involves several steps, including recognition of the target cell by the cytotoxic cell, adhesion and formation of a synapse between both cells, polarization of the lytic granules of the cytotoxic T lymphocytes (CTLs) toward the target cell contact site, and granule contents secretion.

Perforin is a lytic protein synthesized by activated CTL and NK cells that is stored in the lytic granules before its secretion. Perforin is synthesized as a 70 kDa inactive precursor that is cleaved at the C terminus in an acidic compartment to yield a 60 kDa active form (Uellner et al., 1997). This proteolytic cleavage removes a linked glycan within the cleaved piece at the boundary of the C2 domain, allowing exposition and thus calcium-dependent binding of the C2 domain to membrane phospholipids. Following release from lytic granules, perforin is thought to oligomerize to form a pore-like structure in the target

cell membrane that is analogous to the C9 component of complement. This model has not been experimentally demonstrated, however (Henkart, 1985).

The function of Munc13-4 is required at a late stage of the lytic granule secretory pathway. Munc13-4-deficient lymphocytes have normal lytic granule formation. These granules are able to polarize and closely associate with the plasma membrane at the lymphocyte–target cell contact, but secretion of their contents is impaired. Therefore, Munc13-4 likely plays a role in the priming step of lytic granule secretion that follows granule docking and precedes plasma granule membrane fusion (Feldmann et al., 2003). That the granule release cytotoxic pathway is central to defense against viruses and intracellular bacteria had long been suspected and was definitively proven by the immune dysregulation observed in perforin-deficient mice (Binder et al., 1998; Matloubian et al., 1999; Jordan et al., 2004).

How does this cytotoxic pathway regulate T cell proliferation?

Several hypotheses may be proposed involving *cis/trans* processes and different target cells. A *trans*-action of cytotoxic granules is highly supported by the observation that following allogeneic stem cell transplantation, the presence of even a few donor cells in the recipient is usually sufficient to durably control FHL (Landman-Parker et al., 1993). The most likely explanation is that of a transcytolytic action exerted on antigen-presenting cells (APC) (Fig. 41.1). Although T cell-mediated recognition leads to T cell activation and clonal expansion, lymphocytes deficient in cytotoxic function fail to kill the infected cells and thus to remove the source of antigen stimulation. Persistent activated T cells, which produce high quantities of cytokines (e.g., INF- $\gamma$ ), leads to macrophage activation. The sustained macrophage activation results in tissue infiltration and the production of high levels of TNF- $\alpha$ , IL-1, and IL-6, which play a major role in the various clinical symptoms and in tissue damage (Binder et al., 1998; Kagi et al., 1999; Matloubian et al., 1999; Nansen et al., 1999). In fact, there is a striking resemblance between biologic changes induced by inflammatory cytokines and the clinical and laboratory findings that characterize FHL (Henter et al., 1991c).

A recent model of hemophagocytic syndrome induced in *pfp*<sup>−/−</sup> lymphocytic choriomeningitis virus (LCMV)-infected mice emphasizes the determinant role of INF- $\gamma$  in this mechanism. In this model, increased INF- $\gamma$  production by CD8 lymphocytes appears to result from elevated or prolonged antigen presentation (Jordan et al., 2004). Prolonged contact between T cells and APCs occurring in the absence of cytolytic function may rescue activated T cells from activation-induced cell death (AICD). Alternatively, it may induce the formation of a mature activated synapse in place of an immature synapse restricted to lytic function, independent of antigen load (Faroudi et al., 2003), and further increase the secretion of INF- $\gamma$  and other mediators.

Expansion of CTLs can also be limited by a fratricide killing exerted against neighboring T cells. During the killing of target cells, CTLs transiently acquire into their own membrane peptide in association with major histocompatibility complex (MHC) class I molecules at the site of contact with the target cells (Huang et al., 1999; Hudrisier et al., 2001; Stinchcombe et al., 2001b), potentially becoming targets for other CTLs. These various mechanisms are not mutually exclusive and may participate in the considerable sustained expansion of CD8<sup>+</sup> lymphocytes and, to a lesser extent, of CD4<sup>+</sup> lymphocytes observed in cytotoxic-deficient conditions.

**Figure 41.1.** In response to a viral infection, antigen-specific cytotoxic T cells (CTL) will expand, secrete soluble mediators (IFN- $\gamma$ ) that enhance immunity and interfere with viral replication, and mediate lysis of infected cells. These various mechanisms participate in down-regulation of the immune response. In perforin-deficient cells (– perforin), uncontrolled increased expansion of antigen-specific effectors occurs. Activated lymphocytes secrete high levels of IFN- $\gamma$  and induce a feed-back

loop on macrophage and T cells that continuously activate each others and expand. High levels of inflammatory cytokines are secreted including IFN $\gamma$ , TNF $\alpha$ , and interleukins 1, 6, 18. Activated macrophages phagocytose bystander hematopoietic cells (hemophagocytosis). Activated lymphocytes and macrophages infiltrate various organs resulting in massive tissue necrosis and organ failure.

## Mutation Analysis

### Spectrum of mutations

Over 50 different mutations in the perforin gene have been found in FHL2 patients and consist of either microdeletion, nonsense, or missense mutations. These mutations are distributed all along the sequence. Some perforin mutations recur in the same ethnic populations, which suggests common ancestors. For example, the Trp374 stop (G1122A) appears to occur at high frequencies in Turkish families, the L364 frameshift (1090delCT) in the Japanese population, and the L17 frameshift (50delT) alteration in the African population. Some peculiar mutations of the perforin gene have been observed that specifically affect proteolytic cleavage and thus maturation of the protein (Katano et al., 2004) or its calcium binding ability (Voskoboinik et al., 2004; G. de Saint Basile, unpublished data). Most of these mutations result in undetectable expression of perforin in lytic granules. Mutations impairing only partially perforin expression are exceptional (Kogawa et al., 2002, unpublished data).

So far, the mutations identified in FHL patients, even those allowing some residual perforin expression, all lead to severe impairment of the *in vitro* cytotoxic activity of T and/or NK cells, provided that both alleles are mutated. This observation likely explains why clinical and biological analyses of FHL in 14 families could not differentiate between the patients carrying nonsense mutations and those with missense mutations (Feldmann et al., 2002). However, age at diagnosis, which tends to be similar within members of a same family, can be delayed in some patients with missense mutations (Clementi et al., 2001; Feldmann et al., 2002; Ueda et al., 2003). One hypothesis is that, in association with missense mutations, there is a residual *in vivo* perforin

function, allowing other factors such as the nature of the triggering infectious agent to influence the age of disease onset. Perforin gene mutations account for about 30% of FHL cases.

In about 30% of FHL families, disease results from mutation in the gene encoding for hMunc13-4. Six different hMunc13-4 mutations have been identified in FHL3 patients from seven different families. These mutations are predicted to result in major changes in the protein when there is a deletion, splice site mutation, or nonsense mutation within the first part of the protein. The role of hMunc13-4 in granule-dependent cytotoxic activity was unequivocally demonstrated by complementation of patients' lymphocyte defect transiently expressing the wild-type protein (Feldmann et al., 2003).

### Strategies for Diagnosis

Establishing a diagnosis of FHL may indeed be very difficult. Diagnostic guidelines (Henter et al., 1991a) include the association of five criteria: fever, cytopenia (two or three lineages), splenomegaly, hypertriglyceridemia and/or hypofibrinogenemia, and hemophagocytosis. In addition, positive familial history and parental consanguinity are contributing factors. Defective cytotoxic activity makes the diagnosis of FHL very likely.

Diagnosis of FHL due to a perforin defect is highly suggested by defective perforin expression and confirmed by mutation analysis. In patients with normal perforin expression, markedly decreased NK activity and decreased T cell cytotoxic capacity strongly suggest a defect in hMunc13-4 that should be confirmed by mutation detection (Feldmann et al., 2003). The impairment of cell cytotoxic function during the course of the disease and resulting from yet-unknown molecular causes also exists. In contrast, the low NK cytotoxic activity, which may be observed in

patients with secondary HLH, normalizes during the remission period (Janka et al., 1998). This parameter, although difficult to evaluate when immunotherapy is used, may become an important feature for differentiating primary disease (FHL) from secondary forms of HLH. Secondary forms may be associated with severe infections (also termed *virus-associated hemophagocytic syndrome*), autoimmune diseases, or malignancies.

Diagnosis of FHL also depends on the exclusion of the other inherited diseases, which are characterized by the occurrence of the same HLH (Dufourcq-Lagelouse et al., 1999b): the Chédiak-Higashi syndrome, the Griscelli syndrome, and the X-linked lymphoproliferative syndrome. In the two former syndromes, onset of HLH and defective cytotoxic activity are associated with characteristic partial albinism of the skin and the hair. Obviously, only males are affected with X-linked lymphoproliferative syndrome. In addition, cytotoxic activity of NK cells tested during a remission period was shown to be defective only when triggered through 2B4 molecules (Nakajima et al., 2000; Parolini et al., 2000; Tangye et al., 2000).

Diagnosis of FHL thus depends on the association of both positive and negative criteria, including early occurrence and severity of the hemophagocytic syndrome, relapse, evidence of autosomal recessive inheritance, defective cytotoxic activity, and absence of associated albinism. In the group of patients with perforin and hMunc13-4 defects, definitive diagnosis can be obtained.

#### Mode of Inheritance, Carrier Detection, and Prenatal Diagnosis

FHL is a typical autosomal recessive disease. Obligatory carriers are asymptomatic. In families with known mutations in the perforin or hMunc13-4 genes, unambiguous identification of carrier and affected subjects can be made. Through immunostaining, an absence of perforin expression was detected in the cell cytotoxic granules from most of the patients analyzed, regardless of mutation type (Stepp et al., 1999; G. de Saint Basile, unpublished result). Since polymorphisms have been observed in PRF1, even at the protein level, it is well advised that granule perforin detection be linked with mutation analysis of the gene. Prenatal diagnosis can be used only in those families in which a clear association with a perforin or hMunc13-4 defect has been demonstrated.

#### Treatment and Prognosis

Without treatment, FHL is usually rapidly fatal, with a median survival of about 2 months. A number of treatments including cytotoxic agents were initially tried with moderate or no effect, until the usage of the epipodophyllotoxin derivatives etoposide (VP-216) was introduced, which is effective in most cases (Ambruso et al., 1980; Delaney et al., 1984; Fischer et al., 1985; Ware et al., 1990; Blanche et al., 1991). More recently, immunotherapy with antithymocyte globulins (ATG) and cyclosporin A (CsA) have achieved remissions (Stephan et al., 1993; Jabado et al., 1997). The use of intrathecal methotrexate injections helps transiently to treat the neurocerebral involvement and to limit further relapse (Jabado et al., 1997). However, chemotherapy or immunosuppression is sometimes ineffective in treatment of the primary onset and frequently fails to control relapses. Allogeneic bone marrow transplantation (BMT) remains the only curative treatment for this disease (Fischer et al., 1986). Partial engraftment is compatible with long-term remission, and only a small proportion of the donor cells in the patient is sufficient to pre-

vent HLH reactivation in most cases (Landman-Parker et al., 1993).

Clinical observations suggest that there may be some correlation between age of disease onset and prognosis (very early onset being more aggressive), although this has not been statistically proven (Arico et al., 1996). Children with late diagnosis often present with severe and irreversible brain damage.

#### Animal Models

No naturally occurring animal models for FHL are available. However, the perforin gene (*Pfp*) has been disrupted by homologous recombination in mice. The murine gene encoding perforin has approximately 84% homology with the human *PRF1* gene. Perforin knockout mice are generally healthy when maintained in a pathogen-free, controlled environment, although they do have defective granule-dependent cytotoxic activity (Kagi et al., 1994). When challenged with certain strains of viruses, such as LCMV, perforin knockout mice (*pfp*<sup>-/-</sup>) develop an overreactive, virus-specific T cell response, and mice die within a few weeks as a consequence of immune damages mediated by CTLs, macrophages, IFN- $\gamma$ , and TNF- $\alpha$ . Pathology in this case appears to be very similar or identical to that of human HLH (Jordan et al., 2004).

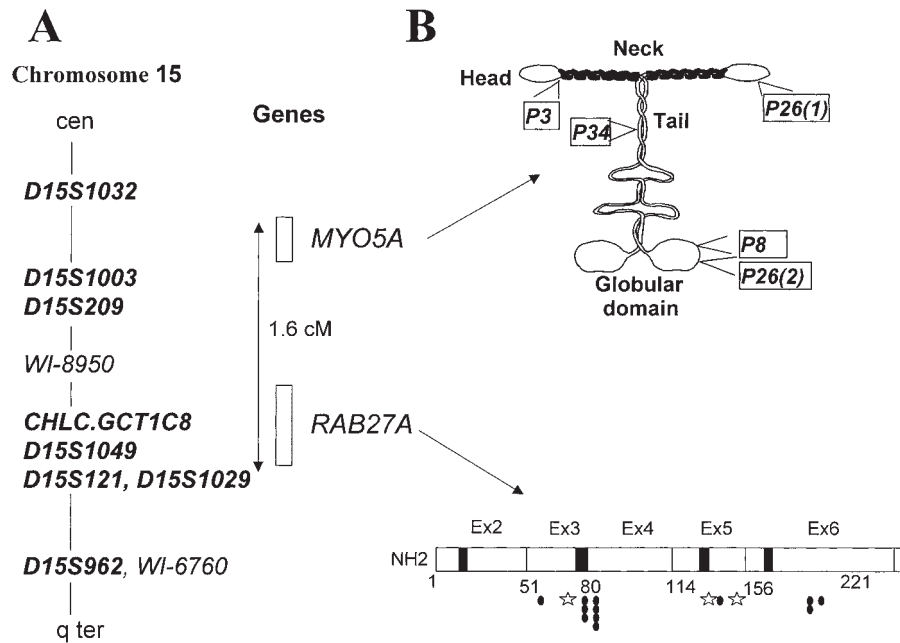

Several studies have shown that death of infected perforin-deficient mice results not from a defect in viral clearance but from persistence of the bulk of activated CD8<sup>+</sup> cells and the deleterious action of the cytokines they secrete (Rossi et al., 1998; Kagi et al., 1999; Matloubian et al., 1999; Nansen et al., 1999; White et al., 2000; Jordan et al., 2004). Depletion of the CD8<sup>+</sup> T cells or induction of thymic tolerance to viral epitope considerably reduces the reactive immunopathology in these mice (Binder et al., 1998; von Herrath et al., 1999; Jordan et al., 2004).

#### Griscelli Syndrome

Griscelli syndrome (GS; MIM 214450) is an autosomal recessive heterogeneous disorder characterized by pigmentary dilution, with silvery gray sheen of the hair and a typical pattern of uneven distribution of large pigment granules easily detectable by light-microscopic examination (Griscelli et al., 1978; Klein et al., 1994). Sun-exposed areas of patients' skin are often hyperpigmented, and microscopic dermoepidermis junction analysis detects accumulation of mature melanosomes in melanocytes contrasting with the hypopigmented surrounding keratinocytes (Griscelli et al., 1978). This typical pigmentary dilution is either associated with the occurrence of an HLH (GS2) or primary neurological feature (GS1) or can be isolated in rare patients (GS3), defining three genetic forms of the syndrome (GS1, GS2, and GS3).

#### Clinical and Pathological Manifestations

The single-most consistent cutaneous expression of partial albinism in patients with GS is a silvery gray sheen to their hair (Klein et al., 1994; Ménasché et al., 2000). This is more obvious in patients with black hair but is also visible in patients with blond hair. Patients generally have lighter hair than that of their unaffected family members. Hypopigmented spots on the retinas have been described in some patients (Klein et al., 1994) but is not a constant feature. In association with this characteristic pigmentary dilution, most patients develop a recurrent hemophagocytic syndrome (or accelerated phases) with features identical to those mentioned above in FHL patients (Table 41.1) or

**Figure 41.2.** Schematic representation of Griscelli syndrome 1 and 2 gene localization, structure, and mutations. (A) Representation of the genetic map of human chromosome 15 q21–22 region encompassing the first two Griscelli syndrome loci; polymorphic markers are shown in bold. (B) From top to bottom: location of patient termination codons on the MyoVa protein, relative to the different domains identified; location

of patient mutations in the Rab27A protein. The Rab consensus sequences for GTP-binding (black boxes) and C-terminal prenylation (gray box) motif, as well as the numbering of the coding exons (Ex), are indicated. An asterisk denotes a missense mutation and a filled oval a termination codon.

observed in Chédiak-Higashi syndrome and X-linked lymphoproliferative syndrome. Similarly, onset of HLH syndrome in this condition is frequently triggered by an infection (Klein et al., 1994; Wagner et al., 1997) and is characterized by hyperactivation and proliferation of T cells and macrophage, in association with fever, edema, hepatosplenomegaly, pancytopenia, coagulation abnormality, liver dysfunction, and features of hemophagocytosis. These patients have been defined as having GS type 2, which results from mutation in the Rab27a gene (*RAB27A*).

Neurological manifestations are frequently observed in association with HLH in GS2 patients, as a result of brain infiltration by activated lymphocytes and macrophages. However, in a few GS patients, severe and static neurological symptoms are noticeable since birth, without any sign of HLH, and consist of hypotonia, absence of coordinated voluntary movements, and severe psychomotor developmental delay (Sanal et al., 2002). These symptoms are similar to the neurological signs described by Elejalde et al. (1979). In this condition, CNS disorder is static and never improves with time.

Patients presenting with the typical hypopigmentation of GS in association with this isolated severe neurological manifestation have been shown to carry mutations in the myosine VA gene (*MYO5A*), which defines GS1 (Pastural et al., 1997). In addition, isolated hypopigmentation with typical hair and skin features of GS was recently observed in a subject, independent of *MYO5A* or *RAB27A* mutation. Hypopigmentation in this case resulted from mutation in the melanophilin gene (*MLPH*) (Ménasché et al., 2003b), defining a third form of Griscelli syndrome (GS3).

### Molecular Basis of Griscelli Syndrome

Genetic linkage analysis performed in several GS1 and GS2 families has enabled localization of both disease loci on the same

15q21 chromosome region (Fig. 41.2). Mutations in either the *MYO5A* gene or *RAB27A* gene, two genes separated by less than 1.6 cM in this genetic region, account for the GS1 and GS2 phenotypes, respectively (Fig. 41.2) (Ménasché et al., 2000; Pastural et al., 2000).

The *dilute* mutant mice and the *ashen* mutant mice were shown to be the mouse counterparts of GS1 and GS2, although *ashen* mice do not develop a spontaneously accelerated phase of the disease (Wilson et al., 2000). In addition, the melanophilin gene, located on chromosome 2q37.3, leads to GS3 when mutated. In this condition, the GS phenotype is restricted to the characteristic hypopigmentation of this condition (Ménasché et al., 2003b). The *leaden* mutant is the mouse counterpart of GS3 (Matesic et al., 2001).

### Functional Aspects

Myosin Va is an unconventional myosin heavy chain implicated in vesicle transport in cells and is particularly abundant in neurons and melanocytes. It has the expected structure for a member of this family—i.e., a globular head domain containing the ATP- and actin-binding sites; a “neck” domain, which is the site of calmodulin (or light-chain) binding; and a tail domain, which is thought to represent the cargo-binding domain (Fig. 41.2). Myosin VA acts as a dimer and moves cargo along actin filaments in a plus-end-directed manner, allowing their capture and accumulation at the periphery of the cells. In addition, there is recent evidence of a role for myosin Va in structural and functional cross-talk between the actin- and microtubule-based cytoskeletons. Myosin Va is required for melanosome transport in melanocytes (Wu et al., 1997) and likely synaptic vesicles in nerve terminals (Prekeris and Terrian, 1997). Study in *dilute* mice has shown that a defect in myosin Va leads to concentration of melanosomes in the

center of the melanocytes; they are also concentrated in dendrites and dendritic tips in wild-type mouse melanocytes. This defect also impairs processing of presynaptic vesicles in the peripheral regions of neurons and the distribution of smooth endoplasmic reticulum in Purkinje cell neurons (Takagishi et al., 1996).

Rab27A is expressed in melanocytes, peripheral leukocytes, platelets, and many other cells and tissue types, except in the brain (Chen et al., 1997). Each member of the Rab protein family has a characteristic intracellular distribution pattern, suggesting their unique function in transport. Like myosin Va, Rab27A colocalizes in part with melanosomes in melanocytes and its defect leads to the abnormal melanosome distribution observed in GS (Bahadoran et al., 2001). In addition, Rab27A is necessary for cytotoxic granule exocytosis and thus cytotoxic activity of T and NK cells, which has been shown to be defective in this group of GS2 patients (Ménasché et al., 2000).

Melanophilin is an effector of Rab27a, which is specifically expressed in melanocytes (Fukuda, 2003). MLPH deficiency leads to the same defective transport of melanosomes as that resulting from MYO5A and RAB27A defects. Pigmentary dilution is indistinguishable among these three molecular defects. A specific role of the three proteins Rab27a, MyoVa, and Mlph in the capture and actin-based transport of melanosomes to the periphery of the dendrites has been demonstrated. Analyses in mouse mutant models determined that Rab27a first associates with the membrane of melanosomes, then interacts with melanophilin, which recruits myosin Va through its tail region (Wu et al., 2002). Binding of the head domain of myosin Va to actin filaments links melanosomes with the peripheral actin network.

Because of the role of myosin-Va in brain tissue, however, only patients with myosin-Va defect develop a primitive and severe neurological impairment with no immunological expression. In contrast, defective Rab27A expression is always associated with abnormal lymphocyte cytotoxic activity, which results in the occurrence of a lymphoproliferative syndrome, as observed in the case of the FHL caused by genetically determined perforin or hMunc13-4 deficiency (Stepp et al., 1999; Feldmann et al., 2003). When neurological signs are observed in GS2 patients, they are the consequence of an accelerated phase, and appear secondary to perivascular lymphohistiocytic organ infiltration.

### Laboratory Findings

The light-microscopic examination and electron-microscopic findings of patients' hair and skin are characteristic. Hair shafts contain a typical pattern of uneven accumulation of large pigment granules, instead of the homogeneous distribution of small pigment granules in normal hair. Fontana-stained silver sections of the skin show hyperpigmented melanocytes, contrasting with poorly pigmented adjacent keratinocytes, instead of the homogeneous distribution of melanin granules observed in melanocytes and surrounding keratinocytes in normal epidermis. Electron microscopy shows that the cytoplasm of melanocytes is filled with numerous mature stage IV melanosomes, predominantly around the nucleus, but have normal dendritic processes (Griscelli et al., 1978; Klein et al., 1994; Takagishi et al., 1996; Chan et al., 1998). These findings are consistently observed and identical in the three groups of patients (with MYO5A, RAB27A, or MLPH mutations).

Immunological abnormalities are restricted to patients with the Rab27A defect. Biological features of the accelerated phase are not specific to GS; they are identical to those observed in FHL patients. The capacity of lymphocytes and NK cells of these

patients to lyse target cells is impaired or absent. This decrease in T and NK cell cytotoxicity, which results from an inability to secrete cytotoxic granules when Rab27a is not functional, is a constant feature in this group of patients (Ménasché et al., 2000; Stepp et al., 2000). Patients have normal numbers of T, B, and NK cells as well as normal B and neutrophil functions, although decreased chemiluminescence and chemotactic responses have been reported (Klein et al., 1994). In addition, impaired skin reactions to tuberculin, streptokinase-streptodornase antigen, and candida have been described in some cases. The lymphocytes proliferate in vitro in response to PHA, purified protein derivative (PPD), or candida, and in mixed lymphocyte reaction (MLR). No immunological abnormalities have been observed in GS patients with a myosin-Va or melanophilin defect. Myosin-Va and melanophilin defects do not affect cytotoxic granule secretion, and these patients never develop an accelerated phase (Ménasché et al., 2000, 2003b).

### Mutation Analysis

#### Spectrum of mutations

RAB27A consists of seven exons, the first two being untranslated. It encodes a 221-amino acid polypeptide with a molecular mass of 25 kDa (Chen et al., 1997). Mutations in RAB27A have been characterized in about 50 independent patients (Ménasché et al., 2000, unpublished results). Only three single missense mutations have been reported: a W73G transition that lies within the conserved GTP-binding motif and affects interaction with a specific effector, and L130P and A152P transitions that disrupt protein folding by affecting residues that are highly conserved among Rab proteins (Menasche et al., 2003a). The other mutations are nonsense mutations, deletions, or splice site alterations, all predicting an early protein truncation. In each case, location of the stop codon predicts truncation of the consensus carboxyl-terminal motif of the protein, involved in Rab protein geranylgeranylation, and thus should leave Rab27a protein in an inactive state.

The MYO5A gene contains an open reading frame of 1855 codons that encodes a protein of 215 kDa (Mercer et al., 1991). MyosinVa is a member of the molecular motor molecules with structurally conserved heads followed by a neck domain, a tail region, and a globular C-terminal domain (Cheney et al., 1993). Alternatively spliced transcripts can be generated within the tail region of MyoVa. Four different mutations in MYO5A have been identified, each leading to a predicted truncated protein. One patient was homozygous for a C2332T transition in codon 779, resulting in a nonsense mutation that leads to a protein lacking the last 1078 residues. The second patient had a homozygous insertion of 47 bp at position 4634 (residue 1545), which resulted in a protein lacking most of the globular domain. The third patient was heterozygous for a 1 bp deletion at nucleotide 4950 as well as a C2893T transition affecting codons 1650 and 965 respectively, each leading to early protein truncation (Fig. 41.2) (G. de Saint Basile, unpublished result). Alternative splicing within the tail region of myosin Va produces different spliced isoforms with tissue-restricted expression: in melanocytes, the majority of myosin Va transcripts contain the longest isoform of myosin Va, whereas brain transcripts contain a shorter isoform lacking exon F (Huang et al., 1998; Lambert et al., 1998; Pastural et al., 2000). In one patient, homozygous intragenic deletion of myosin Va exon F led to a phenotype restricted to typical hypopigmentation of GS without neurological symptoms, demonstrating that exon

F of myosin Va is dispensable for neurological function (Ménasché et al., 2003b).

The *MLPH* gene comprises seven exons spanning 2403 bp and encodes for a protein of 66 kDa. A homozygous R35W substitution was identified in the synaptotagmin-like protein homology domain (SHD) of the protein in one patient, which completely blocked Mlph interaction with the active form of Rab27a (Ménasché et al., 2003a).

### Genotype–Phenotype Correlation

As discussed above, there is a strict correlation between the type of gene affected (*RAB27A/MYO5A/MLPH*) and the phenotype displayed by patients with GS. Although pigmentary dilution is identical in these three groups of patients, only the patients with *RAB27A* mutations have decreased cytotoxic activity resulting in the development of a hemophagocytic syndrome, whereas primary, severe, and irreversible neurological impairment characterizes patients with *MYO5A* mutations (Ménasché et al., 2000).

### Strategies for Diagnosis

The diagnosis of GS must be considered in any child with decreased pigmentation accompanied or not by neurological abnormalities or signs of the accelerated phase, such as hepatosplenomegaly, jaundice, or pancytopenia. Microscopic examination of the hair shaft provides strong support for the diagnosis of GS. The characteristic neurological symptoms and analysis of cytotoxic activity of patient lymphocytes tend to distinguish the three molecular causes. Confirmation can be provided by mutation analysis of patient DNA.

Prenatal diagnosis of GS was first accomplished by light-microscopic examination of the hair shaft (Durandy et al., 1993). With the recent identification of the GS genes, direct mutation-based carrier detection and prenatal diagnosis are now feasible in families with defined *MYO5A* or *RAB27A* gene mutations. In addition, given the proximity of these two genes causing the severe forms of GS, polymorphic markers linked to the GS locus region in 15q21 can be used for this purpose, even if the precise mutation has not been identified in a consanguineous family (Ménasché et al., 2000).

Several additional disorders exhibit clinical similarity to GS but can be clearly distinguished. Chédiak-Higashi syndrome (CHS), a disorder similar to GS, involves variable hypopigmentation of the skin and the hair, frequent pyogenic infections, and defective NK and T lymphocyte cytotoxicity; the recurrent accelerated phase is virtually identical to that of GS2 (Beguez-Cesar, 1943; Blume and Wolff, 1972; Baetz et al., 1995). However, light-microscopic examination of the hair enables distinction between these two disorders, as in CHS the clusters of the pigment are smaller than those in GS, although they remain abnormal. In addition, a hallmark of CHS is the presence of giant organelle inclusion bodies in virtually all granulated cells, including granulocytes, lymphocytes, monocytes, mast cells, melanocytes, Schwann cells, neurons, renal tubular epithelium, and fibroblasts. Studies of these bodies indicate that they are derived from lysosomes in many cell types and represent structurally abnormal but histologically normal granular elements (Windhorst and Padgett, 1973; Burkhardt et al., 1993). Thanks to CHS homology to the beige mutant mouse, CHS has been mapped to chromosome 1q42–43 and its gene, *CHS1*, identified (Barbosa et al., 1996; Barrat et al., 1996; Nagle et al., 1996). In patients with classical form of CHS, nonsense or frameshift mutations have been

reported that lead to early truncation of the protein. In contrast, missense mutations were identified in the few patients described with a milder clinical course (Spritz, 1998; Certain et al., 2000; Karim et al., 2002). Studies of the CHS protein function suggest its role in lysosomal fission (Perou et al., 1997) as well as intracellular protein trafficking or sorting (Faigle et al., 1998; Barrat et al., 1999).

Partial albinism with immunodeficiency, termed *PAID syndrome*, is similar to GS, but with progressive demyelination of the white matter of the brain. This syndrome has been described in eight Saudi Arabian kindred (Harfi et al., 1992). Recent genetic analysis in one family with PAID syndrome from the same origin identified a mutation in the *RAB27A* gene, which indicates that PAID syndrome and GS most probably correspond to the same disorder (G. de Saint Basile, unpublished data). Similarly, Elejalde syndrome, or neuroectodermal melanolysosomal syndrome, was described with the same albinism features as those observed in GS associated with early onset of severe CNS disorder, without signs and symptoms of accelerated phase (Elejalde et al., 1979). This exact phenotype is displayed by the three unrelated GS patients with myosin Va defect (Pastural et al., 2000; Sanal et al., 2000; G. de Saint Basile, unpublished data). These findings strongly suggest that Elejalde syndrome and this form of GS are allelic.

In FHL, X-linked lymphoproliferative syndrome, and virus-associated hemaphagocytic syndrome, patients develop an accelerated phase identical to the one observed in GS, and NK cytotoxic activity is often decreased or absent (Dufourcq-Lagelouse et al., 1999b). However, these disorders do not involve partial albinism, and microscopic examination of the hair shaft allows easy differentiation of GS from these disorders.

### Treatment and Prognosis

The prognosis for long-term survival in GS is relatively poor. In the form caused by the Rab27A defect, GS is usually rapidly fatal within 1 to 4 years. Treatment is similar to that described above for FHL patients. Allogenic bone marrow transplantation, the only curative treatment for this disease, can cure the cytotoxic defect and consequently prevent the occurrence of further accelerated phases. Even a low number of donor cells in the patient bone marrow is enough to control the disease, probably because of the ability of each cytotoxic cell to kill several targets. These findings indicate that successful transfer of a normal *RAB27A* gene, even in a small proportion of patient cells, should be sufficient to restore cytotoxic activity and control immune homeostasis in a gene therapy attempt.

No specific treatment can be proposed for myosin-Va deficiency. The severe neurological impairment and psychomotor delay do not improve with time. Recurrent infections presented by some of these patients have been improved with positional changes and antibiotic treatment.

### Animals Models

Three naturally occurring mutants in mice—the dilute (*d*), ashen (*ash*), and leaden (*lead*) mice—are the ortholog for the three GS forms, which result from myosin-Va, Rab27A, and Mlph deficiency respectively. All murine mutants present with identical pigmentary dilution, normal pigment granule synthesis, but abnormal melanosome transport. The melanosomes are localized mainly in the perinuclear region of the melanocytes (Provance et al., 1996; Wu et al., 1997; Wilson et al., 2000).

Dilute null mice also show a neurological defect, characterized by opisthotonus and ataxia, which results in death of the animal 2–3 weeks after birth (Dekker Ohno et al., 1996; Takagishi et al., 1996). The neurological defect is thought to result from the failure to transport smooth endoplasmic reticulum from the dendritic shaft to the dendritic spines of cerebellar Purkinje cells, which probably affect the regulation of intracellular  $\text{Ca}^{2+}$  and postsynaptic signal transduction. Retroviral integration into the *d* gene in mice (*dv*) allowed its cloning and demonstrated that it encodes an unconventional myosin heavy chain, myosin Va, expressed in nearly all tissues in adults (Jenkins et al., 1981; Mercer et al., 1991). Neurological impairment and pigmentary dilution may vary, however, with the type of myo5a defect (Huang et al., 1998). Murine myosin-Va displays the same dimeric structure function and shares 93% homology with human myosin-Va.

In contrast, *ashen* mice exhibit the same pigmentary dilution as *dilute* mice, but in association with defective cytotoxic activity (Haddad et al., 2001; Stinchcombe et al., 2001a). Like in GS, this defective function results from the role of Rab27a in cytotoxic granule exocytosis. *Ashen* mice have also been described with increased bleeding times and a reduction in the number of platelet dense granules (Wilson et al., 2000), but this feature depends on the genetic background. Meiotic and physical linkage allowed mapping of the *ashen* critical region on murine chromosome 9, which is tightly associated with the *dilute* locus. A splicing defect resulting from a single transversion in exon 4 donor splice site, activation of a cryptic downstream site and abnormal Rab27a transcript was identified in these mice (Wilson et al., 2000). However, no signs of an accelerated phase have been observed in *ashen* mice, a condition that may require viral challenge. Isolated pigmentation dilution identical to that of the *dilute* and *ashen* mice characterizes the *leaden* mice and results from a deletion of seven residues in the SHD of the melanophilin gene (Matesic et al., 2001).

### Acknowledgments

The author thanks Françoise Le Deist, Jérôme Feldmann, Gaël Ménashé, and Rémi Dufourcq-Lagelouse for their stimulating discussion and contribution to this work, and Alain Fischer for insightful advice and chapter review. This work was supported by INSERM, the Association "Vaincre les Maladies Lyso-somiales" (V.M.L.), and l'Association de Recherche contre le Cancer (A.R.C.).

## Genetically Determined Deficiencies of the Complement System

KATHLEEN E. SULLIVAN and JERRY A. WINKELSTEIN

The complement system is composed of a series of plasma proteins that play a critical role in host defense and inflammation. The first patient with a genetically determined deficiency of an individual component of the complement system was described in 1960 (Silverstein, 1960). Since then, inherited deficiencies of nearly all of the individual components of complement have been identified (Ross and Densen, 1984; Figueroa and Densen, 1991). In this chapter, we review the biochemistry and biology of the normal complement system and relate them to the clinical presentation of complement deficiency diseases and their molecular genetic basis.

### The Normal Complement System

Most of the biologic functions of the complement system are mediated by the third component (C3) and the terminal components (C5–C9) (Fig. 42.1). In order to subserve their defensive and inflammatory functions, however, C3 and C5–C9 must be activated. At least three pathways exist by which they may be activated: the classical pathway, the alternative pathway, and the lectin pathway.

#### The Classical Pathway

Activation of the classical pathway (Fig. 42.1) is usually initiated by antigen/antibody complexes (reviewed in Sullivan and Winkelstein, 2001). Antibodies of the appropriate class (IgG or IgM) and subclass (IgG1, IgG2, and IgG3) bind to the antigen, forming an immune complex which then is capable of binding and activating the first component of complement (C1). C1 is composed of three distinct subunits, C1q, C1r, and C1s, present in a molecular ratio of 2:2:1. It is the C1q that binds to the heavy chain of the immunoglobulin molecules and is responsible for

activating C1r, which in turn activates C1s. Activated C1s possesses serine protease activity and activates the fourth component (C4). Activation of C4 results in the cleavage of a small fragment (C4a) from the parent molecule, exposing an intrachain reactive thiolester in the larger cleavage product (C4b). The larger fragment (C4b) is then able to bind covalently to immunoglobulins of the immune complex, or to the surface of the cells that carry the immune complex (e.g., microbes), by esterification of hydroxyl groups of carbohydrates or amidation of amino groups of proteins by the acyl group of the thiolester. Activation of the classical pathway continues with the activation of the second component (C2) by C1s. The activation of C2 results in its cleavage into a small peptide (C2b), which is released into the fluid phase, and a larger fragment (C2a). The C2a remains complexed with the C4b to create a bimolecular enzyme, C4b,2a, which is capable of activating the third component (C3) and initiating the assembly of the terminal components (C5–C9) into the membrane attack complex (MAC).

If the activation of the classical pathway were to proceed uncontrolled, the phlogistic activities of C3 and the terminal components could be produced in excessive amounts, resulting in immunopathologic damage to the host. Fortunately, a number of factors control the assembly and expression of the C3-cleaving enzyme, C4b,2a. First, the C4b,2a enzyme is very labile and undergoes spontaneous decay with release of the C2a and loss of enzymatic activity. Second, the enzymatic activity of both C1r and C1s can be inhibited by C1 esterase inhibitor (C1INH). C1 esterase inhibitor is a serine protease inhibitor that binds covalently to activated C1r and C1s and inactivates them, leading to the dissociation of the C1 macromolecular complex. Third, another protein, C4 binding protein (C4bp), binds to C4b and exerts two regulatory effects. It increases the rate of dissociation of C2a from the C4b and also makes the C4b more susceptible to

**Figure 42.1.** The complement system. The classical pathway is typically activated by immune complexes binding to C1q. The alternative pathway is activated directly by microorganisms. The actions of the two pathways converge on the C3 protein.

the action of yet another inhibitor, factor I. Finally, a fourth inhibitor, decay accelerating factor (DAF), also promotes the release of C2a from the C4b,2a enzyme.

### The Alternative Pathway

Activation of the alternative pathway (Fig. 42.1) can occur without the participation of antibody (Fearon, 1979). Native C3, like native C4, contains an internal thiolester that slowly undergoes spontaneous hydrolysis. This hydrolyzed C3, or C3(H<sub>2</sub>O), is capable of binding factor B, which allows its cleavage by factor D into two fragments. The larger fragment, Bb, remains attached to the C3(H<sub>2</sub>O), creating a low-grade C3-cleaving enzyme, C3(H<sub>2</sub>O),Bb. The cleavage of C3, like that of C4, exposes a reactive thiolester in the larger cleavage product, C3b, allowing covalent binding of the nascent C3b to suitable cell surfaces (such as microbial surfaces) through transacylation with hydroxyl or amino groups. The cell-bound C3b then can bind native factor B, allowing its cleavage by factor D to form a highly efficient C3-cleaving enzyme, C3b,Bb. It should be noted that since activation of the classical pathway results in the generation of nascent C3b, activation of the classical pathway can lead to activation of the alternative pathway. In addition, since C3b is both the product of the alternative pathway C3-cleaving enzyme and also is a component of the enzyme itself, the activation of C3 via the alternative pathway creates a positive amplification feedback loop (Fig. 42.1).

As is the case in the classical pathway, a number of factors act to modulate the activity of the alternative pathway. First, like C4b,2a, the C3b,Bb enzyme rapidly undergoes spontaneous decay as a result of dissociation of Bb. Properdin (P) stabilizes the binding of Bb to the C3b and thereby retards the enzyme's intrinsic decay. Another control protein, factor H, competes with factor B for binding to C3b but also displaces Bb from the enzyme complex. A third control protein, factor I, inhibits the alternative pathway C3-cleaving enzyme by inactivating the cell-bound C3b through proteolytic cleavage to create iC3b, a molecule that is unable to function in the C3bBb enzyme.

### The Lectin Pathway

In recent years, evidence has accumulated that a third mechanism exists by which C3 can be activated. Mannose-binding lectin (MBL) is a member of the collectin family of proteins and is composed of identical subunits. The predominant circulating form is a 600,000 kDa multimer (Lipscombe et al., 1995). Although the binding of each carbohydrate recognition domain is relatively weak, the presence of multiple binding sites probably endows the molecule with significant avidity when it binds to microbial surfaces with repeating sugar groups. MBL is capable of binding to a variety of microorganisms, including bacteria such as *Haemophilus influenzae*, *Neisseria meningitidis*, and streptococci, fungi such as cryptococcus and candida, and several viruses, but the binding is significantly impaired by the presence of a capsule.

MBL is capable of activating C3 via the classical pathway without a requirement for C1q or immunoglobulin, thereby playing a role in so-called natural immunity. The multimer interacts with novel serine proteases, termed *MBL-associated serine proteases* (MASP1 and MASP2), proteins that share 39% homology with both human C1r and C1s. Like C1s, MASP1 and MASP2 can cleave both C4 and C2, thereby generating C4b,2a and its C3-cleaving activity. In addition, there is some evidence to support the ability of the MBL-MASP complex to activate C3 via the alternative pathway and directly.

### Activation of C3 and the Terminal Components

The activation of C3 via either the classical or alternative pathway (Fig. 42.1) results in its cleavage into two fragments of unequal size (reviewed in Hostetter and Gordon, 1987). Cleavage of C3 releases a small peptide (C3a) from the parent molecule, exposing the reactive thiolester in the larger fragment (C3b), which in turn allows the covalent binding of the C3b to immune complexes or cell surfaces. The cell-bound C3b can then act as an opsonin (see below) or combine with either the classical pathway or alternative pathway C3-cleaving enzymes to create two new enzymes, the classical and alternative pathway C5-cleaving enzymes. The classical pathway C3-cleaving enzyme is composed of C4b,2a,3b, whereas the alternative pathway C3-cleaving enzyme is composed of (C3b)<sub>2</sub>,Bb. Activation of C5 by either enzyme results in its cleavage into two fragments of unequal size. The smaller fragment, C5a, is released into the fluid phase where it can act as an anaphylatoxic or chemotactic fragment (see below). If the larger fragment, C5b, combines immediately with C6, it initiates formation of the MAC, a multimolecular complex of C5b, C6, C7, C8, and C9 that possesses cytolytic activity. A number of proteins regulate the formation of the MAC. Homologous restriction factor (HRF), also known as C8 binding protein (C8bp), is an integral membrane protein present on a wide

variety of peripheral blood cells that impedes the formation and insertion of the MAC. A second protein, termed *HRF20* or *CD59*, inhibits the unfolding of C9 that is required for membrane insertion.

### Biological Consequences of Complement Activation

Activation of C3 and C5–C9 results in the generation of a variety of biologic activities that play an important role in host defense and inflammation. The smaller cleavage products of C3 and C5 (C3a and C5a) possess anaphylatoxic activity, causing histamine release from basophils and mast cells, increased vascular permeability, and smooth muscle contraction (Hugli, 1981). On a mole-per-mole basis, C5a is significantly more potent as an anaphylatoxin than is C3a. C5a is also a potent chemotactic agent, attracting mobile phagocytic cells to sites of complement activation (Snyderman and Goetzl, 1981). In addition, it can cause degranulation of phagocytic cells with discharge of lysosomal enzymes, enhanced production of microbicidal oxygen products, and production of leukotrienes.

The larger cleavage product of C3 (C3b) is an important opsonin when fixed to the surface of an activating particle, such as a microorganism, and binding to the phagocytic cell through CR1 receptors (Johnston et al., 1969; Hostetter and Gordon, 1987). Particles bearing the C3b degradation product iC3b on their surface can interact in a similar fashion with another receptor on the phagocytic surface, CR3. Since iC3b is the major C3 cleavage product formed on most particles in the presence of serum, it is probably the most important C3-derived opsonin in vivo.

Bactericidal activity is generated by activation of the terminal components and assembly of C5b–C9 into the membrane attack complex. However, only gram-negative bacteria are susceptible to the bactericidal activity of the complement system because gram-positive bacteria have a thick protective cell wall.

The complement system also plays an important role in the clearance and processing of soluble immune complexes (Schifferli et al., 1986). A number of mechanisms exist by which the complement system can modify the structure of immune complexes, influence their biological properties, and enhance their clearance. First, C3b fixed to an immune complex can act as an opsonin, favoring their ingestion by phagocytic cells. Second, the binding of C3b to immune complexes retards their precipitation from serum (Schifferli et al., 1980, 1985) and their deposition in tissues, and also helps solubilize them once they have precipitated (Czop and Nussenzweig, 1976; Takahaski et al., 1978; Schifferli et al., 1985). Finally, the complement system in primates provides an additional mechanism for immune complex clearance. Primates possess CR1 receptors on their erythrocytes and circulating immune complexes bearing C3b will fix to them. The erythrocytes bearing immune complexes on their surface then pass through the liver and spleen, where Kupffer cells and other phagocytic cells strip the immune complexes from the erythrocytes and return the erythrocytes to the circulation (Corna-coff et al., 1983). In this manner, erythrocytes serve to capture immune complexes in the circulation, prevent them from depositing in organs such as the kidney, and enhance their clearance by the reticuloendothelial system.

The complement system also plays an important role in the production of a normal humoral immune response (Pepys, 1974; Ochs et al., 1983; O'Neil et al., 1988). Animals and humans deficient in C2, C3, or C4 exhibit impaired primary and secondary antibody production (Bottger et al., 1986; Ochs et al., 1983,

1993; O'Neil et al., 1988; Fischer et al., 1996; Ma et al., 1996). Mice deficient in CR1 and CR2 receptors are similarly impaired in functional humoral responses (Molina et al., 1996). The explanation for the impaired antibody responses relates to the loss of C3d stimulation of B cells through the CR2 receptor (CD21) (Dempsey et al., 1996). Antigen associated with C3d stimulates B cells more effectively than antigen alone. Signaling through the CD19–CD21 complex links the complement receptor to distal signaling effects mediated through the antigen receptor complex. Additionally, complement also aids in follicular dendritic cell trapping of antigen, thereby augmenting a humoral response (Ochs et al., 1983; Molina et al., 1996).

### Pathophysiologic Basis of Clinical Manifestations of Complement Deficiencies

The clinical expression of genetically determined deficiencies of the complement system is variable and depends on the role of the deficient component in normal host defense and inflammation (Tables 42.1 and 42.2). Individuals with genetically determined deficiencies of complement components may have an increased susceptibility to infection, rheumatic disorders, or angioedema or may be asymptomatic.

#### Infection

A number of studies in experimental animals have established that the complement system plays a critical role in the host's defense against infection (Table 42.2). Complement is especially important during the first few hours of infection (Winkelstein et al., 1975) and in containing the infection at its initial site (Bakker-Wonderen et al., 1979). If dissemination should occur, complement contributes to the clearance of microbes from the bloodstream (Hosea et al., 1980). Furthermore, complement plays an important role in resistance to infection in both the "immune" host with high levels of antibody and in the "nonimmune" host with little if any antibody.

Although studies in experimental animals have shown that the complement system has the potential to contribute to the host's defense against a wide variety of bacteria, fungi, and viruses, clinical experience would suggest that the greatest susceptibility of complement-deficient patients is to bacterial infections (Ross and Densen, 1984; Figueroa and Densen, 1991). The kinds of bacteria that most commonly cause infections in complement-deficient patients reflect the specific role of the missing component in normal host defense. For example, the major cleavage products of C3 (C3b and C3bi) are important opsonins. Therefore, patients with a deficiency of C3 have a marked increased susceptibility to infection with those bacteria for which opsonization is the primary mechanism of host defense (e.g., *Streptococcus pneumoniae*, *Streptococcus pyogenes*, and *Haemophilus influenzae*). Patients with a deficiency of C1, C4, or C2 also have an increased susceptibility to these same encapsulated bacteria, since these components are necessary for the activation of C3 via the classical pathway. However, they do not appear to be as susceptible as patients with C3 deficiency, since their alternative pathway is intact and able to activate C3.

Activation of the terminal components, C5–C9, results in the assembly of the membrane attack complex and the generation of bactericidal activity for gram-negative bacteria. Therefore, patients with deficiencies of one of the terminal components have an increased susceptibility to infection with those gram-negative bacteria, such as *Neisseria meningitidis*, that are most susceptible to the

bactericidal activities of the complement system. As expected, infections with gram-positive bacteria, such as the pneumococcus, are not seen with any greater frequency in patients with deficiencies of a terminal component because these bacteria are not susceptible to the bactericidal activity of the complement system.

Although blood-borne, systemic infections such as bacteremia and meningitis are the most common bacterial infections reported in complement-deficient patients (Ross and Densen, 1984; Figueroa and Densen, 1991), localized infections such as sinusitis, otitis, and pneumonia have also been seen. Infections in complement-deficient individuals are usually caused by the common encapsulated bacteria to which normal hosts are also susceptible, such as the pneumococcus, streptococcus, and meningococcus. However, systemic infections with unencapsulated strains of pathogenic bacteria such as the meningococcus, which are extremely rare in normal individuals, have been described in a number of complement-deficient individuals (Hummel et al., 1987). Some clinical features of meningococcal infections are different in complement-deficient individuals from those of meningococcal infections in individuals with an intact complement system. Two studies suggest that meningococcal disease is less severe in complement-deficient individuals and is associated with a lower mortality rate (Figueroa and Densen, 1991; Platonov et al., 1993).

### Rheumatic Disorders

The pathophysiologic basis for the occurrence of rheumatic disorders in patients with genetically determined complement deficiencies is not completely understood. There are a number of hypotheses to explain the association of rheumatic disorders and complement deficiencies. One of the more attractive explanations is based on the role of the complement system in the processing and clearance of immune complexes (Schifferli et al., 1986). Another attractive explanation relates to the recently dis-

covered role of the early components of the classical pathway, such as C1q, in the clearance of apoptotic cells (Botto et al., 1998; Navratil and Ahearn, 2000). As cells undergo apoptosis, intracellular constituents are reorganized and appear on the surface of the cell in blebs. Autoantigens targeted in patients with systemic lupus erythematosus (SLE), such as SSA and/or SSB, are often found on the surface in these blebs (Casciolo-Rosen et al., 1994), rendering a normally invisible antigen visible.

Although rheumatic disorders are a common clinical manifestation of genetically determined disorders of the complement system (Ross and Densen, 1984; Figueroa and Densen, 1991), they are seen more commonly in patients with deficiencies of the early components of the classical pathway than in deficiencies of terminal components (Table 42.2). For example, just over 30% of patients with C2 deficiency and nearly 80% of patients with either C4 or C3 deficiency have a rheumatic disease. In contrast, fewer than 10% of patients with deficiencies of C5, C6, C7, C8, or C9 have rheumatic disorders. The risk of developing a rheumatic disease for a given deficiency correlates with the inability of patients with that specific deficiency to process immune complexes. For example, serum from patients with genetically determined deficiencies of C1, C4, C2, and C3 fails to prevent the precipitation of immune complexes (Schifferli et al., 1980, 1985), does not resolubilize immune complexes once they have formed (Czop and Nussenzweig, 1976; Takahaski et al., 1978; Schifferli et al., 1985), and does not support the binding of immune complexes to CR1 receptors on human erythrocytes (Paccaud et al., 1987). Conversely, the sera of patients with deficiencies of terminal components are normal with respect to these activities.

A variety of rheumatic diseases, including SLE, discoid lupus, dermatomyositis, scleroderma, anaphylactoid purpura, vasculitis, and membranoproliferative glomerulonephritis, have been reported in patients with complement deficiencies (Ross and Densen, 1984; Figueroa and Densen, 1991). There are some clinical differences between the SLE seen in patients with C2

**Table 42.2.** Complement Component Deficiencies: Clinical Characteristics

<i>Component</i>	<i>Patients/ Kindreds</i>	<i>Ethnic Predisposition</i>	<i>Clinical Manifestations</i>
C1q	28/20	None	1. SLE 2. Recurrent infections

SLE, systemic lupus erythematosus.

deficiency and the SLE seen in individuals without inherited complement deficiencies. The SLE seen in C2-deficient patients often has its onset in childhood, is frequently characterized by a prominent annular photosensitive dermatitis, and may have relatively mild pleuropericardial and renal involvement. In addition, it is not uncommon for C2-deficient patients to have low (or absent) titers of antibodies to nuclear antigen and/or native DNA (Glass et al., 1976; Provost et al., 1983; Meyer et al., 1985). In contrast, the prevalence of anti-Ro antibodies is reported to be much higher than in non-C2-deficient patients with lupus (Provost et al., 1983; Meyer et al., 1985). The SLE seen in patients with C1q deficiency tends to have severe end-organ effects and is usually associated with positive titers to nuclear antigen (Bowness et al., 1994).

## Epidemiology of Complement Deficiencies

Infections and rheumatic disorders are common clinical manifestations of genetically determined complement deficiencies. Accordingly, a number of studies have attempted to estimate the incidence of complement deficiencies in these disorders to determine how frequently complement deficiencies contribute to their pathogenesis and to evaluate the utility of screening certain groups of patients for complement deficiencies.

### Infection

The prevalence of complement deficiencies is significantly higher in individuals with systemic meningococcal infections than in the general population. The frequency of complement deficiencies in sporadic cases of systemic meningococcal infections has been estimated to be between 1% and 15% (Ellison et al., 1983; Merino et al., 1983; Leggiadro and Winkelstein, 1987; Rasmussen et al., 1987; Platonov et al., 1993). In general, the prevalence is even greater in those patients who have had recurrent meningococcal disease (40%) (Nielsen et al., 1989; Platonov et al., 1993), a positive family history of meningococcal disease (10%) (Nielsen et al., 1989), or an unusual serotype of the meningococcus (20%–50%) (Fijen et al., 1989). On the basis of these studies, it appears reasonable to screen any patient with a systemic meningococcal infection for a complement deficiency. Since there is a relatively high risk for recurrence, early identification of complement deficiency in patients with systemic meningococcal infections may prevent subsequent meningococcal infections.

The evidence that screening patients with systemic pneumococcal, streptococcal, or *H. influenzae* infections for complement deficiencies is useful is less compelling (Rasmussen et al., 1987; Rowe et al., 1989; Densen et al., 1990; Ekdahl et al., 1995). Although sepsis and meningitis caused by these organisms are very common among patients with inherited complement deficiencies (Ross and Densen, 1984; Figueroa and Densen, 1991), one study demonstrated only a single complement-deficient patient in a series of 389 patients with bacteremia and/or meningitis caused by bacteria other than the meningococcus (Densen et al., 1990).

### Rheumatic Disorders

The prevalence of homozygous C2 deficiency is significantly higher in patients with SLE than in the general population. Genetically determined C2 deficiency is found in approximately 1 in 10,000 (0.01%) individuals in the general population (Ruddy, 1986; Sullivan et al., 1994). In contrast, the prevalence of homozygous C2 deficiency in large series of patients with SLE has varied between 0.4 and 2.0 (Glass et al., 1976; Hartung et al., 1989; Sullivan et al., 1994). Although a number of patients with genetically determined C2 deficiency have also had other rheumatic diseases (Ross and Densen, 1984; Figueroa and Densen, 1991), there have been no studies that have documented a significantly increased prevalence of C2 deficiency in these disorders.

## Specific Deficiencies

Deficiencies of all of the soluble complement components and many of the membrane-bound receptors and regulatory proteins have been described in humans (Tables 42.1 and 42.2). Most are inherited as autosomal recessive disorders, although C1 esterase deficiency is inherited as an autosomal dominant disorder and

properdin deficiency is inherited as an X-linked recessive disorder.

## C1q Deficiency

### Molecular biology and pathophysiology

Native C1q is composed of three polypeptides, C1qA, C1qB, and C1qC, each of which is encoded by one of three highly homologous genes on chromosome 1 (Sellar et al., 1991). One of each of the three C1q polypeptides combines to form the C1q subunit, six of which combine to form C1q. Each of the six globular heads of C1q is capable of binding to the CH3 domain of IgM or the CH2 domain of IgG. When at least two of the globular heads of C1q are engaged, C1r becomes activated, which in turn cleaves C1s leading to activation C3 and C5–C9 through the classical pathway. Therefore, deficiency of C1q not only affects the patient's ability to generate those biologic activities related to C3 and C5–C9, such as opsonization, chemotaxis and bactericidal activity, but it also may affect the clearance of apoptotic cells.

In some patients there is no detectable C1q protein (Leyva-Cobian et al., 1981; Berkel and Nakakuma, 1993; Loos and Colomb, 1993). Other patients produce a dysfunctional C1q molecule, which can neither bind to immunoglobulin heavy chains nor activate C1r (Thompson et al., 1980; Chapuis et al., 1982; Reid and Thompson, 1983; Hannema et al., 1984; Slingsby et al., 1996). Patients with C1q deficiency (MIM 120550, 120570, 120575) have markedly reduced serum hemolytic complement activity and C1 functional activity.

The molecular defects causing C1q deficiency are diverse, although there is a nonsense mutation at amino acid position 186 of C1qA that is common among C1q-deficient patients from Turkey (Petry et al., 1996; Berkel et al., 2000). C1q deficiency is not restricted to a specific ethnic heritage and has been identified in people of European, Asian, and Arabic heritage. Mutations in each of the three chains have been identified (McAdam et al., 1988; Petry et al., 1995; Slingsby et al., 1996; Stone et al., 2000). In one case with a premature termination codon and undetectable A chain, B and C polypeptide chains were also absent, which suggests that C1A must be present for formation and secretion of C1q (Petry et al., 1995). Because there are many mutations causing C1q deficiency, carrier detection and prenatal testing rely on the identification of each individual mutation in affected family members. Allele-specific polymerase chain reaction (PCR) has been used to identify carriers of the common Turkish mutation.

### Clinical expression

The most common clinical presentation of C1q deficiency is SLE (Ross and Densen, 1984; Figueroa and Densen, 1991; Bowness et al., 1994). Approximately 30 patients with C1q deficiency have been described and all but 2 have developed SLE (Bowness et al., 1994). This deficiency is the strongest known genetic risk factor for SLE. The basis for this predisposition is believed to be the result of impaired immune complex clearance and/or impaired clearance of apoptotic cells. The manifestations of SLE in patients with C1q deficiency are not markedly different from those seen in complement-sufficient people; however, the age of onset is somewhat earlier and the disease can be very severe, with significant central nervous system (CNS) involvement and nephritis. The cutaneous manifestations are typically prominent, and skin biopsies demonstrate IgG, IgM, and C3 deposition, as is characteristic for SLE.

Patients with C1q deficiency also have an increased frequency of infections with pyogenic organisms, which reflects their inability to activate the classical pathway and efficiently opsonize bacteria.

### Animal model

A C1q-deficient knockout mouse spontaneously develops proliferative glomerulonephritis with subendothelial deposits of C3 and immunoglobulin. These mice have also been noted to have defective immune complex clearance (Botto et al., 1996).

## C1r and C1s Deficiency

### Molecular biology and pathophysiology

The genes for C1r and C1s are highly homologous and lie closely linked on chromosome 12p13 in a tail-to-tail orientation (Kusumoto et al., 1988). Both proteins contain serine esterase motifs, epidermal growth factor motifs, and several short consensus repeat units. Like most other complement components, C1r and C1s are produced primarily in liver and macrophages.

Twelve individuals with C1r deficiency (MIM 216950) have been described (Ross and Densen, 1984; Figueroa and Densen, 1991; Loos and Colomb, 1993). Typically, C1r levels are markedly reduced (1% of normal) and C1s levels are 20%–50% that of normal (Lee et al., 1978; Loos and Colomb, 1993). A single patient has been described in which C1s has been markedly reduced, while C1r levels were 50% that of normal (Suzuki et al., 1992), a finding suggesting that neither monomer is stable in the absence of the other.

Three mutations have been identified in patients with C1s deficiency (MIM 12058). One patient had a 4 bp deletion in exon 10, and two others nonsense mutations in exon 12 (Inoue et al., 1998; Endo et al., 1999; Dragon-Durey et al., 2001). The mutations in patients with C1r deficiency have not been identified, but the fact that 7 of the first 12 patients identified with C1r deficiency have been of Puerto Rican descent suggests that there may be a founder effect.

### Clinical expression

The most common clinical presentation of C1r/C1s deficiency is SLE, although bacterial infections and glomerulonephritis are also seen in these patients (Figueroa and Densen, 1991; Ross and Densen, 1984).

## C4 Deficiency

### Molecular biology and pathophysiology

The fourth component of complement (C4) is synthesized as a single polypeptide that is proteolytically processed into a mature protein composed of three disulfide linked chains. C4 is evolutionarily related to C3, C5, and  $\beta_2$  macroglobulin. It exists as two isotypes encoded by two distinct loci, C4A and C4B, within the major histocompatibility complex (MHC) class III region on chromosome 6 (Carroll et al., 1984). The two isotypes are largely identical but differ with respect to electrophoretic mobility and their specific functional hemolytic activity (Hauptmann et al., 1988). The C4A isotype is more efficient at transacylating with amino groups of proteins, and C4B is more efficient at transacylating with hydroxyl groups of carbohydrates (Dodds et al., 1996). The basis for these functional differences between C4A and C4B is four amino acids located between positions 1101 and

1106 of the  $\alpha$  chain. C4 is the most polymorphic of the complement components; each isotype has dozens of variants. C4 is produced primarily in liver and macrophages, and it is an acute-phase reactant.

Complete deficiency of C4 (MIM 120810, 120820) is the result of being homozygous deficient at both the *C4A* and *C4B* locus (*C4A*\*Q0,*C4B*\*Q0) and is uncommon, with only approximately 20 cases described (Ross and Densen, 1984; Hauptmann et al., 1988; Figueroa and Densen, 1991). Patients who have complete C4 deficiency have markedly reduced levels of total serum hemolytic activity and both functional and antigenic C4 in their serum. Those functions of the complement system that can be mediated by activation of the alternative pathway, such as serum opsonic, chemotactic, and bactericidal activity, are present although reduced, because the alternative pathway is less efficient at activating C3 than the classical pathway.

In contrast to the rarity of patients deficient in both isotypes, deficiencies of one or the other isotype are relatively common (Hauptmann et al., 1988). Individuals heterozygous for the *C4A*\*Q0 null allele are found in 12%–14% of the general population while approximately 15%–16% of individuals are heterozygous for *C4B*\*Q0. The corresponding frequencies for individuals homozygous for each null allele are 1% for *C4A*\*Q0 and 3% for *C4B*\*Q0. C4A deficiency in Caucasians is typically due to a large gene deletion and arises on the extended haplotype HLA-A1-Cw7-B8-C2C-BfS-C4A\*Q0-C4B1-DR3 (Kemp et al., 1987). Additionally, a 2 bp insertion in exon 29 has been identified as the most common cause of nonexpression of an intact C4A gene in Caucasians and is usually linked to HLA-B60-DR6 (Barba et al., 1993). Gene conversion can cause either C4A or C4B deficiency and additional *C4B*\*Q0 alleles are the result of gene deletions (Braun et al., 1990). Most other causes of C4B deficiency have not yet been identified. C4 allotyping and isotyping have been performed in a number of kindreds to determine carrier status in siblings.

#### Clinical expression

Most C4-deficient patients have immune complex disorders such as SLE or glomerulonephritis (Fig. 42.2) (Hauptmann et al., 1988). In fact, the most common manifestation of complete C4 deficiency is SLE. The disease onset is somewhat earlier than for SLE in complement-sufficient patients, and cutaneous features, including Raynaud's phenomenon and vasculitic ulcers, are common. Anti-DNA titers are sometimes absent, as is also seen in C2-deficient SLE patients. Biopsies of inflammatory lesions from C4-deficient patients usually demonstrate the presence of immunoglobulin and C1q, consistent with immune complex deposition and complement activation. C3 deposition has also been identified in kidney and skin, suggesting that the alternative pathway can also play a role in the development of these lesions (Lhotta et al., 1993). Because these patients also have suboptimal functional antibody responses in addition to their defect in opsonization, bacterial infections are also a common cause of morbidity and mortality (Ross and Densen, 1984; Figueroa and Densen, 1991; Ochs et al., 1993).

There may also be some clinical manifestations of isolated C4A or C4B deficiency. For example, the prevalence of homozygous C4A deficiency is approximately 10 times higher in SLE patients than in normal individuals (Christiansen et al., 1983; Fiedler et al., 1983; Howard et al., 1986; Petri et al., 1993), a finding suggesting that loss of C4A functional activity significantly compromises immune complex clearance. SLE patients with C4A deficiency appear to have a lower prevalence of anti-

**Figure 42.2.** Glomerulonephritis in a patient with C4 deficiency. Inherited deficiencies of early complement components are associated with systemic lupus erythematosus and glomerulonephritis. This patient with C4 deficiency developed a malar rash and glomerulonephritis in early adolescence. A renal biopsy demonstrated an increase in mesangial matrix and cellularity. Immunofluorescence confirmed paramesangial deposits of IgG, C3, and C1q. (Courtesy of Thomas R. Welch, M.D.)

cardiolipin, anti-Ro, anti-dsDNA, and anti-Sm antibodies; less neurologic disease and renal disease; and more photosensitivity than other SLE patients (Petri et al., 1993; Welch et al., 1998). Homozygous C4B deficiency is associated with an increased risk of bacterial infection (Rowe et al., 1989; Biskof et al., 1990).

#### Animal model

There is a naturally occurring strain of guinea pigs completely deficient in C4 (Ellman et al., 1970). They exhibit an increased susceptibility to bacterial infections; however, they have no evidence of autoimmune disease. At the time of their initial description in 1970, these animals provided valuable evidence for the existence of an alternative pathway (Frank et al., 1971). They have also been useful in defining the relative roles of the classical and alternative pathways in a variety of complement-mediated biological activities (Ellman et al., 1971; Hosea et al., 1980; Ochs et al., 1983). A C4-deficient knockout mouse has confirmed the importance of C4 in humoral responses and the clearance of endotoxin (Fischer et al., 1996; Ma et al., 1996; Prodeus et al., 1996; Reid et al., 1996).

## C2 Deficiency

#### Molecular biology and pathophysiology

The gene for C2 is closely linked to that for factor B within the class III region of the MHC complex (Carroll et al., 1984). C2 is

a serine protease and is highly homologous to factor B. Both components contain multiple 60-amino acid short consensus repeat units believed to interact with C4 (Ishii et al., 1993). C2 is produced by hepatocytes, macrophages, and fibroblasts.

C2 deficiency (MIM 217000) is the most common of the complete complement deficiencies (Ruddy, 1986; Sullivan et al., 1994). C2-deficient individuals have markedly reduced total hemolytic complement activity and C2 functional activity. Complement-mediated serum activities, such as opsonization and chemotaxis, are present in patients with C2 deficiency and reflect the fact that their alternative pathway is intact (Johnson et al., 1971; Friend et al., 1975). However, they are not generated to the same degree or as quickly as in individuals with an intact classical pathway (Johnston et al., 1969; Friend et al., 1975; Geibink et al., 1977; Repine et al., 1977).

Over 95% of C2-deficient individuals are homozygous for a 28 bp deletion at the end of exon 6, which causes a splicing abnormality and premature termination of transcription (Johnson et al., 1992; Truedsson et al., 1993b; Sullivan et al., 1994). The 28 bp deletion is associated with a conserved MHC haplotype: *HLA-B18, BF\*S, C2\*Q0, C4A\*4, C4B\*2, DR2* (Johnson et al., 1992; Truedsson et al., 1993a; Sullivan et al., 1994). The gene frequency of this deletion has been found to be 0.005–0.007 in Caucasoid populations (Truedsson et al., 1993b; Sullivan et al., 1994), a frequency consistent with previous estimates of the prevalence of homozygous C2 deficiency of approximately 1 in 10,000 (Ruddy, 1986). In addition to the common 28 bp deletion, a 2 bp deletion has been found that results in a premature stop codon (Wang et al., 1998), and two different missense mutations have been identified that impair secretion of mature C2 (Wetzel et al., 1996). Detection of the 28 bp deletion through PCR has been used for both carrier detection and prenatal diagnosis (Sullivan and Winkelstein, 1994).

#### Clinical expression

Approximately 40% of patients with C2 deficiency develop SLE or discoid lupus and approximately 50% develop recurrent infections (Ross and Densen, 1984; Ruddy, 1986; Figueroa and Densen, 1991). Some asymptomatic C2-deficient individuals have also been identified in studies of kindreds. The association of C2 deficiency with SLE is believed to be due to the compromise in immune complex clearance that results when any of the early complement components is deficient (Davies et al., 1993). SLE patients with C2 deficiency possess immune complexes that contain increased amounts of C4 but lack C3 (Garred et al., 1990). In the absence of C3, the immune complexes are not cleared efficiently. Direct identification of immune complex deposition in C2-deficient individuals has determined that splenic uptake is markedly impaired (Davies et al., 1993). Normalization of serum complement after the administration of fresh-frozen plasma returned the immune complex clearance to normal. For this reason, fresh-frozen plasma infusions have been advocated by some investigators for the treatment of SLE in complement-deficient individuals (Steinsson et al., 1989).

Although patients with C2 deficiency express many of the characteristic features of lupus, severe nephritis, cerebritis, and aggressive arthritis are less common than in complement-sufficient SLE patients. However, cutaneous lesions are common in C2-deficient patients with lupus, and many have a characteristic annular photosensitive rash. Patients with C2 deficiency and SLE have a lower incidence of anti-DNA and antinuclear antigen antibodies than do other SLE patients (Glass et al., 1976; Provost

et al., 1983; Meyer et al., 1985), but their incidence of anti-Ro antibodies is higher (Provost et al., 1983; Meyer et al., 1985). A variety of other rheumatic disorders have also been described in C2 deficiency, including glomerulonephritis, dermatomyositis, anaphylactoid purpura, and vasculitis (Ross and Densen, 1984; Figueroa and Densen, 1991).

The bacterial infections seen in patients with C2 deficiency are usually systemic infections (e.g., sepsis and meningitis) with encapsulated organisms (i.e., pneumococcus and *H. influenzae*) and are more common in childhood (Fasano et al., 1990). The infections are thought to result from impaired opsonization of the organism due to the absence of C2 cleavage of C3, although their impaired humoral immune response may also contribute (Ochs et al., 1983).

#### Animal model

C2-deficient guinea pigs were a valuable early model for investigating the role of complement in opsonization. Early gene mapping experiments demonstrated linkage of the mutant C2 in guinea pigs with MHC (Bitter-Suermann et al., 1981).

### C3 Deficiency

#### Molecular biology and pathophysiology

The gene for C3 is located on chromosome 19 (Whitehead et al., 1982). It is produced as a single polypeptide precursor that is processed to yield two disulfide-linked chains. C3 is the most abundant of the complement components in plasma and plays a pivotal role in generating most of the biologically significant activities of the complement system. Most of serum C3 is produced by the liver (Alper et al., 1969), but C3 is also generated by endothelial cells, fibroblasts, renal tubular cells, endometrium, lymphocytes, and neutrophils (Colten, 1992).

Twenty patients with C3 deficiency (MIM 120700) have been described to date (Ross and Densen, 1984; Figueroa and Densen, 1991; Singer et al., 1994a). Total serum hemolytic complement activity and the levels of serum C3 antigen and hemolytic activity are markedly reduced. As a result, those serum activities that are directly related to C3 (e.g., opsonizing activity) or indirectly related to C3 because of its role in activating C5–C9 (e.g., anaphylatoxic, chemotactic, and bactericidal activity) are also markedly reduced. In a limited number of cases the molecular genetic defect has been identified. The first C3-deficient patient to be examined was found to have a mutation in the 5' donor splice site of intron 18, resulting in partial deletion of exon 18, activation of a cryptic splice site in exon 18, frameshift, and a premature stop codon (Botto et al., 1990). The second C3-deficient patient has a donor splice site mutation in intron 10 (Huang and Lin, 1994). An interesting mutation affecting the maturation of proC3 to mature C3 (Singer et al., 1994b), due to a point mutation in exon 13, results in an amino acid substitution that blocks the maturation of intracellular C3. Finally, an Afrikaans-speaking patient was found to have an 800 bp deletion thought to be due to homologous recombination between two Alu repeats flanking the deletion (Botto et al., 1992). This 800 bp deletion has been found with a relatively high gene frequency (0.0057) in the Afrikaans-speaking South African population (Botto et al., 1992).

#### Clinical expression

Infection is the most significant clinical finding in C3-deficient individuals (Ross and Densen, 1984; Figueroa and Densen, 1991;

Singer et al., 1994a). Meningitis, osteomyelitis, sepsis, and pneumonia are all common. The typical organisms include encapsulated bacteria such as pneumococcus, *Haemophilus influenzae*, and *Neisseria* species. Patients tend to present early in life with recurrent severe infections. The severity of the infections emphasizes the important physiologic role of C3 as an opsonin, particularly in early childhood.

Approximately 25% of C3-deficient patients also have rheumatic diseases (Ross and Densen, 1984; Figueroa and Densen, 1991; Singer et al., 1994b). Some patients have had a syndrome involving multiple organs that closely resembles systemic lupus erythematosus. In other patients, the rheumatic disease has involved the kidney and most closely resembles membranoproliferative glomerulonephritis with mesangial cell proliferation, an increase in the mesangial matrix, and electron-dense deposits in both the subendothelium of capillary loops and the mesangium. Still other patients have had isolated vasculitic skin rashes. The predilection for rheumatic diseases may relate to the role of C3 in the clearance of immune complexes. In fact, circulating immune complexes have been found in some C3-deficient patients with rheumatic diseases, but not in all.

#### Animal model

Dogs with genetically determined C3 deficiency were discovered in 1981 (Winkelstein, 1981). Affected animals have both an increased susceptibility to infection and membranoproliferative glomerulonephritis, thereby resembling closely their human counterparts (Blum et al., 1985; Cork et al., 1991). The C3-deficient dog has been useful in demonstrating the role C3 plays in a variety of physiologic functions such as the generation of a normal antibody response (O'Neil et al., 1988) and in resistance to endotoxic shock and multiple organ failure (Quezado et al., 1994). C3-deficient guinea pigs produce normal intracellular C3 and approximately 5% of normal serum levels of C3. They have been useful in demonstrating the importance of C3 in bactericidal activity (Burger et al., 1986). A C3-deficient knockout mouse is most remarkable for impaired humoral responses but has also been noted to have increased mortality after endotoxin challenge (Fischer et al., 1996; Ma et al., 1996; Prodeus et al., 1996; Reid et al., 1996). Recently the role of complement in mast cell-dependent natural immunity was studied in C3-deficient knockout mice (Prodeus et al., 1997). C3-deficient mice were much more sensitive to cecal ligation and puncture than wild-type controls. C3-deficient mice also exhibited reductions in peritoneal mast cell degranulation, production of tumor necrosis factor (TNF), neutrophil infiltration, and clearance of bacteria.

### C5 Deficiency

#### Molecular biology and pathophysiology

C5 consists of two disulfide-linked polypeptide chains transcribed from a single gene located on the long arm of chromosome 9. C5 is distantly related to C3, C4, and  $\beta$ 2-macroglobulin, although C5 does not share the internal reactive thiolester bond (Carney et al., 1991). The liver is the major source of serum-derived C5, although macrophages, lung, intestine, and lymphocytes also produce it.

Approximately 30 patients with C5 deficiency (MIM 120900) have been described. Patients with C5 deficiency have decreased total hemolytic complement activity and very little C5 functional activity. Consequently, their serum is unable to generate any

chemotactic or bactericidal activity. In three African-American patients, the mutations in one allele have been identified. Two patients from unrelated kindreds had a nonsense mutation in exon 1, and the third patient had a nonsense mutation in exon 36 (Wang et al., 1995). The patients represent compound heterozygotes for C5 deficiency. None of these mutations were identified in four Caucasian C5-deficient patients. Therefore, it appears that diverse mutations are associated with C5 deficiency.

#### Clinical expression

The most common clinical manifestation of C5 deficiency has been an increased susceptibility to neisserial infections (Ross and Densen, 1984; Figueroa and Densen, 1991). Recurrent meningococcal infections are the most common, although systemic gonococcal infections are also seen. One C5-deficient patient developed SLE, but it is not clear that this represents a true association between C5 deficiency and lupus (Figueroa et al., 1993).

#### Animal model

A number of inbred strains of mice have been found to have a complete deficiency of C5 (Rosenberg and Tachibana, 1962). Mice deficient in C5 have been of value in defining the relative role of C5 in generating a local inflammatory response in a variety of organs (Snyderman et al., 1971).

### C6 Deficiency

#### Molecular biology and pathophysiology

The genes for C6 and C7 lie in a tail-to-tail orientation at a distance apart of approximately 150 kb on chromosome 5 (Setien et al., 1993). C6 contains several thrombospondin repeat motifs that probably function in protein-protein and protein-phospholipid interactions during the assembly of the membrane attack complex and shares considerable homology with C7, C8, and C9 (Chakravarti et al., 1989). The liver produces most of the serum C6.

C6 deficiency (MIM 217050) is one of the more common complement deficiencies (Ross and Densen, 1984; Figueroa and Densen, 1991). Its prevalence among African Americans has been estimated to be as high as 1 in 1600 (Zhu et al., 2000), while its prevalence among Asians and Europeans is significantly less (Inai et al., 1999). The most common form of C6 deficiency is characterized by undetectable serum levels of C6 and absent serum bactericidal activity. The basis for complete C6 deficiency has been determined in three unrelated North American patients of African-American and Japanese ancestry (Nishizaka et al., 1996a; Zhu et al., 1996). One African-American patient was homozygous for a single base-pair deletion in exon 12 that results in a frameshift and premature termination. A second African-American patient was heterozygous for the same exon 12 deletion and a single base-pair deletion in exon 7. The third patient was a compound heterozygote with a deletion of four nucleotides on one chromosome and an undefined defect on the other chromosome. Complete C6 deficiency occurs most frequently in South Africa, where haplotype determinations of flanking genes have demonstrated that the majority of C6\*Q0 alleles in this population arose from the same distant ancestor (Ferne et al., 1994, 1995). However, in a minority of cases, the C6\*Q0 allele was found on a different haplotype, suggesting that there is some diversity even in this population. These haplotype determinations have been used to identify carriers in individual families.

Another form of C6 deficiency has also been described. Subtotal deficiency of C6 (C6SD for C6 subtotal deficiency) is characterized by 1%–2% of normal serum levels of C6 (Wurzner et al., 1995a). The molecular genetic basis for this deficiency is a loss of the splice donor site of intron 15 and premature termination (Wurzner et al., 1995a). Although the mutated C6 protein is truncated, it can be incorporated into the membrane attack complex, where it supports lytic activity to some degree. None of the C6SD patients have had recurrent infections. C6SD has also been seen in association with subtotal C7 deficiency (Ferne et al., 1995, 1996c) and is the result of two independent mutations.

#### Clinical expression

Individuals with genetically determined C6 deficiency most commonly present with systemic blood-borne meningococcal infections (Ross and Densen, 1984; Figueroa and Densen, 1991). Disseminated gonococcal infections have also been described. Although the terminal complement components do not appear to participate in the clearance of immune complexes, a few C6-deficient patients have been identified with SLE. Whether this is due to an ascertainment bias of complement-deficient individuals within populations of patients with SLE or to an association based on pathophysiology is not known.

#### Animal model

Genetically determined C6 deficiency has been described in rats (Leenarts et al., 1994) and rabbits (Rother et al., 1966). These animals have been especially valuable in demonstrating that extrahepatic synthesis of complement can contribute significantly to some of the biologic functions of the complement system (Brauer et al., 1995).

### C7 Deficiency

#### Molecular biology and pathophysiology

The gene for C7 is linked to that for C6 and C9 on chromosome 5 (Setien et al., 1993). Like C6 and C9, it contains protein domains with homology to thrombospondin, low-density lipoprotein receptor, and the epidermal growth factor receptor (Hobart et al., 1995). Although the liver is the major site of synthesis of C7, a significant amount of serum C7 is derived from synthesis by bone marrow–derived cells (Naughton et al., 1996).

Patients with C7 deficiency (MIM 217070) have markedly diminished total hemolytic complement activity, little if any C7 in their serum, and markedly reduced serum bactericidal activity. A number of different mutations have been found to be responsible for complete C7 deficiency (Nishizaka et al., 1996b; Fernie et al., 1997; Fernie and Hobart, 1998; O'Hara et al., 1998; Horiuchi et al., 1999), although mutations consistent with two independent founders are present in the Irish and Sephardic Jews from Morocco (Ferne et al., 1996a, 1997; O'Hara et al., 1998). A second type of C7 deficiency has been described in which the quantity of C7 is diminished. This has also been seen in association with C6SD. This defect is due to a missense mutation in exon 11, which results in an arginine-to-serine change (Ferne et al., 1996b).

#### Clinical expression

Systemic neisserial infections are the most common clinical expression of C7-deficient individuals (Ross and Densen, 1984; Figueroa and Densen, 1991). However, patients with C7 deficiency have also had SLE, rheumatoid arthritis, pyoderma gan-

grenosum, and scleroderma. The relationship of autoimmune disease to C7 deficiency is not entirely clear.

### C8 Deficiency

#### Molecular biology and pathophysiology

C8 is composed of three polypeptide chains ( $\alpha$ ,  $\beta$ , and  $\gamma$ ), each encoded by distinct genes (*C8A*, *C8B*, and *C8G*). *C8A* and *C8B* are found on the short arm of chromosome 1 while *C8G* is located on the long arm of chromosome 9 (Kaufman et al., 1989). The  $\alpha$  and  $\beta$  chains are covalently linked to form one subunit ( $C8\alpha\beta$ ), which is joined by noncovalent bonds to the other subunit ( $C8\gamma$ ).

Two types of C8 deficiency (MIM 120950, 120960) exist, and both result in loss of total hemolytic complement activity.  $C8\beta$  deficiency is more common in Caucasians and  $C8\alpha\gamma$  deficiency is more common in African Americans. In the case of  $C8\beta$  deficiency, C8 antigen can be detected in the patient's serum using standard immunochemical techniques, since these patients possess the  $C8\alpha\gamma$  subunit. In either form of C8 deficiency, serum C8 functional activity and bactericidal activity are markedly reduced. The overwhelming majority (86%) of *C8B*-null alleles are due to a C-T transition in exon 9, producing a direct premature stop codon (Saucedo et al., 1995). Three additional C-T transitions and two single base-pair deletions causing a frameshift and premature stop codons have also been identified in  $C8\beta$  deficiency (Saucedo et al., 1995). An allele-specific PCR system has been used to detect heterozygous carriers of the common  $C8\beta$  mutation. The molecular basis of  $C8\alpha\beta$  deficiency has been identified in three patients. In five of the six alleles, a 10 bp insertion in *C8A* resulting in a premature stop codon occurs as a result of an intronic mutation that alters the splicing of exons 6 and 7 (Densen et al., 1996a).

#### Clinical expression

Meningococcal meningitis and disseminated gonococcal infections have been the predominant clinical expression of C8 deficiency (Fig. 42.3) (Ross and Densen, 1984; Figueroa and Densen, 1991), reflecting the inability of C8-deficient serum to generate cytolytic activity.

**Figure 42.3.** Meningococcal sepsis in a patient with C8 deficiency. Inherited deficiencies of terminal complement components are associated with an increased risk of meningococcal disease. This patient with C8 deficiency developed meningococcal meningitis and sepsis. (Courtesy of Peter Densen, M.D.)

## C9 Deficiency

### Molecular biology and pathophysiology

C9 is a 70 kDa glycoprotein that has sequence homology to C8 $\alpha$ , C8 $\beta$ , C6, and perforin. The C9 gene lies approximately 2.5 megabase pairs (mbp) from the C6 and C7 genes on chromosome 5. C9 is produced by hepatocytes and is highly developmentally regulated (Lassiter et al., 1994).

Although C9 deficiency (MIM 120940) is relatively common among individuals of Japanese descent, with an estimated prevalence of 1 in 1000 (Horiuchi et al., 1998), it is relatively uncommon in Occidentals (Ross and Densen, 1984; Figueroa and Densen, 1991). Patients with C9 deficiency have markedly reduced levels of C9 in their serum. Because the complex of C5b, C6, C7, and C8 can form small unstable pores in biomembranes, patients with C9 deficiency possess some serum hemolytic and bactericidal activity, although less than in normal serum (Petersen et al., 1976; Inai et al., 1979; Lint et al., 1980; Harriman et al., 1981). The molecular genetic basis for C9 deficiency in individuals of Japanese descent is a nonsense mutation in exon 4 (Horiuchi et al., 1998). In addition, two different point mutations in exons 2 and 4 resulted in direct premature stop codons in a Swiss kindred (Witzel-Schlomp et al., 1997).

### Clinical expression

C9-deficient patients are often asymptomatic, although some patients with C9 deficiency have presented with systemic meningococcal infections (Ross and Densen, 1984; Figueroa and Densen, 1991). A large epidemiologic study in Japan, where C9 deficiency is relatively common, firmly established that there is a relationship between C9 deficiency and systemic meningococcal infections (Nagata et al., 1989). However, the relationship between C9 deficiency and neisserial disease may not be as strong as it is with other terminal complement component deficiencies, reflecting the partial serum bactericidal activity in C9-deficient patients.

## Factor B Deficiency

### Molecular biology and pathophysiology

Factor B is a serine protease that is highly homologous to C2. The gene for factor B is part of the HLA class III region on chromosome 6. Factor B, like C2, carries the active enzymatic site for the subsequent cleavage of C3 and C5 and is expressed primarily in hepatocytes and monocytic cells. A single factor B-deficient patient has been described, and the basis for that patient's factor B deficiency is not yet understood (Densen et al., 1996b).

### Clinical expression

The factor B-deficient patient presented with meningococcemia and was found to have a mildly decreased classical pathway activity and no detectable alternative pathway activity. No functional factor B was detected, and factor B protein had an abnormal molecular weight (Densen et al., 1996b). The association of factor B with meningococcemia is probably not coincidental since most alternative pathway deficiencies are associated with meningococcal disease.

### Animal model

A factor B-deficient knockout mouse model has been developed (Matsumoto et al., 1996). Unlike mice deficient in classical path-

way components, this mouse model demonstrates normal humoral function, suggesting that the alternative pathway does not significantly augment humoral responses.

## Factor D Deficiency

### Molecular biology and pathophysiology

Factor D is identical to adipsin and, unlike other complement components, is not synthesized in the liver but rather in adipocytes, muscle cells, lung, and monocytes/macrophages (White et al., 1992). The precise genetic locus for factor D has not been identified but it maps to chromosome 19.

Only a few kindreds with factor D deficiency (MIM 134350) have been identified and its mode of inheritance has not been firmly established, although it is most consistent with an autosomal recessive trait. In one family, monozygous twins were found to have only 8% of the normal levels of factor D (Kluin-Nelemans et al., 1984), whereas in another family, factor D was undetectable in the proband and present at approximately 50% of normal in the mother (Hiemstra et al., 1989). In all patients identified to date, alternative pathway activity was absent while classical pathway complement activity was normal or near normal. The molecular genetic basis was determined in one family and has been found to be a mutation causing a premature stop codon (Biesma et al., 2001).

### Clinical expression

The patients with factor D deficiency have presented with recurrent sinopulmonary infections or recurrent systemic meningococcal or pneumococcal infections (Kluin-Nelemans et al., 1984; Hiemstra et al., 1989; Weiss et al., 1998).

## C1 Inhibitor Deficiency

### Molecular biology and pathophysiology

C1 inhibitor (C1INH) is encoded by a 17 kb gene on chromosome 11. The primary sequence of C1INH has been determined and it is homologous with other serine protease inhibitors such as  $\alpha_1$ -proteinase inhibitor,  $\alpha_1$ -antichymotrypsin, and anti-thrombin III (Bock et al., 1986).

There are two forms of C1INH deficiency (MIM 106100) and both are inherited as autosomal dominant traits (Rosen et al., 1965, 1971). In the most common form (type I), accounting for approximately 85% of the patients, the serum of affected individuals is deficient in both C1INH protein (5%–30% of normal) and C1INH functional activity (Rosen et al., 1971; Frank et al., 1976; Cicardi et al., 1982). In the other, less common, form (type II), a dysfunctional protein is present in normal or elevated concentrations, but the functional activity of C1INH is markedly reduced (Donaldson and Evens, 1963; Rosen et al., 1965; Frank et al., 1976; Cicardi et al., 1982). The lower than expected levels of C1INH functional activity in heterozygotes is thought to be the result of increased catabolism of the normal protein, although some patients may also demonstrate decreased synthesis (Ernst et al., 1996). In patients with type I C1INH deficiency, the diagnosis can be established easily by demonstrating a decrease in serum C1INH protein when assessed by immunochemical techniques. However, in patients with type II C1INH deficiency, the diagnosis must rest on demonstrating a decrease in C1INH functional activity. In either case, C4 levels are usually reduced below the lower limit of normal both during and between attacks

(Austen and Sheffer, 1965; Pickering et al., 1968; Frank et al., 1976; Cicardi et al., 1982) because of their uncontrolled cleavage by C1s, thus making their measurement useful as a diagnostic clue (Pickering et al., 1968; Frank et al., 1976).

The mediators responsible for producing the edema are incompletely understood. When purified C1s is injected into normal skin or skin of patients with C1INH deficiency, angioedema is produced (Klemperer et al., 1968). The intradermal response to C1s in C2-deficient individuals is diminished, whereas it is preserved in C3-deficient individuals, a result suggesting the direct involvement of C2 in the production of the angioedema. Other evidence suggests that the plasma kallikrein system may also be involved in the generation of the edema. C1INH inhibits the ability of activated Hageman factor to initiate kinin generation, and it inhibits kallikrein activation of the kinin system directly. Blister fluids from C1INH-deficient patients contain active plasma kallikrein, and their serum has decreased amounts of prekallikrein and kininogen (Curd et al., 1980), which suggests activation of the kinin system during attacks of edema. Furthermore, treatment with drugs that inhibit the release of vasoactive mediators is effective prophylaxis (Frank et al., 1972; Sheffer et al., 1972).

This division of C1INH-deficient patients into two forms has no correlation with clinical phenotype and only limited correlation with genotype, as there are some examples of *C1INH* gene mutations in which a dysfunctional protein is produced but is degraded so rapidly that it is not detectable in the serum (Agostoni and Cicardi, 1992; Davis et al., 1993). Alu-mediated deletions and duplications account for the most common genotypes (Stoppa-Lyonnet et al., 1991; Davis et al., 1993). Four of the seven introns in the *C1INH* gene (*C1NH*) contain a total of 17 Alu-repetitive DNA elements. These Alu elements are responsible for most of the large deletions and duplications leading to C1INH deficiency. A variety of single base changes and smaller deletions and duplications have also been identified (Davis et al., 1993). Most patients with detectable but dysfunctional C1INH have a mutation that replaces the reactive center arginine residue. The other mutations identified in patients with dysfunctional protein are found in the hinge region and result in blockade of the reactive center loop, thereby inactivating the C1INH (Davis et al., 1993; Verpy et al., 1995).

#### Clinical expression

Patients with C1INH deficiency most commonly present with recurrent angioedema, which has led to the commonly accepted clinical term for the disorder, *hereditary angioedema* (HAE) (Donaldson and Rosen, 1966; Frank et al., 1976; Oltvai et al., 1991; Agostoni and Cicardi, 1992; Agostoni et al., 1993; Cicardi et al., 1993). The angioedema involves the submucosa of the airway or gastrointestinal tract or the subcutaneous area of the skin. Although most patients present clinically in the first two decades of life, a significant minority of patients do not have symptoms until well into adult life. Since the disease is inherited as an autosomal dominant characteristic, most C1INH-deficient individuals have a family history of angioedema, which assists in establishing the correct diagnosis.

When the angioedema involves the skin it is neither pruritic nor painful. Although the edema is usually pale, there may be a seriginous rash that occurs with the angioedema. It should be noted that urticaria is not a manifestation of HAE. The edema may involve an extremity, the face, or the genitalia and usually progresses for 1–2 days and resolves in an additional 2–3 days.

Involvement of the gastrointestinal tract is very common, with nearly three-quarters of patients having a significant his-

tory of abdominal pain due to bowel wall edema (Frank et al., 1976). Additional clinical symptoms include anorexia and emesis and may occur in the absence of concurrent airway or cutaneous symptoms. Bowel wall edema is unusual in other forms of angioedema and is therefore very suggestive of C1INH deficiency.

The most feared complication in this disorder is edema of the upper airways (Color Plate 42.I). In one series, pharyngeal edema had occurred at least once in nearly two-thirds of the patients and tracheostomies had been performed in one out of every six patients (Frank et al., 1976). The patient may experience a feeling of tightness in the throat, followed by swelling of the tongue, buccal mucosa, and oropharynx. If the edema progresses to involve the larynx, there may be hoarseness and stridor followed by respiratory obstruction.

Although the biochemical mechanisms responsible for initiating attacks are not understood, many patients report that minor trauma or stress precipitates individual attacks. In addition, estrogens and angiotensin-converting enzyme inhibitors may precipitate attacks (Megerian et al., 1992; Agostoni et al., 1993). Exogenous estrogens reduce C1INH levels, as does pregnancy. Angiotensin-converting enzyme inhibitors reduce kinin metabolism and may facilitate angioedema. For therapy, see Management of Complement Deficiencies, below.

### Decay Accelerating Factor

#### Molecular biology and pathophysiology

Decay accelerating factor (DAF), also known as CD55, is a control protein of the classical and alternative pathways. It is a glycosyl phosphatidylinositol (GPI)-anchored membrane protein found on erythrocytes, lymphocytes, granulocytes, endothelium, and epithelium. It is encoded by a 35 kb gene in the RCA region of chromosome 1 (Lublin et al., 1987). The main function of DAF appears to be the protection of cells from complement-mediated cytolysis; however, it also plays a role in T cell and macrophage activation (Shenoy-Scaria et al., 1992; Hammann et al., 1999).

Five patients from three kindreds with DAF deficiency have been reported. A patient from one kindred had no detectable DAF. A single nucleotide substitution affecting codon 53 and resulting in a direct premature stop codon was found to be responsible for the complete deficiency of DAF in this patient who was born to consanguineous parents (Lublin et al., 1994). Members of the other two kindreds had some detectable DAF on the surface of their erythrocytes. In a DAF-deficient individual from one of these two kindreds, a point mutation was identified in one allele that altered antigenicity, and a second mutation, which resulted in utilization of a cryptic splice site that then altered the reading frame, was identified (Lublin et al., 1994).

#### Clinical expression

DAF deficiency (MIM 125240) is associated with the Inab phenotype (absence of all blood group antigens of the Cromer complex) (Telen and Green, 1989). DAF deficiency is not associated with spontaneous hemolysis, although DAF-deficient erythrocytes are moderately more susceptible to hemolysis when complement is activated via the classical pathway (Telen and Green, 1989). Two patients with the Inab phenotype have had severe protein-losing enteropathies, which is of uncertain relationship to the DAF deficiency (Telen and Green, 1989). These patients were originally identified on the basis of blood typing, rather than a specific infectious or rheumatic disease. Although DAF

plays an important role in the prevention of complement-mediated lysis of the individual's own cells, this function can also be served by CD59 and CR1 receptor. In fact, CD59 may play the more important role. Therefore, DAF deficiency may not be associated with any clinical consequences.

## Factor I Deficiency

### Molecular biology and pathophysiology

Factor I consists of two disulfide-linked polypeptides that act to regulate the alternative pathway-cleaving enzyme (C3b, Bb). One polypeptide carries serine protease activity that cleaves C3b to produce iC3b (inactive C3b), a C3-cleavage product that can not function in the C3-cleaving enzyme of the alternative pathway. Factor I is encoded by a gene on chromosome 4q.

Because patients with factor I deficiency (MIM 217030) are missing a major control protein of the alternative pathway, there is no control imposed on the assembly and expression of the alternative pathway C3-cleaving enzyme, C3b,Bb. As a result, there is continuous activation and cleavage of native C3 through the alternative pathway and the production of C3b (Alper et al., 1970a, 1970b; Abramson et al., 1971; Nicol and Lachmann 1973; Ziegler et al., 1975). Patients with factor I deficiency, therefore, have a secondary deficiency of C3 with markedly reduced levels of C3 in their serum, most of which is in the form of C3b (Alper et al., 1970b). Typically, total hemolytic activity of the serum, whether measured through the alternative or classical pathway, is very low or undetectable. Those serum activities that depend directly or indirectly on C3, such as opsonic, chemotactic, and bactericidal activities, are also markedly reduced (Alper et al., 1970b).

Factor I deficiency has been identified in a limited number of patients (Ross and Densen, 1984; Figueroa and Densen, 1991; Vyse et al., 1994). The genetic basis for factor I deficiency has been identified in four patients and found to be diverse (Vyse et al., 1994; Morley et al., 1996). In one patient, substitution of a histidine at position 400 to a leucine suggests that this amino acid is critical.

### Clinical expression

The most consistent clinical feature of factor I deficiency is an increased susceptibility to infection, with neisserial infections reported in approximately half of the patients (Ross and Densen, 1984; Figueroa and Densen, 1991; Vyse et al., 1994). The defect in opsonization also makes these patients susceptible to the same recurrent pyogenic infections, caused by *Streptococcus pneumoniae* and *Haemophilus influenzae*, seen in patients with primary deficiency of C3. Only two of the patients have been asymptomatic. One patient has died of a fatal vasculitis and another suffered from transient serum sickness (Vyse et al., 1994). Heterozygous mutations in factor I have been associated with atypical hemolytic uremic syndrome (Kavanagh et al., 2005).

## Factor H Deficiency

### Molecular biology and pathophysiology

The gene for factor H lies within the RCA gene cluster on chromosome 1 (Holers et al., 1985). Factor H is synthesized in hepatocytes, macrophages, B cells, endothelial cells, and platelets. Factor H, like factor I, is an inhibitor of the alternative pathway. It competes with factor B for binding to C3b in the assembly of

the alternative pathway C3-cleaving enzyme, C3b,Bb, and also displaces Bb once the enzyme has been assembled.

In some families, serum factor H has been undetectable (Brai et al., 1988; Nielsen et al., 1989) whereas in other families factor H has been present but markedly reduced (Levy et al., 1986; Nielsen et al., 1989). Since deficiency of factor H (like factor I) leads to uncontrolled activation of the alternative pathway and C3 consumption, serum levels of C3 are reduced, and total hemolytic complement activity and alternative pathway complement activity are usually significantly reduced.

There have only been a few cases of complete factor H deficiency (MIM 134370) described (Ross and Densen, 1984; Figueroa and Densen, 1991; Sim et al., 1993). In only one of the cases has a specific genetic defect been identified. That patient was a compound heterozygote for two missense mutations affecting conserved cysteine residues (Ault et al., 1997). In another patient, PCR amplification of factor H cDNA recovered from Epstein-Barr virus (EBV)-transformed lymphocytes suggested that a truncated mRNA was produced; however, a specific mutation was not identified (Wurzner et al., 1995b).

### Clinical expression

Renal disease is the most common finding in complete factor H deficiency (Ross and Densen, 1984; Figueroa and Densen, 1991; Vyse et al., 1994). Glomerulonephritis, IgA nephropathy, and hemolytic uremic syndrome have been described in humans with factor H deficiency. Infections with neisserial species and encapsulated organisms are also common. In some kindreds, asymptomatic family members with factor H deficiency have been detected. Heterozygous mutations in factor H as is true for factor I and the transmembrane complement regulator membrane co-factor protein (MCP), are associated with atypical hemolytic uremic syndrome (Sanchez-Corral et al., 2002). A heterozygous or homozygous polymorphism of factor H (Y402H) is responsible for almost 50% of age-related macular degeneration (Edwards et al., 2005; Haines et al., 2005; Klein et al., 2005).

### Animal model

A porcine strain with factor H deficiency spontaneously develops membranoproliferative renal disease (Hogasen et al., 1995). In the porcine model, deposition of complement components occurs along the capillary walls of the renal glomeruli, as is seen in human renal disease associated with factor H deficiency.

## Properdin Deficiency

### Molecular biology and pathophysiology

The gene for properdin is the only gene of the complement system that is located on the short arm X chromosome. It encodes a protein with six thrombospondin repeat units that circulates as cyclic oligomers of 53 kDa subunits (Nolan et al., 1991). Properdin is synthesized by monocytes, hepatocytes, and T cells, and it is a component of the secondary granule in neutrophils. Properdin acts to stabilize the alternative pathway enzymes that activate C3 and C5.

Properdin deficiency (MIM 312060) is inherited as an X-linked recessive trait. In some families, properdin is undetectable (Sjoholm et al., 1982; Densen et al., 1987), whereas in others, affected males may have levels as high as 10% of normal (Nielsen and Kock, 1987; Sjoholm et al., 1988b). In still other kindreds, serum levels of antigenic properdin are normal but the

protein is dysfunctional (Sjoholm et al., 1988a). The serum of patients with properdin deficiency is unable to support the activation of C3 via the alternative pathway. Serum bactericidal activity for some strains of the meningococcus is reduced in properdin-deficient serum.

Mutations have been identified in five properdin-deficient patients. Three patients with no detectable serum properdin had mutations resulting in early stop codons (Westberg et al., 1995; Fredrikson et al., 1996; Spath et al., 1999). In kindreds in whom low levels of properdin were detected, different mutations were identified that resulted in amino acid substitutions (Westberg et al., 1995). One kindred with normal levels of dysfunctional properdin had a single base-pair mutation in exon 9 resulting in the substitution of aspartic acid for tyrosine, rendering the molecule unable to interact with C3b (Fredrikson et al., 1996).

#### Clinical expression

Approximately 50% of the patients with properdin deficiency have had meningococcal disease (Ross and Densen, 1984; Figueroa and Densen, 1991), emphasizing the importance of the alternative pathway in host defense against *Neisseria*. Isolated cases of SLE and discoid lupus have also been described.

### CD59 Deficiency

#### Molecular biology and pathophysiology

CD59 (HRF 20, membrane inhibitor of reactive lysis) is a 20 kDa GPI-anchored glycoprotein that inhibits lysis by C8 and C9 in a species-specific fashion. It is widely expressed on erythrocytes, leukocytes, and endothelial cells, where it functions to prevent intravascular complement attack (Lehto and Meri, 1993).

A single patient with inherited CD59 deficiency (MIM 107271) has been described (Yamashina et al., 1990). He was homozygous for a CD59 gene bearing two mutations in codons 16 and 96 (Motoyama et al., 1992). This form of CD59 deficiency is distinct from paroxysmal nocturnal hemoglobinuria, which is an acquired deficiency of all GPI-anchored cell surface proteins.

#### Clinical expression

The CD59-deficient patient was the product of a consanguineous marriage. He presented with recurrent hemolytic anemia as a child and recurrent cerebral infarctions (Yamashina et al., 1990). Studies of four GPI-anchored proteins, which are typically lost in paroxysmal nocturnal hemoglobinuria, revealed normal levels of all except for CD59. CD59 was absent from the surface of his erythrocytes and fibroblasts. His mother and father expressed half-normal levels, a finding suggesting autosomal recessive inheritance. The recurrent hemolytic anemia reflects the important role of CD59 in the prevention of homologous complement attack.

### Mannose Binding Lectin Deficiency

#### Molecular biology and pathophysiology

Mannose binding lectin (MBL), also sometimes referred to as mannose binding protein (MBP), is composed of a trimer, each chain of which contains a collagen-like region, cysteine repeats, and a lectin domain (Sastri et al., 1989). MBL binds to carbohydrates such as acetylglucosamine and mannose found on both gram-negative and gram-positive bacteria more avidly than to

other sugars. MBL circulates with MBL-associated serine proteases (MASP1 and MASP2) that activate C4 and C2 and ultimately C3.

There are five polymorphic bases in MBL that affect serum concentrations of MBL. Three of these polymorphic bases affect the collagen-like region of the molecule at codon 54 (structural allele *B*), codon 57 (structural allele *C*) and codon 52 (structural allele *D*) and are associated with markedly reduced serum levels of MBL because of decreased stability of the higher-order forms (Madsen et al., 1995). Two other polymorphic variants occur in the promoter region of the gene and are also associated with markedly reduced serum levels of MBL (Madsen et al., 1995). The gene frequency of each of these polymorphisms has recently been defined in several different populations, and four of the polymorphisms have been found with high frequency in at least one population. For example, the codon 54Asp polymorphism is found with a gene frequency of 0.13–0.19 in Caucasians, compared to 0.03 in West Africans, and the codon 57Glu variant is found with a gene frequency of 0.23–0.29 in West Africans, compared to 0.02 in Caucasians (Madsen et al., 1994, 1995; Babovic-Vuksanovic et al., 1999). The two polymorphic promoter variants are in linkage disequilibrium and exist as three haplotypes present in varying proportions in different populations. Because of the high frequency of these polymorphic variants in some populations, it is not uncommon to have homozygous deficient individuals. On the basis of studies that correlated serum levels of MBL with the genotype of the donor, it has been found that the structural variants have a dominant negative effect; however, the promoter variants are autosomal codominant.

#### Clinical expression

MBL deficiency (MIM 154545) is associated with an increased frequency of infection in both adults and children (Sumiya et al., 1991; Summerfield et al., 1995; Kakkanaiah et al., 1998). It has also been found with increased frequency in patients with SLE (Davies et al., 1995; Sullivan et al., 1996).

### Diagnosis of Complement Deficiencies

Most of the deficiencies of the classical pathway (C1 through C9) can be detected by using a hemolytic assay that assesses the functional integrity of the pathway. The most common of these, the CH<sub>50</sub> assay, determines the ability of the patient's serum to lyse antibody-sensitized sheep erythrocytes. Since lysis depends on the functional integrity of the complete cascade, patients who have severe deficiencies of any of the individual components of the classical pathway will usually have less than 5% of normal total serum hemolytic activity. One exception is C9 deficiency. Because lysis of antibody-sensitized erythrocytes can occur in the absence of C9 (Stolfi, 1968), albeit to a lesser degree, patients with C9 deficiency have some total serum hemolytic activity, but usually between 30% and 50% of the normal level.

Deficiencies of components of the alternative pathway (factors B, H, I, and properdin) can be detected by using a hemolytic assay that tests the functional activity of the alternative pathway (AH50). The most common of these use rabbit erythrocytes, which are potent activators of the human alternative pathway (Polhill et al., 1978). Thus, patients with deficiencies of components of the alternative pathway, as well as patients with deficiencies of C5–C9, will fail to lyse rabbit erythrocytes.

Identification of the specific component that is deficient usually depends on both functional and immunochemical tests. Highly specific functional assays are available for each compo-

nent (Nelson et al., 1966). In each case, they depend on reagents that lack the specific component in question but provide the other components of the appropriate hemolytic pathway in excess. Monospecific antibodies are also available for each of the components and can be used in a variety of immunochemical assays to assess the presence or absence of the component in question. In most instances, the component will be deficient when assessed by both functional and immunochemical methods. However, there are some important exceptions. One form of C1 esterase inhibitor deficiency and one form of C1q deficiency are characterized by dysfunctional proteins that are present in immunochemical assays but are reduced in functional assays. In addition, patients with C8 deficiency lack the  $\beta$  chain but possess the  $\alpha$  and  $\gamma$  chains and may therefore have some antigenic C8 while lacking C8 function.

## Management of Complement Deficiencies

The management of complement deficiencies is usually limited to supportive care and relates to the clinical manifestations that are secondary to the specific deficiency.

### Prevention of Infectious Diseases

Two strategies have been attempted to reduce complement-deficient patients' susceptibility to infections and/or modify the clinical course of the infections. One strategy is to immunize these patients against common bacterial pathogens such as *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Neisseria meningitidis*. Unfortunately, there are important factors that may limit the utility of immunizations in these patients in preventing infections. For example, when patients with C4 or C2 are immunized with neoantigens, such as  $\phi$ X 179, their primary response is limited and their secondary response is delayed with reduced isotype switching (Ochs et al., 1983). Other studies have shown that while initial responses to immunization against *Neisseria meningitidis* are normal in patients with deficiencies of C5–C9, their titers fall more dramatically than in complement-sufficient individuals (Andreoni et al., 1993; Biselli et al., 1993; Schlesinger et al., 1994, 2000). Therefore, it is possible that complement-deficient patients require more frequent immunization than a normal host (Fijen et al., 1998). Another limitation to the use of immunizations in complement-deficient patients is that the vaccines may not include all of the serotypes to which complement-deficient patients are susceptible. For example, the new pneumococcal conjugate vaccine is limited to seven serotypes and the meningococcal vaccine contains only serotypes A, C, Y and W.

A second strategy in the prevention of infection is the use of prophylactic antibiotics. Because patients with complement deficiencies have a high risk for recurrent episodes of blood-borne infections and because immunizations may not afford them complete protection, some patients have been placed on antibiotic prophylaxis. However, any recommendation for antibiotic prophylaxis must be viewed in the context of the emergence of antibiotic resistance among bacteria.

### Management of Rheumatic Disorders

Regardless of the rheumatologic disorder, it is most often treated with the same immunosuppressive agents and anti-inflammatory medications as those used in a complement-sufficient patient. In a series of patients with C2 deficiency in Iceland and Great Britain, however, fresh-frozen plasma was used to treat the clinical signs of SLE (Steinsson et al., 1989; Hudson-Peacock et al.,

1997). There were concerns that the provision of additional complement components would accelerate deposition in end organs and exacerbate the inflammation. This was not the case in the two patients for whom this treatment has been attempted. In fact, nearly all clinical indicators improved on this regimen. Although it has only been used in a small number of patients, it is an attractive modality for those complement-deficient patients who are refractory to standard management or who have not done well on immunosuppression.

## Management of Angioedema

Treatment of C1INH deficiency is different from that of other complement deficiencies in that there are specific measures available to ameliorate symptoms and prevent recurrences. In some patients, episodes of angioedema may occur frequently enough or be so difficult to manage as to justify long-term prophylaxis. Attenuated androgens such as stanozolol or danazol are highly effective (Gelfand et al., 1976) and act by increasing transcription of the normal allele of *C1INH* (Agostoni et al., 1993). Another class of agents used for long-term prophylaxis is the antifibrinolytics agents (Frank et al., 1972; Sheffer et al., 1972). Tranexamic acid and aminocaproic acid act by blocking plasmin generation. Although their efficacy is less than that of attenuated androgens, their incidence of side effects is also less than that of attenuated androgens. For this reason, these agents may be preferred in childhood.

In some instances, patients may require short-term prophylaxis for surgery or oral procedures. Attenuated androgens, fibrinolytic agents, fresh-frozen plasma, and C1 esterase concentrate have all been used successfully for short-term prophylaxis (Agostoni et al., 1993).

C1 esterase inhibitor concentrate is the most effective agent for the treatment of acute attacks (Agostoni et al., 1993; Waytes et al., 1996). However, it is not yet approved for use in the United States, and its use is usually restricted to life-threatening situations. Epinephrine, antihistamines, and corticosteroids are of no proven benefit in C1INH-deficient patients.

## Assessment of the Immune System

HELEN M. CHAPEL, SIRAJ MISBAH, and A. DAVID B. WEBSTER

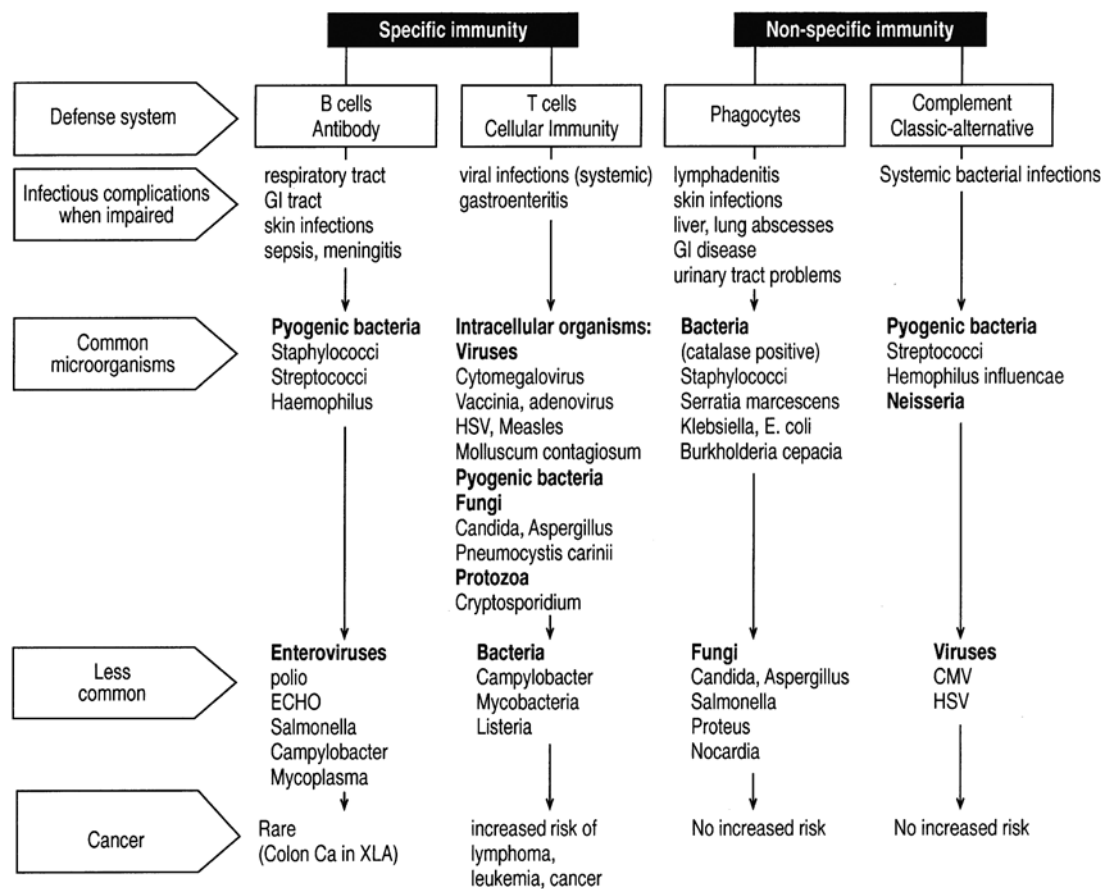

Progress in clinical and molecular immunology has heightened the awareness of primary immune deficiency diseases (PIDD) and improved the diagnostic options and therapeutic choices available to physicians and clinical immunologists. Since many immunodeficiency syndromes can be treated or even cured, early diagnosis is of prime importance. As more physicians become familiar with the clinical and laboratory findings of these syndromes, PIDD patients will live longer and have better-quality lives. The most common reason for diagnostic delay is still lack of awareness of medical advisers and diagnostic centers; a widespread misconception is that PIDDs occur predominantly in children, whereas most of these syndromes present in individuals over 10 years of age. The presenting features, usually an excess of infections, are similar in patients of all ages.

Prime candidates for evaluation of the immune system are patients with recurrent or severe infections or those with infections that fail to respond appropriately to antibiotic therapy. Infants with failure to thrive and patients who develop fevers, suffer from diarrhea or malabsorption, or present with opportunistic infections are also candidates, as are those, especially adults, with chronic obstructive pulmonary disease often associated with bronchiectasis. Finally, patients with recurrent skin infections, poor wound healing, cold staphylococcal abscesses, or persistent or recurrent periodontitis; patients with recurrent neisserial infections; and those with clinical symptoms and findings of syndromes associated with abnormal immune functions—for example, thrombocytopenia and small platelets, albinism, or ataxia-telangiectasia—should also have their immune system evaluated. The diagnostic approach, from a practical point of view, is influenced not only by clinical criteria but also by other factors including age, gender, ethnic background, and consanguineous marriage. Molecular evaluation, if leading to a diagnosis, may allow the identification of carrier females and prenatal

diagnosis. It is extremely important to test infants and children born to families known to have members with PIDD, including siblings or close relatives that fit the pattern of X-linked recessive, autosomal recessive, or autosomal dominant inheritance.

In this chapter, we will discuss the general principles of diagnosis of defects in different parts of the immune system. These are guided by the underlying etiology, involving antigen-specific immunity caused by defective B and T cell function or defects of the innate, non-antigen-specific immune system, such as defects of phagocyte and complement functions. We then go on to outline the diagnostic approach to the individual immune deficiency diseases. Both single-gene defects, which are covered in detail in preceding chapters, and disorders not well defined either phenotypically or genetically—for example, common variable immunodeficiency (see Chapter 23), IgG subclass deficiencies, and hyper-IgE syndrome (see Chapter 34)—are included in this chapter.

A rational approach is presented in Figure 43.1. The type of infectious agent(s) identified in a given patient gives a clue to the type of immune defect. Recurrent bacterial infections are associated with a B cell deficiency, as protection from gram-positive and gram-negative organisms depends on specific antibodies that act as opsonins. In such patients, B cell function and the ability to produce antibody are investigated first. If a patient presents with recurrent neisserial infections, assessment of the complement system is high on the list. Early-onset *Pneumocystis carinii* (recently renamed *jiraveci*) pneumonia (PCP) is a telltale sign of a severe T cell deficiency/abnormality, such as severe combined immune deficiency (SCID) or X-linked hyper-IgM syndrome (and, of course, HIV). Recurrent skin infections with staphylococci, *Serratia marcescens*, or candida suggest a neutrophil defect. The discovery of an unusual infectious agent, such as enterovirus-induced dermatomyositis or encephalitis, points to the diagnosis of X-linked agammaglobulinemia or one of the common variable

**Figure 43.1.** Types of infection and risks of malignancy in primary immune deficiencies affecting different defense systems

immunodeficiency disorders (CVID). As yet unrecognized but particular patterns of infections may prove to be associated with one of the newly recognized defects in innate immunity, such as Toll-like receptor pathway defects.

The age of presentation is also a helpful indicator for the likely diagnosis. Many primary immune deficiencies are caused by a single gene defect (see Chapter 1) and present in infancy or early childhood. However, certain genetic mutations may give rise to less severe disease, a so-called leaky phenotype, with presentation later in life. Others are “acquired” and probably depend on a combination of environmental factors and susceptibility genes, presenting in young adulthood or middle age. Adult patients should be tested for a range of PIDDs, including gene analysis for single gene defects known to have a particular clinical phenotype, as this will influence management and genetic counseling. The so-called acquired PIDDs are diagnoses of exclusion (Conley et al., 1999; Stiehm et al., 2004).

To provide a standard approach to diagnosis, criteria for each of the most common PIDDs have been devised on a collaborative basis between the European and Pan American groups for Primary Immunodeficiencies (see Table 43.1 and European Society for Immunodeficiencies [ESID] Web site provided at the end of the chapter). These criteria use a combination of clinical, laboratory, and molecular features to define a particular diagnosis as definite, probable, or possible.

Patients with a definitive diagnosis are assumed to have a >98% probability that in 20 years they will still be given the same diagnosis (Conley et al., 1999). Since a mutation does not change, there is an assumption that mutation detection is the most reliable method of making a definitive diagnosis. In patients with mutations that re-

sult in the absence of the specific mRNA or protein, the diagnosis can be established by appropriate testing; in others, the mRNA and/or protein may be transiently expressed, produced at very low levels, or be present and nonfunctional. For most diseases functional assays have not yet been developed. To guard against the inclusion of patients who have polymorphic variants in the genes associated with immunodeficiency, the patient must fulfill all the

**Table 43.1.** Primary Immunodeficiency Diseases for Which There Are Diagnostic Criteria

<i>Definite*</i>
Severe combined immunodeficiency (SCID) due to mutations of $\gamma$ c, Jak3, Rag1, Rag2, <i>Artemis</i> , IL- $\gamma$ R, CD45, CD38, ADA, ZAP-70
DiGeorge syndrome (due to 22q11.2 deletion)
MHC class II deficiency (due to mutations of <i>CIITA</i> , <i>RFxANK</i> , <i>RFx5</i> , <i>RfxAP</i> )
Leukocyte adhesion defects (LAD1, LAD2)
Chronic granulomatous disease (due to mutation of <i>gp91<sup>phox</sup></i> , <i>p22<sup>phox</sup></i> , <i>p47<sup>phox</sup></i> , <i>p67<sup>phox</sup></i> )
X-linked agammaglobulinemia due to mutation of <i>Btk</i>
X-linked hyper-IgM (XHIM) due to mutation of <i>CD40L</i>
Ataxia-telangiectasia (due to mutation of <i>ATM</i> )
Wiskott-Aldrich syndrome (due to mutation of <i>WASP</i> )
X-linked lymphoproliferative syndrome (due to mutation of <i>SH2D1A</i> )
<i>Probable†</i>
Common variable immunodeficiency (CVID)

\*These are usually dependent on mutation detection with clinical and laboratory features (with or without a positive family history).

†Diagnosis of exclusion using clinical and laboratory features as well as exclusion criteria.

clinical and laboratory inclusion criteria characteristic of the disorder. The tests used to detect the most consistently abnormal findings in a particular disorder are discussed in the rest of this chapter. The diagnostic tools available range from simple, routine laboratory tests to complex immunologic and genetic procedures. Technical details for the assessment of the immune system can be found in *Current Protocols in Immunology* (Coligan et al., 1994), *Manual of Clinical Laboratory Immunology* (Rose et al., 1997).

## General Assessment of Primary Immunodeficiency Diseases

### History

Primary immunodeficiency disorders caused by a single gene defect often have a family history that points to either an X-linked or an autosomal recessive or dominant mode of inheritance (see

Chapters 2 and 44). A detailed family tree must consider premature deaths, the gender of affected individuals, paternity issues, and the possibility of consanguinity. However, about 50% of patients with an X-linked immunodeficiency, documented by mutation analysis, do not have a family history of immunodeficiency because they represent the first manifestation of a new mutation. The presence of consanguinity increases the possibility that a patient has a rare autosomal recessive immunodeficiency, but many patients with rare disorders are compound heterozygotes—i.e., they have different mutations on each of the pair of affected chromosomes because of mutations in both the maternal and paternal alleles. In a patient with atypical clinical or laboratory findings, the presence of a sibling with more typical disease can suggest a diagnosis, but this does not permit a definitive diagnosis in the absence of mutation detection.

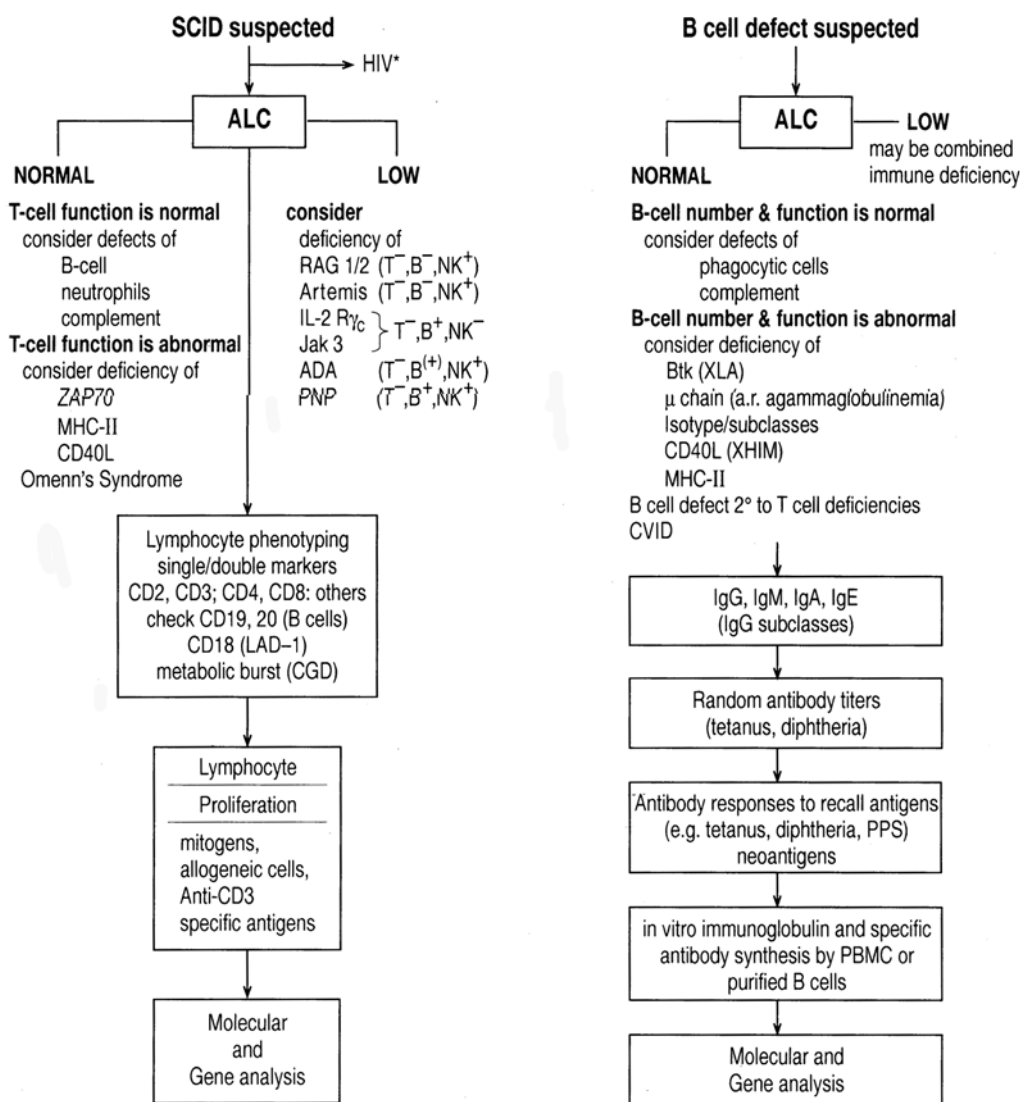

A medical history (Table 43.2) should emphasize the age at onset of symptoms, the nature and etiology of infections, organs

**Table 43.2.** Historical and Physical Findings Suggestive of Primary Immunodeficiencies

<i>Predominant T Cell Deficiency</i>	<i>Phagocytic Defects</i>
Early onset, failure to thrive	Early onset
Oral candidiasis	Gram <sup>+</sup> , gram <sup>-</sup> bacteria
Skin rashes, sparse hair	Catalase + organisms (CGD)
Protracted diarrhea	<i>Staphylococcus</i> , <i>Serratia marcescens</i> , <i>Klebsiella</i> , <i>Burkholderia cepacia</i>
Opportunistic Infections	<i>Candida</i> , <i>Aspergillus</i> , <i>Nocardia</i>
<i>Pneumocystis carinii</i> , CMV, EBV (lymphoproliferation)	Involvement of skin (seborrheic dermatitis, impetigo)
Systemic BCG infection postvaccination	Cellulitis without pus (LAD)
Extensive candidiasis	Prolonged attachment of cord (LAD)
Graft vs. host disease (GVHD)	Lymph nodes (suppurative adenitis) (CGD; hyper-IgE)
Due to maternal engraftment	Respiratory tract: pneumonia, abscesses; pneumatocoles (hyper-IgE)
Due to nonirradiated blood transfusion	Oral cavity (periodontitis, ulcers, abscesses)
Bony abnormalities	Gastrointestinal
ADA deficiency, short-limb dwarfism	Crohn disease (CGD)
Hepatosplenomegaly (Omenn syndrome)	Gastric outlet obstruction (CGD)
Malignancies	Liver abscesses (CGD)
<i>Predominant B Cell Deficiency</i>	Bones
Onset after maternal antibodies have disappeared	Osteomyelitis (CGD)
Recurrent respiratory tract infections	Urinary tract
(gram <sup>+</sup> , gram <sup>-</sup> bacteria; mycoplasma)	Bladder outlet obstruction (CGD)
Otitis media, mastoiditis	<i>Complement Defects</i>
Chronic sinusitis	Onset at any age
Broncho- and lobar pneumonia	Increased susceptibility to infections
Bronchiectasis	Clq, Clr/Cls, C4, C2, C3 (streptococcal, neisserial infections)
Pulmonary infiltrates/granulomas (CVI)	C5, C6, C7, C8, C9 (neisserial infections)
PCP (XHIM)	Factor D (recurrent infections)
Gastrointestinal symptoms, malabsorption	Factor B, factor I, properdin (neisserial infections)
<i>Giardia</i> , <i>Cryptosporidia</i> (XHIM), <i>Campylobacter</i>	Rheumatoid disorders (more often in early C-component deficiencies)
Cholangitis (XHIM)	SLE, discoid lupus, dermatomyositis, scleroderma, vasculitis,
Splenomegaly (CVI, XHIM)	membrane-proliferative glomerulonephritis
Nodular lymphoid hyperplasia, ileitis, colitis (CVI)	C1q, C1r/C1s, C4, C2; (rarely) C6 and C7 (SLE)
Skeletal, muscular	C3, factor F (glomerulonephritis)
Arthritis (bacterial, mycoplasma, noninfectious)	C1 esterase inhibitor (angioedema, SLE)
Dermatomyositis/fasciitis, due to enteroviruses (XLA)	
CNS	
Meningoencephalitis due to enteroviruses (XLA)	
Other findings	
Lymphadenopathy (abdominal, thoracic) (CVI)	
Neutropenia (XHIM, XLA)	
Anemia: hemolytic, parvovirus induced (XHIM)	
Lymphoma, thymoma (CVI)	
Bile duct, pancreatic duct malignancies (XHIM)	
Urinary tract mycoplasma (CVI)	

ADA, adenosine deaminase; BCG, bacillus Calmette Guérin; CGD, chronic granulomatous disease; CMV, cytomegalovirus; CVI, common variable immunodeficiency; EBV, Epstein-Barr virus; LAD, leukocyte adhesion deficiency; PCP, *Pneumocystis carinii* pneumonia; SLE, systemic lupus erythematosus; XHIM, X-linked hyper-IgM; XLA, X-linked agammaglobulinemia.

**Figure 43.2.** Diagnostic overall scheme for T cell deficiencies (SCID) and B cell deficiencies.

involved, the need for and response to antibiotics, as well as acute vs. chronic infections. Infants with T cell abnormalities often present with PCP and fungal infections in addition to bacterial infections, usually before the age of 3 months. Adults with T cell defects may have repeated viral infections, ranging from recurrent shingles to generalized chickenpox, or severe fungal infections. In contrast, most patients with a predominant B cell abnormality do not develop symptoms until maternal antibodies have disappeared in infants. Most adults and children with B cell defects are troubled by bacterial infections of the upper and lower airways. Patients with neutrophil defects may present at any age with skin infections, abscesses, and lymphadenopathy due to *Staphylococcus*, *Serratia marcescens*, *Klebsiella*, or *Aspergillus*. Late complement component deficiencies often cause generalized infections with encapsulated organisms. Older patients with PIDD may present with chronic lung disease, including bronchiectasis, and/or with chronic sinusitis and mastoiditis, diarrhea or other gastrointestinal complaints, or arthritis.

It is essential to have information about exposure to standard immunization antigens to interpret antibody titers. Full details of immunization and all childhood and adult infections are required.

The definite diagnosis of PIDD depends on laboratory evidence including assessment of humoral and cellular immunity and molecular analysis (Fig. 43.2, Tables 43.3 and 43.4), as physical findings are often absent, may be nonspecific, or very discreet. Occasionally, an immune deficiency is an incidental finding during investigation for an unrelated condition. These patients need full investigation to determine the clinical significance of the defect. To confirm the diagnosis of a primary immunodeficiency, secondary immunodeficiencies (e.g., HIV infection, lymphoid malignancies, antirheumatic or anticonvulsant drugs) have to be excluded and the relevant history must be taken.

### Physical Examination

The physical examination (Table 43.2) may be totally negative, as, for instance, in patients with complement component deficiencies or in males with the XLP gene before being exposed to Epstein-Barr virus (EBV). Patients with SCID, by contrast, appear chronically ill; present with failure to thrive; are often pale, irritable, and wasted; and may have chronic nasal discharge and often diarrhea. The skin is frequently affected—erythroderma, eczema, pyoderma, or fungal lesions are common. Extensive

CBC, complete blood count; CGD, chronic granulomatous disease; MHC, major histocompatibility complex; VZ, varicella-zoster.

warts of prolonged duration, persistent generalized molluscum contagiosum, or other recurrent virus-induced skin lesions are associated with T cell defects. Ectodermal dysplasia or severe eczema is also a specific defect in the rare X-linked type of SCID associated with an NF- $\kappa$ B signaling defect (Zonana et al., 2000; Orange et al., 2002a; Smahi et al., 2002). Some features, such as alopecia or sparse hair, are common in any individual who suffers from chronic disease. But in rare cases these features may represent specific syndromes, for example, the human equivalent of the mouse Nude/SCID phenotype (Pignata et al., 2001) or the rare and fatal X-linked condition associated with neonatal polyendocrinopathy and enteropathy (IPEX) syndrome (Bennett et al., 2002) (Chapter 26).

The presence of petechiae and bruises suggests a bleeding problem (Cunningham-Rundles, 2002). Partial albinism in a child with recurrent infections is typical of the Chediak-Higashi syndrome, although this can also be a feature of other genetic abnormalities. The absence of lymph nodes despite repeated infection is a telling sign of a nonfunctional antigen-specific lymphoid system. In patients with a neutrophil defect (such as chronic granulomatous disease), lymph nodes are usually enlarged and suppurative. Sometimes the immunodeficiency is a component of a rare, generalized disorder of metabolism and/or development (e.g., Nijmegen breakage syndrome, glycogen storage disease).

Examination of the oral cavity may provide important clues: therapy-resistant candidiasis suggests a T cell or neutrophil defect and may involve the entire esophagus. Extensive periodontitis is a hallmark of leukocyte adhesion defects. Recurrent mouth ulcers may indicate cyclic neutropenia or recurrent Herpes simplex infection associated with a T cell defect. Lack of tonsillar tissue is a feature of total failure of B lymphocyte development, as in X-linked agammaglobulinemia (see Chapter 26), in contrast to hypertrophy and significant lymphadenopathy in patients with activation-induced cytidine deaminase (AID) deficiency (see Chapter 20).

Gross signs of structural damage are seen in patients with long-standing undiagnosed or untreated PID. Persistent cough at night or early morning suggests the presence of chronic lung disease such as asthma or bronchiectasis; signs of restrictive lung disease are often present during chest examination. Nasal polyps,

#### *B Cell Deficiency*

Quantitative IgG, IgM, IgA, IgE  
IgG subclasses  
B cell numbers in peripheral blood (CD19, CD20)  
Antibody responses to test immunizations, e.g., D/T, Pneumovax  
In vitro IgG synthesis by mitogen-stimulated PBL or purified B cells cultured in the presence of anti-CD40 and lymphokines  
In vitro proliferation of B cells in response to anti-CD40 and IL-4  
Biopsies: rectal mucosa; lymph nodes (if appropriate)  
Molecular and mutation analysis (e.g., Btk,  $\mu$  heavy chain)

#### *T Cell Deficiency*

Absolute lymphocyte count  
T cell, T subset, and NK cell enumeration (CD3, CD4, CD8; also CD16, CD56)  
Delayed-type hypersensitivity skin tests (only in older children and adults) (candida, tetanus toxoid, mumps)  
In vitro proliferation of lymphocytes to mitogens (PHA, ConA), allogeneic cells, and specific antigens (candida, tetanus toxoid)  
Production of cytokines by activated lymphocytes  
Expression of activation markers (e.g., CD40L, CD69) and lymphokine receptors (e.g., IL-2R $\gamma$ , IFN- $\gamma$ R) after mitogenic stimulation  
Enumeration of MHC I and MHC II expressing lymphocytes  
Chromosome analysis (probe for 22q11)  
Enzyme assays (ADA, PNP)  
Biopsies: skin, lymph node, thymus (if appropriate)  
Molecular and mutation analysis (e.g., CD40L,  $\gamma$ c chain, Jak3, ZAP-70)

#### *Deficiency of Phagocytic System*

Absolute neutrophil count (serially to rule out cyclic neutropenia)  
WBC turnover  
Antineutrophil antibody  
Bone marrow biopsy  
Chemotaxis, assessment of adhesion in vivo and in vitro  
CD11/CD18 assessment (flow cytometry)  
Bombay phenotype (LAD2)  
Phagocytosis (baker's yeast)  
NBT slide test; metabolic burst (flow cytometry); chemiluminescence; bacterial assays  
Enzyme assays  
  MPO, G6PD  
  Glutathione peroxidase  
  NADPH oxidase  
Mutation analysis (e.g., gp91<sup>phox</sup>, p22<sup>phox</sup>, p47<sup>phox</sup>, p67<sup>phox</sup>,  $\beta$  integrin)

#### *Complement Deficiencies*

CH50, AH50  
Analysis of quantity and function of C components  
Chemotactic activity of complement split products, e.g., C3a, C5a

#### *Other Diagnostic Tests*

$\alpha_1$ -antitrypsin  
Sweat Cl<sup>-</sup>  
Nasal mucosa biopsy (to rule out immotile cilia syndrome)  
Rule out tracheoesophageal fistula (imaging)

tender sinuses, or damaged tympanic membranes suggest previous recurring upper respiratory tract infections. Since many patients with PID present to ear–nose–throat (ENT) clinics initially, these symptoms may be of long duration (Cooney et al., 2001). Nasal endoscopy and computed tomography (CT) of the

sinuses are indicated if there is persistent infection or if surgery is being considered. Endoscopically guided microswab culture obtained from the middle meatus or sinuses themselves correlate well (80%) with results from now-abandoned antral puncture (Osguthorpe, 2001).

Congenital malformation of the heart and large vessels, especially if associated with hypocalcemia in a newborn, makes DiGeorge syndrome the most likely diagnosis (see Chapter 33). Liver abscesses, suppurative lymphadenopathy, hepatosplenomegaly, and perirectal fistulas are often associated with chronic granulomatous disease (see Chapter 37). Progressive omphalitis, if associated with neutrophilia, suggests an adhesion molecule defect of neutrophils (see Chapter 38). Progressive cerebellar ataxia, in association with discreet or pronounced telangiectasia involving the conjunctiva, ears, and sometimes the face and shoulders are classic findings in ataxia-telangiectasia (see Chapter 29).

### Laboratory Diagnosis

#### Initial screening for immune deficiencies

Initially, an attempt is made to establish the diagnosis of PID by screening the different defense systems and by ruling out rare nonimmunologic disorders, including cystic fibrosis, inhalation of a foreign body, congenital absence of the spleen, immobile cilia syndrome, or anatomic abnormalities, for example, tracheoesophageal fistula. A set of useful initial tests that can be performed in most general laboratories is listed in Table 43.3; such tests benefit from reliable quality assurance measures and are widely available.

A full blood count will reveal a neutropenia, lymphopenia, and thrombocytopenia. Lymphocyte counts are much ignored yet give vital information for the diagnosis of SCID (Gossage and Buckley, 1990). Quantitative determination of serum IgG, IgM, IgA, and IgE is also part of the initial screening. The interpretation of serum immunoglobulin levels may be difficult; not only patient age but also the possibility of protein loss or previous immunoglobulin substitution must be considered. The presence of hemolytic complement activity (CH50), even at reduced amounts, rules out most congenital complement deficiencies of the classic pathway (see Chapter 42). The normal ranges for lymphocytes and lymphocyte subset numbers as well as serum immunoglobulin levels are age-dependent (Erkeller-Yuksel et al., 1992; Melaranci et al., 1992; Stiehm et al., 2004) and comparison with age-matched controls is essential.

In the absence of steroid or immunosuppressive therapy, lymphopenia usually indicates a T cell deficiency, as >60% of circulating lymphocytes are normally T cells. The percentages and absolute numbers of T and B cell subsets are measured by means of flow cytometry (Fleisher and Oliveira, 2004), using monoclonal antibodies that recognize cell type-specific antigens (Tables 43.3 and 43.4). The proportions of these cells in peripheral blood are also age-dependent (Fig. 43.3) (Erkeller-Yuksel et al., 1992; Stiehm et al., 2004). Most patients with SCID or a predominant T cell deficiency have reduced numbers of cells with CD3, CD4, or CD8 antigens on their surface. Those with agammaglobulinemia and a subset of patients with SCID have low numbers of B cells with CD19, CD20, or CD21 expression. The widespread use of flow cytometry and standardization of commercially available monoclonal antibodies, coupled with excellent quality assurance schemes, make these assays reliable screening tests.

**Figure 43.3.** Absolute lymphocyte counts in normal infants and infants with severe combined immunodeficiency.

### Comprehensive and Specific Evaluation for Immune Deficiencies

#### Tests for antibody deficiencies

Primary antibody deficiencies are more common than T cell or combined deficiencies. An approach to the diagnosis of the known types of primary antibody deficiency is shown in Figure 43.2 and Table 43.4. After measurement of the serum levels of the three major immunoglobulin isotypes, the most important investigation is the assessment of specific antibody activity. Failure to produce antibodies to immunizations or after known exposure to common pathogens forms part of the international criteria for primary antibody deficiencies (Conley et al., 1999; Stiehm et al., 2004).

Titers of naturally occurring IgM antibodies such as anti-A or anti-B isohemagglutinins can be determined in a bloodbank-associated laboratory. The presence of serum IgG antibodies to agents to which the individual is known to have been exposed (e.g., varicella, since chickenpox is a distinct clinical entity, or definite immunization) is also helpful. In the absence of such antibodies, the use of test immunizations to measure the kinetics of specific IgG antibody responses to defined antigens is most informative. Serum is collected before and 3–4 weeks after immunization and antibody titers are determined. Normal pre- and postvaccination values are available and assays can be quality assured (Gibb et al., 1995). The most widely used recall antigens are diphtheria/tetanus toxoid and conjugated *Haemophilus influenzae* B (Hib) vaccines; these proteins provoke T cell-dependent IgG responses. The use of protein neoantigens, such as keyhole limpet hemocyanin (KLH) (Kondratenko et al., 1997) and bacteriophage ØX174 (Stiehm et al., 2004), allows precise assessment of primary, secondary, and tertiary responses, including immunologic memory, class switch from IgM to IgG, and amplification following multiple exposures to antigen.

To measure antibodies to polysaccharides (short-lived, relatively T cell-independent responses), a polysaccharide vaccine

(Pneumovax) against 23 pneumococcal serotypes is still available. In most European countries, responses to the vaccine as a whole are determined for diagnosis of immune deficiencies; in the United States, responses to at least 12 serotypes are measured before and after immunization, and a positive response is taken as a significant rise in at least 8 of the 12 (less in children). With the development of an assay for the pure polysaccharide vaccine to *Salmonella typhi* (Typhum Vi) an alternative carbohydrate vaccine has become available, for which the assay has been published (Ferry et al., 2004). Children less than 2 years of age do not respond reliably to unconjugated polysaccharide vaccines.

IgG subclass levels should be measured only under certain circumstances. These include patients with normal or near-normal IgG concentrations and with demonstrable (though often partial) antibody deficiency, or abnormal responses to protein or polysaccharide antigens; patients with selective IgA deficiency who have shown an increased susceptibility to infection to rule out an associated IgG2/IgG4 deficiency; and adults with persistent sinusitis and upper respiratory tract infections and normal serum immunoglobulin levels who may have selective loss of IgG2 or IgG3. Assays are now standardized and quality assured, and age-matched, normal IgG-subclass concentrations are available (Stiehm et al., 2004).

The presence of circulating, mature B cells is determined by flow-cytometric analysis of whole blood. To execute an effective antibody response, B cells, CD4<sup>+</sup> T helper cells, and antigen-presenting cells are colocalized in secondary immune organs, where they form characteristic structures (germinal centers, follicles). Biopsies of rectal mucosa, lymph nodes, and bone marrow may show characteristic structural abnormalities, and absence of a given cell type may be found if immunohistological techniques are used. Determination of the stage of B cell maturation arrest in the bone marrow may provide a clue to the genetic defect in patients with absent circulating B cells (see Chapters 21 and 22). However, these invasive procedures are performed infrequently.

If a single gene defect is suspected, it may be possible to identify the gene product (see Tables 43.5 and 43.6). An example is X-linked agammaglobulinemia (XLA), where Bruton tyrosine

kinase (Btk) deficiency can be detected in about 70%–80% of affected males through demonstration of lack of Btk protein in circulating monocytes and platelets (Futatani et al., 1998, 2001). The protein can also be detected by Western blotting, and mRNA by Northern blotting. Finally, genomic or complementary DNA must be examined by sequence analysis to detect nonfunctional but present protein.

In vitro assessment of immunoglobulin synthesis by stimulated peripheral blood B lymphocytes is used predominantly as a research tool. Purified B cells can be stimulated to produce and secrete immunoglobulins in a T cell-independent manner if directly activated through CD40 and in the presence of exogenous lymphokines. They then proliferate and secrete IgE if interleukin-4 (IL-4) is added to the culture, or secrete IgG and IgM if IL-10 is added (Nonoyama et al., 1993, 1994). These assays have been used to distinguish patients with intrinsic B cell defects from those in whom T cell help is inadequate. With the increased understanding of B cell activation and switched and unswitched memory markers, however, flow cytometry offers more promise (Agematsu et al., 1998, 2002; Warnatz et al., 2002; Piqueras et al., 2003), especially in view of the satisfactory use of whole blood rather than separated peripheral blood mononuclear cells (PBMC) (Ferry et al., 2005).

#### Tests for T cell deficiencies and severe combined immunodeficiencies

Significant and persistent lymphopenia is a hallmark of severe T cell deficiency (Figs. 43.2 and 43.3). Absolute lymphocyte counts and assessment of lymphocyte subsets, both by percentage and absolute number, are readily available and reliable. As for B cells, the method of choice for T cell subset enumeration is flow cytometry. The use of whole blood for analysis by flow cytometry is not only more accurate but is especially useful for pediatric patients because of the small sample volume required. An initial, standard analysis by flow cytometry is shown in Tables 43.3 and 43.4. Interpretation is based on the presence or absence of the three major types of cells involved: T, B, and natural killer (NK) cells (Fig. 43.2).

Total lymphocyte numbers and T lymphocyte subsets are age-dependent, being markedly increased in newborns and young

**Table 43.5.** Diagnostic Approach to X-Linked Inherited Immunodeficiencies

Disorder	Gene	Diagnostic Tests
X-linked agammaglobulinaemia (XLA)	Bruton tyrosine kinase ( <i>Btk</i> )	Btk expression by immunoblotting or flow cytometry (monocytes or platelets) Mutation analysis
X-linked severe combined immunodeficiency (XSCID)	Common gamma chain (c) ( <i>IL2RG</i> )	Gamma c (CD132) expression on activated T cells (flow cytometry) Mutation analysis
Wiskott-Aldrich syndrome (WAS/XLT)	WAS protein ( <i>WASP</i> )	WASP expression (Western blot, flow cytometry) Mutation analysis
X-linked hyper-IgM syndrome (CD40 ligand deficiency)	CD40L ( <i>CD154</i> )	CD40L expression on activated CD 4 <sup>+</sup> T cells (flow cytometry) Mutation analysis
X-linked anhidrotic ectodermal dysplasia with immunodeficiency	IKKBG, NF-κB essential modulator ( <i>NEMO</i> )	EMSA (NF-κB) Mutation analysis
X-linked lymphoproliferative syndrome (Duncan disease; XLP)	SH2D1A ( <i>SAP</i> )	SAP expression Mutation analysis
Immune dysregulation, polyendocrinopathy, enteropathy, X-linked (IPEX)	<i>FOXP3</i>	Lack of regulatory T cells, FOXP3 absent Mutation analysis
X-linked chronic granulomatous disease (XCGD)	<i>gp91<sup>phox</sup></i>	NBT slide test; dihydrorhodamine flow cytometry Mutation analysis
Properdin deficiency	Properdin factor C ( <i>PFC</i> )	AP50, serum properdin levels, mutation analysis

**Table 43.6.** Diagnostic Approach to Autosomally Inherited Immunodeficiencies

Disorder	Gene Name	Diagnostic Tests
Severe Combined Immunodeficiencies (SCID)		
Recombinase-activating gene protein 1 and 2 (RAG1, RAG2) deficiency, Omenn syndrome	RAG1, RAG2	Mutation analysis
Artemis deficiency	Artemis	Radiation sensitivity, mutation analysis
JAK3 deficiency	Jak3	Jak3 protein absent (Western blot) Mutation analysis
T cell receptor deficiencies		
CD3γ	CD3G	Low CD3 expression
CD3ε	CD3E	Mutation analysis
CD3δ	CD3D	
IL-7 receptor deficiency	ZAP70	CD8+ T cells reduced or absent, CD4+ T cells nonfunctional Lack of ZAP-70 (Western blot) Mutation analysis
Deficiency of Purine Metabolism		
Adenosine deaminase (ADA) deficiency	ADA	ADA activity reduced in RBC; purine metabolites increased in RBC, plasma, urine Mutation analysis
Purine nucleoside phosphorylase (PNP) deficiency	PNP	PNP activity reduced in RBC; purine metabolites increased in RBC, plasma, urine Mutation analysis
Major Histocompatibility Complex (MHC) Deficiency		
MHC class I deficiency (bare lymphocyte syndrome type I)	TAP1 TAP2	HLA class I expression (flow cytometry) Mutation analysis
MHC class II deficiency (bare lymphocyte syndrome type II)	CIITA RFXANK RFX5 RFXAP	MHC class II (DR) expression absent on flow cytometry Mutation analysis
Inherited Mycobacterial Susceptibility		
Interferon-γ receptor deficiencies	IFNGR1/2	IFN-γR1/2 decreased or absent
IL-12 deficiency	IL12 p40	IL-12 expression absents
IL-12 receptor deficiency	IL12ReB1	IL-12 receptor expression absent Mutation analysis
Hyper-IgM Syndromes (Autosomal Recessive)		
CD40 deficiency	CD40	B cells lack CD40 expression on flow cytometry
Activation-induced cytidine deaminase (AID) deficiency	AICDA	Very high serum levels of IgM, lymphadenopathy, mutation analysis
Uracil-DNA glycosylase (UNG) deficiency	UNG	High serum levels of IgM Mutation analysis
Common Variable Immunodeficiency (CVID) Subcategories		
ICOS (inducible costimulatory) deficiency	ICOS	CVID-like, mutation analysis
CD19 deficiency	CD19	CVID-like, lack of CD19 expression by B cells, mutation analysis
TACI (tumor necrosis factor receptor [TNFR] super family member 13B) deficiency	TNFRSF13B	CVID-like, mutation analysis
BAFF receptor (TNFR super family member 13C) deficiency	TNFRSF13C	CVID-like, mutation analysis
Autoimmune Lymphoproliferative Syndrome (ALPS)		
Type Ia (Fas/APO-1; CD95 deficiency)	TNFRSF6	>1% double-negative (α/β) T cells (CD4 <sup>-</sup> , CD8 <sup>-</sup> , CD3 <sup>+</sup> ) Defective lymphocyte apoptosis Mutation analysis
Type IIb (FasL, CD178 deficiency)	TNFSF6	
Type IIa (caspase 10 deficiency)	CASP10	
Type IIb (caspase 8 deficiency)	CASP8	
Chromosome Breakage Syndromes		
Ataxia-telangiectasia (AT)	ATM	DNA radiation sensitivity, translocations Mutation analysis
Immunodeficiency, centromere instability, facial abnormalities syndrome (ICF)	DNMT3B (methyltransferase)	Multibranched chromosomal configurations, chromosomal breakage only in lymphocytes Mutation analysis
Nijmegen breakage syndrome (NBS)	NBS1	Radiation sensitivity, chromosome instability, mutation analysis
Bloom syndrome	BLM (α helicase)	Radiation sensitivity, sister chromatid exchange, mutation analysis

(continued)

**Table 43.6.** (continued)

Disorder	Gene Name	Diagnostic Tests
<i>Phagocytic Defects</i>		
Chronic granulomatous disease (autosomal recessive genes)	<i>p47<sup>phox</sup></i> <i>p67<sup>phox</sup></i> <i>p22<sup>phox</sup></i>	p47 <sup>phox</sup> , p67 <sup>phox</sup> , p22 <sup>phox</sup> expression (Western blot) Mutation analysis
Leukocyte adhesion deficiency type I (LAD1)	<i>CD18</i>	CD11/CD18 expression absent
Leukocyte adhesion deficiency type II (LAD2)	Fucose transporter ( <i>NAALAD2</i> )	Sialyl-Lewis X absent (flow cytometry) Mutation analysis
Cyclic neutropenia and Kostman syndrome	Neutrophil elastase	Cyclic or congenital neutropenia, mutation analysis
Chediak-Higashi syndrome	<i>LYST</i>	Giant inclusions in granulocytes Mutation analysis
Griscelli syndrome		
Type 1	<i>M405A</i>	Mutation analysis
Type 2	<i>RAB27A</i>	Mutation analysis
<i>Other Well-defined Immune Deficiency Syndromes</i>		
APECED (autoimmune polyendocrinopathy, candidiasis, ectodermal dystrophy)	<i>AIRE1</i>	Mutation analysis
WHIM (warts, hypogammaglobulinemia, recurrent bacterial infections, myelokathexis)	<i>CXCR4</i>	Mutation analysis

EMSA, electrophoresis mobility shift assay; NBT, nitroblue tetrazolium; RBC, red blood cells.

infants and decreasing with age (Fig. 43.3). In infants under 4 months of age, a CD4 count of  $<1000/\text{mm}^3$  (in infants infected with HIV, a count of  $1500/\text{mm}^3$ ) is generally associated with impaired cellular immunity, whereas in children over age 2 years and in adult patients it is  $<500$  CD4 cells/ $\text{mm}^3$  (Melaranci et al., 1992). In these situations all transfused blood or blood cellular products should be pre-irradiated and live vaccines should be avoided. A CD4:CD8 ratio  $<1.0$ , in the absence of a gross CD8 lymphocytosis, may also indicate abnormal T cell function and a ratio of 0.3 is often associated with profound T cell deficiency.

In vitro lymphocyte proliferation to mitogens, including phytohemagglutinin (PHA), pokeweed mitogen (PWM), and concanavalin A (Con A), or to cross-linking of T cell surface antigens by monoclonal antibodies to CD3 provides a rough estimate of T cell function. These assays are difficult to perform, requiring sterile culture conditions for 3–6 days and, in the past, methods for incorporation and subsequent measurement of radiolabeled thymidine. Recently, nonradioactive methods such as expression of activation markers, cytokine production, or uptake of carboxyfluorescein succinimidyl ester (CFSE), detected by flow cytometry (Table 43.4), are used. A more sensitive way to measure T lymphocyte function in adults and older children is in vitro stimulation with specific antigens to which patients have been previously exposed, such as diphtheria or tetanus toxoid, purified protein derivative (PPD) (following bacillus Calmette Guérin [BCG] immunization), or candida antigen.

Cytokines can be measured in culture supernatants by ELISA or intracellularly by flow cytometry and may help identify a functional T cell defect in rare cases. Kits to quantitate mRNA are now commercially available to measure transcription of most lymphokines during lymphocyte activation on a research basis. However, only one specific cytokine deficiency—IL-12p40 deficiency—has been described to date. There has been a single case of SCID in which transcription of the IL-2 gene and other lymphokine genes were affected (Pahwa et al., 1989).

Mutations affecting interferon- $\gamma$  (IFN- $\gamma$ ) receptors (IFN- $\gamma$ R<sub>1</sub> or IFN- $\gamma$ R<sub>2</sub>), observed in infants with normal numbers of

T cells and severe nontuberculous mycobacterial disease (see Chapter 28), result in defective IFN- $\gamma$  signaling, such as failure of STAT1 phosphorylation following IFN- $\gamma$  activation of patient monocytes (Fleisher et al., 1999) and impaired tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ) production by PBMC in response to a combination of lipopolysaccharide (LPS) and IFN- $\gamma$  (Holland et al., 1998). This approach has been greatly facilitated by a new flow cytometry method for intracellular and nuclear staining of STAT1 and STAT4 in response to IFN- $\gamma$  or IL-12 activation (Uzel et al., 2001). IL-12R $\beta$ 1 deficiency, observed in patients with disseminated nontuberculous mycobacterial and salmonella infections, is confirmed by lack of cell surface expression of IL-12R $\beta$ 1 on stimulated T and NK cells, resulting in depressed IFN- $\gamma$  production by these cells (see Chapter 28).

If the diagnosis of autosomal recessive SCID is suspected, mutations of the purine metabolism enzymes, adenosine deaminase (ADA), or purine nucleoside phosphorylase (PNP) should be considered and the enzyme activities in red blood cells determined (Carlucci et al., 2003). Deficiencies of these enzymes result in intracellular accumulation of purine metabolites, which after release from the cytoplasm, can be demonstrated at high concentration in blood and urine (see Chapter 12). In the case of PNP deficiency, important clues are low serum and urinary levels of uric acid. It is important to determine that the patient has not been recently transfused, as the donor red cells will mask the defective erythrocytes.

Although traditionally skin tests to assess recall antigens (such as mumps, trichophyton, *Candida albicans*, and PPD) have been used to detect T cell function (delayed-type hypersensitivity), these are often unreliable and difficult to evaluate, especially in infants and young children. Except for PPD, antigens have not been standardized for this purpose, and the result at 72 hours (indicative of a cell-mediated reaction) may be obscured by a humoral (Arthus) reaction at 24 hours.

NK cell deficiency may be present as an isolated defect (Biron et al., 1989) or as part of a broad-based immune deficiency, as in

patients with X-linked SCID, Chediak-Higashi syndrome, ectodermal dysplasia associated with *NEMO* mutations, or Wiskott-Aldrich syndrome (Orange, 2002; Orange et al., 2002a, 2002b). In most cases it is adequate to enumerate NK cells by flow cytometry (CD16, CD56); in some situations, functional cytotoxic assays are required to help reach a diagnosis (Bernard et al., 2004).

### Evaluation of phagocytic defects

Evaluation for defects in the phagocytic system (Table 43.4) is indicated in patients with a history of early-onset suppurative staphylococcal skin infections, cellulitis without pus formation, lymphadenitis, liver abscesses, splenomegaly, or the presence of unusual organisms such as *Serratia marcescens*, *Klebsiella*, *Nocardia*, or invasive *Aspergillus* (Fig. 43.1). Neutrophil defects include congenital or acquired neutropenia, cyclic neutropenia (see Chapter 39), adhesion defects (see Chapter 38), and defective bactericidal function (see Chapter 37). Most of these molecularly defined defects can be screened for with relatively simple tests and then confirmed with appropriate functional assay systems and specific molecular techniques.

The absolute neutrophil count may be persistently low, as in Kostmann disease; intermittently low, as in cyclic neutropenia; or high, as in patients with a leukocyte adhesion defect (LAD1, LAD2, LAD3). Neutropenia is considered if the neutrophil count is  $<1500/\text{mm}^3$ , but clinical symptoms may not occur until the neutrophil count is  $<300/\text{mm}^3$ . To demonstrate cyclic neutropenia, often accompanied by short-term symptoms of fever, mouth ulcers, and infections, it is necessary to obtain neutrophil counts two to three times a week for at least 4 weeks, in conjunction with a symptoms diary. The diagnosis has to be confirmed by demonstrating a mutation in the neutrophil elastase gene (Horwitz et al., 1999). A bone marrow examination is required to determine whether the neutropenia is due to insufficient production or increased consumption.

Tests for defective locomotion and phagocytosis are difficult to perform, as there are nonspecific factors that can interfere with *in vivo* and *in vitro* chemotaxis, resulting in secondary failure. Primary diseases of chemotaxis or phagocytosis have not been identified. Most disorders of phagocytosis are the result of opsonic defects rather than intrinsic phagocytic defects (see below).

Flow cytometry is an important tool in the diagnosis of patients lacking adhesion molecules on their surface, such as it is the case in LAD1 and LAD2, for which the molecular defect is currently known (see Chapter 38). Patients with LAD1, lacking the common subunit CD18, are unable to form the heterodimer CD11/CD18. The absence of the subunit of the integrin molecule can be demonstrated by use of anti-CD18 monoclonal antibodies. Patients with LAD2 lack the fucosylated selectin ligand, sialyl-Lewis-X (CD15), on their neutrophils (Etzioni et al., 1999). LAD3, a leukocyte adhesion deficiency associated with impaired integrin rearrangement and a bleeding disorder, has not yet been molecularly defined and has normal CD18 and CD15 expression (see Chapter 38).

Neutrophils from patients with chronic granulomatous disease (CGD) fail to kill catalase-producing bacteria and fungi; during infections the neutrophil count is often abnormally high. The quantitative bacterial killing assay, originally designed to identify such patients, is no longer used for diagnostic purposes. During phagocytosis and killing, normal neutrophils show markedly increased metabolic activity, and several methods to

measure the oxidative metabolic burst have been developed. Easy-to-perform laboratory tests to confirm the diagnosis depend on the reduction of a dye to detect the generation of superoxide. A flow-cytometric method employing dihydrorhodamine is widely used and is both reliable and sufficiently sensitive to pick up female carriers of the X-linked form (Carulli et al., 1996). The small amount of blood needed makes this a useful test for infants or for prenatal diagnosis, and quality assurance measures are available. Defective NADPH oxidase activity is the major cause of CGD and may be the result of mutations of one of several cytoplasmic or membrane-associated components of NADPH oxidase (see Chapter 37). Other screening methods include assessment of glucose metabolism, oxygen consumption, glucose monophosphate shunt activity, chemiluminescence, nitroblue tetrazolium (NBT) reduction, and hydrogen peroxide production by phagocytosing leukocytes, but these are no longer widely used.

A small group of patients presenting with clinical findings of CGD may have a complete absence of functional glucose-6-phosphate dehydrogenase (G6PD) in white cells, defective myeloperoxidase, or abnormal glutathione peroxidase. These metabolic defects can cause defective neutrophil bactericidal activity but are not always associated with symptoms (see Chapter 8).

### Evaluation of complement defects

Patients with complement deficiencies (see Chapter 42) often have immune complex diseases or recurrent, serious infections (Fig. 43.1, Table 43.2). Patients having deficiencies in the early components of the classical pathway present with immune complex diseases and those having defects in the final lytic pathway with meningitis or septicemia due to encapsulated *Neisseria* species—for example, systemic meningococcal disease or generalized gonococcal infections.

Two assays are sufficient to screen for most complement deficiencies (Table 43.4). Function of the classical pathway in serum is measured by the rate of hemolysis of sheep red cells (CH50) and that of the alternative pathway by lysis of either rabbit or guinea pig red cells (AH50). The availability of simple-to-use and cheap kits has resulted in many laboratories undertaking these assays inappropriately; they are exquisitely sensitive to temperature and difficulties in quality assurance mean that they should only be done in laboratories with considerable experience.

### Evaluation of chromosomal defects

Chromosomal abnormalities are pathognomonic for several immunodeficiency syndromes. Deletions within the long arm of chromosome 22, demonstrable with a specific DNA probe, confirm the diagnosis of the DiGeorge syndrome (Goldmuntz et al., 1993) (see Chapter 33), although few patients have evidence of a serious immune defect (Junker and Driskoll, 1995; Ryan et al., 1997). In the presence of clinical features of DiGeorge syndrome but failure to demonstrate a 22q11 defect, chromosome 10q13 should be examined (Markert et al., 2004). Lymphocytes and epithelial cells from patients with ataxia-telangiectasia (see Chapter 29), the Nijmegen breakage syndrome, and Bloom syndrome (both covered in Chapter 30) show chromosomal breaks and sister chromatid exchanges when cultured *in vitro*. These chromosomal breakage syndromes are caused by mutations of genes coding for proteins involved in DNA repair.

### Analysis of Primary Immune Deficiency Disease at the Molecular Level

In recent years, the number of PIDD with a known single gene defect has increased from a handful to over 120 entities (see Table 1.1 in Chapter 1). If the gene product and its function are known, as in ADA deficiency, quantitation of the gene product (usually a protein), including assessment of function, may identify individuals that carry the defect. If the defective gene has been mapped to a specific site on a single chromosome and sufficient family members are available to identify haplotypes carrying the mutation, linkage analysis may identify carriers or affected fetuses even if the gene responsible for the disease has not yet been cloned and sequenced, as, for example, in a subgroup of the hyper-IgE syndrome.

In some families, the mutations result in impaired gene transcription and complete absence of the gene product; in others a nonfunctional gene product may be generated. Using standard protocols (see Tables 43.5 and 43.6), including Western blot analyses, flow cytometry, Northern blot analysis, polymerase chain reaction (PCR), reverse transcriptase (RT)-PCR, and sequence analysis, affected patients can be identified and carriers detected, and prenatal diagnosis can be performed.

For genetic and molecular considerations, carrier females of X-linked diseases can be divided into two categories. For example, in a carrier female of X-linked CGD, the affected neutrophils (as all hemopoietic cells) show random X chromosome inactivation. As a result, approximately 50% of a carrier female's activated neutrophils undergo a normal metabolic burst; this is easily demonstrated by dihydrorhodamine and flow cytometry. This is also true in CD40L deficiency, where the proportion of the activated T cells expressing CD40L will reflect the extent of the randomness of X chromosome inactivation. The second category of carrier females, exemplified by those heterozygous for mutations of Btk (responsible for XLA) or WASP (responsible for Wiskott-Aldrich syndrome, WAS), have nonrandom X chromosome inactivation in those cells that depend on the function of the mutated genes. Carrier women in this category exhibit selective use of the nonmutant, normal X chromosome as the active X chromosome in the relevant cell population, for example, B cells in XLA, all hematopoietic cell lines in Wiskott-Aldrich syndrome (Conley, 1992). X chromosome inactivation studies, although now superseded by molecular analysis for most PIDD, have been useful in the past and are still a useful tool for genetic assessment of X-linked disorders that are not molecularly characterized.

Prenatal diagnosis is now possible in most PIDD. If the syndrome is X-linked, sex determination by high-resolution ultrasound or by DNA analysis of material obtained through chorionic villi biopsy or amniocentesis will identify pregnancies at risk. If the mutation is known, sequence analysis of PCR-amplified fetal DNA is the method of choice for prenatal diagnosis. If the defective gene is unknown or if the mutation within a specific family is not yet determined, fetal blood samples can be obtained to study the characteristic peripheral blood abnormalities. For instance, thrombocytopenia and small platelets in the peripheral blood of a male fetus at risk for Wiskott-Aldrich syndrome will confirm the diagnosis. Similarly, fetuses with SCID and lymphopenia can be identified. For some disorders, such as ADA deficiency, the activity of the gene product in fetal cells can be measured. Protein studies are possible but have not yet been validated in prenatal diagnosis and may not be sufficiently reliable to use as potential indications for pregnancy termination.

### Diagnostic Approaches in Specific Immunodeficiency Disorders

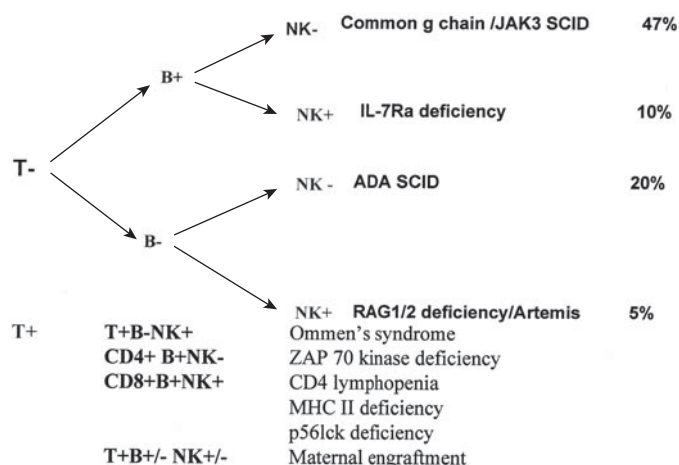

#### Severe Combined Immune Deficiency Diseases

Severe combined immunodeficiency diseases are rare diseases affecting both T and B lymphocytes, and may be inherited as an X-linked or autosomal recessive disorder, although as many as 70% of infants with SCID have a negative family history (Hague et al., 1994). At least 10 molecularly defined SCID disorders with characteristic phenotype and inheritance patterns can be distinguished (Fischer, 2000) (Fig. 43.4) (see Chapter 1, Table 1.1, and Chapters 9–15).

Patients with SCID typically present during the first few months of life with failure to thrive, skin rashes, sparse hair, diarrhea, weight loss, and bacterial, fungal, and viral infections. Absence of a thymic shadow is diagnostically useful only when the X-ray is taken early, before thymic involution has occurred from chronic infection. Primary and secondary lymphoid organs are hypoplastic but some T cell deficiencies may present with hepatosplenomegaly due to graft-versus-host disease (GVHD) following transfer of maternal cells across the placenta (Stephan et al., 1993; Hague et al., 1994) or due to histiocytic infiltrates as in Omenn syndrome. If immunized with BCG, SCID patients often develop lymphadenopathy and local or disseminated BCG-osis.

Once the diagnosis of SCID is suspected, it is vital to transfer the infant, before chronic infections have developed, to a tertiary care center with experience in the diagnosis and care of patients with SCID (Gennery and Cant, 2000). The vulnerability of the SCID infant to bacterial, viral, and fungal infections, to potentially lethal complications from live vaccines, and to GVHD caused by unirradiated blood transfusions makes SCID a legitimate pediatric emergency (Rosen, 1997). Early diagnosis improves the chance of survival by initiating timely transplantation of bone marrow or cord blood stem cells, intravenous immunoglobulin (IVIG) and PCP prophylaxis, polyethylene glycol-adenosine deaminase (PEG-ADA) treatment in ADA deficiency, or high-dose substitution with vitamin B<sub>12</sub> in patients with transcobalamin II deficiency.

The most informative screening test is the absolute lymphocyte count (ALC). In most but not all SCID patients the ALC is

**Figure 43.4.** Type of severe combined immunodeficiency by lymphocyte lineage—i.e., SCID by flow markers.

low (Gossage and Buckley, 1990; Gennery and Cant, 2000). Since the normal range in infants is much higher than that in older children and adults, age-related control values are required for comparison (Fig. 43.3). Assessment of lymphocyte markers by flow cytometry allows the quantitation, in terms of absolute numbers, of T cells, T cell subsets, B cells, NK cells, and cells expressing major histocompatibility complex (MHC) II (Buckley et al., 1997). Age-matched normal values for these lymphocyte subpopulations are available (Erheller-Yuksel et al., 1992; Melaranci et al., 1992; Stiehm et al., 2004). The results of the lymphocyte count and the assessment of the types of lymphocytes present are interpreted together (Fig. 43.2).

Normal ALCs are found in individuals in whom T cell numbers and function are largely normal—namely, in patients with ZAP-70 deficiency (normal number of CD4, decreased number or absent CD8); MHC II deficiency (normal or decreased CD4); Omenn syndrome (often moderately decreased CD4 and CD8); and CD40L deficiency (normal numbers of CD4, CD8). A low ALC may indicate reticular dysgenesis ( $T^-$ ,  $B^-$ ,  $NK^-$ , neutropenia, decreased number of megakaryocytes); Rag1/Rag2 deficiency ( $T^-$ ,  $B^-$ ,  $NK^+$ ); Artemis deficiency ( $T^-$ ,  $B^-$ ,  $NK^+$ ); XSCID or Jak3 deficiency ( $T^-$ ,  $B^+$ ,  $NK^-$ ); interleukin-7 receptor (IL-7R) deficiency ( $T^-$ ,  $B^+$ ,  $NK^+$ ); ADA deficiency ( $T^-$ ,  $B^-$ ,  $NK^{+/-}$ ); IL-2R $\alpha$  deficiency ( $T^-$ ,  $B^+$ ,  $NK^-$ ); or CD3 $\delta$  deficiency ( $T^-$ ,  $B^+$ ,  $NK^+$ ) (Figs. 43.2 and 43.4).

As noted above, there may be normal numbers of T lymphocytes but with poor function; in those PID cases, assessment of proliferation in response to mitogens will indicate the severity of the T cell defect. Those patients whose lymphocytes are nonresponsive to mitogens may tolerate bone marrow or stem cell transplants without conditioning, whereas those responding with significant lymphocyte proliferation or those with substantial numbers of circulating NK cells need to undergo a conditioning regimen (see Chapter 47). Similarly, if maternal lymphocytes can be demonstrated as the cause of GVHD, conditioning is needed prior to marrow transplantation. MHC typing of the entire family is indicated as soon as the diagnosis of SCID has been established as part of the search for either a matched sibling, a matched unrelated donor, or a partially matched cord blood (see Chapter 47).

Patients with significant T cell deficiency should not receive live vaccines; especially dangerous are BCG, attenuated polio vaccine, and measles, mumps and rubella (MMR) vaccine. Blood products containing cellular elements have to be irradiated and blood products from cytomegalovirus (CMV)-positive donors should be avoided.

There are potential pitfalls in the procedures for the diagnosis of SCID (Table 43.7). Serum immunoglobulin levels are often

difficult to interpret in very young infants. Most infants with SCID have low or absent IgM and IgA, and show persistently dropping IgG levels as the maternal antibodies disappear. Some patients, for example, those with Omenn syndrome, may have elevated serum IgE levels. It is essential to rule out congenital HIV infection by testing the mother's serum for HIV antibody and, if positive, the infant for HIV-RNA by PCR.

As illustrated in Table 1.1 (Chapter 1) and Chapters 9–15 of this book, a molecular diagnosis is now possible in >80% of SCID patients.

## Primary T Cell Defects

### DiGeorge syndrome

Affected patients present with some or all of the following findings: congenital cardiac malformation involving the large vessels, hypoplastic thymus, parathyroid deficiency, velopharyngeal insufficiency, cleft palate, dysmorphic features, and an increased risk of autoimmune diseases (see Chapter 33). These abnormalities can be explained by abnormal formation of the neural crest from which the third and fourth pharyngeal arches develop. Most patients with DiGeorge anomaly have microdeletions affecting q11 of chromosome 22, which is also associated with impairment of language and motor development, mild mental retardation, persistent coordination deficits, a high frequency of behavioral disorder with attention deficit during childhood, and a high frequency of psychotic disorders (bipolar disorder and schizophrenia [Piquer et al., 2001]) during adolescence and young adulthood. The possibility of immune deficiency in those with primary psychotic disease and 22q11 deletion has not yet been investigated systematically.

The extent of immunodeficiency varies greatly, but all infants with tetralogy of Fallot, ventricular septal defects, interrupted aortic arch, pulmonary artery atresia, and truncus arteriosus, especially if associated with hypocalcemia and seizures, should be evaluated for DiGeorge syndrome. Most patients have normal T cell numbers and function or only moderate lymphopenia (Junker and Driscoll, 1995; Ryan et al., 1997). Less than 1% of patients with this syndrome present as having SCID (Goldsobel et al., 1987). However, it is important to measure the numbers of CD4 $^+$  T cells because those infants of less than 4 months of age who have <1000/mm $^3$  CD4 $^+$  T cells and older children with <500/mm $^3$  CD4 $^+$  T cells may be at risk of developing PCP and so benefit from PCP prophylaxis. Absolute lymphocyte counts, T cells, and T cell subsets and mitogen responses at the time of diagnosis, at 6 months, and at 12 months of age are useful to follow those patients with reduced numbers of T cells, as the lymphopenia resolves in most patients by the age of 1 year. Patients with normal lymphocyte subsets and normal mitogen responses at 15 months of age can safely be immunized with live vaccines. Older infants (>15 months) with <500/mm $^3$  CD4 cells should not receive live vaccines or unirradiated blood until their CD4 $^+$  T cell numbers are normal for their age (Pierdominici et al., 2000). The diagnosis is confirmed by FISH analysis of chromosome 22 and, if this is negative, by chromosome 10 analysis or, in a few cases, a mutation in the *TBX1* gene (Yagi et al., 2003).

### CD8 deficiency

Familial CD8 deficiency due to a homozygous mutation in the CD8 $\alpha$  gene has recently been described in a 25-year-old Spanish male from a consanguineous family (Chapter 16). The index case suffered recurrent bacterial sinopulmonary infections and a total

**Table 43.7.** Pitfalls in Diagnosis of Severe Combined Immunodeficiency

- Serum immunoglobulin levels may be normal in infants because of masking effect of Maternal IgG  
Paraproteins, underlying the need for serum electrophoresis in all suspected cases
- Presence of normal or increased numbers of oligoclonal T cells, as in Omenn syndrome
- Presentation in later life as “leaky” SCID
- Need for in vitro activation to detect maximal expression of lymphocyte markers, e.g., CD40L
- Compounding effect of blood transfusion or of maternofetal engraftment causing graft-vs.-host disease

absence of CD8<sup>+</sup> T cells (de la Calle-Martin et al., 2001). Two of the patient's six sisters had an identical defect but were clinically asymptomatic.

## Primary Antibody Defects

### X-Linked agammaglobulinemia

The most characteristic finding in infants with X-linked agammaglobulinemia (XLA, see Chapter 21) is the severely decreased number of B lymphocytes in the peripheral blood (Fig. 43.2). If XLA is suspected at the time of birth (e.g., positive family history), cord blood should be collected and analyzed by flow cytometry. Whereas there are normal numbers of circulating CD4<sup>+</sup> and CD8<sup>+</sup> T cells, B lymphocytes are absent or markedly reduced in numbers. The diagnosis should then be confirmed by demonstrating absence of Btk in patient-derived monocytes or platelets and by sequence analysis. Immunoglobulin levels in cord blood or in serum from very young infants are not informative because the transfer of maternal IgG provides affected infants with normal IgG levels (temporarily), and IgM and IgA are physiologically low in normal infants less than 6 months of age. Because of the presence of maternal antibodies, the onset of symptoms is usually delayed, occurring between 6 and 12 months of age.

Patients with XLA fail to produce antibodies in response to routine childhood vaccines. Their lymph nodes lack germinal centers and plasma cells, and rectal mucosal biopsies are void of plasma cells (Ament et al., 1973). Invasive techniques are no longer necessary to reach a diagnosis.

Measurement of the Btk protein and its kinase activity in monocytes (Futatani et al., 1998; Gaspar et al., 1998) or in platelets (Futatani et al., 2001) is a useful screening test but has to be confirmed by identifying a mutation in the *Btk* gene. Some XLA patients with *Btk* mutations have a milder phenotype, with significant serum concentrations of IgG, IgM, and IgA (Ochs and Smith, 1996); these patients may be erroneously classified as having CVID (see below and Chapter 21). Conversely, *Btk* mutations account for only about 70%–80% of unselected males with panhypogammaglobulinemia and lack of B cells. As more molecular defects in B cell development are identified (Chapters 20–22), a wide range of disorders should be considered in the differential diagnosis (Figs. 43.2, 43.5).

If not treated with sufficient IVIG substitution (see Chapters 21 and 46), XLA patients continue to suffer from recurrent upper and lower respiratory infections and many develop bronchiectasis. This is a common finding when the diagnosis has been delayed or when patients were treated inadequately for more than 10 years (Plebani et al., 2002). Patients with XLA are also susceptible to chronic mycoplasma and enteroviral infections, and exposure to attenuated oral polio vaccine can cause paralytic polio. Chronic infection with echovirus and Coxsackie virus causes meningoencephalitis and an unusual fasciitis-myositis, which is often lethal. Positive viral culture or PCR for enteroviruses confirms this complication.

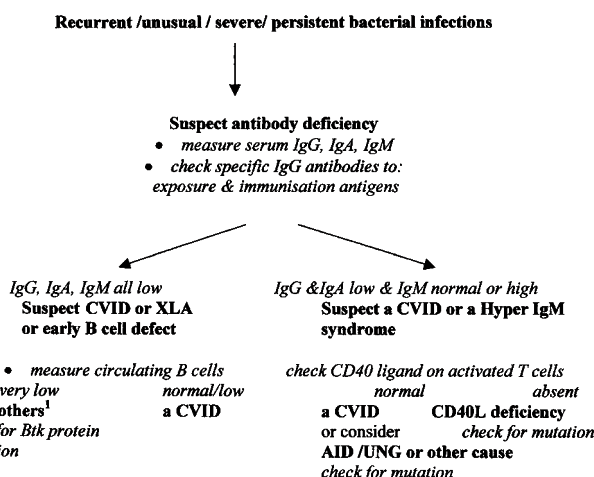

### X-Linked Hyper-IgM and other forms of Hyper-IgM syndromes

Since X-linked hyper IgM (XHIM) is a T cell deficiency (see Chapter 19), it is not surprising that half of the affected male infants present with PCP (Levy et al., 1997) or other infections related to a T cell defect such as cryptosporidium, cryptococcus, or persistent molluscum contagiosum. A high proportion of XHIM patients develop chronic cholangitis associated with cryptosporidia, and tumors of the bile ducts and surrounding tissues have been reported (Hayward et al., 1997). Cryptosporidia can be difficult to detect by microscopy in stools; monoclonal antibody-enhanced immunofluorescent microscopy and PCR can now be used to detect the presence of these organisms in stool and bile (Alles et al., 1995). Neutropenia, either persistent or transient, is common.

Affected patients have low levels of serum IgG and IgA and either normal or elevated IgM at presentation. Absolute numbers of circulating lymphocytes and lymphocyte subsets are normal. Peripheral blood lymphocytes respond to mitogens but often fail to proliferate in vitro in response to specific antigens such as candida and tetanus (Ameratunga et al., 1997). The diagnosis is confirmed by demonstrating that peripheral blood lymphocytes, activated in vitro with phorbol myristate acetate (PMA) and ionophore, fail to express a functional CD40 ligand (CD40L) due to mutations affecting the *CD40L* gene. CD40L can be identified on the surface of activated T cells by specific monoclonal antibodies or by the counter receptor, soluble CD40-Ig, and flow cytometry (Notarangelo and Hayward, 2000). It is worth noting that a subgroup of patients with CVID and all newborn infants express decreased amounts of CD40L. The diagnosis of XHIM is confirmed by sequence analysis of the *CD40L* gene.

Female patients or males with an autosomal recessive form of the hyper-IgM syndrome have a normal *CD40L* gene. Several molecular defects in this group of patients have been identified in recent years. The first group recognized had mutations in the activation-induced cytidine deaminase gene (*AID*) (Revy et al., 2000). *AID* is a key cytoplasmic enzyme restricted to germinal-center B cells and essential for both B cell isotype switching and somatic hypermutation (see Chapter 20). Lymphadenopathy and tonsillar hypertrophy are striking features of *AID* deficiency. Lymph nodes of patients with *AID* deficiency are enlarged and have characterized giant germinal centres, in contrast to the distinct lack of germinal centres in lymph nodes of XHIM patients.

Lack of CD40 expression on circulating B cells and monocytes due to mutations in the *CD40* gene also results in autosomal recessive hyper-IgM syndrome (Ferrari et al., 2001) (see Chapter 19). XHIM and CD40 deficiency appear to have the same clinical phenotype, which is not surprising since they share a defective CD40L–CD40 signaling pathway.

**Figure 43.5.** Approach to diagnosis of antibody deficiencies.

Most recently, mutations of uracil-DNA glucosylase (*UNG*) (Imai et al., 2003), an autosomal recessive disorder (see Chapter 20), and mutations of *NEMO* (X-linked) (Jain et al., 2001) were discovered to cause hyper-IgM syndrome (see Chapter 36). Sequence analysis of these genes is required to confirm these diagnoses.

Common variable immunodeficiency

CVID is a heterogenous group of “acquired” conditions of primary antibody failure. As in other acquired conditions, these may be associated with several susceptibility and/or disease-modifying genes (see Chapter 23). Thus CVID is a diagnosis of exclusion (Table 43.8). Diagnostic criteria define only probable (a >85% probability that in 20 years the diagnosis will be the same) or possible disease, and depend entirely on clinical and laboratory criteria (Table 43.9).

The CVIDs start usually during the second or third decade, although some CVID patients have a history of recurrent res-

**Table 43.9.** Criteria for Diagnosis of Common Variable Immunodeficiency

*Probable*

Male or female patient who has a marked decrease (at least 2 SD below the mean for age) in two of the three major isotypes (IgM, IgG, and IgA) and fulfills all of the following criteria:

1. Onset of immunodeficiency at greater than 2 years of age
2. Absent isohemagglutinins and/or poor response to vaccines
3. Defined causes of hypogammaglobulinemia have been excluded (see Table 43.8)

*Possible*

Male or female patient who has a marked decrease (at least 2 SD below the mean for age) in one of the major isotypes (IgM, IgG, and IgA) and fulfills all of the following criteria:

1. Onset of immunodeficiency at greater than 2 years of age
2. Absent isohemagglutinins and/or poor response to vaccines
3. Defined causes of hypogammaglobulinemia have been excluded (see Table 43.8)

Source: From Conley et al. (1999).

**Table 43.8.** Differential Diagnosis of Hypogammaglobulinemia

*Drug Induced*

Antimalarial agents  
Captopril  
Carbamazepine  
Glucocorticoids  
Fenclofenac  
Gold salts  
Penicillamine  
Phenytoin  
Sulfasalazine

*Genetic Disorders*

Ataxia-telangiectasia  
Autosomal forms of SCID  
Hyper-IgM immunodeficiency  
Transcobalamin II deficiency  
X-linked agammaglobulinemia  
X-linked lymphoproliferative disorder (EBV associated)  
X-linked SCID  
Some metabolic disorders  
Chromosomal anomalies  
Chromosome 18q-syndrome  
Monosomy 22  
Trisomy 8  
Trisomy 21

*Infectious Diseases*

HIV (may be associated with hypergammaglobulinemia)  
Congenital rubella  
Congenital infection with CMV  
Congenital infection with *Toxoplasma gondii*  
Epstein-Barr virus

*Malignancy*

Chronic lymphocytic leukemia  
Immunodeficiency with thymoma  
Non-Hodgkin lymphoma  
B cell malignancy

*Systemic Disorders*

Immunodeficiency caused by hypercatabolism of immunoglobulin  
Immunodeficiency caused by excessive loss of immunoglobulins (nephrosis, severe burns, lymphangiectasia, severe diarrhea)

CMV, cytomegalovirus; EBV, Epstein-Barr virus.

Source: From Conley et al. (1999).

piratory infections starting in early childhood (Cunningham-Rundles, 1989; Hermaszewski and Webster, 1993) and may form a separate subgroup. Symptoms of CVID may also first appear in patients who are 50 years of age or older and have no history of unusual infections at an earlier age.

About 80% of CVID patients have a negative family history except for an increased incidence of autoimmune diseases. Up to 20% of CVID patients may have first-degree relatives with CVID or IgA deficiency (Vorechovsky et al., 1995; Hammarstrom et al., 2000). The presence of unique allotypes within the MHC of chromosome 6 suggests that there is at least one locus of genetic susceptibility in this subgroup of patients. In a few families, an autosomal dominant mode of inheritance has been reported. There are reports of patients presenting first with selective IgA deficiency and then progressing to CVID, supporting the hypothesis that, in the main, these are not purely genetic disorders.

Thymoma with antibody deficiency appears to be a different disease, as it is rare in patients under the age of 40 years. This disorder may become more widely recognized because regular CT scanning is performed to monitor bronchiectasis in patients with primary antibody deficiencies.

Patients with CVID may present with, or develop during the course of the disease, acute or chronic gastrointestinal complaints of a sprue-like syndrome. Pathogens are rarely found on stool culture or microscopy, although patients are known to be susceptible to chronic *Giardia* infection (Ament et al., 1973). The most reliable method of its detection is the collection of multiple biopsies and demonstration of the trophozoites. Direct immunofluorescence (monoclonal antibody-enhanced) assays have increased the sensitivity of detection (Alles et al., 1995), and more recently enzyme immunoassays, which demonstrate *Giardia* antigen in stool specimen, have become available (Maraha and Buiting, 2000; Hanson and Cartwright, 2001). Eradication of the parasites by metronidazole or tinidazole results in disappearance of the gastrointestinal symptoms. Patients with CVID have a high incidence of nodular lymphoid hyperplasia, which can be demonstrated radiologically or by endoscopic examination of the small bowel. Plasma cells in the lamina propria are often absent or markedly reduced.

A subgroup of CVID patients develops severe granulomatous changes in the lungs resembling sarcoidosis. Others present with

lymphadenopathy and hepatosplenomegaly caused by nonspecific lymphoid and/or granulomatous proliferation. Lymphoid interstitial pneumonitis is another complication that is unexplained (Davies et al., 2000). Splenomegaly is present in about 30% of CVID patients and hypersplenism may be severe enough to necessitate splenectomy, although this is best avoided. Lymphadenopathy, especially in the abdominal cavity and the mediastinum, is a frequent finding and may require an exploratory laparotomy to rule out a malignant process. There is an increased incidence of lymphoreticular and gastrointestinal malignancies in older patients with CVID, although this is less marked than originally thought (Mellemkjaer et al., 2002).

The laboratory findings of CVID are heterogeneous (Cunningham-Rundles and Bodian, 1999). By definition, CVID patients have low but demonstrable IgG and at least one other low Ig isotype. Serum IgA is undetectable in two-thirds of patients. IgM is low, in addition to reduced levels of IgG and IgA, in about a quarter of patients meeting the diagnostic criteria for CVID.

The diagnostic criteria require that antibody responses to proteins, polysaccharides, and neoantigens are abnormal. Some patients are able to amplify responses and switch from IgM to IgG; others fail to produce antibody other than IgM, and some patients make barely detectable antibodies (Stiehm et al., 2004). Most patients have normal numbers of lymphocytes and lymphocyte subsets, although a moderate CD4<sup>+</sup> T cell lymphopenia with a reversed CD4:CD8 ratio occurs in about 25% of CVID patients (Spickett et al., 1997). Abnormal in vitro lymphokine production by cultured lymphocytes has been reported (Sneller and Strober, 1990). B cell numbers are often but not always normal, leading to the hypothesis that those with low numbers of circulating B cells form a (as-yet undefined) subgroup. The hypothesis of a T cell defect as one of the causes of another subgroup of CVID is supported by the fact that lymphocytes from some patients fail in vitro to respond to activation by recall antigens, and activated lymphocytes from some patients express only small amounts of CD40L (Farrington et al., 1994). Other studies have shown intrinsic B cell defects in at least 25% of patients (Levy et al., 1998; Schwartz et al., 1999).

In view of the heterogeneity of CVID, it is not surprising that some patients with a provisional diagnosis of CVID have been shown to have mutations in one of several genes known to cause PID, such as *Btk*, *CD40L*, *AID*, *UNG*, and *SH2D1A*. Recent reports suggest that XLP should always be considered when more than one male with CVID is encountered within the same family (Morra et al., 2001). Consequently, a strict diagnosis of CVID can only be made after the exclusion of mutations in these genes. A subgroup of CVID patients was recently found to lack expression of ICOS (inducible costimulator) on activated T cells because of a homozygous deletion within the *ICOS* gene. This is a rare event, however (Grimbacher et al., 2003; Salzer et al., 2004). Other genes found to be mutated in patients with CVID phenotypes include BAFF receptor, CD19, and TACI (Salzer et al., 2005). It is predictable that additional genes required for B cell activation will be identified to cause one of the CVID phenotypes.

#### Antibody deficiency with normal or elevated serum immunoglobulin levels

This entity, more often observed in adults than in children, resembles CVID. Affected patients often present with recurrent pulmonary disease, complicated by chronic lung disease and bronchiectasis. Serum immunoglobulin levels, by definition, are normal or elevated; this makes it difficult to establish the diagno-

sis. A mild T cell abnormality similar to that observed in a subgroup of CVID patients may be present. The most informative diagnostic procedure that effectively identifies these patients is in vivo antibody production to a battery of antigens that include proteins (e.g., diphtheria and tetanus toxoid), polysaccharide antigens (e.g., Pneumovax, Typhim Vi), and neoantigens (e.g., KLH, bacteriophage ØX174). Characteristically, patients with this disorder respond to some antigens but not to others, making it difficult to establish a reliable diagnosis. Replacement immunoglobulin therapy (usually after a failed trial of prophylactic antibiotics) must be monitored with great attention to clinical improvement and documented reduction of significant infections.

#### Isotype and IgG subclass deficiencies

This diagnosis is made by measuring serum immunoglobulin levels and IgG subclass levels. It is important to compare the results with normal age-matched controls (Stiehm et al., 2004). IgA deficiency is considered if serum IgA is <5 mg/dl (0.05 g/l); IgM deficiency, if the serum level is <20 mg/dl (0.2 g/l); and IgG subclass deficiency is considered if the levels are below 2 SD, or less than the fifth percentile of age-matched controls. Most patients with "selective IgA" deficiency are asymptomatic. Those with susceptibility to infections may have associated IgG2 and IgG4 deficiency, and some may respond poorly to antigenic stimulation, resembling CVID.

IgG subclass deficiencies are unlikely to be clinically significant if specific antibody production is intact. It is important, therefore, to determine specific antibody responses to immunizations with protein and polysaccharide antigens and to reserve the diagnosis and treatment to those with documented failure of specific antibody production.

#### The Wiskott-Aldrich Syndrome

Any male infant with petechiae and easy bruising, eczema, bloody diarrhea, and recurrent otitis media has the Wiskott-Aldrich syndrome (WAS) until proven otherwise (Chapter 31). The combination of thrombocytopenia and small platelets is considered diagnostic. There is a subgroup of male infants with congenital thrombocytopenia and small platelets without the other clinical symptoms characteristic for WAS; these patients have been categorized as having X-linked thrombocytopenia (XLT), atypical WAS, or WAS variant. In patients with a classic WAS phenotype, both humoral and cellular immunity are affected (Ochs et al., 1980; Thrasher and Kinnon, 2000). Serum immunoglobulin levels are normal or low for IgG (often with IgG2 deficiency), moderately depressed for IgM, and often elevated for IgA and IgE. Isohemagglutinin titers are very low and antibody responses to polysaccharides (e.g., Pneumovax) are consistently depressed. Antibody responses to diphtheria and tetanus toxoid are often but not always abnormal, and responses to bacteriophage X174 lack immunologic memory, amplification, and isotype switching. Lymphopenia often develops by the age of 6–8 years with a proportional decrease in all lymphocyte subsets. Absolute B lymphocytes remain usually within normal range. In vitro lymphocyte proliferation to mitogens is often diminished, but not absent, and responses to allogeneic cells or immobilized anti-CD3 monoclonal antibodies are markedly depressed.

The diagnosis of WAS or XLT is confirmed by demonstrating a mutation within the WAS protein (WASP) gene, located in Xp11.22–23. As a consequence, cytoplasmic WASP is absent or the amount is decreased (Jin et al., 2004).

### X-linked Lymphoproliferative Disease

Patients carrying the XLP gene (*SH2D1A*) are usually clinically normal until they are exposed to EBV. Following exposure, affected males may develop fulminant infectious mononucleosis, agammaglobulinemia, or lymphoproliferative disorders and lymphoma. Before exposure to EBV, most affected individuals have normal immunologic parameters. The laboratory findings in males with a mutation of the *SH2D1A* gene during acute EBV infection are described in Chapter 32. Recent evidence suggests that patients may be susceptible to other herpes viruses that can provoke an erythrophagocytic picture.

After EBV infection, surviving XLP patients often show a combined T and B cell defect (Sullivan et al., 1983). Some but not all patients will develop a persistent decrease in lymphocyte proliferation to mitogens, a decreased CD4:CD8 ratio with a predominance of CD8 cells, and decreased in vitro immunoglobulin synthesis by B cells in the presence of autologous T cells. Stimulated lymphocytes show a decrease in lymphokine production. Antibody responses to a neoantigen (e.g., bacteriophage X174) are quantitatively normal, but antibody produced by XLP patients after EBV infection is often limited to the IgM isotype.

The diagnosis is confirmed by sequence analysis of *SH2D1A*, the gene responsible for XLP. Those males at risk for XLP, i.e., family members and all male siblings with the diagnosis CVID, should be studied for *SH2D1A* mutations.

### Natural Killer Cell Defects

A novel syndrome characterized by severe prenatal and postnatal growth failure, mild skeletal and facial abnormalities, and primary immunodeficiency was described in two sisters (Bernard et al., 2004). The immune defect consisted of very low numbers of detectable natural killer cells (CD16<sup>+</sup>/CD56<sup>+</sup>), lack of NK cell function, and small numbers of CD8<sup>+</sup> T cells and neutrophils. This novel syndrome is probably caused by an autosomal recessive gene defect impairing both intrauterine growth and NK cell development.

### Neutrophil Defects

#### Persistent neutropenia

Persistent neutropenia has multiple etiologies and may be associated with other disorders, including Shwachman syndrome, X-linked hyper-IgM syndrome, and X-linked agammaglobulinemia. Mutations of neutrophil elastase (Horwitz et al., 1999) can cause congenital neutropenia (Kostmann syndrome) or cyclic neutropenia (see Chapter 39). In small infants, neutropenia can be a sign of overwhelming infection and increased neutrophil consumption. A bone marrow examination is required to see if the neutropenia is due to insufficient production or increased consumption. Consumption due to an autoantibody is detected by the presence of antineutrophil antibodies. In alloimmune neutropenia these have NA1 and NA2 specificities; these can only be identified in a specialized laboratory (Lakshman and Finn, 2001).

#### Defective locomotion and phagocytosis

Defective locomotion and phagocytosis have been observed in a number of syndromes including leukocyte adhesion deficiency, "lazy leukocyte syndrome," Chediak-Higashi syndrome, hyper-IgE syndrome, and the Wiskott-Aldrich syndrome, through techniques available for directed (chemotaxis) and random movement

of neutrophils (Kuijpers et al., 1999). Rebuck skin window or a collecting chamber can be used to measure in vivo adhesion and chemotaxis (Bowen et al., 1982). However, these tests are difficult to perform as there are nonspecific factors that can interfere with in vivo and in vitro chemotaxis, and primary diseases restricted to abnormalities of chemotaxis or phagocytosis are not known. Most disorders of phagocytosis are the result of opsonic defects rather than intrinsic phagocytic defects. If an opsonizing defect is suspected, it is important to test phagocytosis by normal neutrophils in the presence of patient serum.

#### Leukocyte adhesion deficiency

Patients with leukocyte adhesion deficiency (LAD) (see Chapter 38) present in early infancy with characteristic clinical findings. Patients with LAD often present with delayed separation of the cord, omphalitis and cellulitis without pus formation, and neutrophilia that may reach 60,000–80,000/mm<sup>3</sup> during active infection. In vivo and in vitro chemotaxis is abnormal. Patients with LAD1, lacking the common subunit CD18, are unable to form the heterodimer CD11/CD18, demonstrated by flow cytometry with anti-CD18 monoclonal antibodies. Their neutrophils fail to adhere to plastic, glass, or cultured endothelial cells. Sequence analysis of the subunit confirms the diagnosis of LAD1.

Variants of LAD1 deficiency associated with normally expressed but functionally defective  $\beta_2$  integrins (CD11/CD18) as well as combined defects in  $\beta_1$  and  $\beta_2$  integrins have recently been described (Kuijpers et al., 1997; Hogg et al., 1999; Harris et al., 2001). The clinical phenotypes in these LAD variants have ranged from mild to severe. The more recent description of a novel form of integrin dysfunction involving  $\beta_1$ ,  $\beta_2$ , and  $\beta_3$  integrins in a patient with LAD1 and a rare bleeding tendency (termed *Glanzmann thrombasthenia*) due to mutations in the platelet integrin CD41/CD61 illustrates the expanding spectrum of adhesion molecule defects (McDowell et al., 2003).

Patients with LAD2 lack the fucosylated selectin ligand, sialyl Lewis X (SLeX, CD15) (without the demonstration of a mutation) on their neutrophils. They have the Bombay red cell phenotype, as they do not express the blood group antigen H. LAD2 neutrophils fail to roll along the endothelial wall. The defect of LAD2 is a mutation in the fucose transporter gene. The diagnosis is suspected by the combination of the clinical phenotype, the presence of the Bombay blood group, and the absence of SLeX on leukocytes on flow cytometry.

Lack of endothelial expression of E selectin has been described and produces a clinical picture similar to LAD deficiency, with the important exception of a mild neutropenia rather than a neutrophil leucocytosis (DeLisser et al., 1999).

#### Chronic granulomatous disease

Neutrophils from patients with chronic granulomatous disease (CGD) (see Chapter 37) ingest microorganisms but fail to kill catalase-producing bacteria and fungi. Patients present with recurrent abscesses involving lymphnodes, liver and spleen, brain, and bone. The infections are often due to staphylococci and fail to respond to antibiotics, or they are serious fungal infections, often pulmonary. Regional lymphadenopathy (sometimes suppurative), often associated with persistent hepatosplenomegaly, leads to a diagnostic lymph node biopsy, in which granulomata are a feature.

Although several methods to measure the oxidative metabolic burst have been developed, the most useful is the dihydrorhodamine (DHR) test using flow cytometry (Carulli, 1996; Jirapongsananuruk et al., 2003). Defective NADPH oxidase activity

is the major cause of CGD and may be the result of mutations of one of several cytoplasmic or membrane-associated components of NADPH oxidase (see Chapter 37).

### Complement Deficiencies

Complement component deficiencies may affect the early components of the classical complement pathway, or the alternative or the terminal pathway (see Chapter 42). Usually a single component is involved, and this is associated with a homozygous gene defect resulting in absence of that component. Even small amounts of a component allow adequate function of the total pathway; levels of most components are increased in an acute-phase response.

Screening is done with the CH50 (which tests classical and final lytic components except C9) and AP 50 (which tests alternative and final lytic pathways) assays. These tests should only be done in laboratories with considerable experience of these assays, usually specialized clinical immunology laboratories. To avoid misinterpretation due to the possible effects of complement consumption by immune complex formation, it is advisable that the assays be performed when the patient has completely recovered from immune complex disease or infection. Both tests require that blood be taken atraumatically and serum be separated within 1 hour and then stored at  $-70^{\circ}\text{C}$ . Failure to achieve lysis can be due to inadequate storage, release of enzymes on venepuncture, aged red cells, and limited quality assurance.

If either of these screening tests identifies failure of a complement pathway on two occasions, the specific component defect should be determined. Fresh serum should be collected properly and shipped on dry ice to laboratories with expertise in complement assessment. It is preferable that both functional and immunochemical determinations be performed, as a protein may be present but dysfunctional. Enzyme-linked immunosorbent assay (ELISA) techniques measure individual components and functional assays are available to detect present but nonfunctioning proteins. If dysfunctional or missing components cannot be identified, an inhibitor should be considered.

All first-degree family members should be screened with the appropriate hemolytic complement assay (CH50, AP50). Some affected individuals are asymptomatic. A careful family history with analysis of three or four generations may reveal a pattern of inheritance that is compatible with an X-linked, autosomal recessive, or autosomal dominant mode of inheritance. A family history of early death is more informative if it occurred after 1945 when penicillin had become widely available. Consanguinity, or being a member of a close-knit community based on religion or ethnicity, increases the possibility of an autosomal recessive disease. The occurrence of a new mutation in those complement component deficiencies with X-linked inheritance has to be considered, as in any X-linked disease.

### Defects of Antigen-Presenting Cells

#### TAP deficiency syndromes

The TAP (transporter associated with antigen presentation) deficiency syndromes are variants of the bare lymphocyte syndrome type I, characterized by severe down-regulation of HLA class I molecules due to mutations or deletions of genes encoding either TAP1 or TAP2 proteins (Gadola et al., 2000) (see Chapter 18). Clinical features of affected patients vary from severe and ultimately

fatal recurrent bacterial, fungal, and parasitic infections beginning in infancy (group 1, only a few patients described) to those patients who develop necrotizing granulomatous skin lesions on a background of recurrent sinopulmonary bacterial infections (group 3, the largest number of cases but still rare). There have been two families with asymptomatic individuals (group 2). In patients with sinus and nasal involvement, the histology resembles that of Wegener's granulomatosis.

The unifying immunological feature in both groups is defective HLA class I expression on peripheral blood mononuclear cells. Patients in group 1 have also shown a complete lack of antibody production. Analysis of lymphocyte repertoire has shown low numbers of  $\alpha$ - $\beta$  CD8 T cells, with an expansion of NK and  $\gamma$ - $\delta$  T cells in most patients. These latter cell types are activated by bacterial infection and provoke a Th1 response resulting in granulomata.

#### Major histocompatibility complex Class II deficiency

MHC class II deficiency is caused by the absence of MHC class II molecules on the surface of antigen-presenting cells (B cells, dendritic cells, macrophages, thymic epithelial cells, and activated T cells). In MHC class II deficiency, also called bare lymphocyte syndrome type II, the defect is caused by mutations affecting one of at least four transcription factors that control MHC class II gene expression (see Chapter 17). As a result of this defect, both cellular and humoral immune responses are affected and patients are highly susceptible to viral, bacterial, and fungal infections, primarily of the respiratory and gastrointestinal tract.

All antigen-presenting cells from affected patients completely lack MHC class II molecules, even following activation with IFN- $\gamma$ . Affected patients have normal numbers of circulating T and B lymphocytes; however CD4<sup>+</sup> T cells are reduced in number while CD8 T cell numbers are proportionately increased. The diagnosis of bare lymphocyte syndrome type II should be considered in all children with recurrent respiratory tract infections, diarrhea, and failure to thrive. The diagnosis is based on the absence of MHC class II molecules on the surface of B cells, monocytes, and dendritic cells, or IFN- $\gamma$  activated T cells. Early diagnosis is important because the only effective treatment is timely stem cell transplantation.

### Immunodeficiency Associated with Defects of DNA Repair

This group includes three well-described clinical syndromes discussed below and other less-characterized and rare conditions, such as DNA ligase defects, xeroderma pigmentosum, and unrecognized conditions that tend to show a mixture of features including radiosensitivity, antibody deficiency (and predictable consequences), and autoimmunity (Gennery et al., 2000).

#### Ataxia-Telangiectasia

Ataxia-telangiectasia (AT) (see Chapter 29) is an autosomal recessive disorder characterized by progressive cerebellar degeneration, cutaneous or ocular telangiectasia, and immunodeficiency affecting predominantly cellular immunity, sensitivity to ionizing radiation, and a high incidence of malignancies. There is considerable clinical heterogeneity. The characteristic ataxia develops during infancy and is initially difficult to recognize; occasionally, the onset of ataxia is delayed until 4 or 5 years of age. More than two-thirds of AT patients suffer from recurrent bacterial infections due to defective T and B lymphocyte function. Endocrine problems are common.

The most consistent laboratory abnormality, almost pathognomonic for AT, is an elevated  $\alpha$ -fetoprotein level. Most (80%) patients have IgA and IgE deficiency, which is occasionally associated with IgG2 and IgG4 subclass deficiency. Serum IgM may be elevated. Antibody responses to viral and bacterial antigens are often but not always deficient and correlate with the frequency of respiratory infections. T cell abnormalities include depressed proliferative responses to mitogens and specific antigens. Lymphopenia may be present in some patients because of a loss of CD4<sup>+</sup> cells, but in most AT patients lymphocyte subsets are normal. Excessive chromosomal breakage can be observed in lymphocytes and fibroblasts, with breakpoints at 14q32, 14q12, 7q35, and 7p12, corresponding with the sites of gene complexes coding for immunoglobulin heavy chains and the T cell receptor chains  $\alpha$ ,  $\beta$ , and  $\gamma$ , respectively. In culture, cells from AT patients display increased sensitivity to ionizing radiation and radiomimetic chemicals, and uninhibited postirradiation DNA synthesis.

The identification of the AT gene, designated *ATM* (AT, mutated), has allowed the molecular analysis of the defect in affected families and makes carrier detection and prenatal diagnosis possible. The clinical heterogeneity may be explained by the type of mutation; frameshifts are associated with the absence of protein whereas milder phenotypes have missense mutations and some intracellular protein is detected (Gilad et al., 1998).

#### Nijmegen breakage syndrome

Patients with Nijmegen breakage syndrome (see Chapter 30), often of Czech or Polish descent, share many clinical findings with AT patients. They characteristically have microcephaly and growth retardation but they do not develop ataxia nor telangiectasia, and  $\alpha$ -fetoprotein is normal. They share with AT patients a tendency toward recurrent infections, predisposition to malignancies, chromosomal instability, and hypersensitivity to irradiation and alkylating agents, and they have uninhibited postirradiation DNA synthesis.

These patients often present with immunodeficiencies affecting both T and B cells and hypogammaglobulinemia, and they may have deficiency of IgG2 and IgG4 (Gregorek et al., 2002). Flow-cytometric analysis shows a decreased number of CD4<sup>+</sup> T cells and decreased CD4:CD8 ratio. Affected patients often have increased numbers of NK cells. In vitro lymphocyte proliferation to mitogens is impaired.

The gene for the Nijmegen breakage syndrome, *NBS1*, has been localized to chromosome 8q21, and the defective protein, NBS1 (nibrin), shows functional homology to a DNA repair protein in yeast. However, not all patients with Nijmegen breakage syndrome have an NBS1 mutation and other proteins may be involved (see Chapter 30).

#### Bloom syndrome

Patients with Bloom syndrome (see Chapter 30) have characteristic features and may develop a sun-sensitive erythematous skin rash that often but not always occurs along with recurrent bacterial respiratory infections. These patients have a high risk of cancer and a tendency to develop endocrine problems. Lymphocytes and fibroblasts develop sister chromatid exchanges and show gaps and breaks and increased rearrangements.

The associated immune deficiency is characterized by great variability. Some patients have hypogammaglobulinemia; others have normal levels of all immunoglobulin isotypes. Antibody responses to various antigens are either normal or moderately depressed. In vitro lymphocyte proliferation in response to PHA is

generally normal, but some patients have decreased responses to PWM, ConA, and allogeneic cells. The numbers of circulating lymphocytes and lymphocyte subsets are normal.

The gene for Bloom syndrome, *BLM*, is located at 15q26.1 and has recently been cloned and sequenced. It encodes a nuclear protein, which is absent in Bloom syndrome patients. Bloom syndrome is a clinical diagnosis, and the availability of molecular techniques has made it possible to confirm the diagnosis, detect variants, identify carriers, and perform prenatal diagnosis.

#### Other Deficiencies to Be Considered

The hyper-IgE (Job) syndrome, characterized by coarse facial features, recurrent staphylococcal and candida infections, abscess formation, recurrent lung abscesses often resulting in pneumatoceles, and atopic disease, most often occurs sporadically, rarely as an autosomal dominant disorder (see Chapter 34). Affected patients have markedly elevated IgE levels that exceed 5000 IU/ml and may be as high as 50,000–100,000 IU/ml, and often have eosinophilia. The diagnosis is based on clinical presentation, a strikingly elevated IgE level, and presence of associated features (see Table 43.10). A single-locus autosomal dominant trait with variable expressivity has been linked to a proximal region on the long arm of chromosome 4 (Grimbacher et al., 1999a, 1999b) in a subgroup of unrelated, ethnically diverse, familial cases, findings suggesting sporadic mutation. There is ongoing study to examine the variable expression and apparently greater severity in succeeding generations. Autosomal recessive inheritance has been reported in families of Turkish descent (Renner et al., 2004). Serum immunoglobulin levels and specific antibodies to immunization and exposure antigens should be measured, as a few patients have improved with therapeutic immunoglobulin (Bilora et al., 2000).

Chronic mucocutaneous candidiasis is characterized by candida infections at multiple sites affecting the skin and mucosa. The candida infections may spread into the esophagus and lungs. A subgroup of patients may develop autoimmune polyendocrinopathy–candidiasis–ectodermal dystrophy (APECED), an autosomal recessive condition (Ahonen et al., 1990) due to the mutation of AIRE, a recently identified DNA-binding protein expressed by thymic epithelial cells and containing two zinc-finger motifs (Aaltonen et al., 1997) (see Chapter 25). In contrast to patients with cellular immune deficiencies, most patients with this syndrome have normal T cell numbers and normal in vitro lymphocyte proliferation to mitogens. Responses to specific antigen, except to candida antigens, which are often depressed, are variable regardless of whether measured by cytokine production or lymphocyte transformation.

Interleukin 12 (IL-12) and the interferon pathway defects result in familial generalized atypical tuberculosis or generalized infection with BCG (see Chapter 28). Most patients identified to date belong to consanguineous families and are therefore homozygous for the defect and exhibit reduced antigen-induced IFN- $\gamma$  production in vitro. Detection of intracellular phosphorylated STAT-4 by flow cytometry has facilitated the diagnosis of these conditions (Uzel et al., 2001). The precise location of the defect within the pathways is delineated by studies of cell surface expression of the IL-12 and IFN- $\gamma$  receptors, assays of IL-12 and IFN- $\gamma$  production, and mutation analysis of the relevant genes (Lammas et al., 2000). A reduction of TNF- $\alpha$  production is a common secondary feature in this group of patients.

Hereditary transcobalamin II (TCII) deficiency is a recessive disorder caused by a mutation of the TCII gene located on chro-

**Table 43.10.** Diagnostic Features of Hyper-IgE Syndrome\*

Feature	Level Considered Significant	Prevalence in Hyper-IgE	Level of Diagnostic Usefulness†
Neonatal rash	Present	Approaches 100%	Useful
Eczema	Severe	100%	Present, nonspecific
Raised serum IgE level	>2000 IU/ml at highest	97%	Defining hallmark
Eosinophilia	>0.8 × 10 <sup>9</sup> /l	93%	Useful
Recurrent abscesses	>4 separate sites or episodes	87%	Defining hallmark
Pneumonia	X-ray proven Any invasive organism‡	87%	2–3 = useful
Candidiasis in fingernails	Present	83%	Useful
Characteristic facies	Present in adolescence	83%	Useful
Interalar distance	>1 SD above mean for age, gender, ethnicity	80%	Useful
Pneumatocoeles	Present	77%	Defining hallmark
Scoliosis	>15°–20° in patients over 16 years of age	76%	Useful
Delay in shedding primary dentition	>3 primary teeth	72%	Defining hallmark
Hyperextensible joints		68%	Variable, nonspecific
Recurrent fractures or osteoporosis	>1–2 from minimal trauma	57%	Useful

\*Diagnosis is probable if there are three or more defining hallmarks plus two useful criteria. Diagnosis is possible if two defining hallmarks and three useful criteria are present (see below).

†Defining hallmark = scores of 7–10 on diagnostic score sheet; useful = scores of 4–6 on diagnostic score sheet; variable = scores of 0–3 on diagnostic score sheet.

‡For example, *Haemophilus influenza*, *Streptococcus pneumoniae*, *Staphylococcus*, *Pseudomonas*, *Pneumocystis*, atypical mycobacteria, etc.

Source: From Grimbacher et al., 1999a and J. Puck (personal communication).

mosome 22. TCII is required for absorption and transport of vitamin B<sub>12</sub>. Patients with TCII deficiency present in the first few months of life with failure to thrive, diarrhea, ulcers of the oral mucous membrane, irritability, lethargy, delayed neurologic development, severe macrocytic anaemia, and neutropenia. Affected patients often present with decreased serum IgG and defective antibody responses (Hitzig and Kenny, 1975). Since treatment with high-dose vitamin B<sub>12</sub> is highly efficient, establishing the diagnosis at an early age is vital. The human TCII gene has been cloned, and mutations have been identified (Li et al., 1994).

## Genetic Aspects of Primary Immunodeficiencies

JENNIFER M. PUCK

There are three reasons why evaluation of an immunological disorder in any patient should include consideration of potential underlying genetic determinants. First, genetic studies can confirm a suspected diagnosis of immunodeficiency; they can also help to pinpoint a specific genetic etiology even when other available data are unusual, incomplete, or inconclusive. Second, new understanding of the immunological basis and pathogenesis of immunodeficiencies can be gleaned as more disease genes are identified through the partnership between researchers in molecular genetics, clinicians, and affected patients. Finally, diagnosing a genetic disorder in an index patient, or proband, has profound implications for the patient's family members, both affected and unaffected, living and as yet unborn.

Disorders of the immune system may be due to defects in single genes, either already known or currently unidentified. Because we have now recognized frequent new mutations and variant phenotypes for many immunodeficiency genes, we know that even immunodeficient patients lacking a positive family history may have genetic mutations underlying their condition that pose a reproductive risk in their family members. More common in the population than single-gene disorders causing immunodeficiency are many as yet poorly understood immune dysfunctions with a complex etiology, but this complexity probably includes one or more genetic factors that may interact with environmental influences. As the field of genetics advances, the existence of genetic contributions to all categories of human disease, including immunodeficiencies, is becoming increasingly apparent. While this chapter emphasizes the available genetic tests for single gene diseases, the field is changing rapidly. Not only are additional disease genes being discovered, but technologies for finding mutations and determining carrier status are in constant evolution. The technical ability to determine the genetic constitution of an individual will in many instances exceed the capacity of our

medical and social systems to help individuals learn about their risks, to evaluate the potential harms and benefits of genetic testing, and to develop and provide new therapies made possible by genetic advances.

The reader is referred to Chapter 2 for a summary of genetic principles and technologies. This chapter will present an overview of genetic tests used to diagnose inherited immunodeficiencies, but these tests should be viewed in a broad context of evolving basic knowledge, technological advances, and social and regulatory issues. The physician specializing in the diagnosis and treatment of immunodeficiencies should stay in contact with patients and their families to be able to pass on relevant new information. Much can be gained through enlisting the involvement of clinical geneticists and genetic counselors, who specialize in helping individuals and families understand and manage their genetic risks.

### Establishing a Genetic Etiology

#### Positive Family History

The first diagnostic measure when considering any heritable disorder is to obtain a full pedigree and family health history; heritable immunodeficiencies are no exception. Although most of the immunodeficiencies in this book have been identified at the gene level very recently, families can often provide details about potentially affected members in past generations whose presentation and course might be compatible with the disorder (see agammaglobulinemia pedigree and discussion in Chapter 1). Assembly and recall of complete information often require more than one session and interviews with more individuals than just the nuclear family of the proband. Retrieval and review of medical records from relatives can provide critical data and are well worth seeking. Ethnic and geographical ancestry should be

recorded as part of every family history because they may suggest consanguinity or increased risks associated with particular populations.

The X chromosome harbors more recognized immunodeficiency genes than any other chromosome, and the X-linked immunodeficiency diseases occur in disproportionately high frequency (Table 44.1). This is because in males, mutations in genes on the sole copy of the X chromosome are uncompensated, and therefore a single mutation causes overt disease. The X-linked inheritance pattern of multiple affected males related through maternal lines, as discussed in Chapter 2, should be sought in all families with a male presenting with immunodeficiency.

Recessive diseases, in contrast, require defects in both alleles of a gene in order for a disease phenotype to be manifest. One way in which this occurs is through consanguinous marriages, such as with the interferon gamma (IFN- $\gamma$ ) receptor mutations causing susceptibility to mycobacterial infections (Chapter 28). Belonging to a genetically isolated population is another risk factor for homozygous recessive diseases in which the same mutation may be transmitted through both maternal and paternal lines to the patient because of inbreeding. This phenomenon is found in the ataxia-telangiectasia of Jews of Moroccan origin (Chapter 29) and the severe combined immunodeficiency (SCID) of Native Americans of the southwestern United States (Chapter 11) (Li et al., 2002). In many recessive immunodeficiencies, however, such as adenosine deaminase (ADA)-deficient SCID (Chapter 12), most patients have a different mutation in each of their two alleles.

There are relatively few dominant immunodeficiency phenotypes. As a rule, they are characterized by incomplete penetrance (skipping generations in family pedigrees) and/or variable expressivity (a large spectrum of severity among relatives with the same genetic mutation). Examples include DiGeorge syndrome (Chapter 33); autoimmune lymphoproliferative syndrome due to Fas deficiency (Chapter 24); some instances of hyper IgE-recurrent

infection syndrome, or Job's syndrome (Chapter 34); and, importantly, some instances of common variable immunodeficiency (CVID) and IgA deficiency (Chapter 23); and even atopy and allergic disorders (Holgate, 1997). These may turn out to be diseases in which a dominant gene mutation has a predisposing or contributory effect in a group of families, but in which genetic or environmental factors act as modifiers of the phenotype.

Several immunodeficiency syndromes, such as SCID or chronic granulomatous disease (CGD), can be caused by defects in any of several different genes; existence of autosomal phenocopies of the X-linked immune disorders are indicated in Table 44.1. Family history can be critical in differentiating the X-linked from autosomal forms.

### Importance of Family History, Even If Negative

Documentation of a complete family pedigree is helpful even if it fails to reveal any sign of disease comparable to that of a proband affected with immunodeficiency. First, the structure of the pedigree determines the quantity of genetic information. A large kindred with many siblings of both sexes has had more opportunities to have affected relatives, whereas at the other extreme, there may be no information whatsoever about an adopted infant's heredity. Second, the absence of disease in many relatives who could potentially be at risk is useful. For example, if a male with SCID has many healthy maternal uncles, either a new occurrence of an *IL2RG* gene mutation (Table 44.1) or recessive disease is considerably more likely than an X-linked mutation inherited from the patient's grandmother. A third benefit of obtaining a family history is the insight it can provide into the way in which family members will approach a serious immunodeficiency disease. We can provide optimal care for patients and their families only if we understand what the disease means to them. In previous generations or when the initial diagnosis has

**Table 44.1.** X-linked Immunodeficiencies and Their Disease Genes

<i>Immunodeficiency Disease</i>	<i>Gene Name</i>	<i>Protein</i>	<i>Location</i>	<i>Female Skewed X Inactivation</i>	<i>Autosomal Genocopy</i>	<i>Chapter in Book</i>
X-linked chronic granulomatous disease (CGD)	<i>CYBB</i>	Cytochrome oxidase gp91 <sup>phox</sup> that generates reactive oxygen species	Xp21.1	No	Yes	37
Properdin deficiency	<i>PFC</i>	Properdin activator of complement	Xp11.23	No	Yes	42
Immunodysregulation polyendocrinopathy enteropathy syndrome (IPEX)	<i>FOXP3</i>	Forkhead/winged-helix transcriptional regulator critical for regulatory T cells	Xp11.23	No	Not known	26
Wiskott-Aldrich syndrome (WAS)	<i>WAS</i>	WAS protein (WASP) activator of actin polymerization and signal transduction	Xp11.22	Yes: all hematopoietic cells	Probably	31
X-linked severe combined immunodeficiency (XSCID)	<i>IL2RG</i>	Common $\gamma$ chain of cytokine receptors	Xq13.1	Yes: T, B, NK cells (not phagocytes)	Yes	9
X-linked agammaglobulinemia (XLA)	<i>BTK</i>	B cell tyrosine kinase	Xq21.3–q22	Yes: B cells (not T cells, phagocytes)	Yes	21
X-linked lymphoproliferative syndrome (XLP)	<i>SAP, SH2D1A</i>	Lymphocyte signaling activation molecule	Xq25	No	Not known	32
X-linked hyper-IgM syndrome	<i>CD40L</i>	CD40 ligand	Xq26.3–q27.1	No	Yes	19
G6PD deficiency	<i>G6PD</i>	Glucose-6-phosphate dehydrogenase	Xq28	No	No	38
X-linked ectodermal dysplasia with immunodeficiency (NEMO)	<i>NEMO, IKBKG</i>	Inhibitor of $\kappa$ light polypeptide gene enhancer in B cells, kinase $\gamma$	Xq28	Sometimes; females have incontinentia pigmenti	Not known	36

been delayed and treatment was ineffective, children born with immunodeficiencies are likely to have died, leading to parental feelings of guilt, secrecy, and other family stresses. Important family events or beliefs unrelated to immunodeficiency also strongly influence the outlook of family members. Finally, the family history may bring to light facts that influence the type of genetic testing that may be indicated, such as multiple miscarriages (a risk factor for chromosomal rearrangements) or nonpaternity.

### **Genetic Testing for Abnormalities in Immune System Genes**

Inherited immunodeficiencies are sufficiently rare that population-based screening has not been implemented to date. Genetic testing is therefore used to establish the diagnosis in an affected individual or to determine the status of relatives of a person already suspected to have a primary immunodeficiency. Individuals in a family with recognized immunodeficiency for whom genetic testing may be indicated include affected patients who are ill; individuals who may have inherited a defective immune system gene, but as yet show no symptoms (presymptomatic testing); and healthy relatives not at risk for becoming immunodeficient but who may be carriers of a defective copy of a gene and are concerned about their reproductive risks. In addition, prenatal testing has been performed for many immunodeficiencies in pregnancies following the diagnosis of an affected child. No single testing modality is appropriate for all situations. The reader is referred to specific chapters for discussions of the available options for each disease.

### **Techniques That Do Not Rely on Isolation of Patient DNA or RNA**

#### **Biochemical Tests**

The immunodeficiencies associated with enzyme abnormalities such as ADA deficiency can be diagnosed by detecting increased amounts of physiologic precursors, such as deoxyadenosine or dATP, or by direct measurement of enzyme activity *in vitro* (see Chapter 12). Similarly, glucose-6-phosphate dehydrogenase (G6PD) deficiency, associated with impaired intracellular killing by neutrophils, is best detected by enzyme assay (see Chapter 8) (Buetler et al., 1979; Luzzatto and Mehta, 1995). The advantage of this type of testing is that the functional consequences of the underlying gene mutation can be immediately demonstrated without the need for DNA sequencing. Moreover, gene defects that permit production of inactive or partially active protein will be distinguished from DNA sequence variants of no physiologic significance (genetic polymorphisms). A disadvantage, however, is that carrier testing, which relies on demonstrating enzyme activity intermediate between the normal and deficient ranges, may be imprecise because of overlap with the partial activity of some mutant proteins in affected individuals. Careful assay standards with positive and negative controls in every run are essential.

#### **Immunologic Tests**

Enumeration of leukocyte populations, measurement of their secreted products, such as immunoglobulins, and functional tests involving *in vitro* activation are necessary for definitive diagnosis of virtually all immunodeficiencies. Their use in diagnosis is discussed in Chapter 43. In only a few circumstances, however, have these immunologic tests been made specific for a particular

gene product so that they can be used to establish a specific gene diagnosis. One example is X-linked hyper-IgM syndrome due to CD40 ligand (CD40L) deficiency (Table 44.1 and Chapter 19). Stimulated T cells from normals express CD40L, which can be detected by binding to immunofluorescent-tagged soluble CD40 or anti-CD40L monoclonal antibodies (Conley et al., 1994). However, mutations that allow production and expression of defective protein at the cell surface may not all be detected by this test, nor can it be used for testing of female heterozygous carriers, or for prenatal testing early in pregnancy.

Another example of an immunodeficiency with a useful immunologic test is CGD (Chapter 37). Formerly diagnosed by counting cells able to reduce nitroblue tetrazolium (NBT) dye, the inability of CGD granulocytes to produce superoxide is now more accurately measured by flow-cytometric determination of neutrophil NADP oxidase activity (Jirapongsananuruk et al., 2002). Not only are patient cells readily shown to be defective in this test, but the results can be quantified to yield some predictive information about disease severity. Moreover, female carriers of the X-linked form of CGD can be identified because the Lyonization, or random X inactivation of their neutrophils, results in two distinct populations when their cells are analyzed (see below). Cells whose active X chromosome has intact CYBB have normal NADP oxidase, whereas those with an active X chromosome bearing mutated CYBB demonstrate very little or no activity.

A special use of immunologic tests is in the prenatal evaluation of fetal blood samples. By the middle of the second trimester of pregnancy it is possible to obtain blood from the fetal umbilical vein to determine whether functional T cells, B cells, or granulocytes are present in normal numbers (Lau and Levinski, 1988). Fetal blood sampling involves greater risk to the fetus than does either amniocentesis or chorionic villus biopsy and should be performed only in a center with extensive experience in the technique. It is possible for the sample to be contaminated with maternal blood. Only a small volume of fetal blood is collected, and it must be analyzed without delay by an immunology laboratory that has successfully tested normal fetal blood samples as controls. Despite these caveats, fetal blood sampling is sought by some pregnant couples who have had a previous affected child with immunodeficiency, but who lack a gene-specific diagnosis. For example, cell surface staining for T cells and lymphocyte mitogen responses can be tested in a fetal blood sample to rule in or rule out a diagnosis of SCID in a pregnancy at risk, even if the genotype of the SCID of the proband is not known.

#### **Cytogenetic Studies**

Cytogenetics studies involve the analysis of chromosome structure by microscopic examination, usually when the chromosomes are condensed during metaphase of mitosis. Giemsa banded karyotypes can reveal abnormal numbers of chromosomes or large structural changes, such as translocations, deletions, or duplications. The most common cytogenetic abnormality, trisomy 21, or Down syndrome, is associated with many qualitative immune defects, but is almost always diagnosed before immune dysfunction is recognized because of its many obvious physical stigmata. While chromosomal abnormalities should be suspected when immune dysfunction is accompanied by additional congenital anomalies, there are instances in which a cytogenetic abnormality has only an immune phenotype, such as in males with X-linked lymphoproliferative disease due to deletions within Xq25 (Chapter 32). Pursuit of cytogenetic abnormalities has led

directly to the identification of at least one immunodeficiency gene, *CYBB*, in X-linked CGD (Orkin, 1989); a small minority of CGD patients have total *CYBB* deletions that can involve adjacent genes as well and cause a phenotype of CGD plus other abnormalities (Chapter 37). Balanced translocations can be clinically silent except for the disruption of particular genes at the chromosomal breakpoints. However, family history of multiple miscarriages should prompt cytogenetic investigation because offspring undergoing fetal demise may have received an unbalanced parental chromosomal complement. Thus, while the yield of karyotype analysis may be rather low in immunodeficiencies, this simple test is at times extraordinarily helpful in uncovering a genetic basis for a puzzling clinical syndrome and pinpointing the region of the genome involved.

The power of cytogenetics has been greatly extended by fluorescent in situ hybridization (FISH). In this technique, a cloned unique human DNA fragment is tagged with a fluorescent label and allowed to hybridize to its corresponding sequence within chromosomes spread on a microscope slide. Viewed with a fluorescence microscope, the two homologous chromosomes are marked with the fluorescent DNA probe. FISH can be used to localize and diagnose certain immune diseases. For example, DiGeorge syndrome (thymic hypoplasia, hypoparathyroidism, and conotruncal heart malformations) is associated with interstitial deletions on one copy of chromosome 22q11 (Chapter 33). Although some patients have a deletion large enough to be detected by simple karyotype analysis, FISH with fluorescent probes from 22q11 reveals only one signal in 90% of DiGeorge syndrome patients (Color Plate 33.II).

### DNA- and RNA-Based Techniques

Molecular methods for mutation diagnosis are being applied to hundreds of genetic conditions today, and many more genetic tests will be performed in the future. Certain generalizations distinguish mutation detection in immunodeficiency disease genes from that in many other well-studied genetic disorders. In some disorders, such as sickle cell disease, a single mutation predominates (Kan, 1992). Even in the cystic fibrosis disease gene *CFTR*, about two-thirds of mutated chromosomes in Caucasians have the same  $\Delta 508$  mutation (Zielenski and Tsui, 1995), and testing for a panel of 25 mutations can effectively diagnose the great majority of cases (Richards et al., 2002). In contrast, immunodeficiency gene mutations tend to be extremely diverse, with half or more of the mutations unique to a single family. Unlike the dystrophin gene, which is defective in Duchenne muscular dystrophy and in which large deletions and duplications account for 66% of mutations (Worton, 1992), by far the most common immunodeficiency gene mutations are small changes on the order of one to a few nucleotides, occurring in both coding sequences and splice regions. An important new class of mutations described in human neurologic and muscular diseases is the expansion of triplet repeats either in coding regions or in regions near a gene that are subject to silencing by methylation (Everett and Wood, 2004). However, to date no immunodeficiency-causing gene mutation of this type has been described.

In other respects, gene mutations that cause inherited immune disorders are similar to those found in other genetic diseases (discussed in Chapter 2). These include a high proportion, approximately one-third, of newly arising mutations for X-linked disorders (Haldane, 1935). As previously noted for the hemoglobin locus, factor IX locus, and many other genes (Cooper and Krawczak, 1995), the occurrence of C-to-T mutations at CpG

dinucleotides in immunodeficiency genes is greatly increased above the number that would be expected if all nucleotide changes were completely random.

### Linkage to PCR-Based Polymorphic Markers

Linkage analysis is discussed in some detail in Chapter 2. For immunodeficiency diseases mapped to a unique genomic region but not yet identified, linkage analysis can define which chromosome segments in a family carry mutated disease gene alleles, provided there are both affected and unaffected relatives available for testing. Linkage analysis can also be useful when the gene that is defective in a family is known but the specific mutation has not been determined. Linkage diagnosis can be used for carrier testing and for prenatal diagnosis. One should select tightly linked markers that flank the disease locus and are polymorphic in the required members of the family being tested. The alleles at each flanking marker locus are identified for both disease-bearing and normal chromosomes in the parents of the individual at risk. Then the alleles of the person at risk are determined. If the flanking alleles on both sides of the disease locus match parental alleles from an unaffected chromosome, the person is likely to have inherited the entire block of DNA including the normal copy of the disease gene. Similarly, flanking alleles co-inherited from a disease-bearing chromosome predict that a mutated copy of the disease gene has been inherited. The likelihood that such predictions are correct depends on the genetic distance between the markers (see Chapter 2). However, if a genetic crossover has occurred between the flanking markers, the linkage test is uninformative and no prediction can be made.

The first linkage markers to be used were restriction fragment length polymorphisms (RFLPs), nucleotide variations resulting in the presence or absence of a restriction enzyme site in a defined genomic DNA segment (Botstein et al., 1980; Drayna and White, 1985). RFLPs are defined by the variable presence of restriction sites in segments of DNA from different individuals; digestion with the relevant restriction endonuclease will demonstrate allelic variants with either shorter or longer DNA fragment sizes depending on whether the polymorphic restriction site is present or absent. Fragment lengths are assayed by Southern blotting (see below), or other means of visualization.

The discovery of the polymerase chain reaction (PCR) revolutionized linkage analysis. PCR depends on designing short synthetic oligonucleotides flanking a DNA segment to be amplified. These oligonucleotides, called *primers*, are added in excess to genomic DNA along with free nucleotides, magnesium salts, pH buffer, and a heat-stable DNA polymerase enzyme, such as *Taq* polymerase. First, the reaction mixture is denatured by heating to 95°C so that the DNA helices unwind and the DNA becomes single stranded. Next, the mixture is cooled to a moderate temperature, typically between 50° and 65°C, enabling the oligonucleotides to bind by complementary base pairing to the particular regions of template DNA that they exactly match. Finally, warming the mixture to 72°C allows the polymerase to synthesize new DNA by using the oligonucleotides as primers and adding free nucleotides to form new complementary strands. Each repetition of this sequence of denaturation, annealing, and extension produces a doubling of each template strand. This succession of temperatures constitutes one cycle of PCR. In each successive cycle the segment of DNA between the primers is exponentially amplified. Eventually the amount of product becomes large enough to be detected by either hybridization or direct visualization after gel electrophoresis and staining. More

details about PCR protocols can be found in textbooks such as the one by Erlich (1992).

Segments of DNA that are polymorphic can be readily detected by PCR. If the primers flank a polymorphic restriction site, the product can be digested to assign the restriction site allele. Another type of polymorphism is called a microsatellite or short tandem repeat polymorphism (STRP). The most common repeated unit, occurring on average once every 50,000 nucleotides throughout the genome, is CA on one DNA strand, and TG on the opposite strand (Litt and Luty, 1989; Weber and May, 1989). Other repeats of units of two to five nucleotides also occur frequently. Very often, assorted numbers of repeated units are found in chromosomes from different individuals, and the number of repeats represents a stable polymorphism that is inherited from parents to offspring. PCR amplification of the DNA segment containing a series of simple repeated units followed by size separation by gel electrophoresis reveals the length differences between the polymorphic alleles. Each lane of the gel on the left of Figure 44.1 shows DNA from an unrelated male amplified with appropriate primers surrounding the CA repeat present at the STRP marker DXS441 in Xq13 very close to the X-linked SCID locus (Ram et al., 1992). Alleles of six distinct sizes are seen, indicating that the number of CA units can vary considerably between individual X chromosomes. The right side of Figure 44.1 shows a family linkage study using another X chromosome STRP, GATA182e04 in Xq28, for which the repeated unit is the tetranucleotide GATA. The maternal allele A1, with the smaller number of repeat units, has been inherited by two of her sons, while four other sons and her daughter have inherited her A2 allele. The daughter has also inherited the A1 allele from the paternal X chromosome.

STRPs have several advantages over RFLPs, reflecting the power of PCR as a tool for molecular genetic analysis. Foremost is the very high frequency of these polymorphisms throughout the genome. For family linkage studies, useful STRPs can be found that flank any known immunodeficiency gene. STRPs are also very quickly and easily assayed by PCR, and high-throughput genotyping of STRPs makes possible genome-wide linkage scans to identify the locus of disease genes. Miniscule amounts of input DNA template can be successfully amplified, and DNA can be rescued for PCR from dried blood cards or formalin-fixed tissues and histologic slides, even if an affected patient has died without having had samples preserved specifically for molecular analysis. Finally, the multiplicity of commonly observed alleles means that it is very likely that a child's

alleles can be unambiguously traced to one or the other parent; or, in mathematical terms, the information content at each locus is high.

Even more common than STRPs are single nucleotide polymorphisms, or SNPs, which occur at a rate of around 1 per 1000 nucleotides of genomic DNA sequence. Unlike highly informative STRPs, SNPs have only two alleles, but the huge numbers of SNPs can make up for this inconvenience; an initial map of 1.42 million SNPs in the human genome was assembled in 2001 (Sachidanandam et al., 2001), and far more are now available in the database dbSNP at the National Center for Biotechnology Information (NCBI), at <http://www.ncbi.nlm.nih.gov>. Clusters of neighboring SNPs tend to be inherited together in haplotype blocks, sizable regions that have been maintained with little crossing over since ancestral origins of humans (Gabriel et al., 2002; The International HapMap Consortium, 2005). SNP tags will be able to identify haplotype blocks in humans of diverse ancestral origins, facilitating linkage analysis by automated technology. Furthermore, SNPs with functional importance that alter the expression or activity of gene products promise to shed light on genetic risks for diverse health outcomes and make possible tailoring of medical treatment to the genetic makeup of each individual.

#### Southern Blotting, Evaluation of Genomic DNA

Southern blotting, named for its inventor (Southern, 1975), is the prototypic technique for specific gene detection. A cloned segment of DNA is labeled by incorporation of radioactive nucleotides containing  $^{32}\text{P}$  and used as a probe to hybridize to a complex mixture of DNA, such as genomic DNA prepared from the cells of a particular person. Now considered too labor-intensive for most clinical applications, this was the method historically used for evaluation of RFLP markers and changes in genomic DNA before the development of PCR. First the DNA to be probed is digested with a restriction enzyme, producing fragments varying in size. Because of the complexity of mammalian DNA, these fragments appear to form a continuous smear when they are separated by size using the technique of agarose gel electrophoresis. The size-separated lanes of DNA are denatured into single strands and transferred from the gel to a solid membrane where they are permanently stuck. Single-stranded probe DNA is then incubated with the filter under conditions that favor annealing of DNA complementary sequences. After washing off excess labeled probe, the only probe left sticking to the filter is located in

**Figure 44.1.** Short tandem repeat polymorphism (STRP). Left: DNA from eight unrelated males amplified with primers defining STRP locus DXS441 in Xq13 (Ram et al., 1992). Six alleles, numbered according to their increasing numbers of CA repeat units, were amplified using flank-

ing PCR primers. Darker bands are the primary signal; lighter "shadow" bands seen below each primary band are typical artifacts in CA repeat STRPs. Right: DNA from family members in the illustrated pedigree, amplified with primers defining the STRP GATA182e04 at Xq28.

a band corresponding to the size of the genomic DNA fragment with the same nucleotide sequence as the probe (Sambrook et al., 1989; Ausubel et al., 1994).

Southern blotting can detect disease-causing mutations that involve either large DNA deletions or rearrangements in the disease gene of an affected individual; it can also detect single nucleotide changes that alter the restriction enzyme pattern produced. In such circumstances, a probe from the disease gene will fail to detect in affected patient DNA one or more bands seen in unaffected controls; alternatively, or in addition, the probe may hybridize to DNA fragments of unexpected size. Southern blot alterations have often provided the first clue that a candidate gene in fact harbors deleterious mutations in individuals affected with inherited immunodeficiencies or other genetic disorders. For example, they were used to find some of the first *BTX* mutations in patients with X-linked agammaglobulinemia (XLA) (Vetrie et al., 1993).

Because the great majority of immunodeficiency gene mutations are small changes at the level of one to a few nucleotides, Southern blot analysis is insensitive for finding suspected mutations in new patients. Moreover, finding altered Southern blot band patterns does not readily indicate the location or specific nature of a mutation. However, in families with a previously documented disease-associated Southern blot abnormality, this test can be successfully applied for carrier and prenatal diagnosis in relatives at risk of having inherited the same defect.

#### Northern Blotting and Reverse Transcription-PCR

Many mutations within or adjacent to exons of genes affect the quantity or size of the mRNA produced. These changes can be detected by Northern blot analysis, which is carried out in a manner similar to that of Southern blots (Sambrook et al., 1989; Ausubel et al., 1994). RNA is isolated from cells and electrophoresed through a gel so that all mRNA species are ordered by size. After transferring all the RNA to a membrane and allowing a labeled nucleic acid probe to hybridize to it, the mRNA with the specific nucleotide sequence of interest can be detected. Mutations can produce differences in the expected size or amount of RNA detected by Northern analysis.

As with DNA analysis, PCR has greatly enhanced our ability to analyze RNA through a process called reverse transcriptase PCR (RT-PCR). First, a complementary DNA strand (cDNA) is created by incubating mRNA with the enzyme reverse transcriptase and a DNA oligonucleotide primer. Even the nanogram quantities of RNA that can be purified from small numbers of cells can yield enough cDNA for successful amplification by PCR. Amplified cDNA can be sequenced, sized by gel electrophoresis, and even quantitated to reflect the amount of cellular mRNA originally present (provided carefully monitored conditions and appropriate controls are used).

Mutations that disrupt the 3' and 5' splice motifs prevent normal processing of newly made mRNA. These mutations are generally associated with low or undetectable levels of correctly spliced mRNA in the cytoplasm of cells. However, some aberrantly spliced mRNA species may be detected, such as molecules that fail to undergo intron removal, or that skip one or more exons adjacent to the mutation. Coding sequence missense or frameshift mutations that generate termination signals within exons in the 5' portions of genes also usually cause destabilization of mRNA (known as nonsense-mediated decay) or exon skipping.

Studies of mRNA are important in assessing the actual consequences of a mutation in DNA sequence. Nonetheless, investiga-

tion of mRNA quantity or sequence is often complex and therefore not well suited to clinical diagnostic testing for patients and relatives in families with immunodeficiency.

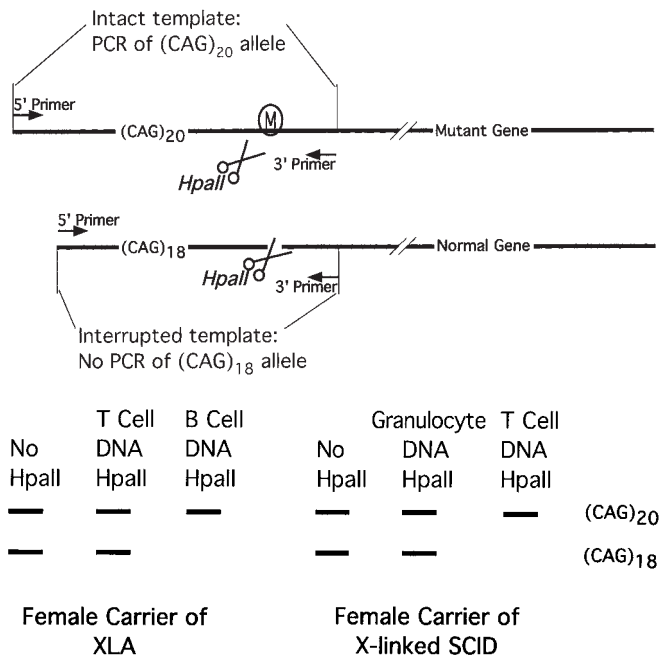

#### X Chromosome Inactivation Pattern in Potential Female Carriers

The high frequency of immunodeficiencies linked to the X chromosome and the special property of inactivation of one of the two X chromosome in females have been exploited for identification of carriers of immunodeficiency diseases (Table 44.1). A unique feature of the sex chromosomes is that males have one X and one Y, whereas females have two X chromosomes. As first hypothesized by Mary Lyon (1966), the problem of expression of double doses of genes from the female's X chromosomes is solved in mammals by inactivation of one X chromosome in all somatic tissues.

A random inactivation of either the maternally or the paternally derived X chromosome occurs before differentiation of specialized tissues in the early female embryo (but, interestingly, not in the placenta, where the paternal X is preferentially inactivated). The random X inactivation imprint of each embryonic cell is maintained throughout subsequent cellular proliferation and differentiation, so that the contribution of maternal and paternal active X chromosomes in all tissues statistically follows a normal distribution. Thus the blood cells of normal women show on average 50% maternal and 50% paternal active X chromosomes. In individual women, however, this ratio can vary substantially. The variance of the distribution (the broadness of the distribution curve) of X chromosome inactivation can be used to estimate the number of primordial embryonic cells that eventually develop into blood cells. For example, if only one cell in the embryo was fated to be the precursor of all blood cells, that one X chromosome would be active in all the blood cells. Estimates using several independent techniques predict a precursor pool size of around 10–20 embryonic cells that eventually become hematopoietic progenitor cells. As a result, some normal women by chance have X inactivation ratios quite different from 50:50 (Puck et al., 1992).

Carriers of certain X-linked immunodeficiencies have negative selection superimposed on the underlying inactivation pattern in the hematopoietic cells lineages affected by the gene defect they carry. If one of the X chromosomes bears a mutation in a gene that confers a survival advantage upon cells of a particular lineage, then cells of that lineage will have skewed X inactivation. As indicated in Table 44.1, this is the case for B cells of carriers of XLA (Fearon et al., 1987; Conley and Puck, 1988; Allen et al., 1994); T, B, and natural killer (NK) cells of carriers of X-linked SCID (Puck et al., 1987; Conley et al., 1988; Wengler et al., 1993); and all hematopoietic cells of carriers of Wiskott-Aldrich syndrome (WAS) (Prchal et al., 1980; Puck et al., 1990b). In contrast, there is no selective pressure on X inactivation in carriers of X-linked CGD. Thus, as discussed under immunologic assays for CGD above, two populations of granulocytes can be detected in female carriers—one with the mutated and one with the normal copy of the disease gene *CYBB*. In a rare circumstance of extreme, constitutional unbalanced X inactivation, a female carrier of a *CYBB* mutation whose normal X was inactive was diagnosed with severe CGD (Anderson-Cohen et al., 2003).

To assay X inactivation one must both distinguish the two X chromosomes from another and determine whether the chromosomes are active. This was first done by isolating the active X chromosomes of several cells from a female subject in a panel of

**Figure 44.2.** X inactivation testing for female carriers of selected X-linked immunodeficiencies. Top: Differential methylation of the HpaII recognition sequence near the (CAG)<sub>n</sub> polymorphism in the androgen receptor gene (AR). The upper chromosome with a (CAG)<sub>20</sub> allele bears the mutant immune disease gene and is inactive and therefore methylated (M). The lower X chromosome with (CAG)<sub>18</sub> has a normal copy of the disease gene and is active, unmethylated, and susceptible to cutting by the methylation-sensitive enzyme HpaII. After exposure of DNA from the test cell lineage to HpaII, only the template from the mutation-bearing X chromosome is intact and able to undergo amplification with AR 5' and 3' PCR primers. Bottom: Patterns of allele amplification visualized after separation of the two alleles by gel electrophoresis. In the test cell lineages of female carriers, only the inactive, mutation-bearing AR allele has been amplified by PCR. For these examples, women with AR alleles with (CAG)<sub>18</sub> and (CAG)<sub>20</sub> repeats are illustrated, but any other heterozygous allele combinations are assayed in the same manner.

human-rodent hybrid cell lines and using RFLPs, and later STRP polymorphisms and PCR, to count how many times each X chromosome was the active one (Puck et al., 1987). A more efficient method is to use a PCR-based STRP that includes cytosine (C) nucleotides that are methylated only on the inactive X (Fig. 44.2). The androgen receptor (AR) gene is an X-linked gene with a variable number of CAG glutamine codons in its first exon; 90% of women have two different lengths of CAG repeats on their two X chromosomes and can therefore be tested by this assay. A nearby HpaII restriction site has a C that is methylated and therefore not subject to digestion by HpaII when present on an inactive X chromosome. Primers have been designed to surround both the repeat and the methylation-sensitive restriction sites, as shown at the top of Figure 42.2 (Allen et al., 1994). In the most informative utilization of this test, DNA is isolated from a purified control cell lineage and test cell lineage of a suspected female carrier. As shown in the lower part of Figure 42.2, appropriate control and test lineages for XLA would be T cells (not dependent on Btk expression for their development and survival) and B cells, respectively. Similarly, for X-linked SCID, control and test lineages could be granulocytes (not dependent on the cytokine receptor common  $\gamma$  chain) and T cells. Restriction enzyme

digestion with the methylation-sensitive enzyme HpaII is followed by PCR and allele separation by gel electrophoresis. PCR of DNA from an affected cell lineage from a carrier will amplify only the allele from her inactive X chromosome, diagrammed in the lower portion of Figure 42.2. Samples not exposed to HpaII, samples from uninvolved cell lineages, and samples from all cell lineages of noncarriers will show PCR amplification of alleles from both X chromosomes.

X inactivation testing was an invaluable research tool for mapping SCIDX1, WAS, and XLA. Moreover, discovery of which hematopoietic lineages are targeted by each gene defect was accomplished before the disease genes were found by observing which lineages had skewed X inactivation in obligate carriers. Carrier diagnosis by X inactivation analysis can be clinically useful when a specific mutation, or even genotype (autosomal vs. X-linked recessive), is not known, such as in an affected male with no positive family history. Demonstration of maternal lineage-specific skewed X inactivation in a clinical setting of SCID, for example, has been used to prove that the inheritance pattern was X-linked, thus making possible genetic counseling and prenatal testing (Puck et al., 1990a). The technique has similarly been applied in XLA, comparing X inactivation of isolated B cells, the potentially affected lineage, to that of T cells in women at risk for being carriers (Allen et al., 1994). In WAS, there is no hematopoietic control lineage because of the selective disadvantage of all cells failing to express the normal gene product WASP. This is an important limitation of the test, because a small percentage of women who do not carry any X-linked immune disease gene have markedly unbalanced X inactivation ratios simply by chance or for other underlying reasons involving the X inactivation process itself (Naumova et al., 1996; Puck and Willard, 1998).

As alluded to in the context of CGD above, females can be encountered who demonstrate moderate or even severe phenotypes of X-linked genetic disorders because they have one mutated copy of a disease gene on an X chromosome that is active in most of their cells. X inactivation should be kept in mind when evaluating females affected with CGD, combined immunodeficiency, features of WAS, or other phenotypes usually seen in males with X-linked hemizygous gene defects. Specific mutation detection is a more accurate diagnostic approach than X inactivation analysis.

### Mutation Detection

All of the newer mutation detection techniques begin with PCR amplification of genomic DNA or cDNA of individuals affected with immunodeficiencies or at-risk relatives. Cloning of these DNA segments into plasmids makes possible the preparation of larger amounts of DNA template for analysis and also separates DNA derived from each chromosomal allele of an individual, results of which can be potentially important for diagnosis of individuals with compound heterozygous mutations causing autosomal recessive disease as well as individuals with dominant disorders and carriers. However, direct analysis without cloning is rapid and accurate in many applications. Because even a single molecule of DNA can be amplified in the proper conditions, PCR is extremely sensitive to contamination. Strict attention to laboratory design and sample flow as well as extensive monitoring with positive and negative controls are needed to avoid contamination of test samples with cloned or already amplified DNA or even with normal DNA from the hands of laboratory workers. Mutation screening techniques are designed for detection of

**Figure 44.3.** Dideoxyfingerprinting (ddF). Shown are dideoxy-T sequencing reactions of exon 5 of *IL2RG* in DNA from an X-linked SCID patient (P), his carrier mother (M), and an unrelated control (C). Multiple bands with altered mobility are seen in the patient's lane, starting with two extra bands and a missing band, marked by arrows. The band pattern in the lane of the heterozygous carrier mother is a composite of the patient's hemizygous mutated pattern and the control pattern.

single nucleotide changes or small insertions and deletions, the most commonly encountered mutations in immunodeficiency diseases. Elucidation of large disruptions, such as deletions or duplications of several kilobases of DNA, may require Southern blots or other methods.

The simplest technique for mutation screening is single-strand conformation polymorphism (SSCP) (Orita et al., 1989; Hyashi and Yandell, 1993; Sheffield et al., 1993; Puck et al., 1997a). In this method, amplified DNA segments of up to 300 nucleotides in length are denatured by heating and then quickly chilled so that they assume single-stranded conformation depending on their primary nucleotide sequence. The single-stranded segments are separated on nondenaturing acrylamide gels to preserve the secondary structure. Even single base changes can alter the mobility of one or both of the single strands. However, this method fails to detect about 10% of mutations, particularly those close to the primers at either end of the segment.

An improvement in sensitivity of mutation detection to nearly 100% can be achieved by using a dideoxy nucleotide mixture from a dideoxy terminator sequencing reaction instead of PCR of an entire fragment to make single strands of DNA for conformation testing. This method is called *dideoxy fingerprinting* (ddF) (Sarkar et al., 1992; Puck et al., 1997a). Increasing lengths of DNA from under 50 bases to 300 bases or more show more conformations than only a full-length fragment as in SSCP. The lanes of a ddF autoradiogram viewed from bottom to top, as in Figure 44.3, show abnormal bands from the level in the sequence ladder at which a mutation is introduced (bottom arrow); above this level, multiple band shifts are apparent in a hemizygous mutated X-linked SCID (XSCID) patient (P, left lane) compared to the control (C, right lane). The middle lane shows the DNA from the patient's heterozygous mother (M), revealing a composite of both sets of bands from her mutated and wild-type *IL2RG* alleles. In a study of 87 unrelated patients with XSCID, *IL2RG* mutations were detected in all cases by ddF (Puck et al., 1997b).

**Figure 44.4.** Fluorescence-based sequence determination. Left: Wild type (upper), carrier (middle), and X-linked SCID patient (lower) sequences from exon 3 of the *IL2RG* gene. The patient's deletion of two nucleotides in codon 181, normally specifying histidine (H), results in a frameshift specifying glutamine (Q) followed by several further missense codons and a premature termination. The mother's genomic sequence is a composite of wild type and mutant, reflecting the two *IL2RG*

alleles on her two X chromosomes. Right: *IL2RG* gene sequence in exon 3 showing wild type and three generations of a kindred with XSCID. The second tracing shows minor mosaicism in the grandmother for the mutant TAA allele (encoding a termination signal instead of the wild-type tyrosine [Y] residue). Her daughter, the mother of the patient, is a carrier of this mutation with roughly equal wild-type and mutant signals, while her male fetus is hemizygous for the mutant allele.

Determination of the actual nucleotide sequence of mutant DNA is the gold standard for mutation detection. Regardless of whether prescreening with SSCP or ddF is used, sequence determination must be carried out to learn the exact nature of the mutational event. Nucleotide changes detected by any DNA-based evaluation must be interpreted in light of expression studies and functional data before concluding that they are pathogenic mutations.

Radioactive isotopes were initially used for sequencing, but fluorescent technologies now give superior length and quality of sequences from PCR-amplified genomic DNA. The left side of Figure 44.4 shows detection by fluorescent sequencing of a two-base deletion in *IL2RG*. The wild-type sequence and reading frame (upper tracing) and frame-shifted, deleted sequence of a patient with XSCID (lower tracing) can be seen superimposed in the central tracing from the patient's heterozygous mother. Sequence analysis of another XSCID kindred, shown in Figure 44.4 on the right, reveals the origin of the premature termination mutation in exon 3, V105X. The tracing of blood-derived DNA from the grandmother, whose son died of infections in infancy, shows only a minor admixture of an A base at the position that is a T in the wild type, indicating somatic mosaicism for this mutation in blood cells. The grandmother must also have had the new mutation in some of her egg cells, accounting for her affected son (not shown) and daughter, whose tracing in Figure 44.4 with equal amounts of mutant T and wild-type A is diagnostic of a heterozygous carrier state. Amniocyte DNA from the male fetus of this carrier demonstrates presence of the mutant allele, in which a TAT tyrosine codon has become an immediate TAA termination codon. This fetus was therefore predicted to be affected with XSCID.

In the future, detection of specific gene mutations may be further automated. Detection of mutations in cancer susceptibility genes, such as *BRCA1*, have used hybridization of PCR enriched DNA to chips containing microarrays of partially overlapping oligonucleotides that span the gene's normal coding sequence and include specific mutated oligonucleotides for known mutations (Hacia et al., 1996).

### Genetic Counseling

Genetic testing has received increasing public attention because of the rapidly growing number of tests that can be performed for gene mutations associated with a wide variety of conditions. Testing is becoming publicly available in some cases before research has established its true ability to predict future development of a disease, such as breast cancer (Struwing et al., 1997). Our society is in the process of adjusting to increasing genetic information, but many issues, such as population screening, testing of minor children, protection of confidentiality, and insurability of persons carrying genetic mutations, remain to be resolved (Clarke et al., 1994; American Society of Human Genetics and American College of Medical Genetics Boards of Directors, 1995; Rowley et al., 1997). Unlike most other forms of medical evaluation, molecular genetic testing has implications not just for the proband but also for all of his or her relatives who share the same DNA. For all of these reasons, genetic counseling should precede genetic testing. Counseling should preferably be done by a geneticist or genetic counselor rather than the medical team primarily involved with treating an affected child who may be critically ill. A genetic diagnosis that becomes available while a child is in the hospital should be reviewed with the family at a later time when the information can be processed more fully, questions can be answered, and implications for each family member sorted out.

Molecular diagnostic testing is usually undertaken to establish a diagnosis in an affected individual. Parents of an affected child are likely to be concerned about the risk of recurrence in a future pregnancy. For autosomal recessive diseases it is assumed that the parents are both carriers and the recurrence rate is one in four for pregnancies of either sex. For X-linked diseases in which the mother of an affected child is demonstrated to be a carrier, there is a 50% chance that each subsequent male pregnancy will be affected and a 50% chance that each female pregnancy will carry the mutation but not be affected with immunodeficiency.

Risks for being affected with the disease in question or for having affected children of one's own can be calculated for other family members. For example, a sibling of a proband affected with an autosomal recessive disease may be a carrier, but unless his or her mate is also a carrier of a mutation in the same gene (which is very unlikely unless the members of the couple are related to each other), the risk of having affected offspring is exceedingly low. On the other hand, sisters of males with X-linked diseases are at 50% risk of being carriers, in which case their male offspring will be at risk of being affected with the disease.

Now that many males with X-linked immunodeficiency diseases have been successfully treated and are reaching adulthood, it is important to help them understand that their reproductive risks have not changed, even if their disease has been permanently treated, such as by bone marrow transplantation. Affected males will pass on their mutation-bearing X chromosome to all of their daughters, who will be carriers; however, none of their sons will be affected because they will inherit the Y chromosome, and not the X chromosome, from their father.

Prenatal testing is possible for a large number of immunodeficiencies, and the chapters in Part II of this volume outline specific considerations for prenatal evaluation of each disorder. However, bringing the findings and techniques of research laboratories into a clinical setting has lagged. Because of high costs and low numbers of DNA-based diagnostic tests for each immunodeficiency gene, many tests have not yet been offered by clinical laboratories certified by the Clinical Laboratory Improvement Amendments of 1988 (CLIA) Act (Regulations, 1992). Fetal cells can be sampled by chorionic villus biopsy as early as the ninth week of pregnancy, or amniotic fluid can be obtained some weeks later as a source of fetal DNA for molecular testing. Fetal blood sampling between 16 and 20 weeks of pregnancy has also been used to evaluate the number and function of leukocytes in pregnancies at risk for well-defined abnormalities.

Preimplantation diagnosis is another procedure for families in which the specific mutation(s) for the pregnancy at risk are known. This was first performed successfully in humans in the setting of cystic fibrosis in which the parents were both carriers of the common  $\Delta F508$  mutation in the *CFTR* gene (Ao et al., 1996). In vitro fertilization was carried out with superovulated eggs and sperm from the parents, embryos were grown to the eight-cell stage, and a single cell from each embryo was removed and genotyped by PCR. Embryos with an unaffected genotype were reimplanted into the mother. Of 22 couples in one early study, 5 had singleton pregnancies carried to term with the birth of healthy, unaffected infants.

Only limited information is available to indicate how parents with an at-risk pregnancy weigh the difficult choices that confront them. When a fetus is diagnosed as affected, pregnancy may be terminated, but neonatal and even prenatal treatment options are increasingly available. The parents' perceptions of the burden of the disease are undoubtedly distinct for each immunodeficiency and are colored by the particular experience each

person has shared with his or her affected relatives. A series of families followed with pregnancies at risk for XSCID indicated that most couples wanted to have prenatal testing, but few affected pregnancies were terminated (Puck et al., 1997a). In this disease, the improving outlook over the past two decades of bone marrow transplantation therapy has given families hope. Couples anticipating delivery of affected infants took advantage of the information gained through counseling and prenatal testing to learn about options for treatments. Pediatric centers performing bone marrow transplantation for immunodeficiency were contacted and financial and care arrangements were made. In some cases, the prenatal sample was HLA typed to identify potential matched bone marrow donors, either among the parents' healthy children or in an unrelated donor registry. One family chose an experimental in utero bone marrow transplant; this treatment may become successful with a variety of immune disorders (Flake et al., 1996; Flake and Zanjani, 1997).

A further development is the harvesting of cord blood at delivery as a source of autologous hematopoietic stem cells in which the gene defect could be corrected by gene therapy. Retroviral gene transfer has proven effective for XSCID and ADA-deficient SCID (Chapter 48). However, the development of leukemia due to retroviral insertional mutagenesis in XSCID patients receiving this treatment has delayed the acceptance of gene therapy for this form of SCID until safety can be improved.

### Population-Based Newborn Screening for Immunodeficiencies

Primary immunodeficiencies are underdiagnosed and frequently diagnosed late because of their low incidence and insufficient awareness on the part of physicians and the public. Screening of newborns for a variety of treatable genetic conditions has been a successful public health measure to achieve early recognition and prompt intervention (Wilson and Jungner, 1968; Khoury et al., 2003). Criteria for evaluating whether newborn screening is indicated for a given disease include the following: the disease is serious and not evident by physical examination in the nursery; the disease is treatable; early treatment offers a better outcome; and incidence and test availability make screening cost-effective. Several inherited immunodeficiencies could potentially meet these criteria. For example, failure to recognize SCID leads to devastating or even fatal infections. Although the true incidence is not known, SCID is estimated to occur in 1 in 50,000 to 1 in 100,000 births, within the range of some metabolic disorders currently widely included in state newborn screening panels (Chan and Puck, 2005). Development of an inexpensive, sensitive screening test that could be performed on the dried blood filters already collected from all infants would be required. One test under consideration for SCID is quantitation by PCR of the presence of T cell receptor excision circles (TRECs), formed in maturing thymocytes as a byproduct of T cell receptor rearrangement (Douek et al., 1998). In contrast to dried blood spots of healthy infants, the original blood spots collected from infants subsequently diagnosed with SCID were negative for TRECs in a pilot study, as were blood spots made from SCID infants at the time of their diagnosis (Chan and Puck, 2005).

## Immunodeficiency Information Services

JOUNI VÄLIAHO, CRINA SAMARGHITEAN, HILKKA PIIRILÄ,  
MARIANNE PUSA, and MAUNO VIHINEN

Primary immunodeficiencies (PIDs) are a group of over 100 mainly rare disorders (Fischer, 2001; Vihinen et al., 2001) affecting the immune system. Although a lot of information is available on the Internet, it is scattered throughout cyberspace, especially data on rare diseases like immunodeficiencies. Therefore, a navigation starting point and knowledge service are very much needed. We have compiled all major data on immunodeficiencies into a server, the Immunodeficiency Resource (IDR), which contains thousands of useful and interesting links in addition to our own pages (Väliaho et al., 2000, 2002). Fact files for each disease function as the core of the IDR.

Over 3700 mutations have been discovered in unrelated families with PIDs (Vihinen et al., 2001) (Table 45.1). During the last few years many genes affected in PIDs have been cloned and analyzed (Chapter 1), and mutations have been identified from a number of patients, giving clues to disease mechanisms. In order to handle the ever-growing amount of information, immunodeficiency mutation databases (IDbases) have been established for a large number of diseases (Lappalainen et al., 1997; Vihinen et al., 2001). These registries make it possible to carry out detailed mutation studies.

We also maintain a directory of laboratories performing genetic and clinical analysis for patients with immunodeficiency. Because immunodeficiencies are such rare disorders, there are not many laboratories carrying out genetic testing for patients. The IDdiagnostics server is directed primarily at physicians and other health care professionals to enable them to find a laboratory where they can order the genetic and/or clinical diagnostics. In addition to providing contact information, the registry aims to promote the appropriate use of genetic services in patient care and increase the general awareness of immunodeficiency disorders, efforts important to fast and reliable diagnosis and proper treatment.

### Immunodeficiency Resource

Although the Internet contains billions of pages of information, it is often difficult to find that specific piece of knowledge one is looking for. The IDR is maintained in order to collect and distribute all the essential information and links related to immunodeficiencies (Väliaho et al., 2000, 2002). The IDR aims to provide comprehensive, integrated knowledge on immunodeficiencies in an easily accessible format and offer data for clinical, biochemical, genetic, structural, and computational analysis.

The IDR is a compendium of information on immunodeficiencies available online via the Internet (<http://bioinf.uta.fi/idr/>). The service contains several introductory texts. From the IDR one can find classification and diagnostic criteria on immunodeficiencies (Conley et al., 1999). There is a plenty of genome-related information available, including that on immunodeficiency-related genes and their locus on the genome, reference sequences on three levels (genome, RNA, and protein), and markers, etc.

Validation of the information on the IDR is of prime importance. The service is maintained with the assistance of regional experts and expert curators and all data are validated. Each disease has its own curators, who are established scientists and experts on this particular field and who go through all the data submitted to the IDR. Nurse (INGID) and patient societies (IPOPI) are also included (see Table 45.2). The IDR offers tens of thousands of validated links to other sites, which are periodically automatically checked.

The IDR also contains articles, instructional resources, and analysis tools, as well as advanced-search capabilities. Extensive cross-referencing and links to other services are available. It is possible to search for any text string or multiple strings with Boolean logic search facility across IDR pages. The IDR pages

**Table 45.1.** Immunodeficiency Mutation Databases

<i>Database</i>	<i>Immunodeficiency</i>	<i>OMIM</i>	<i>Internet Address of Database</i>	<i>Public Cases</i>	<i>Reference</i>
ADAbase	Adenosine deaminase deficiency	608958	<a href="http://bioinf.uta.fi/ADAbase/">http://bioinf.uta.fi/ADAbase/</a>	60

General information	
Disease	<b>X-linked agammaglobulinemia</b>
Alternative names	<ul style="list-style-type: none"> <li>XLA</li> <li>Bruton type agammaglobulinemia</li> <li>X-linked hypogammaglobulinemia</li> </ul>
Description	Defects in the Bruton tyrosine kinase (BTK) gene cause agammaglobulinemia. Agammaglobulinemia is an X-linked recessive immunodeficiency characterized by failure to produce mature B lymphocytes and associated with a failure of B-cell class maturation.
Classification	<ul style="list-style-type: none"> <li>Deficiencies Profoundly Affecting Antibody Production</li> <li>Agammaglobulinemia</li> </ul>
OMIM	300360 Bruton agammaglobulinemia tyrosine kinase; BTK
Cross references	<b>Related immunodeficiencies</b> <ul style="list-style-type: none"> <li>BTK factor for X-linked hypogammaglobulinemia with growth hormone deficiency</li> <li>BTK factor for SCID</li> <li>BTK factor for IgA deficiency</li> <li>BTK factor for IgM deficiency</li> <li>BTK factor for IgG deficiency</li> <li>BTK factor for IgA deficiency</li> <li>BTK factor for IgM deficiency</li> </ul>
Incidence	1/250,000
Clinical information	
Description	Most patients with XLA develop recurrent bacterial infections, particularly otitis, sinusitis and pneumonia, in the first two years of life. The most common organisms are <i>S. pneumoniae</i> and <i>H. influenzae</i> . The serum IgG is usually less than 200 mg/dL and the IgM and IgA are generally less than 20 mg/dL. Approximately 20% of patients present with a dramatic, overwhelming infection, often with <i>Candida</i> . Another 10-15% have higher concentrations of serum immunoglobulin than expected or are not recognized to have immunodeficiency until after 2 years of age.
Diagnosis	<b>ESID/AGID recommendations by IDI</b> <b>Additional information:</b> <ul style="list-style-type: none"> <li>Diagnosis and Family Handbook For The Primary Immune Deficiency Diseases by IDI</li> <li>X-Linked Agammaglobulinemia by The Jeffrey Modell Foundation (JMF)</li> </ul>

patient registry has recently undergoing a major revision and reorganization. A new, online-based database has been set up that is accessible via standard Internet browsers (<http://www.esid.org/>). A clinical data management system that fulfills a number of central needs, all of which are relevant to a modern approach to a multicenter clinical research database system, is being developed.

The new online PID database will greatly increase data accessibility to 24 hours a day, making a standard Internet browser and a valid login and password the only prerequisites for access. Moreover, the system will be very flexible and will enable follow-

up of patients and increase the amount of collected data via automated data entry. Tools will also be developed to allow shared analysis of research data between new European PID database and the existing public mutation database hosted at Tampere University.

Currently there are more than 90 immunodeficiency mutation databases maintained mainly at the University of Tampere's Institute of Medical Technology (IMT) Bioinformatics (Table 45.1). Mutation data submissions from the community are instrumental for keeping the databases up-to-date. Scientists analyzing mutations are encouraged to submit their data by either contacting the

**Figure 45.3.** Montage of pages in BTKbase. Some main features of the BTKbase. Top left: Distribution of mutations in the BTK exons and introns. Top right: Distribution of mutations in families with X-linked agammaglobulinemia (XLA). Middle: Mutations causing XLA in the

PH domain. Mutations above the sequence cause either severe (classical) or moderate XLA, whereas those below the sequence cause clinically mild disease. Bottom left: Short description of a mutation entry. Bottom right: Restriction enzyme recognition sites in the cDNA of BTK.

curators or using the Web submission option available on the homepages of databases. Many of the IDbases contain plenty of information in addition to the actual relevant mutation, making these registries valuable for physicians and scientists from a variety of different fields. The IMT Bioinformatics-maintained databases are also accessible via mobile devices by use of BioWAP (<http://bioinf.uta.fi/>) service (Riikonen et al., 2001, 2002).

All data in the IDbases are arranged according to concepts applied to sequence databases. Lines are organized into logical groups: first are the lines necessary for identification of the entry, accompanied by a description of the mutation in English. These are succeeded by reference lines and lines that formally characterize the mutation. The remaining lines describe various parameters from patients. The entries are linked to other data sources, such as sequence databanks, PubMed, OMIM (On-line Mendelian Inheritance in Man, 1998), and SwissProt. The databases also provide direct access to the sequence retrieval system search engine for potential further analysis and comparison to other registries (Ezold et al., 1993).

It is vital that representation of the information in the databases be standardized. We have developed a program suite, MUTbase (Riikonen and Vihinen, 1999), which provides interactive and quality-controlled submission of information to our mutation databases. It is a system for collecting, maintaining, and analyzing the data of disease-causing mutations. The MUTbase system generates new information from the raw data, part of which is added to the entries and the other part written on numerous interactive Web pages.

Several Web pages indicate the type of mutation and their distribution in the protein domains as well as that in the exons or introns of the gene (Fig. 45.3). The pages are interactive, providing access to patient and mutation information. The localization of mutations on the gene and the protein can be analyzed on the pages containing sequence information. Interactive graphic pages show the number of disorder-related families having different mutation types at each residue. Mutations are also listed according to mutation types. In addition to the disease-causing mutations, polymorphisms or variations are also included in separate files.

The IDbases may provide new insights into both genotype-phenotype correlations in patients and protein structure-function relationships for the encoded proteins and DNA-level phenomena (Vihinen and Durandy, 2005). These registries have a variety of users, including physicians and research scientists from various fields. The databases have been used to retrieve retrospective and prospective information on clinical presentation, immunologic phenotype, long-term prognosis, and efficacy of available therapeutic options. The information may be essential to develop new treatments including drug design.

## Immunodeficiency Diagnostics Registry (IDdiagnostics)

The diagnosis of immunodeficiencies can be daunting because similar symptoms may be caused by several disorders (Samarghi-tean et al., 2004). A further complication is that many immunodeficiencies are rare. Early and reliable diagnosis is often crucial for efficient treatment of these diseases. Delayed diagnosis and management of immunodeficiency disorders can lead to severe and irreversible complications, even resulting in the death of the patient. Early or possibly prenatal molecular diagnosis allows enough time for the most suitable management and selection of treatment, which is crucial for the survival of the patient.

### CLINICAL TESTS FOR IMMUNODEFICIENCIES

#### 1 IMMUNE STATUS

##### 1.1 Complete Blood Count

- ☐ Red Blood Cells (RBC)
- ☐ White Blood Cells (WBC)
  - ☐ Neutrophils
  - ☐ Lymphocytes
  - ☐ Eosinophils
  - ☐ Monocytes
  - ☐ Basophils
- ☐ Platelets

##### 1.2 Quantitative Serum Immunoglobulins

- ☐ IgG
- ☐ IgG1
- ☐ IgG2
- ☐ IgG3
- ☐ IgG4
- ☐ IgA
- ☐ IgA1
- ☐ IgA2
- ☐ IgM
- ☐ IgE
- ☐ IgD
- ☐ Immunoglobulin (κ, λ) light chains
- ☐ Detection of monoclonal / oligoclonal components of immunoglobulins

##### 1.3 Enumeration of Blood Cell Populations and Evaluation of Functional Molecules - Flow Cytometry (absolute counts are requested)

###### 1.3.1 T cell subsets

- ☐ Total T cells
- ☐ CD3<sup>+</sup>CD4<sup>+</sup>
- ☐ CD3<sup>+</sup>CD8<sup>+</sup>
- ☐ CD4
- ☐ CD8
- ☐ CD4<sup>+</sup>CD45RA<sup>+</sup> in CD4
- ☐ CD4<sup>+</sup>CD45RO<sup>+</sup> in CD4
- ☐ CD3<sup>+</sup> TCR α/β
- ☐ CD3<sup>+</sup> TCR γ/δ
- ☐ CD3<sup>+</sup>CD4<sup>+</sup>CD8<sup>+</sup>
- ☐ CD3<sup>+</sup>CD4<sup>+</sup>CD8<sup>+</sup>
- ☐ Polymyositis
- ☐ Varicella-zoster
- ☐ Other antiviral antibodies, please specify

##### 1.3.2 Antibodies to neoantigens

- ☐ Keyhole limpet hemocyanin (KLH)
- ☐ Bacteriophage Φ X174

##### 1.3.3 Cell Function

###### 1.3.3.1 Study of *in vitro* lymphocyte activation and proliferation by flow cytometry upon stimulation with mitogens or antigens

- ☐ Surface activation markers/molecules on T cells
- ☐ CD69
- ☐ CD25
- ☐ CD371
- ☐ HLA-DR
- ☐ CD45RO
- ☐ CD45RA
- ☐ CD154 (CD140 ligand)
- ☐ IL-12 receptor
- ☐ Cell (intra-cellular detection) cytokine production
- ☐ Blastogenesis (forward light scatter FSS/side light scatter SS)
- ☐ Cell proliferation (DNA content, BrdU incorporation)
- ☐ Cell proliferation (tritiated thymidine incorporation)

###### 1.3.3.2 *In vitro* studies of phagocytic cell metabolism

- ☐ Oxidative burst (oxidation of dihydrorhodamine-123 DHR stimulation with PMA or with *E. coli*) by flow cytometry
- ☐ Phagocytosis of (fluorescent) *E. coli* by flow cytometry
- ☐ Nitroblue tetrazolium (NBT) test
- ☐ Glucose metabolism
- ☐ Oxygen consumption
- ☐ Glucose monophosphate shunt activity
- ☐ Chemiluminescence

###### 1.3.3.3 *In vitro* studies of phagocytic cell chemotaxis

- ☐ Chemotaxis under agarose
- ☐ Chemotaxis across a membrane filter (e.g., Boyden chamber)

##### 1.3.2 B cells

- ☐ CD19
- ☐ CD20
- ☐ CD19κ
- ☐ CD19λ

##### 1.3.3 NK cells

- ☐ CD16/CD56 (CD3 negative)
- ☐ CD8/CD56
- ☐ CD3/CD16
- ☐ CD3/CD16/CD56<sup>+</sup>

##### 1.3.4 HLA-DR on monocytes

- ☐ HLA-DR/CD14

##### 1.3.5 *ex vivo* Activation markers

- ☐ CD69
- ☐ CD3/HLA-DR (activated T cells)
- ☐ CD3/CD25 (activated T cells)
- ☐ CD3/CD69
- ☐ CD19/CD23 (activated B cells)

##### 1.3.6 Adhesion molecules

- ☐ CD18 on leukocytes
- ☐ Sialyl Lewis X (on phagocytes)
- ☐ CD11a (LFA1c)
- ☐ CD11b (MO1, CR3)
- ☐ CD11c

##### 1.3.7 Functional molecules

- ☐ CD132 (common γ chain of IL's receptors)
- ☐ IFNγ receptor 1 (CD 119)
- ☐ ILk
- ☐ IL-4
- ☐ IL-5
- ☐ IL-12R
- ☐ IL7RA
- ☐ WASP

##### 1.3.8 MHC class I and MHC class II on leukocytes

- ☐ by flow cytometry (using common MAb)
- ☐ HLA class I (monomorphic epitopes of loci A, B, C)
- ☐ HLA class II (DR or DP/DQ/DR antigens)

##### 1.3.9 Identification of TCR clonality

- ☐ by flow cytometry
- ☐ by PCR

#### 2 STUDIES OF FUNCTION

##### 2.1 Antibody Response

###### 2.1.1 Natural antibodies (titer)

- ☐ anti-A isohemagglutinin (IgM)
- ☐ anti-B isohemagglutinin (IgM)

###### 2.1.2 Antibodies to vaccination or exposure antigens (total IgG and IgG subclass specific)

- ☐ Diphtheria
- ☐ Tetanus
- ☐ Hepatitis B
- ☐ Rubella
- ☐ Haemophilus influenzae b (Hib)
- ☐ Pneumococcal polysaccharide
- ☐ Measles
- ☐ Mumps

##### 2.3 Enzyme assays

- ☐ Adenosine deaminase (ADA)
- ☐ Purine nucleoside phosphorylase (PNP)
- ☐ Glucose-6-phosphate dehydrogenase (G6PD)
- ☐ Glutathione peroxidase (GSH-Px)
- ☐ Myeloperoxidase (MPO)

##### 2.4 Complement function

- ☐ CH50 (Hemolytic activity, classical pathway)
- ☐ AH50 (Hemolytic activity, alternate pathway)
- ☐ Function of C1 esterase inhibitor
- ☐ Assay of components
  - ☐ C1
  - ☐ C1 esterase inhibitor
  - ☐ C2
  - ☐ C3
  - ☐ C4
  - ☐ C5
  - ☐ C6
  - ☐ C7
  - ☐ C8
  - ☐ C9
  - ☐ B
  - ☐ D
  - ☐ Properdin
  - ☐ Other, please specify

##### 2.5 Apoptosis assays

- ☐ Fas/Fas-ligand (flow cytometry, other)
- ☐ BCL-1
- ☐ Caspase expression
- ☐ Cells with reduced DNA content (fluorescent DNA stain with cell permeabilization, flow cytometry)
- ☐ Strand breaks in cell DNA (TdT incorporation of fluorescence labelled nucleotides, e.g., TUNEL, flow cytometry)
- ☐ Translocated phosphatidylserine on cell membrane (adsorption of Annexin V, flow cytometry)
- ☐ functional assays of apoptosis

##### 2.6 Other diagnostic tests

- ☐ Sweat Cl<sup>-</sup>
- ☐ α1-antitrypsin
- ☐ Uric acid (serum)
- ☐ α-fetoprotein

#### 3. COMMENTS AND ADDITIONAL TESTS

**Figure 45.4.** The IDdiagnostics Clinical Tests submission form. A submission page for IDdiagnostics Clinical Tests, also available at <http://bioinf.uta.fi/cgi-bin/submit/IDClini.cgi>.

## Data submission to IDdiagnostics registry

Please fill in one form per disease or use the electronic submission available at

<http://bioinf.uta.fi/IDdiagnostics/> and send to Prof. Mauno Vihinen, Institute of Medical Technology,

FI-33014 University of Tampere, Finland or fax to +358-3-35517710

The definitive diagnosis of immunodeficiency disorders depends on genetic and clinical tests, as the physical signs may be nonspecific, very discreet, or absent. In many cases the diagnosis has to be based on the analysis of genetic defect(s). Because of the rareness of the diseases there are generally not many laboratories analyzing a particular disease. The IDdiagnostics registry contains two databases, genetic and clinical, that are collected to provide a service for those trying to find quickly the nearest and/or most suitable laboratory conducting immunodeficiency testing. It consists of a list of laboratories performing genetic and clinical testing for patients with inherited immunodeficiencies.

Contact addresses for laboratories performing diagnoses are provided in the IDdiagnostics registry along with the assay method(s) used. Mutation detection can be done by several methods. Many laboratories use direct sequencing, whereas others rely on fast screening methods followed by sequencing. Only with sequencing is it possible to analyze all the mutations, as most of the immunodeficiency-related genes are so large that primary scanning for the gene defect within an exon or intron can be more cost- and time-effective. Because the IDs are rare disorders, only large centers may have enough samples to run certain analyses on a constant basis. To get an idea of the time required to receive diagnostic details, the frequency with which the samples are run, and the number of samples studied annually, data are provided in the gene test laboratories database. The cost of analyses varies according to the method used, the type of laboratory, and the research interest in a particular disease. More common diseases are analyzed routinely. Laboratories can have special requirements for samples and their handling. These data are also available through the IDdiagnostics service. Physicians should consult the laboratories before sending any samples to learn about conditions, shipment details, and expected time for the test.

The IDdiagnostics database provides search facilities that allow users to run text-based search queries. Gene test laboratories can be searched by disease name (also alternative names), gene symbol, OMIM code, laboratory, laboratory location, and free text. Similar searches are available for clinical laboratories. A search engine makes it easy to find laboratories for certain disease(s), methods, and/or geographic locations. Physicians should contact the laboratory before sending in any samples as the standards vary across laboratories. The cost of the analysis also varies greatly, depending on whether testing is carried out for commercial or research purposes. Further information and submission pages for both genetic and clinical testing can be found at <http://bioinf.uta.fi/IDdiagnostics/> and in Figures 45.4 and 45.5. The preferred method is Web submission. Laboratories carrying out testing are encouraged to fill out the form and send it to the database curators.

## Conclusions

The IDR, IDbases, and IDdiagnostics have been developed over several years. They all have increasing numbers of users (e.g., there were about 158,000 requests sent to the IDR from 100 countries in the year 2005). This expanded use demonstrates that the Web is an effective way to deliver complex and updated information to the medical community. It also demonstrates the feasibility of IDML language to organize and distribute complex data and knowledge bases interlinked with other services on the Internet.

These services are aimed at collecting and distributing relevant information about immunodeficiency disorders in a systematized manner, starting with mutation data and ending with

clinical information. They will serve as useful, fast, and easy instruments for physicians, nurses, researchers, and patients and their families in their fight against these diseases. All three registries are also an important instrument in the education of physicians and in providing health-care authorities information on the incidence of immunodeficiency disorders, the need for early diagnosis, updated diagnostic criteria, and the availability of different treatments and centers.

## Conventional Therapy of Primary Immunodeficiency Diseases

E. RICHARD STIEHM and HELEN M. CHAPEL

Long-term care of patients with primary immunodeficiencies is aimed at prevention of infections and their long-term sequelae as well as treatment of breakthrough infections. The extent of both the protection required and the appropriate prophylaxis depends on the nature of the immune deficiency. For this reason, this chapter is divided into two sections: the first describes general measures applicable to all forms of immune deficiency, and the second details specific measures for patients with individual diseases.

The management of all forms of immunodeficiency disease requires interaction between generalists and specialists with experience and expertise in primary immune deficiencies. This usually requires a team of a primary care pediatrician or internist and an immunologist with assistance and advice from other specialists (e.g., dermatologists, pulmonologists, gastroenterologists, and radiologists) as necessary, since it is important that patients continue to have the benefit of optimal diagnostic procedures and new drugs for all organ-based complications they may develop.

For example, patients with bronchiectasis following repeated bronchial sepsis need not only regular monitoring with pulmonary function tests and computed tomography (CT) scans but also access to chest physiotherapists, and those with asthma require the latest and most effective bronchodilators. In the same way that the immune system is multi-organ, the failure of this system manifests diverse complications requiring organ-based specialist medical care.

### General Considerations

#### Treatment

Because many patients with immunodeficiency will have a normal life span on immunoglobulin (Ig) or other therapy, their parents and relatives must avoid making the patient an emotional

cripple through overprotection. A child should be encouraged to be outdoors, play with other children in small groups, attend nursery and regular school, and participate in sports and other extracurricular activities. The aim is to teach such children to live in a near-normal fashion with their disease, in much the same way as a diabetic child taking insulin would. Adolescents and even adults need advice about the importance of regular exercise (especially to improve bronchiectasis). They should not smoke, inhale second-hand smoke, or use illegal drugs. Like tobacco, marijuana is a pulmonary irritant and should be avoided.

Patients with immunodeficiency require extraordinary amounts of care to maintain general health and nutrition, prevent emotional problems related to their illness, and manage their numerous infectious episodes. This regimen applies equally to adults and children. Usually, no special dietary limitations are necessary; the aim is to provide a well-rounded, nutritious diet. Patients with immunodeficiency should be protected from unnecessary exposure to infection. They should sleep in their own beds, preferably with rooms of their own, and keep away from individuals with obvious serious respiratory or other infections.

### Nutrition and Gastrointestinal Functions

The height and weight of children with immunodeficiency should be documented at 3- to 6-month intervals with a standard growth chart. Adults should be weighed regularly as well. A falling off of growth or an absolute weight loss is an ominous feature of immunodeficiency and suggests that infections are not under good control or that other medical conditions (e.g., hypothyroidism, chronic diarrhea, malignancy) are present. Chronic antibiotic therapy may decrease appetite and cause diarrhea. Febrile episodes with severe chronic infections will decrease appetite, increase metabolic demands, and result in slow growth.

Nutritional assessment including a calorie count may be indicated, and a dietary supplement might be tried. A multivitamin and mineral supplement is also advisable.

If there is noninfectious chronic diarrhea, a search for malabsorption, food intolerance, and hypovitaminosis is indicated. Symptoms of night blindness, proximal weakness, ataxia, or tremor should raise suspicions of secondary deficiencies of fat-soluble vitamins that are reversible on treatment (Aukrust et al., 2000). Coeliac disease may not necessarily present with frank malabsorption or even diarrhea; weight loss alone should lead to investigation of the gastrointestinal tract. However, it is important to remember that partial villous atrophy is common and due not just to coeliac disease. There should be a careful search for microbial agents, inflammatory bowel disease, and structural abnormalities of the gastrointestinal tract.

Many immunodeficiencies are associated with autoimmune or viral hepatitis and past or present use of intravenous immunoglobulin (IVIG) may result in hepatitis C (Centers for Disease Control, 1994). Liver function tests should be done at yearly intervals, although more regularly (3 to 6 months) in those receiving immunoglobulin therapy since early treatment of hepatitis C has been shown to be more effective (Chapel et al., 2001).

### Respiratory and Pulmonary Problems

Sinusitis, bronchitis, and recurrent pneumonia are common in patients with most forms of immunodeficiency and are often the chief cause of morbidity and mortality (Hermananski and Webster, 1993). Sinusitis must be suspected if the patient has one of the following: purulent nasal discharge, frontal headaches, chronic nasal obstruction, postnasal drip, a decreased gag reflex, or unexplained coughing or wheezing. A microbial diagnosis including fungal cultures should be sought. Waters view sinus films are of value, particularly in youngsters, but a CT scan of the sinuses is used for definitive diagnosis. Treatment consists of prolonged courses of antibiotics, nasal decongestants, and nasal steroids. Nasal polyps should be surgically removed. Surgical sinus drainage is sometimes indicated if long-term antibiotics are not curative.

Many patients with a significant immunodeficiency develop pneumonia at one time or another and must be treated promptly. Vigorous exercise including team sports should be encouraged. A chronic cough due to bronchiectasis or wheezing is cause for special concern; attempts to detect structural damage or reversible airways disease are essential. Under such circumstances, pulmonary function tests are conducted, including the response to bronchodilator therapy. If bronchiectasis is found on CT scan, regular physiotherapy should be instigated. If the patient has antibody deficiency, a trial of a higher-dose IVIG (400–800 mg/kg) might be used and has been shown to improve pulmonary function (Bernatowska et al., 1987; Roifman et al., 1987; Eijkhout et al., 2001). If the patient is old enough, routine pulmonary function testing at 6-month or yearly intervals is recommended for all but the mildest immunodeficiency syndromes.

Patients who develop pulmonary infiltrations not responsive to antibiotics should undergo bronchoalveolar lavage or lung biopsy for an exact microbiologic diagnosis. Lung biopsy may reveal nonmicrobial granulomatous disease (Mechanic et al., 1997); Viallard et al., 1998; Wislez et al., 2000), lymphoid interstitial pneumonitis (LIP) (Davies et al., 2000), or even frank lymphoma.

Immunodeficient individuals with chronic lung disease should be started on a program of pulmonary therapy including postural drainage, the use of a flutter device to loosen secretions, and inhaled bronchodilators or other agents (Atrovent, cromolyn, an-

tibiotics). It is particularly important to identify patients likely to develop chronic lung disease early so that periodic assessment of pulmonary function, management of sinus disease, and vigorous treatment of early pulmonary infections can be undertaken. Pneumatoceles and abscesses must be treated surgically. Some patients with phagocytic deficiency also have IgE-mediated allergies and benefit from inhaled corticosteroids and oral antihistamines.

### Skin Problems

Patients with immunodeficiency often have cutaneous abnormalities (telangiectasia, molluscum contagiosum, warts, eczema, etc.). The most common cutaneous complication is chronic skin infection, particularly in the hyper-IgE immunodeficiency syndrome and in certain T cell deficiencies such as mucocutaneous candidiasis. Most of these patients require local and systemic antibiotics, usually prophylactically.

Chronic eczema is a common problem in the immunocompetent population but this may be more severe or become infected in the immunodeficient patient. It is a cardinal feature of Wiskott-Aldrich syndrome (see Chapter 31). Local steroids, tacrolimus ointment, and antipruritic medications are the mainstays of therapy. If there is cracking, weeping, or regional lymphadenopathy, antibiotics, either local or systemic, should be used. Clarithromycin is particularly well tolerated in chronic eczema. Severe warts are not uncommon (Barnett et al., 1983) and may be the indicator of a rare syndrome, warts, hypogammaglobulinemia, infection, myelokathexis (WHIM) (see Chapter 23), and are often refractory to usual methods of control. Some success has been achieved with increased doses of immunoglobulin.

Alopecia or vitiligo are also relatively common in antibody deficient adults with common variable immunodeficiency (CVID); both of these distressing conditions are untreatable. Subcutaneous granulomata (as well as pulmonary and gastrointestinal granulomata) are not uncommon in CVID. There are several reports suggesting that these granulomas respond to anti-tumor necrosis factor (TNF) therapy with etanercept (Smith and Skelton, 2001; Lin et al., 2006) or infliximab (Hatab et al., 2005; Thatayatikom et al., 2005).

### Vaccines

A review of immunization strategies in special clinical circumstances is provided in the "Rod Book" (American Academy of Pediatrics, 2000). Live attenuated vaccines including smallpox, poliomyelitis, measles, mumps, rubella, bacillus Calmette-Guérin (BCG), and varicella should be avoided in all severe antibody or cellular immunodeficiencies because of the risk of vaccine-induced infection. The evidence from HIV-infected children suggests that it is safe to give live virus vaccines to those with CD4 counts above  $200 \times 10^9/l$ . These vaccines have also been given without sequelae to patients with selective IgA deficiency, mucocutaneous candidiasis with intact cellular immunity to other antigens, and phagocytic and complement immunodeficiencies and to children fully reconstituted following bone marrow transplantation.

Paralytic poliomyelitis, chronic encephalitis, and prolonged poliovirus shedding from the gastrointestinal tract together are recognized complications of attenuated live poliomyelitis vaccination in immunodeficiency (Wyatt, 1973). Parents, siblings, and other household members should be given inactivated poliomyelitis vaccine because of the risk of spread to the patient of live vaccine-strain virus.

Other routine vaccines should be given to patients with adequate antibody immunity, including a yearly influenza vaccine. We

also administer killed vaccines to patients with partial antibody deficiencies (e.g., IgG subclass deficiency, ataxia-telangiectasia). The antibody response to these vaccines can be used to assess their B cell function. Many such patients have a short-lived antibody response that subsequently decreases in 6–12 months. Vaccines (except for attenuated poliovirus) should also be given to family members of patients with immunodeficiency. Individuals with a propensity to lower or upper respiratory infection and some antibody function should be given pneumococcal polysaccharide vaccine. For patients with intact cellular immunity, periodic tuberculin testing may be indicated, particularly if steroid therapy is anticipated.

### Antibiotics and Antivirals

Antibiotics are life saving in the treatment of infectious episodes of patients with immunodeficiency. The choice and dosage of antibiotics for specific infections are identical to those used in normal subjects but it is essential that treatment be started early. Culture specimens may be obtained prior to therapy; these will be especially important if the infection does not respond promptly to the initial antibiotic chosen.

Patients should be overtreated for infectious episodes, even if this necessitates frequent or chronic use of antibiotics and occasional unnecessary hospitalizations. If the infection does not respond promptly to antibiotics, the physician should consider the possibility of fungal, mycobacterial, viral, or protozoal (*Pneumocystis carinii* also named *jiraveci*) infection. Invasive procedures such as bronchoalveolar lavage or biopsy may be necessary.

Antiviral therapy can be used effectively in many immunodeficiencies. Exposure to influenza or early symptomatic influenza infection can be managed with amantadine or rimantadine or the neuraminidase inhibitor drugs zanamivir and oseltamivir. Severe herpes simplex infection, chickenpox, or herpes zoster should be treated with acyclovir. Ribavirin aerosols have been used in the treatment of respiratory syncytial virus and parainfluenza viral infections occurring in severe immunodeficiencies (McIntosh et al., 1984). Acyclovir can also be used in the incubation period to modify or prevent chickenpox (Asano et al., 1993). Topical cidofovir has been used successfully to treat severe molluscum contagiosum (Davies et al., 1999).

Antibiotics should be given prophylactically with each dental or surgical procedure. Amoxicillin and gentamycin can be given intravenously 1 hour before and 8 and 18 hours after major surgery, or 3 days of oral broad-spectrum antibiotics can be used for less serious manipulation (e.g., dental procedures).

### Antimicrobial Prophylaxis

Continuous prophylactic antibiotics often are of benefit in immunodeficiencies. They are especially useful in disorders characterized by rapid, overwhelming infections (e.g., complement deficiencies or in Wiskott-Aldrich syndrome if splenectomized or not receiving immunoglobulin therapy). They can also be used in patients with antibody deficiencies, especially in those with structural damage, when recurrent infections occur despite optimal immunoglobulin therapy, and in phagocytic disorders in which no other form of therapy is available. In these instances, penicillin, ampicillin, or dicloxacillin given orally, 0.5–1.0 g/day in divided doses, is recommended. Alternatively, azithromycin given once daily (5 mg/kg, maximum 250 mg/day) for 3 consecutive days every 2 weeks may be effective. In those rare babies with significantly delayed maturation of antibody production

**Table 46.1.** Recommendations for Prophylaxis Against *Pneumocystis carinii* in HIV and Primary Immunodeficiency on the Basis of CD4 Lymphocyte Count

Age	CD4 count
<12 months	<1500 cells/l
12–23 months	<750 cells/l
2–5 years	<500 cells/l
>5 years	<200 cells/l
Adults	<200 cells/l
Patients with a CD4 count <25% of total lymphocytes	
Past history of <i>Pneumocystis carinii</i> infection	
Patients with X-linked hyper-IgM syndrome (CD40L mutations)	
All patients with severe combined immunodeficiency	

associated with recurrent bacterial infections, temporary prophylaxis may be used until the immune system has matured.

*Pneumocystis carinii* pneumonia (PCP) prophylaxis is recommended for children with significant primary and secondary cellular (T cell) immunodeficiencies (Centers for Disease Control, 1991) (see Table 46.1). Prophylaxis consists of trimethoprim-sulfamethoxazole (TMP/SMX), 160 mg/M<sup>2</sup> of body surface per day of the TMP and 750 mg/M<sup>2</sup> per day of SMX given orally in divided doses twice per day three times per week, with frequent checks of the leukocyte count. Alternative drugs for PCP prophylaxis include pentamidine, dapsone, and atovaquone.

### Immunoglobulin Therapy

Two types of human immunoglobulin formulation are available for therapeutic use: intravenous immunoglobulin (IVIG) and the concentrated liquid products (IMIG, SCIG), occasionally used for intramuscular use but now mostly used for subcutaneous infusions. The route of administration depends on the dose needed to keep the patient free of infection and patient preference. Immunoglobulin therapy is indicated only for those patients with proven antibody deficiency (see Table 46.2). Immunoglobulin is not of value in the treatment of cellular, phagocytic, or complement immunodeficiencies, and it is of only limited value in combined antibody and cellular

**Table 46.2.** Primary Immunodeficiencies in Which Human Intravenous or Subcutaneous Immunoglobulin May Be Beneficial

#### Antibody Deficiencies

X-linked and autosomal agammaglobulinemia (Chapters 21, 22)  
Common variable immunodeficiency, including deficiencies of ICOS, Baff receptor, CD19, and TACI (Chapter 23)  
Hyper-IgM syndromes (both X-linked and autosomal recessive forms, Chapters 19, 20)  
Transient hypogammaglobulinemia of infancy (in selected cases)  
IgG subclass deficiency, with or without IgA deficiency (in selected cases)  
Antibody deficiency with normal serum immunoglobulins

#### Combined Deficiencies

Severe combined immunodeficiencies (all types prior to BMT and after BMT, if reconstitution of B cells has failed, Chapters 9–16)  
Wiskott-Aldrich syndrome (if associated with severe immunodeficiency)  
Ataxia-telangiectasia (if antibody deficiency, Chapter 29)  
Short-limbed dwarfism or cartilage hair hypoplasia  
Bare lymphocyte syndromes (Chapters 17, 18)  
X-linked lymphoproliferative syndrome (possible benefit) (Chapter 32)  
22q11 deletion syndromes (if severe antibody deficiency) (Chapter 33)

BMT, bone marrow transplantation; ICOS, inducible costimulator.

**Table 46.3.** Preparation of Intravenous Immunoglobulin from Cohn Fraction II\*

1. Physical removal of aggregates by ultracentrifugation or gel filtration
2. Treatment with proteolytic enzymes
3. Treatment with chemicals that reduce sulfhydryl bonds, followed by alkylation of the free SH bonds
4. Addition of disaccharides as stabilizing agent
5. Incubation at low pH

\*These methods are used to eliminate high-molecular weight complexes.

lar immunodeficiencies, though used routinely prior to bone marrow transplantation (BMT) and also in those BMT recipients in whom only the T cell system is reconstituted.

Immunoglobulin of either type is extracted from plasma pooled from 10,000–50,000 donors; the individual donor units are first screened for hepatitis B and C viruses and HIV (see below). After the cryoprecipitate is removed, cold ethanol (Cohn) fractionation of the resultant precipitate is used in several steps to concentrate the immunoglobulin and remove other serum proteins and live organisms, thus providing a sterile product (see Table 46.3). It contains a wide spectrum of antibodies to viral and bacterial antigens.

Immunoglobulin is >95% IgG, but trace quantities of IgM and IgA are present. The IgM and IgA globulins are therapeutically insignificant because of their short half-lives (less than 7 days) and their low concentrations in the immunoglobulin preparation. Immunoglobulin contains all IgG subclasses and multiple IgG allotypes (Gm and Km types). It is then treated by solvent-detergent or other chemicals, by pasteurization or nanofiltration for viral inactivation or virus removal, and brought to a 16.5% concentration for subcutaneous or intramuscular use.

#### Intravenous immunoglobulin therapy

IVIG is the most widely used treatment for several primary and secondary immunodeficiency syndromes (Table 46.2) (Stiehm, 1977). It is prepared from Cohn fraction II by eliminating high-molecular weight complexes and their resultant anticomplementary activity. Over 20 IVIG preparations have been used worldwide, and because of patent laws, all are slightly different and may therefore have minimally different risks. In practice, all of these preparations offer acceptable serum half-lives (18–25 days), contain all IgG subclasses, have minimal anticomplementary activity, have a good and diverse antibody content, and are negative for hepatitis B surface antigen (HBsAg), hepatitis C virus (HCV), and HIV.

There are several advantages to the administration of immunoglobulin by the intravenous route (see Table 46.4). Dosage,

methods of administration, and adverse reactions are discussed in the section specifically devoted to antibody deficiencies.

#### Subcutaneous immunoglobulin therapy

Immunoglobulin for subcutaneous (SCIG) (and intramuscular) use is a sterile 16.5% (165 mg/ml) solution preferably without preservative. Immunoglobulin preparations for intramuscular injection in the United States may have thimerosal as a preservative and are therefore unsuitable for subcutaneous or higher dosage intramuscular use. An exception is Gamastan (Talecris), formulated as a 16% preparation without preservative, licensed in the United States for single intramuscular dose, but also used for subcutaneous infusion. Additional immunoglobulin preparations suitable for subcutaneous infusion are now available (Viva-globin, ZLB-Behring).

Since there is no further modification step, the final product contains large molecular-weight complexes that are strongly anticomplementary and probably account for the occasional systemic reactions to 16% immunoglobulin if inadvertently injected intravenously; intravenous injections are contraindicated.

Slow subcutaneous infusion of IVIG at a concentration of 10%–12% has been given in the United States without adverse events (Welch and Stiehm, 1983; Stiehm et al., 1998). Dosage, methods of administration, and adverse reactions are discussed in the section devoted to antibody deficiencies.

#### Intramuscular immunoglobulin therapy

Intramuscular immunoglobulin therapy with the 16% product was used exclusively for the treatment of antibody deficiency up through the early 1980s, when IVIG was introduced. The recommended dose was 100 mg/kg per month, based on studies of the British Medical Research Council (1969). Treatment was given weekly at a dose of 25 mg/kg because of the large volumes needed (50 ml/month for a 70 kg adult).

Intramuscular injections are painful and have occasionally resulted in sterile abscesses at the site of injections. Adverse events were relatively uncommon, other than the local reactions. Occasional anaphylactic reactions have been reported, as well as one case of acrodynia in the United States from the mercury preservative (Matheson et al., 1980).

Presently, only an occasional patient is treated by this route because the amount of immunoglobulin that can be administered intramuscularly is limited and serious breakthrough infections may still occur.

### Hepatitis C–Contaminated Intravenous Immunoglobulin

Hepatitis C virus has been transmitted through a number of IVIG lots (Lever et al., 1984; Ochs et al., 1985; Bjorkander et al., 1988; Williams et al., 1989; Bjoro et al., 1994; Centers for Disease Control, 1994; Schiff, 1994; Yap et al., 1994; Yu et al., 1995; Christie et al., 1997; Razvi et al., 2001). It has not been transmitted through commercial immunoglobulin made for intramuscular use even when given in large doses subcutaneously. SCIG preparations produced in recent years undergo testing for HCV by polymerase chain reaction (PCR) and viral inactivation steps.

The most recent outbreak of hepatitis C (Centers for Disease Control, 1994; Schiff et al., 1994; Yu et al., 1995; Healey et al., 1996; Christie et al., 1997; Razvi et al., 2001) followed the exclusion of plasma containing antibodies to HCV. Because HCV does not induce the production of detectable antibodies for up to 6 months after exposure in immunocompetent individuals (the

**Table 46.4.** Advantages and Disadvantages of Intravenous Immunoglobulin

#### Advantages

- Ease of administering large doses
- More rapid action
- No loss in tissues from proteolysis
- Avoidance of painful intramuscular injections

#### Disadvantages

- Requires venous access
- Long duration of infusion
- Occasional serious side effects

open-window period), unchallenged virus from a few viremic donors may have contaminated a limited number of batches (Yu et al., 1995). Over 200 patients worldwide became infected (Centers for Disease Control, 1994; Schiff, 1994; Yu et al., 1995; Healey et al., 1996; Christie et al., 1997). The Gammagard/Polygam preparations involved in the outbreak were replaced with Gammagard-SD and Polygam-SD, whose manufacture now include a solvent-detergent treatment to inactivate HCV and other membrane-enveloped viruses.

In a previous outbreak, Bjoro et al. (1994) reported that immunocompromised patients had a severe and rapidly progressive course of hepatitis C infection, and the responses to interferon (IFN) were poor. However, this was a study of patients with chronic infection of undefined length and unknown or mixed genotypes of HCV.

The 1993/1994 outbreak in the United Kingdom and United States provided a unique opportunity to study the long-term rate of progression of HCV and responses to therapy in patients with known onset of infection and a single genotype, genotype 1a (Christie et al., 1997; Razvi et al., 2000; Chapel et al., 2001). With early (acute phase) high-dose IFN- $\alpha$  therapy, over half the patients cleared the virus and remain clear at 5 years (Chapel et al., 2001). Razvi et al. (2001) reported that 16 of 58 (27%) immunodeficient patients who developed HCV infection from IVIG resolved their infection; this rate of recovery was the same as that in IFN- $\alpha$ -treated patients and those receiving no therapy.

There have been no further reports of HCV infections transmitted by IVIG since 1994. Manufacturers of IVIG are now required to show that the virus inactivation processes are relevant to human disease. They have substantiated the antiviral efficacy of low pH and pepsin treatment and other procedures to inactivate HCV and other viruses including solvent-detergent, caprylate precipitation, heat treatment, and nanofiltration. Each of the various methods has been validated to be effective, but none can guarantee the total absence of known infectious virus, let alone unknown or new viruses.

No cases of HIV transmission have been identified with IVIG administration (Henin et al., 1988; Schiff, 1994) because of the efficient inactivation or partitioning of retroviruses by cold ethanol fractionation.

### Prion Disease and Intravenous Immunoglobulin

Several IVIG lots derived from plasma obtained from donors subsequently found to be at risk for Creutzfeldt-Jakob disease (CJD) have been recalled, although no cases of CJD or variant CJD (vCJD) associated with mad cow disease transmitted by IVIG have been reported to date. Tests to identify prions in serum are being developed.

Vigilance is needed in this area, and the International Union of Immunological Societies (IUIS) Committee for Primary Immunodeficiency Diseases encourages early referral to the Edinburgh Surveillance Unit of immunoglobulin recipients, especially those on long-term, repeated therapy, if they develop unexplained neurological or psychiatric symptoms. Ziegner et al. (2002) have reported unexplained neurodegeneration in 14 immunodeficient patients treated with IVIG in the United States and Europe, although none of these patients has proven to have prion disease.

Currently, British plasma and that from individuals who have lived in Great Britain for more than 3 months between 1980 and 1996 or who have stayed in Europe for an accumulative time of

more than 5 years since 1980 are excluded from use for immunoglobulin production in the United States.

### Special High-Titered Immune Globulins

Following chickenpox or herpes zoster exposure of the immunodeficient child, varicella-zoster immune globulin (VZIG) may be given to prevent chickenpox. Alternatively, or in combination, oral acyclovir can be used. For antibody-deficient children receiving regular IVIG infusions at monthly intervals, VZIG is not usually given because IVIG contains antibody to varicella/zoster virus. Even if not prevented, varicella infections are markedly attenuated by IVIG.

RSV-IG (RespiGam), licensed in 1996 in the United States, was a high-titered human IVIG that prevented or modified respiratory syncytial virus (RSV) infections in high-risk infants such as ex-prematures and infants with bronchopulmonary dysplasia (Groothuis et al., 1993) during the respiratory virus season (November–April). RSV-IG was also recommended in the United States for patients with severe primary or secondary immunodeficiencies who were under the age of 2, and was used in infants under age 2 with combined immunodeficiency who were undergoing stem cell transplantation. RespiGam was replaced in 2003 with monthly intramuscular injections of the RSV monoclonal antibody palivizumab (Synagis, 15 mg/kg), along with regular IVIG infusion.

RSV-specific antibody has been used for treatment of infants with life-threatening RSV infections, in combination with ribavirin. Proof of efficacy in treatment protocols is lacking, however.

The prophylactic use of other high-titered immunoglobulins such as tetanus immunoglobulin (TIG) and hepatitis B immunoglobulin (HBIG) following exposure to these agents is particularly important in the unimmunized immunodeficient patient.

### Corticosteroids

Corticosteroids are occasionally necessary in patients with immunodeficiency for such problems as asthma, lymphoid interstitial pneumonitis, and obstructive gastrointestinal or genitourinary tract lesions of chronic granulomatous disease, hemolytic anemia, anaphylactic reactions, or graft-versus-host disease. Short-term courses are well tolerated; if chronic or high-dose corticosteroid therapy is used, PCP prophylaxis should be considered. We have used inhaled corticosteroids in children with chronic granulomatous disease and local steroids for eczema in Wiskott-Aldrich syndrome and other immunodeficiencies without complications.

Prolonged high-dose corticosteroids will severely depress the lymphocyte count, including that of T and B cell subpopulations, in normal children, lymphoproliferative and antibody responses usually remain intact (Lack et al., 1996).

### Prenatal and Neonatal Management

If a previous sibling has had a severe T cell immunodeficiency and the mother is again pregnant, a number of options must be considered and prior planning is imperative. Fetal blood sampling is possible by 18–20 weeks gestation and can be used for the study and identification of cellular elements. If the molecular defect is known through gene analysis of affected family members, prenatal diagnosis can be performed by analyzing fetal DNA obtained by means of choriovillous biopsy (CVS) or by collecting amniocytes.

Cesarean section may be performed if a difficult labor is anticipated; however, it is not routinely indicated. Cesarean section

prior to labor is recommended when neonatal thrombocytopenia is anticipated, such as in Wiskott-Aldrich syndrome, to prevent a cerebral bleed during labor. At birth, cord blood should be obtained for blood count, immunoglobulin assays, B and T cell enumeration, phytohemagglutinin (PHA) stimulation, and human leukocyte antigen (HLA) typing to detect maternal chimerism. The rest of the cord blood may also be cryopreserved for possible future gene therapy.

Newborns suspected to have combined immunodeficiency should remain in a protective environment with reverse isolation or in an isolator with food and liquid sterilized until his or her immunologic status is clarified or definitive treatment completed. A chest X-ray for thymic size should be done as soon as possible; an absent thymic shadow in an unstressed newborn is highly suggestive of a T cell immunodeficiency. Gastrointestinal sterilization (with nonabsorbable antibiotics) and PCP prophylaxis (with TMP-SMX) should be considered for patients with severe T cell immunodeficiency. PCP prophylaxis is indicated for young infants (after age 6 weeks) with suspected cellular immunodeficiency and CD4 cells  $<1500$  cells/ $\mu\text{L}$ <sup>3</sup>, which is less than the fifth percentile for that age-group (Stiehm et al., 2004).

The importance of an early diagnosis and treatment of primary immune deficiency to prevent death or long-term complications cannot be overemphasized. However, prevention of immunodeficiency is limited. In the main, it is only applicable to those with a previous affected pregnancy or positive family history. These considerations are of particular importance in countries where consanguineous marriages are common. Measures include providing genetic counseling to a family at risk, arranging for prenatal diagnosis, and, in certain circumstances, termination of pregnancy.

Prenatal diagnosis is of value if early treatment, therapeutic abortion, or cesarian section are possibilities. In utero tissue typing of the fetus is sometimes of value to identify a potential matched 400 related or unrelated donor, or an umbilical cord transplant donor (Vowels et al., 1993). In utero haploidentical BMT has been accomplished (Flake et al., 1996; Bartolome et al., 2002).

### Family Studies

Immunoglobulin and complement levels should be obtained in the immediate family of all patients with antibody or complement deficiencies to determine a familial pattern. If other family members have suggestive histories, they should also be studied. Newborn siblings of an affected patient are followed carefully from birth for manifestations of a similar disorder. In disorders in which procedures are available for heterozygosity testing, the parents, siblings, and children of the affected subject can be tested.

### Support Groups

Participation in support groups (listed at end of this chapter) provides essential information and help for patients and their families with schooling, insurance, access to medical care, etc. Medical and nursing teams can provide only limited resources to help families cope with the social, economic, emotional, and psychologic issues that these diseases impose on families. Other patients and families can offer a perspective and mutual support not obtainable from medical personnel.

### Antibody Deficiencies

In patients with severe symptomatic antibody deficiency (see Table 46.2), such as X-linked agammaglobulinemia, common

variable immunodeficiency, and the hyper-IgM syndromes, human immunoglobulin replacement therapy is the mainstay of therapy.

### Immunoglobulin Therapy

Like the well-controlled diabetic on insulin therapy, many patients on regular immunoglobulin replacement are able to live symptom-free. However, some immunodeficient subjects given immunoglobulin remain chronically ill or undergo a progressive downhill course. Often these patients have immunologic or hematologic deficits other than antibody deficiency or have developed chronic lung or gastrointestinal disease. Patients with IgG subclass deficiency, transient hypogammaglobulinemia of infancy, and selective IgA deficiency should not be treated with immunoglobulin unless there is documented failure to produce specific antibodies following immunization.

#### Intravenous immunoglobulin

**Dosage.** Several studies indicate that larger doses of IVIG (400–800 mg/kg) are superior to lower doses (100–200 mg/kg per month) in terms of subjective improvement, reduced hospitalization rates, improved chest X-rays or CT scans, normalization of pulmonary function, and decreased incidence of major or minor infections (Montanaro and Pirofsky, 1984; Ochs et al., 1984; Bernatowska et al., 1987; Roifman et al., 1987; Garbett et al., 1989; Liese et al., 1992; Haeney, 1994; Stiehm, 1997). The aim of IVIG therapy is to maintain the serum IgG concentration at a sufficient level to keep the patient free of infection, usually at a trough level of IgG that is within the normal range or at least 400 mg/dl above the pretreatment baseline level.

A common practice is to start IVIG at 400 mg/kg at monthly intervals but give additional doses at the onset of therapy to raise the IgG level quickly. After initiation of IVIG, the trough level of IgG increases over several months as the tissue spaces become saturated with immunoglobulin. After 3 months the preinfusion IgG level is assessed and the dose adjusted (Stiehm, 1997). A few patients with chronic lung disease, vasculitis, rheumatic complaints, chronic diarrhea and protein-losing enteropathy, or failure to thrive may require a higher dose (e.g., 0.8–1.0 g/kg per month) to control disease manifestations (Roifman et al., 1987; Eijkhout et al., 2001).

**Administration of intravenous immunoglobulin.** IVIG administration requires venous access, which is sometimes a problem in small children. The use of EMLA cream, a local analgesic, applied to the infusion site 1 hour prior to starting the infusion, or a more rapidly acting spray, makes venipuncture much more acceptable to young children.

Close monitoring is initially required, especially during the first two infusions, when close to half of adult patients, particularly those with CVID, develop fever, chills, muscle ache, or nausea. However, adverse reactions are infrequent when IVIG is given regularly and at adequate doses, provided the correct rates for infusions are observed and the patients are not infused during a breakthrough infection (Brennan et al., 1995).

In Europe and the United States, IVIG infusions have been shown to be sufficiently safe to enable some patients (adults and children) to receive infusions at home with the help of either a home infusion service or a responsible adult family member or by self-infusion. Self-infusion without another informed adult in the house is discouraged. In one study, the number of adverse reactions in selected patients was 0.1%, and universally the reactions were mild (Brennan et al., 1995). Nurses, parents, or patients

who perform home infusions must be taught to recognize and treat adverse reactions, and their competency documented.

In patients who have received infusions without adverse events, self- or parent administration at home can be accomplished at great cost savings (Ashida and Saxon, 1986; Sorensen et al., 1987; Kobayashi et al., 1990). Until recently, when subcutaneous infusion was introduced, this type of therapy was used by 75% of patients in the United Kingdom and some parts of Europe. In the United States, however, most IVIG infusions, with some exceptions, are performed in a clinic setting or by professional home infusion personnel.

Typically, an IVIG infusion requires 2–4 hours to administer. The initial rate is 0.5 mg/kg/min (0.01 ml/kg/min of the 5% product) and this can be doubled at 20- to 30-minute intervals if there are no side effects, to a maximal rate of 2 to 3 mg/kg/minute (0.04–0.06 ml/kg/minute). Adverse events tend to be associated with rapid infusion rates in patients with concurrent acute infections or previously untreated patients, or when significant time between infusions has transpired (>4-week intervals). On the other hand, if infusions are given more frequently, for example, every 2 weeks, the rate of adverse events is very low indeed.

*Side effects of intravenous immunoglobulin therapy.* Typical reactions associated with infusions include headaches, nausea and vomiting, flushing, chills, myalgia, arthralgia, and abdominal pain (Ochs et al., 1980; Duhem et al., 1994; Stiehm, 1997). Occasionally, chest tightness, hives, and anaphylactoid reactions can occur. Very rarely, severe, life-threatening anaphylactic reactions may be triggered.

Immediate minor reactions can be avoided or diminished by slowing the infusion rate. Patients with minor side effects such as headaches, shaking chills, nausea and vomiting, or myalgia/arthralgia can be treated (and for subsequent infusions pretreated) with oral acetaminophen or a nonsteroidal anti-inflammatory drug and antihistamines. Severe reactions are treated with parenteral epinephrine, antihistamines, and corticosteroids.

If a severe reaction is anticipated, in addition to oral acetaminophen and antihistamines, hydrocortisone (6 mg/kg, maximum 100 mg) can also be given intravenously 1 hour before infusion. These drugs can be repeated after 3 or 4 hours if the infusion is not finished. Occasionally, switching to a different IVIG product may alleviate reactions.

Serious late but very rare adverse reactions are almost always confined to high-dose usage of IVIG in immunomodulating doses (Duhem et al., 1994). These include aseptic meningitis (Kato et al., 1988; Vera-Ramirez et al., 1992), thrombosis and disseminated intravascular coagulation (Woodruff et al., 1986; Comenzo et al., 1992), renal (Miller et al., 1992) and pulmonary (Rault et al., 1991) insufficiency, and hemolytic anemia (Brox et al., 1987).

IVIG is contraindicated in patients who have had an anaphylactic reaction to IVIG or other blood products. IVIG is initially given with great caution in patients who have IgG subclass deficiencies with IgA deficiency and/or anti-IgA antibodies (Burks et al., 1986), as these patients may be at higher risk of a serious reaction.

Certain brands of IVIG may be more reactogenic. In one study of Kawasaki disease, the two IVIG brands used were equivalent therapeutically, but one had a 12-fold (2% vs. 25%) increase in side effects (Rosenfeld et al., 1995).

A few investigators have given high concentrations (9%–12% solutions) infused rapidly over a period of 20–40 minutes. This rapid rate can be tolerated by some but not all patients (Schiff

et al., 1991). This dosage should be administered only by experienced personnel equipped to manage serious adverse reactions.

### Subcutaneous immune globulin

Subcutaneous infusion of immunoglobulin (SCIG) has been developed as an alternative to IVIG. The monthly dose is the same as that for IVIG, starting typically at 0.4 g/kg per month, in divided doses every week. Initially, SCIG was given as a 16% formulation by slow subcutaneous infusion at a rate of 0.05 to 0.2 ml/kg/hour or 1–10 ml/hour, using a syringe driver as a pump (Berger et al., 1980). Because of contamination of an early IVIG product with HCV in Scandinavia and the availability of SCIG at costs lower than that of IVIG preparations, subcutaneous infusion of a 16% preparation became the predominant mode of immunoglobulin prophylaxis in northern Europe (Gardulf et al., 1991).

Rapid (“express”) SCIG infusions at up to 40 ml/hour are well tolerated (Gardulf et al., 1995, 2001; Hansen et al., 2002). Because the technique of inserting a 23- or 25-gauge needle subcutaneously is simple and severe side effects are not encountered, the injections are self-administered into the abdominal wall and/or thighs by use of a battery-powered pump. The injections are well tolerated with minimal local reactions (pain or redness), and rarely do systemic reactions occur (Gardulf et al., 1991, 1995; Abrahamson et al., 1996; Chapel et al., 2000; Berger, 2004; Gardulf et al., 2006; Ochs et al., 2006).

Because subcutaneous infusions are well tolerated and not associated with serious adverse events, there are no strict guidelines on how to initiate subcutaneous infusions. The following techniques have been used in several centers and accepted by most patients. The preparations best suited for subcutaneous infusion are those with 16% IgG and without preservatives. This type of preparation is licensed for intramuscular injections in the United States, under the trade name Gamastan. ZLB Behring has recently released its 16% IgG preparation (Vivagloblin) after extensive testing (Gardulf et al., 2006; Ochs et al., 2006) in Europe and the United States.

The standard dose is 100 to 150 mg/kg/week, approximately 45–60 ml of a 16% solution for a 70 kg patient. The infusion sites are most often the four abdominal quadrants and alternatively the lateral thighs and the lateral aspect of the upper arms. For administration, 23- to 25-gauge butterfly steel needles are preferred. Depending on the thickness of the subcutaneous tissue, the needle can be bent at the base 0° to 90° and secured with tape. If more than 20 ml is needed, a “Y” tubing or “triple” tubing allows simultaneous infusion at two or three sites. A simple syringe driving pump (e.g., Autosyringe AS-3B or Graseby MS16) can be used to deliver quantities of between 10 and 50 ml. Infusion of not more than 15 to 25 ml per site is recommended. Most patients infuse 20 ml per site over a 1-hour interval and are highly satisfied (Nicolay et al., 2006).

Patients switched from IVIG to subcutaneous infusion should receive their first dose within 1 week after the last IVIG infusion. Newly diagnosed patients who have not been treated with any form of immunoglobulin replacement can be started directly on subcutaneous treatment by loading with several daily doses of immunoglobulin (Berger, 2004). Ugazio et al. (1982) and Waniewski et al. (1993) have demonstrated that administration of five daily subcutaneous infusions (at 100 mg/kg each) can bring patients very rapidly to an apparent steady state that is then maintained by weekly subcutaneous infusions. Local anesthetic such as EMLA cream is widely used, especially in pediatric patients.

In infants and small children, subcutaneous infusions of 2 to 3 ml per site can be given directly without a pump over a 2- to

5-minute period. Depending on the size of the child, one or two subcutaneous injections per week may be sufficient. Daily direct injections without a pump are preferred by some adult patients so as to avoid the use of a pump. For a 70 kg patient, the daily volume of 16% SCIG would be approximately 6 ml, or  $2 \times 3$  ml per site.

A multicenter comparison of the efficacy and safety of IVIG vs. SCIG replacement therapy showed no significant differences in rates of breakthrough infections or adverse reactions (Chapel et al., 2000). Two recent multicenter studies that included both pediatric and adult patients in a comparison of hospital-based IVIG to home-based SCIG therapy demonstrated that home-based SCIG therapy improved several important aspects of quality of life and provided patients and their families with greater independence and better control of aspects of treatment and daily life (Gardulf et al., 2004; Nicolay et al., 2006). Subcutaneous administration of immunoglobulin by infusion from a small pump or by direct injection is safe and easy to learn and represents an alternative to IVIG treatment regimens.

Intravenous immunoglobulin for treatment of enterovirus encephalitis and polymyositis

Chronic meningoencephalitis and polymyositis or fasciitis due to disseminated enterovirus infection (usually ECHOvirus) may occur in patients with X-linked agammaglobulinemia (XLA) (Wilfert et al., 1977; Mease et al., 1981; Erlendsson et al., 1985; Johnson et al., 1985; Lederman and Winklestein, 1985; Prentice et al., 1985; Crennan et al., 1986; McKinney et al., 1987; Schmugge et al., 1999; Quartier et al., 2000) and to a lesser extent in patients with CD40L deficiency (Cunningham et al., 1999) or CVID. Polymerase chain reaction may be required for establishing the diagnosis (Chesky et al., 2000). Since the introduction of IVIG, the incidence of disseminated enteroviral infections has dropped dramatically, but it still may occur in some patients receiving adequate doses of IVIG (Rotbart, 1990; Misbah et al., 1992) or in children prior to a diagnosis of XLA.

Treatment with high-dose IVIG may modify the severity of infection and improve survival (Mease et al., 1981; Erlendsson et al., 1985; Prentice et al., 1985; Quartier et al., 2000), but failure of high-dose IVIG has been reported (Johnson et al., 1985; Crennan et al., 1986). The response to IVIG may depend on the titer of neutralizing antibodies in the preparation against the specific echovirus (Mease et al., 1981). A review of published reports (Stiehm and Keller, 2004) indicates that more affected patients treated with IVIG survived than those given intramuscular immunoglobulin or immune plasma; of those who did not receive IVIG, none survived. The use of intraventricular infusion of IVIG contributed to the eradication of the virus in some patients but not in others. Patients originally responding appropriately to high-dose IVIG may relapse later (Mease et al., 1985; H.D. Ochs, personal observation).

Intravenous immunoglobulin for treatment of other viral infections

IVIG has been advocated for the treatment of chronic Epstein-Barr virus (EBV) infection. In uncontrolled studies, selected patients have shown clinical improvement (Tobi and Straus, 1985; Finberg, 1988). It has been suggested that IVIG be used prophylactically in EBV-seronegative infants and children known to have inherited a mutated *SH2D1A*, the gene responsible for X-linked lymphoproliferative syndrome (XLP) (see Chapter 32) to prevent EBV infection. One EBV-seronegative college student

known to have inherited the disorder died from overwhelming EBV infection despite monthly IVIG infusions (Okano et al., 1991). IVIG is still used prophylactically in XLP by some investigators and data on the success or failure are being collected by means of disease-specific registries and databases (Valiaho et al., 2000). To collect meaningful data, it is particularly important to ascertain the underlying molecular diagnosis and to differentiate XLP (see Chapter 32) from CVID (see Chapter 23) (Morra et al., 2001), X-linked hyper-IgM syndrome (see Chapter 19), and XLA (see Chapter 21).

High-dose IVIG (500 mg/kg/daily) may be of value in the treatment of immunodeficient patients with other viral diseases, including cytomegalovirus (CMV) infection, parvovirus-induced pure red cell aplasia (Kurtzman et al., 1989; Seyama et al., 1998), and respiratory virus infections such as parainfluenza or adenovirus (Stiehm et al., 1986). RSV-IG with high-titer antibody (replaced by the monoclonal anti-RSV preparation Synagis in 2003) may be used on a monthly basis to prevent RSV infection in young immunodeficient subjects (vide supra).

Oral immunoglobulin (150–300 mg/kg body weight) has been used in a few patients with antibody deficiency to stop enteroviral shedding following inadvertent poliomyelitis immunization (Losonsky et al., 1985) or to treat rotavirus infections (Barnes et al., 1982).

### Other Therapies

A subset of patients with antibody deficiencies have concomitant and usually transient neutropenia (e.g., X-linked hyper-IgM syndrome, XLA). High-dose IVIG (2 g/kg) may reverse persistent and clinically significant neutropenia and should be tried first. In patients with X-linked hyper-IgM syndrome, granulocyte colony-stimulating factor (G-CSF) therapy may be required (see Chapter 19).

Continuous or intermittent antibiotic therapy may be necessary to keep some antibody-deficient patients free of infection or to prevent progression of chronic simopulmonary disease and bronchiectasis. We use full therapeutic doses of a set of antibiotics, including cephalosporin, ampicillin, clarithromycin, or TMP-SMX, which are rotated at 2-week or monthly intervals.

It is important to correct avitaminosis with replacement vitamins, especially the fat-soluble vitamins A, D, and E, by injection if they are not absorbed orally (Aukrust et al., 2000).

Most attempts to stimulate antibody synthesis by immunologic-enhancing agents have been unsuccessful. Of particular interest is the use of PEG-IL-2, an experimental preparation of interleukin-2 (IL-2) conjugated to polyethylene glycol (PEG) (Cunningham-Rundles et al., 1994). In one study, PEG-IL-2 was given to 15 CVID patients (Cunningham-Rundles et al., 2001). After 6 to 12 months of therapy, in vitro proliferative responses improved and antibody responses to a neoantigen developed (in 4 of 8 patients tested), but clinical benefit was minimal. Isolated successes have been reported with cimetidine (White and Ballou, 1985) and retinoic acid (Saxon et al., 1993). Blys (also known as BAFF), a cell surface molecule that activates B cells, looks promising in animal experiments, but robust clinical trials have not been initiated.

In antibody deficiency associated with drug treatment (e.g., IgA deficiency following phenytoin use or hypogammaglobulinemia following gold therapy), discontinuation of the drug may result in reversal of the disease. In some cases, however, the antibody deficiency persists indefinitely (Snowden et al., 1996; Cunningham-Rundles, 2004).

## Cellular Immunodeficiencies

### Precautions

Patients with a predominant T cell deficiency need preventive measures to avoid infective complications before attempting curative immunotherapy. As in antibody deficiencies, immunization with live attenuated vaccines is contraindicated. Progressive poliomyelitis, measles encephalitis, and mumps encephalitis have been recorded in T cell-immunodeficient patients following routine childhood immunization. Additionally, siblings and other close contacts should be immunized with inactivated polio vaccine (which is used exclusively in most developed countries) because live virus may be transmitted to the patient.

Special care must be taken in administering blood products. Blood or blood cell components given to patients with primary (or secondary) T cell immunodeficiencies should be CMV negative and must be irradiated with 2700 rads (27 Gy) to prevent graft-vs.-host reaction. Radiation of blood products is a simple procedure and can be accomplished rapidly in most blood banks.

Tonsillectomy and adenoidectomy are rarely indicated. Splenectomy is contraindicated, except in unusual circumstances, because the removal of an important immune organ and the creation of a *de facto* phagocytic defect in addition to the already existing immunodeficiency may result in sudden, overwhelming sepsis. Broad-spectrum prophylactic antibiotics may be of value in patients with recurrent or chronic bacterial disease.

### Prophylactic Antimicrobial Therapy

Patients with a significant T cell deficiency are at risk for PCP. Those over age 5 years with CD4 counts  $<200/\mu\text{l}$  are candidates for PCP prophylaxis, and for those patients less than age 5, PCP prophylaxis should be considered at higher CD4 count levels (Stiehm et al., 2004) (see Table 46.1).

Continuous antifungal medications such as oral nystatin, ketoconazole, fluconazole, itraconazole, and caspofungin (Candida) are used to prevent or treat chronic candidiasis and other fungal infections.

All patients with severe combined immunodeficiency require prophylactic treatment with IVIG prior to stem cell transplantation because their B cells, if present, will either be nonfunctional or lack costimulation by T cells. Even if the T cell defect is relatively mild (as in X-linked hyper-IgM syndrome), the patient may have severely impaired B cell function and should be evaluated for abnormal antibody production. If it is deficient, IVIG therapy is indicated (Table 46.2). The dose of IVIG is similar to that discussed earlier for antibody deficiency.

Varicella-zoster immune globulin (VZIG) and/or acyclovir following chickenpox exposure and amantadine or rimantadine following influenza virus exposure may prevent or diminish the severity of infections.

### Other Treatment

In patients with lymphopenia due to gastrointestinal lymphocyte loss as part of severe protein-losing enteropathy or lymphangiectasia of the gut not amenable to medical or surgical treatment, oral medium-chain triglycerides may be of value.

Endocrine abnormalities may be associated with T cell deficiency, notably hypoparathyroidism in DiGeorge anomaly and chronic mucocutaneous candidiasis, and hypothyroidism and hypoadrenalism in ataxia-telangiectasia and chronic mucocutaneous

candidiasis. These should be treated appropriately, although correction of the endocrinopathies will not affect the T cell deficiency.

Restoration of immunity, short of transplantation, is rarely feasible in T cell immunodeficiencies. Immunomodulating agents such as thymic hormones, levamisole, and transfer factor have not been of proven benefit despite isolated reports of success.

An exception is the treatment of adenosine deaminase (ADA) deficiency (see Chapter 12) with PEG-ADA, given once or twice weekly at a dose of 30 U/kg. Close monitoring of plasma ADA levels and lymphocyte adenosine deoxyribonucleotides (dAXD) is required to assess the patient's response to therapy (Hershfield, 1995). Clinical and immunologic improvement are observed in most patients and include restoration of antibody responses and *in vitro* lymphocyte proliferation. PEG-ADA treatment is of particular value for patients who are too sick to undergo transplantation or who lack an HLA-matched bone marrow donor. A few patients have developed an antibody to PEG-ADA in association with increasing resistance to enzyme therapy. This complication was reversed by increasing the dose of enzyme and by a short course of corticosteroids and high-dose IVIG (Chaffee et al., 1992).

In the rare condition of multiple carboxylase deficiency, often associated with candidiasis and severe viral and bacterial infections, substitution with the coenzyme biotin given orally at a dose of 1–40 mg/day completely corrects the symptoms (Ochs et al., 2004).

### Cytokine Therapy

The role of IL-2 substitution in individuals with poorly described T cell deficiencies has been explored. A few patients with phenotypic severe combined immunodeficiency were reported to have a defect of IL-2 synthesis with intact IL-2 receptors. IL-2 therapy resulted in temporary restoration of some cellular immunity in a patient with defective IL-2 synthesis (Pahwa et al., 1989). Other patients with T cell defects have been treated with IL-2 and appear to have achieved some improvement of *in vitro* T cell function (Flomenberg et al., 1983), but controlled studies are lacking. Cunningham-Rundles et al. (1999) used PEG-IL-2 in a single patient with idiopathic CD4 lymphopenia and attained a favorable clinical and laboratory response.

Interferon- $\gamma$  therapy is of unproven efficacy in most T cell immunodeficiencies but has some theoretical value in the treatment of Griscelli syndrome, natural killer (NK) cell deficiency, and bare lymphocyte major histocompatibility complex (MHC) class I deficiency in that it may replace deficient production, enhance NK cytotoxicity, or increase expression of HLA class I antigens. High-dose IFN- $\gamma$  therapy is of benefit in the treatment of patients with a partial IFN- $\gamma$  receptor deficiency or in patients with IL-12 or IL-12 receptor defects. (Jouanguy et al., 1997; Holland, 2000) (see Chapter 28).

G-CSF is of value in certain T cell deficiencies where there is an associated neutropenia (e.g., X-linked hyper IgM syndrome). It is also useful in patients who have recently undergone stem cell transplantation for immunodeficiency disorders to hasten granulocyte recovery (see Chapter 47).

### Stem Cell transplantation and Gene Therapy

The treatment of choice, since it may be curative, is hematopoietic stem cell transplantation from a matched or partially matched donor using bone marrow, peripheral blood, or cord blood as the source of stem cells (see Chapter 47). More recently, gene therapy has been successfully performed in patients

with common  $\gamma$ -chain deficiency (X-linked severe combined immunodeficiency) and with ADA deficiency (see Chapter 48).

## Phagocytic Immunodeficiencies

### General Care

Patients with phagocytic immunodeficiencies including chronic granulomatous disease (CGD) (see Chapter 37), leukocyte adhesion defects (LAD 1, 2, and 3) (see Chapter 38), and hyper-IgE syndrome (see Chapter 34) are particularly susceptible to cutaneous soft tissue infections and generally do well on continuous antimicrobial therapy, particularly TMP-SMX. Most patients with hyper-IgE syndrome need chronic antistaphylococcal treatment such as oral cloxacillin or dicloxacillin and antifungal therapy such as fluconazole or itraconazole. Those with demonstrable antibody deficiency improve on immunoglobulin therapy. Severe cutaneous infections in these patients are treated with intravenous and/or local antibiotics, and often in combination with local steroid therapy.

Patients with neutropenia or defects of cell adhesion and movement are particularly susceptible to periodontitis and oral ulcerations. Good oral hygiene must be stressed, and an antibacterial mouthwash (Peridex) should be used on a regular basis. Prophylactic antifungal drugs should be given if thrush or esophageal candidiasis has occurred. G-CSF can be used for most forms of persisting or cyclic neutropenia (see Chapter 39).

### Chronic Granulomatous Disease

#### General treatment

In addition to prophylactic antibiotics, particularly TMP-SMX, vigorous treatment of each infectious episode is of crucial importance (see Chapter 37). Leukocyte transfusions may be of value in severe refractory infections such as hepatic abscesses or osteomyelitis (Yomtovian et al., 1981), but surgical therapy is required in most instances. Systemic corticosteroid therapy has been used successfully to reverse the gastrointestinal or genitourinary obstructive lesions that are a frequent complication in CGD (Chin et al., 1987). Multiple short courses of high-dose oral steroids may be necessary.

#### Interferon- $\gamma$ prophylaxis

A randomized, double-blind study showed that recombinant human IFN- $\gamma$  reduced the frequency and severity of infectious episodes in CGD patients (International Chronic Granulomatous Disease Cooperative Study Group, 1991). This was particularly true for a subgroup of CGD patients that did not receive adequate antibiotic prophylaxis and as a result had a significant reduction of the number of infective episodes compared with those receiving placebo. In fact, the frequency of infections fell to that of the group receiving antibiotics alone. The infections that did occur in IFN- $\gamma$ -treated CGD patients were less severe, requiring fewer days of hospitalization and parenteral antibiotic treatment. The most frequent reactions to IFN- $\gamma$  injections were flu-like symptoms, headache, myalgia, and mild fever, usually effectively prevented by acetaminophen.

In patients receiving either placebo or IFN- $\gamma$ , no differences in NADPH oxidative response, bacterial killing, or cytochrome  $b_{558}$  levels were noted. This finding suggests that nonoxidase biologic responses may contribute to enhanced resistance in patients treated with IFN- $\gamma$  (Klebanoff et al., 1992; Malmvall and Follin, 1993). The minimal toxicity and significant clinical effectiveness

have led to the recommendation to treat CGD patients of all inheritance patterns in the United States with IFN- $\gamma$ , 50  $\mu\text{g}/\text{M}^2$  body surface, administered subcutaneously three times each week. In Europe, prophylaxis with TMP-SMX and antifungals remains the cornerstone of therapy in adults and older boys (see Chapter 37).

#### Transplantation

Bone marrow transplantation has been successful in CGD patients (Seger et al., 2002). A recent report of 10 patients (5 adults and 5 children) in whom nonmyeloablative conditioning combined with T cell depletion was performed indicated success in 8 of 10 transplants and a 70% survival rate at almost 2 years (Horwitz et al., 2001). Early transplantation before major infection occurs is associated with improved survival. Clinical trials of gene therapy are under way with early promising results (R. Seger, personal communication).

### Leukocyte Adhesion Defects

The severe mouth ulcers and periodontal disease observed in patients with CD11/CD18 deficiency (LAD1) and in those with defective fucose transport (LAD2) necessitate good oral hygiene (see Chapter 38). Continuous antimicrobial therapy may be necessary to prevent cutaneous and deep-seated infections. Daily white blood cell transfusions for 1 or more weeks may be needed to treat severe, life-threatening infections.

De Ugarte et al. (2002) have used GM-CSF formulated for local application to treat nonhealing wounds in leukocyte adhesion defects and other granulocyte abnormalities (e.g., chronic granulomatous disease, glycogen storage disease type Ib).

Bone marrow transplantation is readily accomplished in patients with this disorder because the adhesion molecules that LAD1 patients lack contribute to graft rejection (Le Deist et al., 1989).

### Hyper-IgE Syndrome

Continuous antimicrobial therapy is usually necessary to keep these patients' cutaneous and deep-seated abscesses under control (Buckley, 2004). Prompt treatment of infections, notably sinusitis and bronchitis, and in many cases continuous prophylactic treatment with antibiotics, may prevent acute pneumonia, lung abscesses, and pneumatocele formation (see Chapter 34).

No specific immunotherapeutic regimen has been successful (Roberts and Stiehm, 1996). Interferon- $\gamma$  and IVIG reduce the IgE level but are without proven clinical benefit. Transfer factor, cimetidine, and ascorbic acid have been used without clinical benefit. Levamisole was inferior to placebo in a controlled, double-blind study (Donabedian et al., 1982). Isotretinoin was used in a single case without proven benefit.

### Glycogen Storage Type 1b

These patients have neutropenia, functional defects of neutrophil function, and recurrent infections including sinusitis, pneumonia, and septicemia. Continuous therapy with TMP-SMX has been recommended and GM-CSF or G-CSF may be beneficial (Hurst et al., 1993).

### Chediak-Higashi Syndrome

Although vitamin C corrects some of the defects in vitro, its use in patients with Chediak-Higashi syndrome has not been effective

(Gallin et al., 1979). Affected patients have an in vitro defect of NK cell function, amenable to IFN- $\gamma$  correction, but its use in vivo has not been documented. Bone marrow transplantation has been successful in these patients (see Chapter 40).

## Complement Deficiencies

### General Treatment

No specific treatment is available for most complement deficiencies (Sullivan and Winkelstein, 2004). Careful management, however, can improve the health and survival of affected patients (see Chapter 42). Complement-deficient patients, notably those with C2, C3, C5, C6, C7, C8, properdin, factor H, or factor I deficiencies, should be treated promptly with antibiotics at the first onset of fever. An antipneumococcal drug has to be included in the case of C2 deficiency, and an antineisserial drug should be used if the deficiency is of a late-acting component or involves properdin. Long-term penicillin therapy should be considered when meningococcal disease is endemic and for patients with a history of previous severe infections (Potter et al., 1990).

The patient and close household contacts should be immunized against *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Neisseria meningitidis*. Repeat vaccinations (every 3–5 years) may be necessary if titers diminish to nonprotective levels. The use of the new conjugated pneumococcal vaccines is recommended, although with caution, in view of the reduced number of serotypes included in Prevnar.

A deficiency of an early-acting component predisposes to collagen-vascular disease, which should be treated appropriately. Carriers of C2 deficiency may also have a propensity to develop autoimmune diseases. Other family members should be studied in the case of any genetic complement deficiency, and genetic counseling can be offered as indicated.

### Specific Treatment

An exception to the rule that no specific therapy for complement deficiencies exists is hereditary angioedema (HAE), an autosomal recessive disorder associated with deficiency or abnormal function of C1 inhibitor (C1INH). The therapy of HAE involves (1) the treatment of acute attacks and (2) prophylaxis of recurrent attacks.

Management of an acute episode of angioedema must be tailored to the extent of the problem. Laryngeal swelling or disabling abdominal pain requires intervention. The most effective therapy is C1INH concentrate given as an intravenous infusion, which is effective within 30 to 60 minutes. C1INH concentrate has not been approved by the U.S. Food and Drug Administration but is presently being clinically evaluated in the United States. Therefore, attenuated androgens are the most common specific treatment of an acute attack. Because androgens do not begin to have an effect until 24 to 48 hours, patients with serious symptoms have to be carefully monitored in a hospital to ensure that the angioedema does not progress.

Patients with a history of laryngeal obstruction or serious gastrointestinal involvement are candidates for long-term prevention of attacks. Impeded androgens such as Danazol, Stanozolol, and Oxandrolone are frequently used to increase serum concentrations of the normal C1INH by increasing transcription of the wild-type C1INH gene. Danazol is typically prescribed at a dose of 50 to 600 mg/day, Stanozolol at 1 to 10 mg/day, and Oxandrolone at 2.5 to 20 mg/day in adult patients. The goal of this

prophylactic therapy is to maintain the C1INH functional level at approximately 50% of normal. Long-term therapy in adults is possible, but patients have to be monitored for adverse reactions including abnormal liver function tests, microscopic hematuria, and weight gain. Attenuated androgens should not be used in children with open epiphysis on a long-term basis. However, intermittent treatment is acceptable. Regular plasma infusions could theoretically be used to replace a missing complement component, especially C3 or C4. However, the short half-life of these proteins, the low levels in normal plasma, and the possibility of developing an antibody response to the missing complement component make such an effort futile.

## Concluding Remarks

General care of the immunodeficient patient requires close monitoring of growth, nutrition, personal hygiene and habits, living conditions, school and work situations, and psychologic adjustment to the disease. The most important aspect of the care of an immunodeficient patient is to prevent, recognize, and vigorously treat infectious episodes. Associated disorders such as anemia, thrombocytopenia, respiratory or gastrointestinal problems, and autoimmune and inflammatory disorders are managed by conventional therapy. Avoidance of live-virus vaccines, unirradiated blood, and CMV antibody-positive blood is crucial for living with some of these illnesses. PCP prophylaxis is necessary in T cell immunodeficiency.

Specific therapies that are effective include immunoglobulin replacement therapy in patients with antibody deficiency, PEG-ADA injections for ADA deficiency, and IFN- $\gamma$  for CGD and for deficiencies of IL-12 and IL-12 receptor, and partial deficiencies of the IFN- $\gamma$  receptors. Other cytokines, including G-CSF and GM-CSF, and possibly IL-2 are of value in certain selected disorders. Stem cell transplantation has been pioneered in patients with primary immunodeficiency and continues to be a life-saving procedure for patients with many of these disorders. Minimal conditioning ("mini-transplants") is being increasingly performed in selected syndromes as a safe alternative to bone marrow transplantation and full conditioning. Progress in our understanding of the molecular basis of these disorders has paved the way for gene therapy, which is promising and at the same time a challenge.

## Bone Marrow Transplantation for Primary Immunodeficiency Diseases

REBECCA H. BUCKLEY and ALAIN FISCHER

Bone marrow transplantation was first attempted in the 1950s as a treatment for aplastic anemia. Except in identical twins (Pillow et al., 1966), however this therapy was unsuccessful until the late 1960s when the human major histocompatibility complex (MHC) was discovered (Amos and Bach, 1968). Shortly after that, immune function was successfully restored in two patients with fatal primary immunodeficiency diseases by transplants of unfractionated human leukocyte antigen (HLA)-identical allogeneic bone marrow. One patient had severe combined immunodeficiency (SCID) (Gatti et al., 1968) and the other had Wiskott-Aldrich syndrome (WAS) (Bach et al., 1968). The correction of these two conditions, as well as the later correction of many other forms of immunodeficiency by bone marrow transplantation (Friedrich, 1996; Buckley et al., 1999; Antoine et al., 2003), implied that the defects in most such conditions are intrinsic to cells of one or more hematopoietic lineages and that they are not due to failure of the microenvironment to support the growth and development of those cells.

### The Principle of Bone Marrow Transplantation

In the early 1950s it was observed that the hematopoietic systems of lethally irradiated animals could be reconstituted by bone marrow cells (Lorenz et al., 1952). This was shown to be due to the presence of self-replicating cells in normal bone marrow that can give rise to erythrocytes, granulocytes, cells of the monocyte-macrophage lineage, megakaryocytes, and immunocompetent T and B cells (Brenner et al., 1993; Wu et al., 1967, 1968). Marrow transplantation has, therefore, been used in attempts to replace defective, absent, or malignant cells of the recipient with normal replicating hematopoietic and immunocompetent cells. Unfractionated bone marrow transplantation offers little

risk to the donor, as it involves removal of a tissue that is readily regenerated. Bone marrow cells are usually obtained by aspiration from multiple sites along the iliac crests, the sternum, or (in children) from the upper one-third of the tibia, while the donor is under general anesthesia (Thomas et al., 1975; Martin et al., 1987). The aspirate is placed in heparinized tissue culture medium and then passed through metal screens to remove bone spicules. If T cell depletion is necessary, the marrow is processed to remove T cells; nucleated marrow cells are then enumerated and the cells are given intravenously to the recipient.

### Special Considerations in Bone Marrow Transplantation for Primary Immunodeficiency Diseases

#### Primary Goal: Immune Reconstitution

Unlike the situation in patients with malignancies or global bone marrow failure, the goal of bone marrow transplantation in patients with primary immunodeficiency is to provide normal cells of hematopoietic origin to correct underlying genetic deficits in the immune system. In SCID, no immunosuppression is needed because these patients lack T cells and are thus unable to reject a graft (Buckley, 2004). In other forms of primary immunodeficiency, however, there is usually enough T cell function to cause rejection. Therefore, immunosuppressive agents must be used. Drugs commonly used to ensure the acceptance of solid organ grafts have deleterious effects on the very cells one is trying to engraft in patients with genetically determined immunodeficiency. Thus, chemotherapy must be given *prior* to infusion of the marrow to avoid injury to the donor cells.

High Susceptibility to Graft-versus-Host Disease

In further contrast to the situation in solid organ transplantation, successful marrow engraftment until recently required HLA identity (at least for HLA class II determinants) between donor and recipient, primarily because of extreme susceptibility of marrow transplant recipients to graft-versus-host disease (GVHD). This is particularly problematic for patients with SCID and complete DiGeorge syndrome, who are highly susceptible to GVHD from T cells in transfused blood products even before transplantation because they cannot reject foreign T cells. Previously, this situation meant that an HLA-identical sibling donor was needed, and the likelihood that any given sibling will be a match is only 25%. However, one of the most important advances in the treatment of primary immunodeficiency diseases over the past two decades has been the development of methods to avoid GVHD by T cell depletion and thus to enable transplantation of half-matched (haploidentical) parental stem cells (Buckley et al., 1999; Antoine et al., 2003; Buckley, 2004).

The Problem of Ongoing Infections

Because infants and children with primary immunodeficiency often become infected with opportunistic infectious agents before a diagnosis has been made, such organisms cause particular problems from the standpoint of urgency of need for transplantation and in limiting the ability to use chemotherapeutic conditioning agents. This is particularly true for infections with viruses such as cytomegalovirus (CMV), Epstein-Barr virus (EBV), adenoviruses, and parainfluenza viruses, for which no effective antibiotic is available (Buckley, 2004).

Persistence of Transplacentally Acquired Maternal T Cells

Leukocytes from the mother often enter the fetal circulation during pregnancy; fetuses with SCID have no capacity to reject such cells. Therefore, persistence of maternal T cells in the infant's circulation is frequent. These maternal T cells are usually unable to respond normally to mitogens and fail to correct the infant's underlying immunodeficiency. They may or may not cause clinical signs of GVHD, such as eczema or splenomegaly. They can, however, create special problems (or benefits) when bone marrow transplantation is performed for SCID infants. If a donor other than the mother is used and no pretransplant chemotherapeutic conditioning is used, there is always the potential complication of a graft-versus-graft (GVG) reaction. If unfractionated HLA-identical sibling marrow is infused, this can lead to rejection of the maternal T cells, with or without a clinical GVG reaction (Friedman et al., 1991). By contrast, if a T cell-depleted haploidentical graft is given from the father without pretransplant conditioning, rejection of the paternal graft can occur, again with or without a clinical GVG reaction. On the other hand, if T cell-depleted haploidentical stem cells are given from the mother without pretransplant conditioning, immune reconstitution is often accelerated (Barrett et al., 1988), again with or without GVHD. GVHD that does occur in this setting usually requires either no treatment or only transient use of steroids.

Conditioning Regimens Are Not Always Needed

In contrast to the situation in patients with malignancy or marrow aplasia, it has been repeatedly shown that infants with

SCID or with complete DiGeorge syndrome who have absent T cell function do not require pretransplant immunosuppression for successful bone marrow transplantation because they are unable to reject grafts (Buckley et al., 1999; Myers et al., 2002; Buckley, 2004). Some transplant centers have recommended conditioning for SCID patients with high numbers of natural killer (NK) cells because these patients are recognized as having a poorer outcome (Antoine et al., 2003). However, the underlying molecular defect, and not the NK cells may be the problem, as SCID infants with interleukin-7 receptor  $\alpha$  (IL-7R $\alpha$ ) deficiency with high numbers of B and NK cells accept these grafts readily without conditioning (Buckley, 2004). Patients with most non-SCID types of primary immunodeficiency need to be preconditioned with chemotherapeutic agents to prevent graft rejection (see below) (Parkman, 1991a).

Post-transplant Graft-versus-Host Disease Prophylaxis Is Not Always Needed

As is the case for pretransplant conditioning, post-transplantation prophylaxis against GVHD is not always needed for bone marrow transplantation for primary immunodeficiency. This is particularly true for patients with SCID who are not given pretransplant conditioning, since conditioning enhances the likelihood that GVHD will occur (see below).

Sources of Stem Cells for Bone Marrow Transplantation and Donor Selection

The various potential sources of stem cells are listed in Table 47.1. All types of SCID and many other forms of primary immunodeficiency can be cured by bone marrow transplantation (Friedrich, 1996; Haddad et al., 1998; Antoine et al., 2003; Buckley, 2004).

Unfractionated HLA-Identical Bone Marrow or Peripheral Blood

If a patient with SCID or another form of primary immunodeficiency is fortunate enough to have an HLA-identical sibling, unfractionated bone marrow cells can be given, and this is the treatment of choice. In most cases, both T cell and B cell immunity have been fully reconstituted by such matched transplants, with evidence of function detected as early as 2 weeks following transplantation. Patients with SCID have required far fewer unfractionated nucleated marrow cells for successful immune reconstitution than the number needed to treat leukemic or aplastic patients; as few as  $4 \times 10^6$  cells/kg of recipient body weight have

Table 47.1. Sources of Stem Cells for Transplantation

resulted in immunologic reconstitution (Friedrich, 1996). However, there is some evidence that higher numbers of stem cells result in better immune reconstitution (Buckley et al., 1999). Unfractionated marrow cells will also become engrafted in HLA-disparate SCID recipients who lack cellular immunity, but fatal GVHD can be anticipated because unfractionated marrow cell suspensions contain mature T cells in addition to stem cells.

### T Cell-Depleted Haploidentical Bone Marrow Transplantation

If a SCID infant has no HLA-identical family members, the treatment of choice then becomes a T cell-depleted haploidentical marrow stem cell transplant from a half-matched family member. Following the leads from his own work in mice (Reisner et al., 1978) and from Muller-Ruchholtz et al.'s (1976) work in rats, Reisner et al. (1983) demonstrated in the early 1980s that removal of most mature T cells from half-matched parental marrow allowed successful immune reconstitution of human infants with SCID by the remaining cells without subsequent GVHD. Since that time, this principle has been successfully applied many times in the treatment of SCID (but not as successfully in other primary immunodeficiency diseases) (Table 47.2) (Buckley et al., 1986, 1999; Fischer et al., 1986a; O'Reilly et al., 1986; Moen et al., 1987; Wijnaendts et al., 1989; Dror et al., 1993; Stephan et al., 1993; Giri et al., 1994; Antoine et al., 2003). One condition in which this type of transplant is expected to have no benefit is the complete DiGeorge syndrome, where T cell-depleted marrow cells are ineffective because there is no thymus to "educate" the

donor stem cells. The successful outcome after unfractionated HLA-identical marrow transplants into complete DiGeorge patients is due to the adoptive transfer of mature T and B cells that were educated in the donor's thymus (Goldsobel et al., 1987). The option of using a haploidentical donor, however, virtually ensures that all infants with SCID can have a related donor. Usually a mother or father (rather than a sibling) is the donor, since the volume of marrow donation required is much larger for this type of transplant. Because a high percentage of SCID infants have persistence of transplacentally transferred maternal T cells, the mother is often a better donor than the father, unless there are health issues that preclude use of the mother (e.g., if she is pregnant or positive for HIV or hepatitis antigen).

### In Utero Bone Marrow Transplants

Availability of early prenatal diagnosis for several primary immunodeficiencies offers the option of in utero treatment. Two infants with  $\gamma_c$ -deficient SCID who were diagnosed in utero received CD34<sup>+</sup> paternal stem cells intraperitoneally during the first half of gestation, and immune function developed in both postnatally (Flake et al., 1996; Wengler et al., 1996). In both instances, however, invasive procedures were performed on these fetuses on more than one occasion, there was the potential of a GVG reaction because of the likely presence of transplacentally transferred maternal T cells, and if either GVG or GVHD had occurred, there was no way of detecting it. Thus fetal wastage is a risk of this approach. Previous experience with in utero transplants was not very successful (Touraine, 1996). Benefits of in

utero transplantation over immediate postnatal transplantation in settings where parents do not wish pregnancy termination have to be carefully assessed. In utero bone marrow transplantation obviously reduces the risks of infectious complications. On the other hand, early postnatal haploidentical bone marrow transplantation in SCID has been found to be successful in more than 97% of cases (Buckley et al., 1999; Myers et al., 2002; Buckley, 2004), making it difficult to justify the risk to the fetus of in utero transplantation.

It is likely that haploidentical bone marrow stem cell transplantation performed in utero later than 12 weeks of gestation will not be possible in conditions other than SCID, since development of the fetal T cells in those conditions will be an obstacle for engraftment.

### Methods of T Cell Depletion

By far the best preventive approach to GVHD is the removal of mature T cells from the donor marrow.

#### Soybean lectin, sheep erythrocyte agglutination

The most successful method for rigorous T cell depletion involves agglutination of most mature marrow cells with soybean lectin, followed by sedimentation of these clumped cells and subsequent removal of T cells by sheep erythrocyte rosetting and density-gradient centrifugation (Reisner et al., 1983; Schiff et al., 1987). For an adequate yield of stem cells, it is necessary to collect approximately 1 liter of bone marrow from the donor. This is usually not a problem, since a parent is usually used as the donor, and the donations are made under general anesthesia. After soy lectin agglutination, there are still numerous T cells in the nonagglutinated fraction (Schiff et al., 1987). To remove T cells, two steps of sheep erythrocyte rosette depletion are required. The final cell preparation, representing <5%–10% of the initial number of nucleated marrow cells, consists of immature myeloid cells and stem cells, contains few if any lymphocytes, and is phytohemagglutinin (PHA) and mixed leukocyte culture (MLC) nonresponsive. (Schiff et al., 1987). This method, unlike CD34 selection, leaves all other immature marrow cells (including CD34-negative stem cells) available in the cell suspension for use in the transplant.

Some investigators have used sheep erythrocyte rosette-depletion alone to remove T cells from the donor marrow (Fischer et al., 1986a). Because different centers have used different numbers of rosette depletions and different methods of modifying the sheep red cells, there have been varying degrees of effectiveness of this approach to remove post-thymic T cells.

#### Monoclonal antibody and complement lysis

Another method of depleting post-thymic T cells from donor marrow is incubation with monoclonal antibodies to human T cells plus a source of complement (Reinherz et al., 1982; Filipovich et al., 1984; Waldmann et al., 1984; Morgan et al., 1986). Antibodies employed for this purpose have included T12, Leu 1, CT-2, and Campath-1 (Hale et al., 1988; Hale and Waldmann, 1994). T cell depletion by antibody and complement is not as effective as the above approach, possibly because of modulation of T cell antigens from the surface of the T cells, which then escape destruction. As a consequence, somewhat more frequent and severe GVHD has been observed.

#### CD34<sup>+</sup> cell selection by affinity columns

Probably the most common method of T cell depletion employed in most transplant centers today is the use of commercially avail-

able antibody affinity columns that positively select for CD34<sup>+</sup> cells (Handgretinger et al., 2001; Gordon et al., 2002). In this method, all other cells are discarded. In the earlier version of these columns there was a problem with trapping of T cells, such that an additional T cell depletion step was necessary to avoid GVHD. Reportedly, newer versions result in greater purity of CD34<sup>+</sup> cells (Schumm et al., 1999). However, success with this type of T cell depletion may not be as great as with methods that just remove T cells, possibly because fewer cells are usually given. In addition, CD34<sup>−</sup> negative stem cells are discarded, along with other cells that could be important in promoting immune reconstitution, such as dendritic cells. Recently, the pentaspan molecule CD133 has been judged to be a marker of primitive hematopoietic progenitors. Lang et al. (2004) evaluated a CD133-based selection method in 10 pediatric patients given stem cells from matched unrelated ( $n = 2$ ) or mismatched-related donors ( $n = 8$ ). Engraftment occurred in all patients (sustained primary,  $n = 8$ ; after reconditioning,  $n = 2$ ). No primary acute GVHD of a magnitude greater than grade II or chronic GVHD was observed.

### Unfractionated, Matched Unrelated Adult Marrow

Most patients with primary immunodeficiency will not have an HLA-identical donor. T cell-depleted marrow transplants are not as effective for non-SCID primary immunodeficiency conditions in which pretransplant conditioning is required (see below). Therefore, an alternate source of stem cells will have to be selected if immune reconstitution is to be possible, such as a matched unrelated marrow donor (MUD). The problem with both matched unrelated adult bone marrow donors and unrelated cord blood donors is that, because humans are an outbred population, the matching can never be perfect (Tiercy et al., 2000). Minor locus histocompatibility antigen differences are also much more likely to be present than in the related donor setting, resulting in a high probability of GVHD. Another drawback with the use of MUD adult donors is that it takes approximately 4 months (6 weeks to 12 months) to identify an unrelated adult donor.

### Cord Blood

One rich source of hematopoietic stem cells for transplantation is unfractionated cord blood (Wagner et al., 1995). Part of the rationale for using cord blood is that the incidence and severity of GVHD appears to be lower with MUD cord blood than with MUD adult unfractionated marrow transplants, even with one to two HLA antigen mismatches (Barker and Wagner, 2002; Wagner et al., 2002). In addition, it generally takes less time to locate a cord blood unit than an adult donor. Several successes with cord blood transplantation from HLA identical siblings have been reported, notably in patients with genetic disorders—including immunodeficiencies (Vowels et al., 1993; Wagner et al., 1995, 2002; Stary et al., 1996; Barker and Wagner, 2002; Grewal et al., 2003). The graft failure rate could be increased, however. Affecting the success rate of cord blood transplants is the number of nucleated cells present in the unit, especially the number of CD34<sup>+</sup> cells. It has been shown that at least  $1.7 \times 10^5$  CD34<sup>+</sup> cells/kg recipient body weight are needed (Wagner et al., 2002). In addition, there is a much longer period of thrombocytopenia following cord blood transplants than that after HLA-identical unfractionated marrow transplants (Thomson et al., 2000).

Most of the current protocols for cord blood transplantation call for pretransplant conditioning, regardless of the underlying

diagnosis of the patient. If a patient with primary immunodeficiency is already infected, particularly in the case of SCID, these drugs increase risk for demise. Successful umbilical cord transplantation has, however, been achieved in SCID without pre-transplant conditioning, even in an infant with NK cells (Toren et al., 1999). More importantly, GVHD prophylaxis is routinely given after transplants from either unrelated adults or cord blood donors and, in the case of cord blood transplants, this is continued for at least 9 months. The conditioning and GVHD prophylaxis both contribute to a long period of immune impairment post-transplantation, which is self-defeating if the goal of transplantation is immune reconstitution.

### Usefulness of Computerized Bone Marrow Donor Banks

In 1989, the Italian Bone Marrow Donor Registry was established to facilitate donor search and marrow procurement for patients lacking an HLA-identical donor (Dini et al., 1996), and in 1992 the National Marrow Donor Program was established in the United States. Several similar registries have been established elsewhere. All are listed in the Bone Marrow Donors World Wide (BMDWW) directory, which includes more than 9,000,000 donors in its latest edition. These registries are quite useful if (1) the transplant is not an emergency and (2) if the patient has relatively common HLA antigens. It is often difficult to find donors for patients belonging to certain racial and ethnic groups, however, and the expense involved in conducting such a search is high (Tiercy et al., 2000). In addition to the above registries, a cord blood bank has been established in the United States.

### Graft Rejection and Graft-versus-Host Disease

Unlike solid organ transplantation, allogeneic bone marrow transplantation is complicated not only by the possibility of graft rejection by the recipient but also by the potential of immune cells in the transplanted marrow to reject the recipient, causing GVHD.

#### Prevention of Graft Rejection

As noted above, immunosuppressive and myeloablative agents used to prevent graft rejection must be given prior to infusion of marrow cells so as to avoid injury to the donor cells. In transplant recipients who have the potential to reject grafts, factors influencing the likelihood of engraftment of donor marrow cells are (1) the degree of immunocompetence of the recipient; (2) the degree of MHC disparity between donor and recipient; (3) the degree of presensitization of the recipient to the histocompatibility antigens of the donor; (4) the number of marrow cells administered; (5) the type of conditioning regimen given the recipient; and (6) whether or not T cell depletion techniques are used. Initially, total body irradiation (TBI) was used to prepare non-SCID immunodeficiency patients for bone marrow transplantation. It was later recognized that TBI could be safely replaced by busulphan at dosages (16 to 20 mg/kg total) that did not produce comparable adverse late effects (Blazar et al., 1985), because preparation of the recipient need only be directed at immunosuppression and "spacing"—i.e., making room in the marrow for donor cells. It was also found that such doses of busulfan were sufficient for young patients (below the age of 2 to 4 years), despite the reduced bioavailability of busulphan in this age group (Blazar et al., 1985; Vassal et al., 1993). There is now general

consensus on the use of busulphan at 2 or 4 mg/kg daily for 4 days, together with cyclophosphamide at 50 mg/kg daily for 4 days, with or without anti-thymocyte globulin (ATG), as a conditioning regimen for patients with non-SCID immunodeficiency to be treated by HLA-identical bone marrow transplantation (Parkman, 1991a). However, studies have demonstrated a high variability of busulphan disposition among young children (by a factor of 6) (Vassal et al., 1993). These results demonstrate the need for an individual, close adjustment of busulphan in infants and young children. The development of an intravenous form of busulfan has helped to reduce this problem immensely; much better control of dosing is possible by the intravenous route and the drug can be given once or twice a day (Fernandez et al., 2002; Bostrom et al., 2003; Dalle et al., 2003). The above agents may be insufficient for chemoablation in young patients with phagocytic cell disorders. Alternatively, other myeloablative drugs can be used, such as thiopeta (Przepiorka et al., 1994).

### Nonmyeloablative Bone Marrow Transplantation

For patients with preexisting organ damage, there is significant morbidity and mortality from traditional conditioning regimens employing busulfan and cyclophosphamide or TBI. Therefore, there has been increasing interest in developing conditioning regimens that are less toxic (Nagler et al., 1999; Barta et al., 2001; Feinstein et al., 2001; Horwitz et al., 2001; Pulsipher and Woolfrey, 2001; Woolfrey et al., 2001; Gaspar et al., 2002; Mielcarek et al., 2002). Either total lymphoid irradiation or a combination of nucleoside analogs and anti-lymphocyte antibody preparations can be used to attain less toxicity. Although these regimens are significantly less cytotoxic than high-dose alkylating agents and TBI, they are profoundly immunosuppressive. Opportunistic infections such as the reactivation of CMV remain clinical obstacles when nonmyeloablative stem cell transplants are performed using these agents, especially in elderly and previously immunosuppressed patients. GVHD prophylaxis with cyclosporine and methotrexate, with added mycophenolate mofetil in some cases, has been necessary because GVHD is common following nonmyeloablative transplantation.

### Use of Campath 1 Monoclonal Antibody In Vivo

It has become common practice to include the *in vivo* administration of alemtuzumab (anti-CD52, Campath 1) in reduced intensity or conventional pretransplant ablation protocols for patients with malignancies who are receiving peripheral blood stem cell transplants; the antibody is then also continued post-transplantation as prophylaxis against GVHD (Chakrabarti et al., 2004). While this approach has been effective in controlling GVHD and improving engraftment in the cancer transplant setting, it has also been associated with a much longer period of immunodeficiency post-transplantation (Chakrabarti et al., 2004) and with the development of lethal lymphoproliferative disease (Snyder et al., 2004). Therefore, this approach would appear to be counterproductive in transplants done with the goal of achieving immune reconstitution in immunodeficient patients.

### Graft-versus-Host Disease

GVHD is the major barrier to widespread successful application of bone marrow transplantation for the correction of many different

diseases (Glucksberg et al., 1974; Martin et al., 1987; Deeg and Henslee-Downey, 1990; Ferrara and Deeg, 1991; Parkman, 1991b). Acute GVHD begins 6 or more days post-transplantation (or post-transfusion in the case of nonirradiated blood products) (Anderson and Weinstein, 1990) with high, unrelenting fever, a morbilliform maculopapular erythematous rash, and severe diarrhea (Glucksberg et al., 1974). The rash becomes progressively confluent and may involve the entire body surface; it is both pruritic and painful and eventually leads to marked exfoliation. Eosinophilia and lymphocytosis develop, followed shortly by hepatosplenomegaly, abnormal liver function tests, and elevation in blood conjugated bilirubin levels. Watery diarrhea occurs and may become voluminous and bloody as the disease progresses. Nausea, vomiting, and severe, cramping abdominal pain occur as a consequence of the gastrointestinal involvement, which is also accompanied by a protein-losing enteropathy. The latter condition contributes to marked generalized edema ("third spacing") seen in more severe, acute GVHD. The most severe forms of acute GVHD are also characterized by bone marrow aplasia, marked susceptibility to infection (Gratama et al., 1987; Parkman, 1991b; Skinner et al., 1986), and death in a high proportion of cases.

### Staging

Staging of GVHD is based on severity and on the number of organ systems involved (Glucksberg et al., 1974). The four categories generally defined are as follows:

- Grade 1: 1+ to 2+ skin rash without gut involvement and with no more than 1+ liver involvement
- Grade 2: 1+ to 3+ skin rash with either 1+ to 2+ gastrointestinal involvement or 1+ to 2+ liver involvement or both
- Grade 3: 2+ to 4+ skin rash with 2+ to 4+ gastrointestinal involvement with or without 2+ to 4+ liver involvement. Decrease in performance status and fever also characterize Grades 2 and 3.
- Grade 4: The pattern and severity of GVHD are similar to those in Grade 3 with extreme constitutional symptoms.

### Chronic Graft-versus-Host disease

If the patient does not succumb and the acute GVHD persists, it is termed chronic after 100 days. Chronic GVHD may evolve from acute GVHD or may develop in the absence of or after resolution of acute GVHD. It occurs in 45%–70% of conditioned patients receiving HLA-matched bone marrow transplants from unrelated donors (Martin et al., 1987; Weisdorf et al., 1990; Parkman, 1991b). Skin lesions of chronic GVHD resemble scleroderma, with hyperkeratosis, reticular hyperpigmentation, atrophy with ulceration, and fibrosis and limitation of joint movement. Other manifestations include the sicca syndrome, disordered immunoregulation, as evidenced by autoantibody and immune complex formation and poly- and monoclonal hyperimmunoglobulinemia (Noel et al., 1978; Graze and Gale, 1979), idiopathic interstitial pneumonitis, and frequent infections (Skinner et al., 1986; Parkman, 1991b).

### Pathogenesis

Graft-versus-host disease is almost invariable in the case of HLA class II antigen differences between the donor and recipient, because the immunocompetent donor T cells recognize the foreign transplantation antigens of the recipient. In the case of HLA-identical marrow transplants, GVHD is likely due to responses by donor T cells (Theobald et al., 1992; Schwarzer et al., 1993) to recipient minor locus histocompatibility or Y chromosome-associated transplantation antigens, since a significantly higher

incidence of GVHD occurs in male patients given unfractionated MHC-matched female marrows than in patients receiving MHC-matched and sex-matched marrows (Bortin and Rimm, 1977; Martin et al., 1987; Ferrara and Deeg, 1991; Parkman, 1991b). However, female marrow transplanted into male recipients does not appear to be a problem in the case of T cell-depleted grafts (Buckley et al., 1999; Buckley, 2004). GVHD is usually mild and self-limited in SCID hosts who receive unfractionated HLA-identical marrow, because there is no need for them to receive pretransplant immunosuppression (Parkman, 1991b). However, in 60% of recipients given pretransplant irradiation or immunosuppressive drugs, GVHD is moderate to severe despite HLA identity, and it is fatal in 15%–20% (Glucksberg et al., 1974; Martin et al., 1987; Deeg and Henslee-Downey, 1990). The severity of GVHD increases with the recipient's age (Parkman, 1991b; Storb et al., 1986), the use of HLA-matched unrelated donors, and, if a related donor is not HLA-identical, the degree of genetic disparity.

### Prevention of Graft-versus-Host disease

The best approach to GVHD is prevention. As already noted, removal of T cells from the donor marrow or blood is the most effective means of preventing GVHD. For patients undergoing unfractionated HLA-identical marrow transplants and receiving pretransplant chemotherapy to prevent rejection, GVHD prophylaxis is necessary. GVHD prophylaxis ordinarily consists of a short course of methotrexate (15 mg/M<sup>2</sup> on the first day post-transplantation and 10 mg/M<sup>2</sup> on the third, sixth, and eleventh days), together with daily cyclosporine given for 6 months, as has been used in other transplant settings (Storb et al., 1986; Martin et al., 1987; Parkman, 1991b). Recently, studies have indicated that the addition of mycophenylate mofetil to this regimen improves the prevention of GVHD (Wang et al., 2002). Acute GVHD greater than grade II is 24% for patients in the European registry for immunodeficiencies. In addition, for unfractionated, unrelated matched cord blood transplantation, high doses of methylprednisolone are given from the time of transplantation until approximately 6 months post-transplantation.

### Treatment of Graft-versus-Host disease

The above-mentioned agents have not prevented GVHD entirely, and they can delay and/or suppress the development of immune function. However, once severe GVHD has become established, it is extremely difficult to treat. Many regimens have been employed to mitigate GVHD in both MHC-incompatible and MHC-compatible bone marrow transplants. Anti-thymocyte globulin, steroids, cyclosporine, mycophenylate mofetil, and murine monoclonal antibodies directed against human T cell surface antigens have ameliorated GVHD in some cases, but fatal GVHD has still occurred in others even though treated (Martin et al., 1987; Deeg and Henslee-Downey, 1990; Parkman, 1991b). Anticytokine and anticytokine receptor antibodies have also been employed to mitigate GVHD (Deeg and Henslee-Downey, 1990); the most useful of these has been antibody to the IL-2 receptor  $\alpha$  chain (anti-CD25) (Srinivasan et al., 2004).

## Sequelae of Pretransplant Chemotherapy for Bone Marrow Transplantation

### Veno-occlusive Disease

Veno-occlusive disease (VOD) is a major cause of mortality following conditioning regimens employing cytoreductive agents

that damage the hepatic vascular endothelium (McDonald et al., 1985; Eltumi et al., 1993). Distinguishing VOD from other causes of liver damage can be difficult after bone marrow transplantation, particularly when thrombocytopenia poses an unacceptable risk for diagnostic percutaneous liver biopsy in the early post-transplant period. Most often the diagnosis has been made on clinical criteria; however, serum concentrations of the aminopropeptide of type III procollagen (PIIINP) above a standard deviation (SD) score of 8 have been predictive of VOD and are also useful in the diagnosis and monitoring of this condition (Eltumi et al., 1993). In addition to hepatic damage caused by chemotherapeutic agents for pretransplant conditioning, such agents can also result in considerable pulmonary toxicity post-transplantation, leading to prolonged oxygen dependency. Often this problem is difficult to distinguish from infectious pulmonary complications post-transplantation, such as CMV pneumonia.

### Growth Retardation and Hormonal Disturbances

Growth retardation and hormonal disturbances frequently occur in children who have received pretransplant conditioning and who are long-term survivors (Clement-De Boers et al., 1996). However, the effect on height is not very great unless TBI is used. Hormonal disturbances leading to delayed puberty and sterility can be due either to TBI or to the effects of alkylating chemotherapy (cyclophosphamide). Elevated levels of follicle-stimulating hormone are found in those so affected.

### Immune Reconstitution after Bone Marrow Transplantation

#### Bone Marrow Transplantation for Severe Combined Immunodeficiency

Bone marrow transplantation has been more widely applied and more successful in infants with SCID than in any other primary immunodeficiency (Friedrich, 1996; Buckley et al., 1999; Antoine et al., 2003; Buckley, 2004). Since the first such transplant was done, more than 800 patients with SCID worldwide have received transplants of HLA-identical or haploidentical bone marrow or of unrelated marrow or cord stem cells (Haddad et al., 1998; Antoine et al., 2003; R.H. Buckley, personal survey). In a recent report from the European Group for Blood and Marrow Transplantation and the European Society for Immunodeficiency, 475 infants with SCID were reviewed who had received bone marrow transplants from 1968 to 1999 (Table 47.2). One hundred fifty-three had received marrow from a genotypically or phenotypically HLA-identical relative and 77% survived, whereas 294 had received T cell-depleted haploidentical related transplants and only 54% survived (Antoine et al., 2003) (Fig. 47.1). Previously published survival rates for SCID patients transplanted at the two largest centers in Europe, Hopital Necker in Paris (Stephan et al., 1993) and the University of Ulm (Friedrich et al., 1993), were very similar—i.e., 80% for HLA-identical unfractionated marrow recipients and approximately 55% for recipients of haploidentical, T cell-depleted marrow. Similar survival statistics have also been reported by SCID transplant centers in the

Number at risk	0	6	12	24	36	60	120
Related genotypically identical	104	83	53	46	42	36	19
Related phenotypically identical	49	36	28	25	20	12	8

**Figure 47.1.** Cumulative probability of survival in SCID patients according to donor source (related or unrelated donor), HLA matching, and year of transplantation. (From Antoine et al., *Lancet* 361:553-560, 2003, with permission.)

United States (O'Reilly et al., 1986; O'Reilly, 1991; Dror et al., 1993). Even though the survival rate has been less with haploidentical donors, this is still a major accomplishment, because SCID is 100% fatal without marrow transplantation or, in the case of enzyme-deficient SCIDs, without enzyme-replacement therapy. However, the latter is helpful for only a small percentage of SCIDs, as adenosine deaminase (ADA) deficiency accounts for only approximately 16% of SCID cases (Stephan et al., 1993; Buckley et al., 1997; Buckley, 2004). Only 28 patients with SCID were reported in the European series as having received MUD transplants, and 63% were still surviving (Antoine et al., 2003). MUD transplant survival was somewhat better in a series from Brescia, Italy, and Toronto, Canada (Grunebaum et al., 2006).

One of the most significant findings from the European investigation was that there has been steady improvement over time in the survival rates of both HLA-identical and haploidentical marrow transplants in SCID recipients (Fig. 47.1), most likely because of more effective prevention or treatment of complications, notably infections and GVHD related to transplantation. Unfortunately, there is currently no similar comprehensive published summary for this time period for the overall experience in the United States.

Over the past 24 years, Buckley and associates have transplanted 152 infants with SCID, and 118 of these (78%) are currently surviving, for up to >24 years (Buckley, 2004). No pre-transplant conditioning was given to any of these SCID patients prior to the marrow transplants. Only 16 of these 152 SCID patients had HLA-identical donors; all of them are surviving with functioning grafts. One hundred thirty-six patients received half-matched stem cells prepared by the T cell depletion technique in which soy lectin is followed by sheep red blood cell (SRBC) rosetting (Reisner et al., 1983; Schiff et al., 1987), without any pretransplant conditioning or GVHD prophylaxis. One hundred and two, or 75%, of these patients have survived. Most of the 34 deaths occurred from opportunistic viral infections—CMV in 6 patients, EBV/lymphoma in 3, enterovirus and adenovirus in 2 each, and parainfluenza and herpes simplex in 1 each. One patient died of multiple brain infarcts and another died of an unrelated mitochondrial defect.

Survival was clearly superior in those SCID infants transplanted soon after birth. Of 44 patients transplanted in the first 3.5 months of life, 42, or 95%, have survived (Fig. 47.2) (Buckley et al., 1999; Myers et al., 2002; Buckley, 2004). Unfortunately, although SCID could be diagnosed routinely at birth, there is no newborn screening. Consequently, most patients are diagnosed later, after they have developed serious infections.

Four of Buckley's SCID patients who received non-HLA-identical marrow were subsequently given matched, unrelated cord blood transplants because of resistance to engraftment of half-matched parental stem cells or for other reasons. One was a male infant with X-linked SCID (X-SCID) who engrafted T cell-depleted marrow from his IgA-deficient mother and, after immune function appeared, developed severe autoimmune cytopenias requiring long-term immunosuppressive agents. He then developed an mycobacterium avium complex (MAI) infection and was subsequently given a matched, unrelated cord blood transplant after chemotherapy to ablate his mother's graft; but unfortunately he died of CMV pneumonia. The second patient was a Jak3-deficient female SCID infant who became chimeric with T cell-depleted paternal marrow, but did not achieve adequate T cell function, even following a booster transplant from her father 10 months later. She was then given a successful MUD cord blood transplant after chemotherapy to ablate her father's

**Figure 47.2.** Kaplan-Meier survival curve for 44 consecutive infants with severe combined immunodeficiency (SCID) who received bone marrow transplants at R.H. Buckley's institution from HLA-identical ( $n = 5$ ) or haploidentical ( $n = 39$ ) donors before they were 3.5 months of age without pretransplantation chemoablation or post-transplantation graft-versus-host disease (GVHD) prophylaxis. Forty-two (95%) infants survived for periods of 2 months to 24 years after transplantation. The two deaths occurred from cytomegalovirus and EBV infections.

graft, and she is still surviving. Another X-SCID patient was given a cord blood transplant along with pretransplant ATG, but no post-transplant GVHD prophylaxis; and this patient developed grade 4 GVHD. The fourth patient, who had SCID of unknown molecular type, died of VOD after receiving pretransplant chemotherapy and a MUD cord blood transplant.

### Problems Encountered with T Cell-Depleted Haploidentical Transplants

The period of vulnerability to infection is longer for recipients of T cell-depleted marrow than that for recipients of unfractionated HLA-identical marrow because of the 90–120 days required for donor stem cells to develop into T cells in the thymus and the fact that there are no adoptively transferred donor T cells. The occurrence of B cell lymphoproliferative disease is also a significant problem with this type of transplantation, whereas it does not occur in recipients of unfractionated HLA-identical marrow (Trigg et al., 1985; Filipovich et al., 1994; Levine, 1994). Most of these cases have been EBV positive (Shearer et al., 1985) and most have been in recipients of marrow T cell-depleted by monoclonal antibody. Again, the long period before development of normal T cell function is thought to be related to the propensity to develop such tumors.

Other problems encountered following haploidentical T cell-depleted transplants include resistance to engraftment and frequent failure to obtain engraftment of donor B cells or to develop B cell function. The latter is a particular problem in  $\gamma\text{C}$ -deficient and Jak3-deficient SCID. Buckley has attempted to overcome both of the latter two problems by “booster” transplants, performed in 33 (24%) of the 152 patients previously discussed; 21 of these are currently surviving. Twenty-four patients received T cell-depleted booster transplants from the same parental donor without pre-booster conditioning; 8 (33%) of these patients died of opportunistic viral infections. Nine patients received T cell-depleted booster transplants from the other parent, again without conditioning; 4 (44%) died of infection. Immune function

improved or normalized in a majority who received the booster transplants.

### Kinetics of Development of Immune Function

The time to development of immune function following haploidentical stem cell grafts is quite different from that after unfractionated HLA-identical marrow. In contrast to the rapid development of immune function within 2 weeks after the latter type of grafts, lymphocytes with mature T cell phenotypes and functions fail to appear in significant numbers until 3–4 months after transplantation of T cell-depleted marrow (Fig. 47.3) (Buckley et al., 1986; Moen et al., 1987; Wijnaendts et al., 1989; Dror et al., 1993). This result holds true even if pretransplant conditioning is given (Friedrich et al., 1993) or if T cell-depleted, HLA-identical sibling marrow is used (R.H. Buckley, unpublished results). Thus, regardless of whether the donor is HLA-identical or haploidentical, it takes between 90 and 120 days for stem cells in T cell-depleted marrow to mature into

functioning T cells in SCID infants. The reason for this delay is not known, but presumably this is how long it takes for thymic maturation of stem cells to occur. This period of time is not unlike that in intrauterine life, in which PHA responsive T cells do not appear until around 12 weeks of gestation. The first function to develop after transplantation is NK cell function (in those molecular types in which this function is missing). Shortly after NK cells, T cell function appears, simultaneously with the development of phenotypically normal T cells (Fig. 47.3). Karyotype studies reveal that such T cells are always 100% of donor origin (Buckley et al., 1999). Thus, the tiny, architecturally abnormal epithelial thymi of patients with all forms of SCID treated thus far appear to have the ability to cause normal stem cells to become phenotypically and functionally normal T cells (Patel et al., 2000).

B cell function develops much more slowly, averaging 2 to 2.5 years for normalization in some patients; others fail to develop B cell function altogether, despite normal T cell function (Buckley et al., 1986, 1999; Moen et al., 1987; Wijnaendts et al., 1989; Dror

**Figure 47.3.** Results of sequential immunologic studies in a male infant with Jak3-deficient SCID before and after transplantation of T cell-depleted haploidentical maternal marrow stem cells, displaying (A) T cell phenotypes and (B) T cell responses to mitogens. T cell phenotypes and function appeared simultaneously, but not until more than 90 days post-transplantation. All dividing T cells in (B) were of female karyotype. Con A, concanavalin A; PHA, phytohemagglutinin; PWM, pokeweed mitogen.

et al., 1993; Giri et al., 1994; Buckley, 2004). Genetic analyses of the cells from such chimeric patients have revealed that all T cells are of donor origin, whereas the B cells, antigen-presenting cells, neutrophils, platelets, and red cells remain of recipient origin in a large majority of cases unless pretransplant conditioning is given (Buckley et al., 1986; Schouten et al., 1988; Friedrich et al., 1993; Vossen et al., 1993; van Leeuwen et al., 1994; Brady et al., 1996). Even following pretransplant conditioning, B cell engraftment and/or B cell function are not guaranteed. Indeed, in a careful evaluation of post-transplantation B cell function in SCID patients treated at a single center, B cell function was no better in those who had received pretransplant chemotherapy than in those who had not; however, the conditioning used was not fully myeloablative (Haddad et al., 1999). These observations suggest that the thymic microenvironment of most infants with SCID is capable of differentiating half-matched normal stem cells to become mature and functioning T lymphocytes that can cooperate effectively with host B cells for antibody production (Buckley, 2004). Thus, the genetic defect in SCID appears not to involve the thymus, except to the extent that it is small and morphologically abnormal because of a lack of interaction with normal developing thymocytes.

**Bone Marrow Transplantation for Immunodeficiencies Other than Severe Combined Immunodeficiency**

Allogeneic bone marrow transplantation has been found effective in conferring improved immune function to at least 21 distinct immunodeficiencies other than SCID (Tables 47.3 and 47.4) (Fischer et al., 1986b, 1990, 1994; Le Deist et al., 1989; Friedrich, 1996; Buckley and Fischer, 1999). A recent publication from the European Group for Blood and Marrow Transplantation and the European Society for Immunodeficiency (covering 37 centers in 18 countries) reported on the outcomes of 444 patients with these various forms of immunodeficiencies who had been transplanted from 1968 to 1999 (Antoine et al., 2003).

Indications

Indications for bone marrow transplantation in non-SCID primary immunodeficiency obviously depend on a critical assessment of life expectancy as well as quality of life in a given setting. Disease prognosis alone is not usually sufficient to lead to such a decision.

**Table 47.3.** Immunodeficiencies of the Lymphoid System That Are Curable by Allogeneic Bone Marrow Transplantation

Adenosine deaminase deficiency
Purine nucleoside phosphorylase deficiency
X-linked SCID ( $\gamma_c$ deficiency)
AR SCID with B cells (IL-7R $\alpha$ , Jak-3, CD3 $\delta$ , and CD3 $\epsilon$ deficiencies)
AR SCID without B cells (Rag1/Rag2 and Artemis deficiencies)
Omenn syndrome
Reticular dysgenesis
Defective T cell activation (including ZAP-70 deficiency, calcium flux deficiency, and cytokine production deficiency)
HLA class II expression deficiency
Cartilage-hair hypoplasia
Wiskott-Aldrich syndrome
X-linked hyper-IgM syndrome (CD40 ligand deficiency)
X-linked lymphoproliferative syndrome (SH2D1A deficiency)
Lymphoproliferative syndrome with Fas (CD95 deficiency)

AR, autosomal recessive inheritance.

**Table 47.4.** Immunodeficiencies of the Phagocytic System That Are Curable by Allogeneic Bone Marrow Transplantation

Chronic granulomatous diseases (X-linked and AR)
Leukocyte adhesion deficiency, type I
Chediak-Higashi syndrome
Immunodeficiency with partial albinism (Griscelli disease)
Familial hemophagocytic lymphohistiocytosis
Interferon- $\gamma$ receptor deficiencies
Severe congenital neutropenia and other neutropenias (cyclic neutropenia, Shwachmann syndrome)

AR, autosomal recessive.

Age, past clinical history and sequelae of illnesses (chronic viral infection, immunosuppressive treatment required for control of autoimmunity, organ dysfunction), clinical course of previously affected family members, gene mutation determination when available, context of medical care (distance from specialized centers), and psychological assessment of the child and the family are some of the many factors to be taken into consideration when attempting to decide for or against bone marrow transplantation.

As greater experience with bone marrow transplantation has been gained, many of the factors leading to increased mortality and morbidity have decreased with time. It is not appropriate to assess the risks associated with bone marrow transplantation in the 1990s on the basis of results reported in the early 1980s. For instance, in Europe, the rate of success in bone marrow transplants performed from October 1985 up to March 1991 was 81.5% vs. 52% before October 1985 (Antoine et al., 2003). A specific example is seen in the case of the chronic granulomatous diseases, where recent comparisons of conservative treatment vs. bone marrow transplantation are leading to a possible change in attitude toward this treatment (see below). These remarks emphasize the need for careful updating of bone marrow transplantation registries to aid the medical community in decision making for treatment of this and other primary immunodeficiency diseases. Younger age at the time of bone marrow transplantation is associated with excellent outcome, and progress has been made in recent years, particularly in infection prevention with intravenous immunoglobulin [IVIG] and antiviral drugs (Antoine et al., 2003).

**Bone Marrow Transplantation in Non-SCID Immunodeficiencies**

Bone marrow transplantation has not been as uniformly effective in the treatment of patients with non-SCID T cell immunodeficiencies such as phagocyte disorders, as it has in SCID (Fig. 47.4). Such patients have somewhat less severe immune dysfunction than those with SCID, and this enables them to reject marrow grafts. However, a number of transplants with HLA-identical sibling marrow, matched unrelated adult marrow, peripheral blood stem cells, or cord blood have been successful after chemoablation (Tables 47.2 and 47.5). Following the improved results with T cell-depleted, HLA-haploidentical bone marrow transplantation for the treatment of SCID, this approach was tried for the treatment of other lethal immunodeficiency diseases. However, unlike the situation in SCID, there are relatively few reports of successful HLA-haploidentical bone marrow transplantation in non-SCID immunodeficiencies because of a high incidence of graft rejection (up to 75%) and of infectious complications (Fischer et al., 1986b, 1991). Delay in the development of T and B cell function (6 to 40 months) causes significant infectious

**Figure 47.4.** Cumulative probability of survival in non-SCID patients, according to donor source (related or unrelated donor) and HLA matching (From Antoine et al., *Lancet* 361:553–560, 2003, with permission.)

complications that remain a major concern in recipients of T cell-depleted, HLA-haploidentical transplants. For example, 16 of 71 patients who underwent two or three HLA antigen-incompatible, T cell-depleted bone marrow transplantations for immunodeficiencies (excluding SCID) had EBV-induced B lymphocyte proliferative syndromes, and 10 of them died from this complication (Fischer et al., 1994). Lymphoproliferative disease was particularly frequent in Wiskott-Aldrich patients who underwent HLA haploidentical bone marrow transplantation. In a European survey, 39% of such patients (compared with 12% of patients with combined immunodeficiency and 3% of those with SCID) developed a lymphoproliferative disorder after HLA haploidentical marrow transplantation (European Bone Marrow Transplantation/European Society of Immunodeficiency Diseases Registry, unpublished data). This result may have been caused by poor T cell control of EBV replication. Because of these outcomes, the preferred bone marrow donors in this group of patients are HLA-matched siblings. If this is not possible, a search for a matched unrelated donor should be undertaken.

**Table 47.5.** Three-year Survival in Non-SCID Patients According to Primary Disease and Donor–Recipient Compatibility

Disorder	n	Genotypically Identical HSCT	Related, HLA-Mismatched HSCT
		% Survival (95% CI)	% Survival (95% CI)
Phagocytic cell disorders	23	70 (49–91)	14 69 (44–95)
Wiskott-Aldrich syndrome	32	81 (67–94)	43 45 (30–60)*
Hemophagocytic syndrome	32	68 (48–87)	28 49 (30–67)
T cell deficiency	47	63 (50–77)	72 35 (24–46)

CI, confidence interval; HSCT, hematopoietic stem cell transplantation.

\* $p < 0.001$ , for difference between genotypically identical and related, mismatched transplants.

## Matched Unrelated Donors

More recently, success has been obtained in non-SCID immunodeficiency diseases by bone marrow transplants from matched unrelated donors (MUD) (Ash et al., 1990; Kernan et al., 1993). In a survey of MUD transplantation, Kernan et al. (1993) indicated that the success rate of bone marrow transplantation for patients with inborn errors was 50%. Filipovich et al. (1992) reported successful MUD bone marrow transplantation in six of eight SCID recipients, two of two patients with WAS, and two of two patients with Chediak-Higashi syndrome. Some success using HLA partially incompatible, unrelated donor marrow has also been reported, especially when the degree of incompatibility was restricted to one HLA antigen and provided that marrow was T cell depleted (Ash et al., 1990; Filipovich et al., 1992). Perhaps the greatest success has been in WAS (see below) (Filipovich et al., 2001).

## Wiskott-Aldrich Syndrome

This defect (see Chapter 31) is the second most common primary immunodeficiency for which bone marrow transplantation has been applied. After only partial correction by the first bone marrow transplant given a WAS patient in 1968 (Bach et al., 1968) full correction was achieved in other WAS patients in 1978 by use of a more effective conditioning regimen (Parkman et al., 1978). HLA-identical bone marrow transplantation has thus far been successful in 85%–90% of WAS patients who had an HLA-identical sibling donor (Tables 47.2 and 47.5) (Brochstein et al., 1991; Ozsahin et al., 1996).

Rumelhart et al. (1990) reported success with haploidentical transplants in three of four WAS patients, while Brochstein et al. (1991) reported success in only one of six with the same condition. In general, however, T cell-depleted haploidentical marrow transplants have not been very successful in WAS. Because of this result, MUD bone marrow, peripheral blood, and cord blood transplants have been carried out in a significant number of WAS patients (Lenarsky et al., 1993; Miano et al., 1998; Knutsen et al., 2003). In a report from the International Bone Marrow Transplant Registry, 170 patients with WAS had been transplanted, and the 5-year probability of survival (95% confidence interval) for all subjects was 70% (63%–77%) (Filipovich et al., 2001). Probabilities differed by donor type: 87% (74%–93%) with HLA-identical sibling donors, 52% (37%–65%) with other related donors, and 71% (58%–80%) with MUD ( $p = 0.0006$ ). Boys who had received a MUD transplant before age 5 had survival rates similar to those receiving HLA-identical sibling transplants.

All aspects of WAS are corrected by marrow transplantation, including the eczema, autoimmunity, and risk of lymphomas. This outcome indicates that these disease complications are related to the immunodeficiency. Similarly, thrombocytopenia and the bleeding tendency have disappeared after successful bone marrow transplantation. Bone marrow, peripheral blood stem cell, or cord blood transplantation is recommended for patients with WAS and should be performed as early in life as possible. While the ideal donor is an HLA-identical sibling, it is clear that matched unrelated marrow, peripheral blood stem cells, or cord blood transplants can be effective if given to patients under the age of 5 years.

The poor results with T cell-depleted HLA haploidentical bone marrow transplants in WAS stress the need for careful evaluation of whether even to attempt an HLA haploidentical bone marrow transplantation in WAS patients who lack both

HLA-identical related and unrelated donors (Fischer et al., 1994). Mullen et al. (1993) stressed that splenectomized WAS patients can survive at least until adulthood. Nevertheless, WAS patients who develop refractory thrombocytopenia and/or severe autoimmune manifestations could be considered for HLA haploidentical bone marrow transplantation.

### Omenn Syndrome

Forty-five patients with Omenn syndrome have been reported in the literature (Fischer et al., 1994; Gomez et al., 1995; Lanfranchi et al., 2000; Loechelt et al., 1995) or to one of the authors (R.H.B.) as having received marrow transplants since 1968, and 23, or 51%, were alive at the time of this writing. As with the other non-SCID defects, however, the greatest success was in patients with HLA-identical sibling transplants, 9 out of 12 (75%) of whom were still surviving, whereas only 11 of 27 (41%) haploidentical marrow and 3 of 6 (50%) MUD marrow recipients were alive.

### X-Linked Hyper-IgM Syndrome (CD40 Ligand Deficiency)

X-linked hyper-IgM syndrome (XHIM; see Chapter 19) was for a long time considered to be a pure B cell immunodeficiency because of the observed defective production of IgG, IgA, and IgE. Following the discovery that deficiency in CD40 ligand expression on activated T cells caused the disease, it was better appreciated that many XHIM patients suffered from consequences of T cell deficiency as well, including opportunistic infections caused by microorganisms such as *Pneumocystis carinii*, *Toxoplasma*, and *Cryptosporidia*. The last organism induces in many patients chronic cholangitis, leading to cirrhosis. A recent survey has shown that the likelihood of survival of patients with XHIM to adulthood is <25% (Levy et al., 1997). It is unclear how additional genetic or environmental factors significantly modify the disease prognosis.

Bone marrow or cord blood transplantation are the only curative treatments for XHIM; transplantation has been carried out thus far in only 56 patients, 40 of whom were surviving at the time of this writing (Duplantier et al., 2001; Fasth, 1993; Thomas et al., 1995a; Scholl et al., 1998; Khawaja et al., 2001; Ziegner et al., 2001; Leone et al., 2002; Gennery et al., 2004; Jacobsohn et al., 2004). Early bone marrow transplantation is recommended if an HLA-identical donor is available. Non-X-linked forms of the hyper-IgM syndrome do not share the same poor outcome. Therefore, there is currently no indication for bone marrow transplantation in non-X-linked hyper-IgM patients, except possibly in those who lack CD40.

### X-linked Lymphoproliferative Syndrome

This syndrome (see Chapter 32) is caused by mutations in the *SH2D1A* gene at Xp28 that encodes the SLAM-associated protein (SAP) necessary for control of SLAM signaling and for NK cell function. Patients with this condition are typically well until they contract EBV infections. However following EBV exposure they die of fulminating EBV infection, develop lymphoma, or develop a condition clinically indistinguishable from CVID. No patient has been reported alive beyond the age of 38 years; most have died before the age of 20 (Sullivan and Woda, 1989). Following a first unsuccessful attempt, several patients have been cured by either bone marrow or cord blood transplantation (Vowels et al., 1993; Williams et al., 1993; Pracher et al., 1994; Gross

et al., 1996; Ziegner et al., 2001). Diagnosis of the condition prior to EBV infection is difficult, since, in the absence of a family history, there is no clear biological marker of the disease. However, if there is a family history, mutation analysis can be carried out in potentially affected males so that transplantation can be carried out before an EBV infection occurs (Morra et al., 2001) (see Chapter 32).

### Other Predominant T Cell Immunodeficiencies

Other T cell immunodeficiency syndromes for which transplantation with stem cells from various sources have been used include reticular dysgenesis (9 of 11 surviving) (De Santes et al., 1996; Knutsen and Wall, 1999); purine nucleoside phosphorylase (PNP) deficiency (6 of 12 surviving) (Broome et al., 1996; Carpenter et al., 1996; Classen et al., 2001; Baguette et al., 2002) cartilage-hair hypoplasia (4 of 7 surviving) (Berthet et al., 1996); IL-2 deficiency (2 of 2 surviving) (Berthet et al., 1994); common variable immunodeficiency (CVID) (none of 4 surviving); defective binding of nuclear factor of activated T cells (1 of 1 surviving) (Feske et al., 1996); chronic mucocutaneous candidiasis (1 not surviving); ataxia-telangiectasia (none of 4 surviving); and Fas (CD95) deficiency (1 of 1 surviving) (Benkerrou et al., 1997).

Buckley and associates have also transplanted 58 patients with non-SCID immunodeficiency, with the following survival rates: 11 of 26 with CID (42%); 5 of 7 with leukocyte adhesion deficiency (LAD) (71%); 2 of 2 with Chediak-Higashi syndrome (100%); 3 of 3 with chronic granulomatous disease (CGD) (100%); 2 of 2 with ZAP-70 deficiency (100%); 4 of 7 with Omenn syndrome (57%); 2 of 4 with PNP deficiency (50%); 1 of 2 with WAS (50%); 2 of 2 with XHIM (100%); 1 of 2 with IFN- $\gamma$ R2 deficiency; and 0 of 1 with Griscelli syndrome.

Without bone marrow transplantation, survival to adulthood is rare in most of these conditions (Berthet et al., 1994; Fischer et al., 1994; Antoine et al., 2003). When bone marrow transplantation is performed, death is often related to complications of prior viral infection or organ failure. Patients with immunodeficiencies less pronounced than SCID may survive for several years. However, many harbor latent or subclinical infections, such as with facultative intracellular microorganisms, and these infections are exacerbated following myeloablative and immunosuppressive conditioning regimens. Early diagnosis of non-SCID immunodeficiencies should permit bone marrow transplantation as early as possible, if a suitable donor is available, to offer maximal likelihood of survival and immunoreconstitution. Indeed, in a European survey, transplants performed before the age of 2 years gave a 79% success rate vs. 48% over 4 years of age (Fischer et al., 1994).

Gaspar and associates at Great Ormond Street, United Kingdom, have reported on the outcomes of their treatment of 21 patients with a variety of different immunodeficiencies using four different nonmyeloablative conditioning regimens: (1) fludarabine/melphalan/ATG or Campath 1H ( $n = 16$ ), (2) fludarabine/cyclophosphamide/Campath 1H ( $n = 1$ ), (3) TBI/CyA/MMF ( $n = 1$ ), and (4) fludarabine/melphalan/busulphan/ATG ( $n = 3$ ) (Gaspar et al., 2002). In 13 cases, matched ( $n = 9$ ) and 1 antigen (Ag) mismatched ( $n = 4$ ) unrelated donors were used, and in 8 cases transplants from matched siblings ( $n = 4$ ), an Ag mismatched sibling ( $n = 1$ ), a matched parent ( $n = 1$ ), and haploidentical parents ( $n = 3$ ) were performed. At a median post-transplantation follow-up of 13 months, 19 of 21 (90%) patients were still alive. Despite using T cell-replete grafts and unrelated donor grafts in

the majority of these patients, no significant organ disease was evident. Immune reconstitution in terms of CD3<sup>+</sup> and CD4<sup>+</sup> T cell recovery and function was reported to be equivalent to that of a historical cohort (Gaspar et al., 2002).

### Major Histocompatibility Complex Class II Deficiency

Bone marrow transplantation for HLA class II deficiency disease (Chapter 17) deserves specific comments. In the absence of immune reconstitution, patients lacking HLA class II molecule expression suffer from recurrent infections, including frequent, devastating cryptosporidial infections and viral infections of the CNS. Life expectancy is 5 years on average, with no improvement in recent years, despite supportive care with parenteral nutrition and antibiotic therapy. Bone marrow transplantation can cure the disease, provided it is performed before complications leading to severe organ failure develop (Klein et al., 1993). The relatively low overall success rate of transplantation in HLA class II antigen deficiency, compared with that of some other forms of immunodeficiency (i.e., only a 54% survival rate following HLA-identical transplantation), may reflect the considerable heterogeneity in clinical presentation of these disorders and in age at transplantation. Two interesting observations have been made on long-term survivors of successful transplants (Klein et al., 1995); (1) persistence of a relative CD4 T cell lymphopenia, possibly due to a lack of HLA class II molecules on thymic epithelial cells, even though the donor-derived CD4<sup>+</sup> T cells are functional; and (2) absence of detrimental consequences secondary to defective expression of HLA class II molecules on non-hematopoietic cells. Finally, heterogeneity of the disease, because of the existence of at least four different disease genes, prevents making a clear-cut prognosis.

### Phagocytic Cell Disorders

A number of the inherited phagocytic cell disorders remain lethal, either because of the severity of infections in the absence of alternative therapy, or because of the onset of specific complications, such as the acute phase of the Chediak-Higashi syndrome.

### Chronic Granulomatous Disease

Most CGD patients can survive to adulthood, because prophylaxis with trimethoprim/sulfamethoxazole, itraconazole, and/or interferon- $\gamma$  (IFN- $\gamma$ ) (International Chronic Granulomatous Disease Cooperative Study Group, 1991) has considerably reduced the incidence of life-threatening infections (see Chapter 37). It is estimated, however, that the risk of severe aspergillosis remains at 1 in every 100 patients per year, with a death rate of 30%. Also, some CGD patients develop other debilitating complications, such as granulomas of the lung, esophagus, bladder, or colon, requiring long-term steroid therapy. Therefore, it was recommended some years ago that bone marrow transplantation be considered as a therapeutic option in CGD patients who have developed severe complications and who have an HLA-matched donor (Kamani et al., 1988).

Seeger et al. (2002) have reviewed the outcomes of 27 transplantations for CGD, from 1985 to 2000, reported to the European Bone Marrow Transplant Registry for primary immunodeficiencies. Twenty-five of the transplant recipients were children who had received bone marrow transplants from HLA-identical sibling donors. The 23 children who received myeloablative condi-

tioning were fully engrafted with donor cells, whereas only 2 of 4 patients who had received myelosuppressive regimens were fully engrafted. Overall survival was 23 of 27, with 22 of 23 cured of CGD (median follow-up, 2 years). Survival was especially good in patients without infection at the moment of transplantation (18 of 18). Preexisting infections and inflammatory lesions had cleared in all survivors, except in one patient who had autologous reconstitution. Myeloablative conditioning followed by transplantation of unmodified hemopoietic stem cells, if performed at the first signs of a severe course of the disease, is a valid therapeutic option for children with CGD who have an HLA-identical donor (Table 47.5) (Seeger et al., 2002). Buckley has also had recent success in curing three young patients with CGD with HLA-identical sibling, unfractionated bone marrow transplants following full myeloablative conditioning. Thus, as with other immunodeficiency syndromes with predictable serious complications, in CGD, HLA-matched stem cell transplantation is best if carried out early in life before such complications arise and is recommended.

Nonmyeloablative bone marrow transplantation has also been used for patients with CGD when HLA-identical sibling donors were available (Nagler et al., 1999; Horwitz et al., 2001). The conditioning regimens used were fludarabine, busulfan, and ATG in one case (Nagler et al., 1999) and cyclophosphamide, fludarabine, and ATG in 10 cases (Horwitz et al., 2001); 7 of the 11 patients were surviving at this writing with mixed chimerism and good health. However, in view of the success with full myeloablative conditioning, there appears to be little indication for this approach (Seeger et al., 2002).

### Leukocyte Adhesion Deficiency, Type I

Leukocyte adhesion deficiency, type I (LAD1) is a rare disease characterized by defective expression of the  $\beta_2$  integrin subunit shared by the leukocyte adhesion proteins (see Chapter 38). Its complete absence leads to the severe phenotype of LAD, which predisposes to severe bacterial infections, often causing death within the first years of life. HLA-identical bone marrow transplantation is the treatment of choice for this condition. Aggressive conditioning, including the use of etoposide or thiopeta, may be required for appropriate marrow ablation (Fischer et al., 1994). Results of allogeneic bone marrow transplantation have been quite satisfactory.

### Chediak-Higashi Syndrome, Pigmentary Dilution (Griscelli) Syndrome, and Familial Hemophagocytic Lymphohistiocytosis

HLA-identical bone marrow transplantation can cure the hematological manifestations of Chediak-Higashi syndrome (Haddad et al., 1995) (Chapter 40) and of immunodeficiency with partial albinism (Griscelli syndrome) (Schneider et al., 1990) (Chapter 41).

As in the above two conditions, bone marrow transplantation can cure the hematological manifestations of familial hemophagocytic lymphohistiocytosis (FHL) (Blanche et al., 1991; Henter et al., 2002) (Chapter 41). In these instances, bone marrow transplantation prevents relapse of lymphohistiocytic activity. It is worth noting that mixed chimerism is sufficient to achieve disease control (Landman-Parker et al., 1993). This result indicates that an abnormal regulatory process, rather than a malignant process, underlies these conditions. Use of TBI is not necessary, and a combination of busulphan and cyclophosphamide appears both a safe and efficient conditioning regimen

for these diseases. Optimal control of the acute phase before bone marrow transplantation appears to be of crucial importance to avoid graft rejection and/or major toxic complications such as VOD after bone marrow transplantation. ATG treatment given immediately prior to cytoreduction is sufficient to achieve remission. Attention should also be paid, however, to ongoing CNS disease. Exclusion of the diagnosis of FHL in siblings of FHL patients is extremely difficult, since no pre-symptomatic disease markers are available. Siblings who were 5 and 8 years of age have been found affected after they had donated marrow for their younger affected siblings (Blanche et al., 1991; G. Morgan, personal communication).

### Severe Congenital Neutropenias

The prognosis of severe congenital neutropenias (SCN) has been considerably modified by the use of granulocyte-colony stimulating factor (G-CSF). Injections of G-CSF enable almost all of these patients to have near-normal granulocyte counts and thus few or no infections so that they can enjoy good health (Dale et al., 1993). In a proportion of these patients, however, myelodysplasia and overt leukemia have developed. It is possible that the malignancies are associated with the presence of acquired clonal heterozygous mutations of the G-CSF receptor (Dong et al., 1995). Therefore, detection of such a mutation in marrow cells of a patient with SCN could be a good marker to indicate a need for bone marrow transplantation, provided that there is a matched donor (Rappeport et al., 1980).

### Cytokine Receptor Deficiencies

It is also possible that patients with severe idiopathic mycobacterial infections, some of them caused by deficiencies in the IFN- $\gamma$  receptor (see Chapter 18), could benefit from allogeneic bone marrow transplantation (Jouanguy et al., 1996; Newport et al., 1996). Unfortunately, with one or two exceptions (Reuter et al., 2002; R.H. Buckley, unpublished results), the experience to date has been not very successful, for reasons that are unclear.

### Long-term Outcome

Similar to the case with all types of transplants in infants with SCID (Fig. 47.1), the long-term (10-year) outcome of HLA-identical bone marrow transplantation for most forms of primary immunodeficiency appears reasonably satisfactory. Correction of the underlying deficiency is sustained, despite frequent mixed chimerism in the absence of TBI usage. Sequelae are generally limited to consequences of the primary disease. Chronic GVHD is of limited frequency (<10%) in these young patients (Fischer et al., 1986b).

### Overcoming Resistance to Engraftment and Prevention of Graft Rejection

In the mid-1980s, one of the authors (A.F.) was surprised by the consecutive success of three HLA haploidentical bone marrow transplants for patients with the severe phenotype of LAD following pretransplant conditioning (Le Deist et al., 1989). These data have since been confirmed in nine patients with the severe phenotype of LAD who received SRBC-T cell-depleted, HLA haploidentical bone marrow following pretransplant conditioning. Engraftment occurred in all and seven are alive with partial

or full correction of their LAD (Thomas et al., 1995b). This is in sharp contrast to the engraftment rate of T cell-depleted haploidentical marrow transplanted under the same conditions in other immunodeficiency patients (excluding SCID), for whom the engraftment rate was 26% (Fischer et al., 1986b). Therefore, it was postulated that the defective expression of the LFA-1 molecule on graft rejection effector cells (cytotoxic T cells and NK cells) impaired cell contact with donor marrow cells and thereby permitted engraftment, as shown in a murine model (van Dijken et al., 1990). This finding led to the pretransplant infusion of a monoclonal anti-LFA-1 (anti-CD11a) antibody to inhibit LFA-1-ligand interactions in humans undergoing T cell-depleted haploidentical marrow transplantation (Fischer et al., 1991). Patients with functional T cell immunodeficiencies (including HLA class II deficiency) have a poor prognosis (median survival 5 years) in the absence of bone marrow transplantation (Klein et al., 1993; Berthet et al., 1994). In a multicenter trial, it was found that a 10-day course of 0.2 mg/kg of antibody per day reduced the graft failure rate from 74% to 28% following transplantation of T cell-depleted marrow into patients with various non-SCID forms of immunodeficiency and into some with osteopetrosis (Fischer et al., 1991). No late rejection occurred. Acute GVHD was observed in 35.5% of cases, and chronic GVHD occurred in 12.9%. The survival rate with a functioning graft was 47% in 42 patients (median follow-up, 50 months), instead of 20% in similar patients who did not receive anti-LFA-1. An update of these data showed a 74% engraftment rate, with 45% long-term survival in 38 immunodeficient patients who were treated with anti-LFA-1, while engraftment occurred in only 37.5% and survival in 20.8% of 24 patients not given anti-LFA-1 (Fischer et al., 1994).

Surprisingly, recipients of closely matched related (phenotypically identical or one HLA antigen mismatched) marrow were found in a recent survey not to have a better outcome than those of two or three HLA antigen mismatched related marrow (Fischer et al., 1994). These results may be related to the low number of patients ( $n = 22$ ) in this group (Fischer et al., 1994). The simultaneous infusion of another anti-adhesion antibody (anti-CD2), as performed in 43 patients, resulted in an engraftment rate of 80% without additional toxicity, with 55% survival. By using this strategy, five of nine patients with FHL have been cured by SRBC-rosetted T cell-depleted haploidentical bone marrow transplantation (Jabado et al., 1996). Unfortunately, at this writing anti-LFA-1 antibody is no longer available for clinical use. Apart from LAD (see above), HLA haploidentical bone marrow transplantation for patients with phagocytic cell disorders remains highly investigational, given the high risk of failure.

Other approaches aimed at selectively inhibiting graft rejection have been developed experimentally and could be of potential benefit. Anti-CD4 and anti-CD8 antibody infusions promote engraftment of H-2 incompatible marrow in mice (Cobbold et al., 1986). Selective T cell subset depletion of marrow might prevent complications such as EBV-induced B lymphocyte proliferative disorders (Cavazzana-Calvo et al., 1994).

Another approach to enhancing the rate of engraftment has been to transplant a higher number of hematopoietic stem cells than has been traditionally used. The theoretical possibility exists that higher numbers of CD34<sup>+</sup> stem cells could accelerate the development of T cell function. Aversa et al. (1994) reported success with this approach in adults with leukemia by infusion of 3- to 10-fold more CD34<sup>+</sup> cells (derived from donor peripheral blood after mobilization with G-CSF) than would have been possible with marrow transplantation alone. A very high rate of

engraftment was achieved, with only limited GVHD. Handgretinger et al. (2001) transplanted 39 children, 6 of whom had primary immunodeficiencies, with high-dose ( $20.7 \pm 9.8 \times 10^6$  kg), affinity-purified CD34<sup>+</sup>, rigorously T cell-depleted, G-CSF-mobilized, peripheral blood haploidentical parental stem cells. In 32 patients, no GVHD was seen despite the fact that no GVHD prophylaxis was given. Only 15 of the patients survived; 13 died of malignancy relapse. However, this method may have little added benefit in immunodeficient patients, who are mostly young children, since a relatively high number of CD34<sup>+</sup> cells/kg of the recipient is already infused with T cell-depleted, haploidentical marrow transplants. It is also possible that addition of cytokines such as IL-7 could contribute to improved engraftment (Bolotin et al., 1997).

### Future of Bone Marrow Transplantation in the Treatment of Primary Immunodeficiency

It is abundantly clear that allogeneic bone marrow transplantation can provide a cure for many children with life-threatening immunodeficiency diseases. Until gene therapy is perfected, bone marrow transplantation will remain the standard of care for such conditions. Thus far, bone marrow transplantation seems to be associated with acceptable long-term sequelae, although outcome beyond a follow-up of 30 years is not yet known. There is evidence of waning thymic output in some SCID marrow recipients in the second decade post-transplantation (Patel et al., 2000), and some long-term survivors have had extensive lesions of verruca vulgaris (Laffort et al., 2004). Except in the case of SCID, major problems still exist for the many patients who lack an HLA-identical sibling. Stem cell and lymphocyte manipulation may provide better success in the future, while alternative therapies might be developed for more diseases. Better assessment of genetic mutations associated with diseases, as well as individual genetic and environmental cofactors, should also lead to a better delineation of which child should be transplanted.

## Gene Therapy

FABIO CANDOTTI and ALAIN FISCHER

As currently practiced, gene therapy can be defined as the transfer of exogenous genes to somatic cells of a patient in order to correct an inherited or acquired gene defect, or to introduce a new function or trait. In the last 15 years, gene therapy has moved from the speculative stage to clinical applications as clinical gene transfer protocols have been applied to inherited genetic defects, malignancies, and infectious diseases. Primary immunodeficiency diseases (PIDs), especially severe combined immunodeficiency (SCID) disorders, have played a major role in this process as they have provided a proving ground for the first therapeutic applications (Blaese et al., 1995) as well as the first evidence that gene therapy can be curative (Cavazzana-Calvo et al., 2000; Hacein-Bey-Abina et al., 2002). Several advantageous characteristics have made PIDs attractive candidate diseases for gene therapy. First, PIDs are often curable by allogeneic hematopoietic stem cell transplantation (HSCT), which translates into the possibility that they should also be treatable with procedures combining ex vivo manipulation and reinfusion of autologous, gene-corrected hematopoietic stem cells. Second, the target cells reside in the bone marrow, a readily accessible tissue, which makes them amenable to harvest for ex vivo gene transfer, the procedure that currently offers the best success. In addition, the regulation of genes responsible for many PIDs (i.e., adenosine deaminase deficiency, chronic granulomatous disease, X-linked severe combined immunodeficiency, leukocyte adhesion deficiency) appears relatively simple and, while currently available technology does not allow reproducing the physiological control mechanisms of gene expression, the available gene transfer vectors are more than adequate to provide expression of these genes at levels required for clinical benefit. Finally, for several PIDs, gene-corrected progenitors and mature cells have a survival advantage over the unmodified, affected cell populations. This selective survival translates into the very advanta-

geous circumstance that even low gene transfer efficiency can have therapeutic effects.

Because of the extensive recent progress in the molecular and biological characterization of PIDs, several PIDs also fulfill the general prerequisites for any gene therapy approach that are based on the comprehensive knowledge of the molecular and cellular basis of the candidate disease. In general, the sequence of the cDNA of the gene responsible for the disease represents one critical piece of information for preliminary experiments of corrective gene transfer; however, the elucidation of the genomic organization and the characteristics of the promoting element(s) are also of great practical importance. Moreover, the specific function(s) and regulatory mechanisms of expression of the gene of interest should be understood, and the potential deleterious effects of overexpression investigated. Where possible, the safety and efficacy of gene transfer protocols should be tested in animal models, either naturally occurring or experimentally generated. Finally, it is fundamental to verify that the correction of the genetic defect can induce the restoration of gene function(s) in affected cells.

The complete and careful consideration of these issues is critical for development of new gene therapy strategies and should help in defining the answer for the ethical dilemma that is proposed whenever the traditional treatment for the candidate disease is already highly successful, but not completely curative.

Performing gene therapy for PIDs involves a series of specific difficulties. As mentioned, the ultimate target of corrective gene transfer for PIDs is the hematopoietic stem cell (HSC). Targeting the HSC is an exceptionally challenging task for several reasons. First, cells with the characteristics of true hematopoietic progenitors are extremely infrequent in hematopoietic tissues and have thus far eluded all attempts to define their specific cellular phenotype, making their collection and enrichment laborious and

**Table 48.1.** Present Status and Challenges of Gene Therapy Approaches for Primary Immunodeficiency Diseases

<i>Disease</i>	<i>Efficacy of BMT</i>	<i>Potential Target Cells for Gene Transfer</i>	<i>Status of Corrective Gene Transfer Studies</i>	<i>Challenges</i>	<i>Available Animal Model</i>
ADA-SCID	Good (HLA-identical)	BM, CB, T	Ongoing clinical trials	Adequacy of immune repertoire in T cell-directed protocols	muKO
CGD	Good (HLA-identical)	BM, CB	Ongoing clinical trial	No selective advantage	muKO

\*Very few cases reported, \*\*Mild phenotype.

inefficient. In addition, HSC are mostly quiescent and therefore resistant to the insertion of genetic material by viral vectors requiring active cell division. Extensive studies have been dedicated to the identification of “ex-vivo” culture conditions that could stimulate HSC to proliferate, thus making them susceptible to gene integration, without inducing differentiation and loss of long-term repopulating ability. In addition to the original cytokines and growth factors such as interleukin (IL)-3, IL-6, and stem cell factor (SCF), new molecules and culture supports such as thrombopoietin, Flt-3 ligand, and fibronectin (Hanenberg et al., 1996; Dao et al., 1997; Piacibello et al., 1997, 1999; Zandstra et al., 1997; Kohn, 1999). Have been demonstrated to be of primary importance to this goal. Research efforts have resulted in a major improvement in our ability to efficiently introduce genes into HSC in large animal models (Kiem et al., 1998; Tisdale et al., 1998). However, the current levels of gene transfer may still not be adequate for achieving therapeutic effects in hematopoietic diseases in which corrected cells do not have a strong selective advantage over the mutated ones (e.g., thalassemias or sickle cell disease). On the other hand, progress has resulted in successful clinical protocols for X-linked SCID and adenosine deaminase (ADA) deficiency (Cavazzana-Calvo et al., 2000; Aiuti et al., 2002a; Hacein-Bey-Abina et al., 2002), thus providing the basis for future clinical applications for other PIDs.

Another obstacle to gene therapy for PIDs is that several of the causative genes that have been identified have expression restricted to specific hematopoietic elements or particular cellular phases of cell development (see Table 48.1). In the gene transfer vectors currently available for clinical use, the gene of interest is under the transcriptional control of strong viral promoters and is therefore expected to give rise to unregulated expression of the gene in transduced HSCs and all deriving cell lineages. This strong, ubiquitous promoter activity raises the concern that constitutive expression of an ectopic gene could have detrimental

consequences on the differentiation and/or function of targeted populations. The necessity of tissue-specific and/or precise regulation of gene expression represents a formidable challenge for the development of future gene therapies. Theoretically, the use of gene-specific promoting and/or enhancing elements could be exploited to obtain physiologically regulated expression of the therapeutic gene; alternatively, inducible or repressible systems could also be used to modulate gene expression.

Finally, patients with inherited disorders of immunity may present with complete lack of expression of the affected gene(s) or show detectable levels of nonfunctional (mutated) gene product(s). It is not obvious which one of these two possibilities represents the better scenario for successful gene therapy. In the case of subjects carrying “null” mutations, there is the possibility that the newly expressed molecule could induce an immune response resulting in the elimination of the transduced, therapeutic cell populations. In the presence of mutations allowing for the expression of an inactive gene product, by contrast, the mutated molecules could manifest dominant negative effects in the presence of the correct protein(s), generating the necessity of obtaining very high levels of expression of the transgene to achieve therapeutic effects.

### Methods for Gene Transfer

A variety of systems have been developed for gene transfer and expression in mammalian cells. In the case of inherited genetic errors, the choice of a gene delivery system is dictated by the need for persistent expression of the therapeutic gene. This can be most readily achieved if the exogenous genetic material is stably integrated into the host cell genome, thus ensuring the transmission of the transferred gene to the progeny of that cell during normal mitotic cell division. In the absence of integration, the inserted gene will be diluted out as the cell divides and thus the

**Figure 48.1.** Schematic representation of the Moloney leukemia virus (MoMuLV) and MoMuLV-based LXSN (Miller and Rosman, 1989) and MFG (Dranoff et al., 1993) retroviral vectors. The organization of MoMuLV *gag*, *pol*, and *env* genes, as well as of splice donor (SD) and acceptor (SA) sites, packaging signal sequence ( $\psi$ ), and long tandem repeats (LTRs) are represented. The of MoMuLV *gag*, *pol*, and *env* sequences are deleted to obtain the backbone of retroviral vectors. The

MFG cassette is an example of “splicing vector” and maintains both splice donor and acceptor sites of the MoMuLV *env* coding sequence, thus mimicking the natural pattern of viral mRNA splicing. In the LXSN cassette and the MoMuLV 5' LTR is replaced with the homologous region from the Moloney murine sarcoma virus (MoMuSV). MCS, multiple cloning site; *neo*, neomycin resistance gene; SV40p, SV40 early promoter region.

therapeutic effects will ultimately be lost. Gene transfer vectors based on integrating viral systems such as murine oncoretroviruses, lentiviruses, and adeno-associated viruses represent efficient tools for stable gene expression. Of these, only vectors derived from murine oncoretroviruses have been used to date in clinical applications of gene therapy for PIDs.

### Vectors Based on Retroviruses

*Retroviral vectors*, the most commonly used gene transfer systems in human gene therapy, are gene transfer constructs that reproduce the replication and integration mechanisms of retroviruses. The Moloney murine leukemia virus (MoMLV) of the mammalian type C retroviruses is the most extensively studied retrovirus model (Miller, 1992), although other viruses from this group have also been exploited. More recently, vectors based on the two other major groups of retroviruses, lentiviruses and spumaviruses, have also been extensively studied.

#### MoMLV vectors

A complete, wild-type MoMLV particle is composed of two copies of the viral RNA contained within a protein capsid and an external phospholipid envelope. Important enzymes, such as the retroviral reverse transcriptase, integrase, and protease, are also packaged within the virion.

The retrovirus life cycle is constituted by (1) binding of the retroviral envelope to a specific receptor on the cell membrane followed by internalization of the viral capsid; (2) un-coating and reverse transcription of viral genomic RNA to produce double-stranded viral DNA; (3) migration of this DNA through the cytoplasm to the nucleus; and (4) integration of the proviral DNA into the host cell genome. Integration occurs, however, only if the targeted cells are actively proliferating, presumably because nuclear membranes must be disrupted for nuclear DNA transport. After reverse transcription, the viral genome (provirus) consists of 8.3 kb of double-stranded DNA containing the *gag*, *pol*, and *env* genes flanked by the viral long terminal repeats

(LTR). The *gag* and *env* genes encode the structural proteins of viral core and envelope, respectively, while the reverse transcriptase, integrase, and protease are derived from the *pol* region. The two identical LTRs contain sequences promoting and enhancing transcription, as well as a polyadenylation signal (polyA). Between the 5' LTR and the *gag* gene is a region of the genome termed  $\psi$  containing the encapsidation sequence that is necessary for efficient packaging of newly produced viral genomic RNA into the capsid structure (Temin, 1984).

To obtain viral vectors incapable of replicating in transduced cells, the genes encoding viral proteins are deleted and replaced with selectable markers and/or multiple cloning sites for the insertion of experimental genes (see Fig. 48.1). To obtain complete and infectious viral particles, “packaging” cell lines have been developed that express the *gag*, *pol*, and *env* genes products, but are unable to encapsidate the viral genomic RNA because of mutations or deletions in their  $\psi$  region. However, these cells allow packaging of the genome of retroviral vectors in which the  $\psi$  region is conserved (see Fig. 48.2).

Several packaging cell lines are now available. They are characterized by different host ranges, in turn determined by the specificity of their *env* genes. Among these, the PG13 (Miller et al., 1991) and the FlyRD18 (Cosset et al., 1995) packaging lines incorporate the gibbon-ape leukemia virus (GALV) and the cat endogenous virus (CEV) envelope proteins, respectively. In hematopoietic cells and progenitors, the expression levels of receptors for GALV and CEV are higher than that of the receptor for the Moloney envelope. In some cases, receptors can be metabolically up-regulated (Bunnell et al., 1995). These characteristics make packaging cells effective tools for diseases potentially treatable by gene transfer into peripheral blood elements or hematopoietic stem cells (Kiem et al., 1998; Kelly et al., 2000).

Another packaging system is based on the incorporation of the vesicular-stomatitis virus envelope protein G (VSV-G) into the virions of MoMLV-derived vectors. The particles carrying VSV-G have the advantage of a broader host range compared to virions encapsidated into the amphotropic envelope protein, and

**Figure 48.2.** Production of retroviral vector supernatants. The retroviral construct is transfected into the packaging cell line that contains the “helper” MoMuLV modified genomes. The *gag*, *pol*, and *env* genes provide the necessary viral proteins, whereas deletions of the packaging signal sequences prevent the encapsidation of the helper genomic RNA into virions. The retroviral vector, however, contains the complete packaging signal and generates RNA molecules that can be efficiently encapsidated. Finally, infectious viral particles containing the recombinant retroviral vector can be obtained in the culture supernatant.

allow the generation of concentrated, high-titer retroviral vector preparations (Rebel et al., 1999).

In vitro gene transfer is usually achieved by single or repeated exposure of the target cells to retroviral supernatants. Alternative procedures involving cocultivation of retroviral producer and target cells can increase gene transfer efficiency, but pose significant hurdles to development of clinical protocols.

Advantages of retroviral vectors for gene transfer include the broad range of infectable cell types and the efficient gene integration that can be achieved with dividing cells. Retroviral-based vectors, however, also present drawbacks. The maximum amount of DNA that these vectors can accommodate is ~8 kb, a size that prevents the transfer of large genomic sequences. Furthermore, retroviral vector integration into the host cell genome raises a twofold problem. First, the levels of gene expression can drastically vary from cell to cell depending on the particular site of proviral integration. These *position effects* are thought to depend on the basal chromatin structure at the integration site and can completely silence transgene expression in some cases while augmenting expression in others. Clearly, for many genes a tightly regulated range of expression is required, and this wide variability is not acceptable. Second, the integration events could theoretically disrupt critical nearby genetic sequences leading either to cell death or to activation of oncogenes, resulting in malignancy. The risk of insertional oncogenesis is unfortunately real, as recently indicated by the development of leukemia-like disorders in subjects receiving retroviral-mediated gene transfer as a treatment for X-linked severe combined immunodeficiency (XSCID) (Hacein-Bey-Abina et al., 2003a, 2003b).

#### Lentiviral vectors

Gene transfer vectors based on lentiviruses including human immunodeficiency virus type 1 (HIV-1) may have advantages over retroviral vectors for transduction into quiescent lymphocytes and hematopoietic stem cells. The genome of HIV-1 is more complex than that of other retroviruses. In addition to the structural *gag*, *pol*, and *env* genes, it also contains two regulatory genes, *tat* and *rev*, and four additional transcripts, *vif*, *vpr*, *vpu*, and *nef*, which

encode accessory proteins critical for viral replication and pathogenesis.

In contrast to type C retroviruses like MoMLV the lentiviruses' replicative cycle is independent of cell division and dissolution of the nuclear envelope during cell mitosis. Lentivirus vectors are therefore potentially able to integrate into the genome of non-dividing host cells. A number of gene transfer systems based on HIV-1, HIV-2, and nonprimate lentiviruses, such as equine infectious anemia virus (EIAV) and feline immunodeficiency virus (FIV), have been described (Naldini et al., 1996b; Reiser et al., 1996; Arya et al., 1998; Olsen, 1998; Poeschla et al., 1998a, 1998b; Uchida et al., 1998). Naldini et al. (1996a) first developed an HIV-1-based gene transfer system in which replication-defective viral particles were obtained by pseudotyping the HIV-1 core—that is, packaging it into the heterologous envelope of the Moloney leukemia virus or the VSV-G-protein. This strategy not only increased the safety of the system by excluding the HIV envelope but also broadened the tropism of the vectors to allow transduction of many cell types. Several groups have confirmed that lentiviral vectors can efficiently transduce nondividing cells in experimental conditions (Naldini et al., 1996a; Kafri et al., 1997; Miyoshi et al., 1997, 1999; Zufferey et al., 1997; Poeschla et al., 1998a, 1998b; Uchida et al., 1998; Case et al., 1999). Therefore, these vectors have the potential to become useful tools for gene therapy of diseases affecting tissues composed of quiescent or postmitotic cells, such as neuronal and retinal cells, hepatocytes, myocytes, and lymphohematopoietic cells.

However, clinical applications await resolution of biosafety concerns, particularly in the case of vectors derived from HIV-1, a highly pathogenic human virus. Unwanted recombination events during vector production could generate replication-competent viruses. If this occurred, patients receiving gene therapy could be at risk for infection by an HIV-like virus. In addition, treated patients carrying integrated HIV sequences might subsequently come in contact with wild-type HIV, in which case recombination between virus sequences in vivo could mobilize the gene therapy vector, leading to spread of a new virus to additional patient cells or even to infection of individuals in contact with the patient. Already, the

newer systems use nonoverlapping split-genome packaging constructs and self-inactivating vector cassettes to decrease these risks (Dull et al., 1998; Miyoshi et al., 1998; Zufferey et al., 1998).

Recent mapping studies of lentiviral vector integration sites seem to indicate, however, that these vectors may have less tendency to target dangerous transcription start sites than vectors based on MoMLV (Wu et al., 2003; Hematti et al., 2004), thus suggesting that these vectors may be less prone to induce insertional oncogenesis.

In addition to questions about safety, further discussion is warranted to identify suitable genetic diseases for initial gene therapy clinical trials using lentiviral vectors.

#### Foamy virus vectors

Foamy viruses (FV) are nonpathogenic retroviruses commonly found in mammals. In contrast to other retroviruses, reverse transcription in FV occurs during virion formation, and infectious viral particles therefore contain DNA genomes. This characteristic may improve transduction of quiescent cells, in which inefficient reverse transcription can prevent transduction by oncoviral or lentiviral vectors. This and other favorable characteristics, including broad tropism, large genome size (>13 kb), and lack of pathogenicity, have stimulated their development as gene transfer vectors. The FV genome contains the *gag*, *pol*, and *env* genes, but also three additional genes (*bel1*, *bel2*, *bel3*) located between *env* and the 3' LTR and expressed from an internal viral promoter. The *bel1* gene encodes for Tas, a transcriptional transactivator of the FV LTR and internal promoter. In the absence of Tas, the FV LTR is silent. The function of the *bel2* and *bel3* genes is unknown. The FV Gag protein contains a functional nuclear localization signal, raising the possibility that nuclear entry of FV genomes is independent of mitosis (Rethwilm, 1995).

In the last 5 years, replication-defective FV vectors have been generated and perfected. The initial version of the vectors carried deletions that abolish *bel1* expression and contain expression cassettes (composed on an internal promoter and the gene of interest) within the two FV LTRs. More recent constructs have reduced the FV sequences to a minimum, making abundant space (>9 kb) for a transgene (Russell and Miller, 1996; Wu et al., 1998; Wu and Mergia, 1999; Park et al., 2002; Trobridge et al., 2002). Transient expression systems or packaging cells provide the structural and regulatory FV gene products and allow for production of complete, infectious viral particles (Russell and Miller, 1996; Wu and Mergia, 1999; Trobridge et al., 2002). The virions are stable, are not inactivated by human serum (Russell and Miller, 1996), and can be concentrated by ultracentrifugation to titers of  $\sim 10^7$  (Trobridge et al., 2002).

FV vectors have been shown to efficiently enter quiescent cells where functional vector genomes survive until the cells are stimulated to divide, suggesting that, similar to HIV vectors, a stable intracellular transduction intermediate is formed (Russell and Miller, 1996; Mergia et al., 2001). This property may account for the ability of FV vectors to efficiently transduce hematopoietic cells, including murine and human pluripotent hematopoietic stem cells (Vassilopoulos et al., 2001; Josephson et al., 2002; Trobridge et al., 2002; Zucali et al., 2002). Such findings suggest that they will be useful for clinical gene transfer applications.

#### Vectors Based on Adeno-Associated Viruses

Adeno-associated viruses (AAV) integrate their DNA into the host cell genome and are not pathogenic for humans (Berns, 1995). These important characteristics have made them a very appealing

model for the development of gene transfer systems. AAV are a subfamily of single-stranded DNA parvoviruses that requires the presence of a coinfecting helper virus (from the adenovirus, herpes, or vaccinia virus families) to undergo a complete infectious cycle leading to virus replication and cellular lysis (Berns, 1995). In absence of a coinfecting helper virus, wild-type AAV undergo chromosomal integration (with a specific tendency to target human chromosome 19) and may persist in latent phase for extended periods of time (Cheung et al., 1980; Kotin et al., 1990).

The human AAV serotype 2 presents two major genes (*rep* and *cap*) flanked by viral inverted terminal repeats (ITRs). The *rep* gene is responsible for a series of critical steps of the AAV life cycle, including DNA replication and accumulation, while the *cap* gene products are necessary for AAV encapsidation. The ITR sequences have been shown to be essential for AAV chromosomal integration as well as for viral DNA replication and packaging (Srivastava et al., 1983).

Gene transfer vectors based on AAV are produced by deleting the *rep* and *cap* genes and replacing them with a transcriptional unit consisting of the promoter plus experimental gene of interest (Samulski et al., 1989). Complete recombinant AAV particles are then obtained by cotransfection of the plasmid containing the foreign gene with a helper plasmid providing the expression in *trans* of *rep* and *cap* genes onto cells infected with helper adenovirus. Being based on a transient expression method, the AAV packaging system can only provide a limited supply of viral vector. For this reason, stable AAV producer cell lines are under development (Flotte et al., 1995).

AAV vectors have been tested for a variety of gene transfer application, both in vitro and in vivo. Evidence emerging from these studies indicates that recombinant AAV vectors may either persist in an episomal stage or integrate in the host cell genome. In contrast to wild-type AAV infections, however, integration of AAV-based vectors seems to take place only at very high multiplicity of infection, and is not directed to chromosome 19 (Flotte et al., 1994; Halbert et al., 1995).

Even more limited than retroviral vectors, AAV constructs cannot accommodate more than 4.7 kb of foreign DNA in between the ITRs. The major advantages of AAV vectors for gene transfer are their nonpathogenic nature and their ability to transfer and express genes into nondividing cells (Podsakoff et al., 1994). However, AAV vector-mediated gene expression can be demonstrated in the absence of integration (Flotte et al., 1994), and the reliability of DNA insertion using these vectors in the absence of cell replication is not fully proven (Russell et al., 1994).

AAV vectors can infect hematopoietic tissues and have been tested in preclinical studies for the treatment of hemoglobinopathies (Walsh et al., 1992; Goodman et al., 1994; Miller et al., 1994). More recent data obtained using highly purified recombinant AAV stocks seem to indicate that these vectors can transduce primitive human hematopoietic cells efficiently, but only transiently. Clinical trials will be needed to determine the real potential of AAV-based gene transfer into human hematopoietic stem cells (Nathwani et al., 2000).

### Results of Gene Therapy Trials for Immunodeficiencies

#### Adenosine Deaminase Deficiency

Genetic defects resulting in loss or severe reduction of ADA (MIM \*608958, #102700; EC 3.5.4.4) result in extreme reduction of lymphocyte numbers and impairment of immune functions

(Hirschhorn, 1993; Markert, 1994) (see Chapter 12). Complete ADA deficiency causes SCID, or ADA-SCID.

In the mid-1980s, ADA deficiency was identified as the initial candidate disorder for trials of gene therapy because of a combination of favorable characteristics. The organization of the ADA gene and cDNA were well known, and ADA gene function and regulation had been defined (Orkin et al., 1983; Valerio et al., 1983; Wiginton et al., 1983). A wide array of enzyme concentrations ranging from 10% of normal to about 50 times the normal mean was known to be compatible with normal immunity (Valentine et al., 1977; Daddona et al., 1983). This situation provided an ideal scenario where the expression of the transferred gene was not required to be tissue-specific, nor tightly regulated. In addition, the experience from allogeneic bone marrow transplantation (BMT) experiments suggested that normal ADA-expressing cells had a selective advantage over the ADA-deficient bone marrow progenitors, thus potentially eliminating the need for myeloablation preceding the infusion of the patient gene-corrected HSCs. Finally, the fact that some BMT patients achieving engraftment of only donor T cells were shown to have full reconstitution of lymphocyte functions provided the rationale for the correction and reinfusion of patient mature T lymphocytes as an alternative, and technically less complex, gene therapy approach than HSC gene transfer.

The first clinical gene therapy protocol for ADA deficiency was begun September 14, 1990, at the United States (U.S.) National Institutes of Health (NIH). It enrolled two ADA-deficient girls with persisting signs of immunodeficiency despite the institution and regular administration of polyethylene glycol-ADA (PEG-ADA) replacement therapy. This protocol involved apheresis of the patient's peripheral blood and culture of peripheral blood mononuclear cells with IL-2 and anti-CD3 antibody to stimulate intense proliferation of the small number of T lymphocytes from the patient's circulation. Once actively proliferating, cells were exposed to supernatants containing retroviral vectors carrying the human ADA cDNA, and expanded ~100-fold before being reinfused into the patient (Blaese, 1990). Over a 2-year period, both patients underwent a series of treatments with the intention to target, and thus correct, a large proportion of each patient's T cell repertoire. Both children improved or developed *de novo* several aspects of humoral and cellular immune function, including production of IgM *in vitro* upon stimulation of cultured cells with pokeweed mitogen (PWM), *in vivo* antibody responses to vaccines against *Hemophilus influenza B* (HIB) and tetanus toxoid, titers of isohemoagglutinin antibodies, T cell counts, cutaneous delayed-type hypersensitivity (DTH) to various antigens, T cell production of IL-2 after stimulation with tetanus toxoid and influenza A virus, and *in vitro* cytolytic T cell-specific activity against allogeneic cells and influenza A virus-infected autologous cells. All of these immune responses were absent or barely detectable before gene therapy (Blaese et al., 1995).

Ten years after the last cell infusion, ~20% of circulating T cells from the first patient still contained the ADA vector and expressed the transgene, whereas <0.1% of T cells from the second patient had detectable vector sequences. Both patients continue to receive weekly injections of PEG-ADA, although at a reduced dose. Even as the dose of PEG-ADA was lowered by ~50%–60%, numbers of peripheral blood CD3<sup>+</sup> T cells remained in the normal range for 7 years, but more recently showed signs of decline. Proliferative responses to mitogens and recall antigens have remained at the lower range for healthy controls in both patients.

The marked difference between the two patients in the achieved level of gene marking and ADA expression appears to be the result of several factors. *In vitro* proliferation of cells from the second patient was poor, limiting the transduction efficiency. In addition, this patient developed a persistent immune response against the retroviral envelope and the lipoprotein components of the fetal calf serum used to culture the cells, and these responses may have induced immune-mediated elimination of infused cells (Tuschong et al., 2002; Muul et al., 2003).

The long-term clinical benefit of this first gene therapy trial is difficult to evaluate because of the concomitant administration of PEG-ADA. Nevertheless, several unique pieces of information could be drawn from this study, including the apparent safety of administering genetically modified autologous T cells, the long persistence (>12 years) of such cells *in vivo*, and the long-term transgene expression that can be obtained *in vivo* by the Moloney retroviral promoter (Muul et al., 2003). In addition, the results of this trial point out that immune responses, even in immunodeficient patients, can confound the outcome of gene therapy experiments in unpredicted ways (Tuschong et al., 2002; Muul et al., 2003).

Following protocol and vector preparations identical to those used in the NIH trial, in August 1995, Dr. Sakiyama and colleagues from Hokkaido University School of Medicine, in Sapporo, treated a Japanese ADA-SCID patient with 11 infusions of genetically modified autologous T lymphocytes over a period of 20 months. Periodic analysis of peripheral blood lymphocytes showed transduction frequencies of 10%–20% (Egashira et al., 1998; Onodera et al., 1998), accompanied by gradual increases of ADA enzyme activity in the patient's circulating T cells to levels comparable to those of a heterozygous carrier. Evidence of improvement of the patient's immune function after gene therapy included increased T lymphocyte counts and DTH responses, appearance of isohemoagglutinins, increase in serum immune globulin levels, and specific antibody production (Egashira et al., 1998; Onodera et al., 1998; Kawamura et al., 1999). Similar to the first patient in the NIH trial, follow-up studies demonstrated long-term persistence of transduced, polyclonal T cells (Misaki et al., 2001).

A second gene therapy clinical trial for ADA deficiency was begun in 1992 in Milan, Italy. Bordignon and coworkers used two distinguishable forms of the same retroviral vector to transduce separately the lymphocytes and bone marrow cells from two ADA-deficient patients who had shown a progressive decline of efficacy of PEG-ADA therapy. This study involved the *in vitro* culture, retroviral transduction, and reinfusion of patients' lymphocytes and bone marrow cells in an attempt to define the specific contribution of gene-corrected mature T lymphocytes and bone marrow progenitors to long-term immune reconstitution (Bordignon et al., 1993). The two patients were treated with intravenous infusions of autologous transduced cells over a period of 9 to 24 months, during which PEG-ADA dosage was decreased. Normalization of lymphocyte counts and isohemoagglutinins titers, restoration antigen-specific antibody production, and mitogen- and antigen-specific T cell proliferation were observed in both patients. At the molecular level, both forms of the integrated provirus were individually detectable in the patients' peripheral lymphocytes, with the clear long-term predominance of the construct used to transduce bone marrow cells. Of particular interest, vector-derived ADA activity was detectable in bone marrow cells, peripheral lymphocytes, and also mature granulocytes and erythrocytes, indicating that the correction of bone marrow progenitors was stably transferred to their progeny of multiple lineages (Bordignon et al., 1995).

Similar to the U.S. previous study, the clinical impact of gene therapy in these patients was difficult to assess because of concomitant administration of PEG-ADA, which, on the one hand, might have contributed to the immunological improvement but, on the other, may also have abolished any selective advantage of genetically engineered cells over the defective cell populations in ADA-deficient patients. One of the patients treated in Italy with multiple infusions of transduced peripheral blood lymphocytes offered the opportunity to evaluate the latter hypothesis directly when complications attributed to the PEG-ADA treatment developed that justified the discontinuation of the enzyme injections. Withdrawal of PEG-ADA led to a selective growth advantage of gene-transduced, ADA-expressing circulating T lymphocytes that, from a prevalence of ~3%, eventually reached nearly 100%. Absolute CD3<sup>+</sup> T cell counts also rose to levels significantly higher than those observed during PEG-ADA treatment, and intracellular ADA activity increased to levels of approximately 50% of that of normal individuals. These findings were accompanied by full restoration of T cell function that had been inadequate during PEG-ADA treatment. The increase of lymphocyte ADA activity, however, was not sufficient to achieve systemic detoxification; red blood cell deoxyribonucleotides (dAXP) increased to levels substantially higher than those observed in ADA-deficient patients treated with HSCT (Aiuti et al., 2002b). These findings suggest that even high numbers of genetically corrected lymphocytes were insufficient for achieving full, lasting metabolic correction of ADA deficiency and justified additional attempts by the same investigators at correcting the HSC as a more efficacious approach for gene therapy of this disease.

Recently, these efforts have resulted in the first clear evidence that gene therapy following a low-intensity conditioning regimen can result in clinical benefit for ADA deficiency when administered in the absence of PEG-ADA treatment. Reasoning that an initial developmental advantage was important for the transduced HSC, the Italian investigators decided to create space in the bone marrow by administering a low dose of busulfan (2 mg/kg per day for 2 days before infusion of gene-corrected cells) to four ADA-deficient patients before the infusion of gene-corrected cells. The degree of myelosuppression was mild in patients 2 and 4, but resulted in short-term neutropenia and more prolonged thrombocytopenia and neutropenia in patients 1 and 3, respectively. All patients showed an increase in peripheral blood lymphocyte counts that reached normal values in patients 1 and 3. Development of gene-corrected T, B, and natural killer (NK) cells and restoration of *in vitro* proliferative responses to mitogens and antigens was observed in all patients, as was improvement of serum immunoglobulin levels and production of specific antibodies following vaccination. Moreover, the biochemical abnormalities characteristic of ADA-deficient patients (low intracellular ADA activity and accumulation of toxic adenosine metabolites) were corrected. The presence of the retroviral ADA gene in myeloid cells (megakaryocytes, erythroid cells, and granulocytes) ranged between 0.1% and 10% and correlated with the dose of infused gene-corrected CD34<sup>+</sup> cells and the patient's response to the myelosuppressive agent. All patients were well, at home more than a year after treatment (Aiuti et al., 2002a). Because in addition to receiving chemotherapy these patients also were not given PEG-ADA, it remained to be established what circumstance had an impact on the outcome of the procedure.

The very exciting, successful results described above marked a clear difference from those obtained from previous clinical gene transfer attempts into the HSC of ADA-deficient patients that were carried out in the mid 1990s in the U.S. and Europe

with neither chemotherapy nor withholding of PEG-ADA. One of these trials had been initiated by Kohn and collaborators in 1993 at the Childrens Hospital Los Angeles. Notably, this was the first gene therapy protocol using umbilical cord blood CD34<sup>+</sup> hematopoietic progenitors, a cell source very rich in HSC. Three newborns were enrolled in this protocol, which involved separation of CD34<sup>+</sup> progenitors from the cord blood immediately after birth, repeated retroviral transductions with the normal ADA cDNA, and intravenous infusions into the patients on their fourth day of life. PEG-ADA treatment was also instituted and maintained in all three patients. Patients' peripheral and bone marrow hemopoietic cell populations were analyzed over time to determine the efficacy of the engraftment of ADA-transduced CD34<sup>+</sup> progenitors and their contribution to the patients' hematopoiesis. Serial molecular studies demonstrated that integrated vector sequences were detectable in bone marrow-derived CD34<sup>+</sup> cells, granulocyte-macrophage colony forming units (CFU-GM), and both the mononuclear and polymorphonuclear mature leukocyte populations of all three infants (Kohn et al., 1995).

Four years after the infusion of gene-corrected cells, 1%–10% of circulating T lymphocytes contained the transduced gene, whereas only 0.01%–0.1% of other hematopoietic elements were vector positive. After PEG-ADA treatment was stopped in the patient carrying the highest percentage of gene-corrected T lymphocytes (~10%), the proliferative response to tetanus toxoid was lost, as were most of the circulating B and NK cells. Reduction of total numbers of CD3<sup>+</sup> and CD4<sup>+</sup> T lymphocytes was also observed; however the percentage of circulating T cells containing the transduced ADA gene increased to 30%–100% and lymphocyte proliferation response to phytohemagglutinin (PHA) was retained. These findings and the development of an upper respiratory tract infection induced the investigators to reinstate PEG-ADA therapy, leading to restoration of clinical and laboratory findings to pre-withdrawal levels. The low levels of ADA gene marking and expression did not justify the suspension of PEG-ADA treatment in the other patients (Kohn et al., 1998).

These observations supported the notion that ADA gene-corrected T cells have a selective survival advantage over unmodified lymphocytes. However, the trial also demonstrated that the level of transduced progenitors (particularly for B and NK cells) was not sufficiently high to guarantee sustained, adequate immune function in the absence of enzyme replacement. A possible contributing reason for these findings was that the expression of ADA afforded by the LASN vector in HSCs was not adequate to allow differentiation and function of large numbers of mature lymphocytes. Based on this last hypothesis a two-site trial using ADA vectors with higher expression capabilities was started in 2001 at Children Hospital Los Angeles and the NIH with the aim of comparing the relative efficacy of two different vectors *in vivo* after transduction in bone marrow CD34<sup>+</sup> cells. In this trial, patients were maintained on PEG-ADA treatment. The initial results of this trial indicate that long-term marking was achieved in two of four treated patients. However, the level of marking was low, and the patients did not show immunological improvement (Candotti et al., 2003).

An additional French and British pilot trial of gene therapy for ADA deficiency in 1993 involved retroviral transduction of HSCs isolated from bone marrow (Hoogerbrugge et al., 1996). Three ADA-deficient children were enrolled. The results were disappointing because vector-containing cells were detectable by polymerase chain reaction (PCR) 6 months after the treatment in the bone marrow of only one patient, and no signal was detected in the peripheral blood of any of the three children. No clinical

improvement was observed in these patients. On the basis of their preclinical results in the *Rhesus* model, the authors theorized a need for preemptive myeloablation to obtain efficient engraftment of gene-corrected stem cells in ADA deficiency. Interestingly, the recent results from Italy described above (Aiuti et al., 2002a) are in line with this hypothesis.

In summary, while BMT from an HLA-identical sibling remains the therapy of choice for ADA deficiency, the results obtained by the pioneer and current clinical trials indicate that gene therapy approaches can be effective and to date maintain a record of safety. At present, however, it is not clear whether the selective advantage of gene-corrected cells is sufficient to provide immune reconstitution in the absence of preparative chemotherapy. A clinical trial in Japan enrolled two patients in 2003 to receive gene-corrected CD34<sup>+</sup> bone marrow cells after discontinuation of PEG-ADA, but without chemotherapy. This trial will likely provide insights into the relative importance of chemotherapy and PEG-ADA withdrawal (Otsu et al., 2005). This and other ongoing efforts are expected to advance gene therapy for ADA deficiency to phase II and III trials to obtain definitive conclusions as to the efficacy of this therapy.

### Chronic Granulomatous Disease

Genetic defects involving both gp91<sup>phox</sup> and p22<sup>phox</sup>, as well as in p47<sup>phox</sup> and p67<sup>phox</sup> have been identified in chronic granulomatous disease (CGD) patients who, because of impaired superoxide production in phagocytic cells, usually present early in life with abscesses and/or granulomas in the skin, liver, lungs, or bone resulting from catalase-positive bacteria and fungal pathogens (see Chapter 37). Current management of CGD patients includes antibiotic prophylaxis, administration of interferon- $\gamma$  (IFN- $\gamma$ ), and allogeneic HSC transplantation (Lekstrom-Himes and Gallin, 2000). For several patients, however, available therapeutic options remain unsatisfactory. Cloning of the genes encoding all the elements of the NADPH oxidase system (Forehand and Johnston, 1994; Roos, 1994) has allowed gene therapy strategies to be developed.

Several groups have demonstrated the feasibility of viral vector gene transfer in reconstituting the respiratory burst activity of B cell lines and monocytes from CGD patients (Thrasher et al., 1992, 1995a, 1995b; Sekhsaria et al., 1993; Li et al., 1994). The ultimate target for gene correction of CGD, however, is the HSC because of the very limited life span and the reduced proliferative state of mature phagocytes.

In vitro preclinical studies have demonstrated that CD34<sup>+</sup> hematopoietic progenitors derived from peripheral blood after G-CSF mobilization and genetically corrected by retroviral-mediated gene transfer showed restoration of superoxide production when induced to differentiate into mature monocytes and neutrophils (Sekhsaria et al., 1993; Li et al., 1994; Porter et al., 1996; Weil et al., 1997; Becker et al., 1998). In addition, in vivo restoration of respiratory burst in p47<sup>phox</sup> and gp91<sup>phox</sup> knock-out mice has been demonstrated, following gene correction of bone marrow cells with retroviral vectors (Bjorgvinsdottir et al., 1997; Mardiney et al., 1997). On the basis of these encouraging results, Malech and coworkers at the NIH initiated a phase I clinical study for gene therapy of the autosomal recessive form of CGD due to defective expression of the NADPH complex p47<sup>phox</sup> subunit. Five CGD patients were subjected to pharmacological mobilization of CD34<sup>+</sup> hematopoietic progenitors that were then collected from the peripheral blood by apheresis. Enriched CD34<sup>+</sup> cells were transduced in vitro using a retroviral

vector expressing cDNA encoding p47<sup>phox</sup>. The transduced cells were then reinfused into the patients. Appearance of NADPH oxidase activity in PMA-stimulated peripheral blood granulocytes was followed in each subject over time. At variable intervals between 15 and 32 days after infusion of transduced progenitors, all patients showed oxidase-positive granulocytes, with maximum percentages ranging between 0.004% and 0.05%. Presence of the transduced gene in the DNA of peripheral blood lymphocytes was confirmed by PCR. Oxidase-positive cells were detected for a minimum of 79 and a maximum of 172 days (Malech et al., 1996). Although silencing of the transduced gene has not been excluded, these findings are most consistent with loss of the transduced cells and with the possibility that lineage-committed progenitors, rather than true self-renewing HSC, were the primary transduction target in this study.

More recently, the same research group has conducted a second clinical trial aimed at correction of the more common X-linked form of CGD (X-CGD), caused by mutation of the gp91<sup>phox</sup> subunit of NADPH oxidase. Using a high-titer retroviral vector and improved transduction procedures, three X-CGD patients each received two infusions of gp91<sup>phox</sup>-transduced CD34<sup>+</sup> cells. Preliminary results indicated that levels of NADPH-positive neutrophils were markedly higher than those observed in the previous trial and ranged from 0.2% to 0.06% at 3–4 weeks after treatment (Malech et al., 1998).

Similar results were obtained by Dinuer et al. in another phase I trial for X-CGD at the University of Indiana Medical School, although the results observed at this center have not been formally reported yet.

The results of these phase I clinical gene transfer studies for CGD suggest the following considerations. Because of the lack of a strong selective advantage of gene-corrected populations in this disease, significant levels of HSC transduction and engraftment or conditioning chemotherapy will likely be needed to obtain clinical benefit. More efficient methods of gene transfer are being developed based on lentiviral vectors (Saulnier et al., 2000; Roesler et al., 2002). Alternatively, in vivo selection of gene-corrected cells could be engineered by the addition of drug resistance markers such as the multidrug resistance (MDR) or dihydrofolate reductase (DHFR) genes to gene transfer vectors. Studies of these approaches in animal models are ongoing and are likely to provide clear indication on the prospects of future success of gene therapy for CGD.

Marrow conditioning prior to reinfusion of transduced cells is being evaluated by several groups in the U.S., England, and Germany to help achieve higher levels of engraftment of corrected stem/progenitor cells. In January 2004, a new trial in Germany by Grez and collaborators used a retroviral vector to target G-CSF-mobilized CD34<sup>+</sup> progenitor cells of two patients with X-linked CGD. Before infusion of gene-corrected cells, patients were given intravenous busulfan (4 mg/kg for 2 consecutive days), which resulted in transitory myelodepression from which patients recovered by day 30 after treatment. Preliminary results of a 6-month follow-up have shown significant levels of gene marking and therapeutic levels of NADPH oxidase activity (Ott et al., 2004). These results are encouraging, although long-term evaluation is needed to support definitive efficacy and safety of this approach.

### Leukocyte Adhesion Deficiency Type 1

Leukocyte adhesion deficiency type 1 (LAD1) is an inherited defect of leukocyte functions caused by absence or reduced levels of expression of the common  $\beta_2$ -integrin subunit (CD18) (Harlan,

1993). In LAD1 granulocytes fail to migrate into inflamed tissues to exert their phagocytic functions. Affected patients initially present retarded separation of the umbilical cord and subsequently develop recurrent severe bacterial and fungal infections (Fischer et al., 1988; Etzioni, 1994) (see Chapter 38). Allogeneic BMT from an HLA-matched related donor has been curative for this disease. The insertion of normal cDNA into the HSC of a patient may therefore lead to correction of this disease phenotype, and studies using viral vectors have demonstrated in vitro functional reconstitution of CD18 molecules in transduced LAD1 lymphocytes (Hibbs et al., 1990; Wilson et al., 1990; Bauer et al., 1995).

The expression of CD18 is limited to myeloid cells and lymphocytes; however, functional adhesion complexes require dimerization of CD18 molecules with other subunits (CD11a, CD11b, or CD11c) also expressed only by the same cell types. Expression of CD18 in other lineages derived from gene-corrected HSCs and not normally expressing CD18 should therefore not result in unregulated and unwanted expression of complete adhesion complexes.

Similarly to CGD, because of the short life span of myeloid cells, the target for corrective gene transfer of LAD1 is necessarily the HSC. Retroviral vectors have been used to reconstitute CD18 expression in granulocytes that differentiate in vitro from gene-corrected CD34<sup>+</sup> cells (Bauer et al., 1998; Yorifuji et al., 1993). Following these studies, a clinical protocol for gene therapy of LAD1 at the University of Washington in Seattle used retroviral-mediated correction of G-CSF-mobilized peripheral blood CD34<sup>+</sup> cells in two LAD1 patients (Bauer and Hickstein, 2000). Peripheral blood CD34<sup>+</sup> cells were obtained after mobilization with G-CSF and exposed to a retroviral vector expressing CD18 before being reinfused into the patients. One month after the infusion of transduced CD34<sup>+</sup> cells, both patients showed low percentages (0.03%–0.04%) of CD18<sup>+</sup> myeloid cells, and in one patient there was some evidence of functional correction, as CD18<sup>+</sup> myeloid cells were demonstrated to migrate into a site of inflammation. Unfortunately, gene-corrected cells were not detectable beyond 2 months after treatment (Bauer and Hickstein, 2000).

Allogeneic HSC transplantation studies in a canine model of LAD1 have shown that very low levels of donor CD18<sup>+</sup> neutrophils (<500/ $\mu$ l) were sufficient to reverse the disease phenotype (Bauer et al., 2004). However, no selective survival advantage of gene-corrected myeloid cells is expected in LAD1. As with CGD, strategies involving preparative myeloablation, engineered vectors to confer in vivo selection, and the use of more efficient vectors will likely be required to improve the outcome of future gene therapy trials for LAD1.

### X-linked Severe Combined Immunodeficiency

The X-linked recessive form of severe combined immunodeficiency (XSCID) is caused by mutations of the common  $\gamma$  chain ( $\gamma_c$ ) of the receptors for IL-2, IL-4, IL-7, IL-9, IL-15, and IL-21 (Noguchi et al., 1993; Puck et al., 1993). Affected males present combined impairment of T and B cell immunity, despite the presence of B cells in normal or even elevated numbers (see Chapter 9). Allogeneic BMT can be curative for these patients, and it generally shows good success in terms of survival (Antoine et al., 2003; Buckley, 2004) (see Chapter 47). However, especially in the case haploidentical donors, transplanted patients often achieve only partial chimerism of hematopoietic lineages with persistence of autologous B lymphocytes and poor humoral immune function that requires continuous replacement therapy

with immunoglobulins (Antoine et al., 2003). Such unsatisfactory results have prompted the development of gene therapy approaches for XSCID.

In preclinical studies, several groups of investigators have shown that retroviral-mediated transfer of  $\gamma_c$  into B lymphoblastoid cell lines derived from XSCID patients could correct a series of cellular defects, including  $\gamma_c$  membrane expression, IL-2 high affinity binding and internalization, ligand binding-mediated phosphorylation of JAK3 and JAK1 tyrosine kinases, and IL-2-induced cell proliferation (Candotti et al., 1996; Hacein-Bey et al., 1996; Taylor et al., 1996b). More importantly, normal development of mature T lymphocytes and NK cells could be demonstrated from gene-corrected XSCID stem cells in vitro (Hacein-Bey et al., 1998; Cavazzana-Calvo et al., 1996; Tsai et al.,). In addition, in vivo experiments in mouse models of XSCID have shown safety and efficacy of  $\gamma_c$  gene transfer in bone marrow stem cells with reconstitution of lymphoid development and function in these animals (Lo et al., 1999; Otsu et al., 2000, 2001; Soudais et al., 2000; Aviles Mendoza et al., 2001).

These results formed the basis for the first clinical gene transfer protocol for XSCID that was launched in 1999 in Paris, France. This trial involved retroviral  $\gamma_c$  gene transfer into CD34<sup>+</sup> bone marrow cells harvested from XSCID patients who lacked HLA-identical bone marrow donors and has enrolled 11 patients to date. The results observed in typical XSCID patients have shown that as soon as 60–90 days after the infusion of gene-corrected cells, T lymphocytes expressing  $\gamma_c$  appeared in the circulation and reached normal values within 4 to 8 months in eight patients (Cavazzana-Calvo et al., 2000; Hacein-Bey-Abina et al., 2002, 2003b). Most importantly, these T lymphocytes were polyclonal and functionally competent as demonstrated by normal responses to stimulation with mitogens and specific antigens. In contrast to the T lymphocytes, the NK cell counts declined to values lower than normal after an initial significant rise during which restoration of NK cell function could be demonstrated. In addition, despite the fact that less than 1% of the patients' B cells carried the  $\gamma_c$  transgene, close to normal serum levels of IgM and IgG were demonstrated in three patients who developed specific antibody responses to tetanus and diphtheria toxins, as well as to poliovirus vaccines. Not surprisingly, based on the predicted lack of selective advantage in myeloid lineages, only 0.01%–1% of the patients' monocytes and granulocytes showed evidence of genetic correction (Sun et al., 1997; Cavazzana-Calvo et al., 2001; Hacein-Bey-Abina et al., 2002).

The first series of 5 patients clearly demonstrated that  $\gamma_c$  gene transfer can restore the immune system in XSCID patients (Hacein-Bey-Abina et al., 2002). Although the restoration was incomplete with regard to the numbers of gene-corrected B and NK cells, the effects of the treatment were sufficient to provide protective immunity and to allow the patients to return home and lead a normal life. Similar results were obtained in 5 out of 6 additional patients enrolled in the trial. The failure of the treatment in 2 of the total 11 patients treated in Paris was attributed to the specific clinical conditions of these two patients, who had chronic infections that may have affected the engraftment of gene-corrected cells (Hacein-Bey-Abina et al., 2002). In addition, one of these two patients was an atypical patient of 15 years of age at the time of treatment, raising the possibility that loss of thymic function may have contributed to the failure of the procedure in this case.

Late in 2002, two patients who had been treated with gene therapy about 3 years earlier presented with uncontrolled clonal

proliferation of mature ( $\text{TCR}\gamma\delta^+$  or  $\text{TCR}\alpha\beta^+$ ) T lymphocytes. The malignant behavior of such proliferation required conventional treatment for T-cell acute lymphoblastic leukemia to be administered that in one case was followed by matched unrelated bone marrow transplantation.

In both cases, the adverse event was the result of insertional oncogenesis due to the aberrant expression of the *LMO2* gene (LIM domain only-2; OMIM 180385) induced by the integration of the  $\gamma_c$  retroviral vector in the proximity of the *LMO2* regulatory region (Hacein-Bey-Abina et al., 2003a, 2003b). *LMO2* is a cysteine-rich protein required for normal hematopoiesis. *LMO2* is activated in childhood acute T cell leukemias by chromosomal translocation and its deregulated expression in transgenic mice promotes high incidence of T cell tumors (Larson et al., 1994). Although our understanding of the mechanism underlying the development of *LMO2*-mediated lymphoproliferation remains incomplete, it appears plausible that the enhancer activity of the retroviral vector promoter was responsible for the activation of the *LMO2* promoter and consequent deregulated *LMO2* gene expression. Vigorous cell proliferation of *LMO2*-expressing cells due to the selective advantage conferred to them by the concomitant expression of the  $\gamma_c$  gene may have provided a "second hit" needed for the onset of the overt malignancy.

Whether the leukemic transformation observed in these patients can be therefore attributed to a specific cooperation between  $\gamma_c$  and *LMO2* in the context of a strong selective advantage conferred by the genetic correction remains to be established, but it is obviously of critical importance, as it could change the assessment of the risk that similar events may occur after retroviral-mediated gene transfer into HSC for other diseases. It is worth noting that the patients who developed *LMO2*-associated T cell leukemias were the youngest enrolled in the trial and had received the highest numbers of gene-corrected cells/kg body weight (Hacein-Bey-Abina et al., 2003a, 2003b). Specific biological characteristics of hematopoietic stem cells obtained at a very young age may be conducive to insertional mutagenesis through mechanisms that are still unknown. These serious adverse events have had major repercussions on the field of gene therapy. It is clear that a complete reassessment of the risks of gene therapy for XSCID and of the validity of previous safety studies in animal models is warranted to provide an understanding of how to proceed with an approach that has provided clear clinical benefit, but also unintended severe complications.

Despite aggressive therapy, one of the two patients who developed lymphoproliferation died, while the other remains in continuous remission >2 years after the diagnosis of leukemia and treatment with conventional chemotherapy. In January 2005, a third case of uncontrolled T cell proliferation was observed. Characterization of this last case is under way at this writing (<http://afssaps.sante.fr/hlm/10/filcoprs/indco.htm>).

In July 2001, a second gene therapy trial for XSCID was started by Thrasher et al. at the Great Ormond Street Hospital in London. The protocol design was similar to the French trial with the exception of culture conditions (lower concentration of IL-3 and use of serum-free medium) and the use of a vector pseudotyped with a gibbon-ape-leukaemia virus (GALV) envelope. Data published on the first 4 enrolled children, 4 to 33 months of age at treatment, indicated that all patients showed substantial clinical improvements and immunological reconstitution. The latter included recovery of T cell numbers (up to normal in 2 of 4 patients), normal T cell-proliferative responses, and a polyclonal TcR V $\beta$  repertoire. Improvement of humoral immunity was

also observed that allowed discontinuation of prophylactic immunoglobulin replacement treatment in 2 patients. With a follow-up of 2 to 4 years, none of the patients has manifested serious adverse events (Gaspar et al., 2004). Altogether, these data confirm the successful correction of immunity obtained in the French trial and corroborate the notion that gene therapy can be curative for XSCID.

One additional trial was begun at the NIH in 2003 with the aim of offering a rescue treatment option for older XSCID patients who had failed previous haploidentical BMT treatment. In this trial, the target cells were G-CSF-mobilized peripheral blood  $\text{CD34}^+$  cells. Three patients have been enrolled and preliminary results on the first subject (11 years old) were published in abstract form (Chinen et al., 2004). Administration of gene-corrected cells was followed by amelioration of clinical features, including resolution of chronic diarrhea, rashes, and alopecia, although no increase in T cell numbers was observed. Gene marking could be detected in T and B lymphocytes as well as NK cells at 6 months after treatment (Chinen et al., 2004). Additional follow-up will determine the potential of this strategy and provide important information on the prospects of gene therapy in older X-SCID patients in whom reduced thymopoiesis may pose an obstacle to the success of the procedure.

### JAK3 Deficiency

The JAK3 member of the Janus family of protein tyrosine kinases is a lymphoid tissue-specific tyrosine kinase (Kawamura et al., 1994) involved in the signal transduction pathway of several cytokines, including IL-2, IL-4, IL-7, IL-9, IL-15, and IL-21 (Johnston et al., 1995; Asao et al., 2001; Habib et al., 2002). Patients with mutations of JAK3 usually present with autosomal recessive SCID (Macchi et al., 1995; Russell et al., 1995; Candotti et al., 1997; Notarangelo et al., 2001) with clinical characteristics virtually identical to those presented by XSCID patients, except that JAK3 deficiency is found in both male and female patients (see Chapter 10).

Because of the clear similarities between the effects of  $\gamma_c$  and JAK3 genetic defects, the theoretical possibilities for gene therapy are analogous. Retrovirally mediated gene correction has reconstituted IL-2 and IL-4 responses in JAK3-deficient cell lines (Candotti et al., 1996; Oakes et al., 1996), leading to the hypothesis that the gene correction of HSC may be a useful therapy for JAK3-deficient patients. Preclinical in vivo studies have demonstrated the feasibility of retroviral-mediated gene correction of JAK3 deficiency in murine models using irradiated adult recipients and nonirradiated newborn animals (Bunting et al., 1998, 1999, 2000). Of note, an in vivo selective advantage of transduced cells over untransduced JAK3-deficient counterparts was demonstrated for lymphoid lineages, a finding suggesting that similar treatment procedures as those used in the gene therapy trial for XSCID could lead to successful results in JAK3 deficiency. On the basis of these results, Sorrentino et al. at the St. Jude Children's Research Hospital in Memphis attempted the genetic correction of bone marrow  $\text{CD34}^+$  cells of a JAK3-deficient patient who had failed HSCT. Infusion of retrovirally transduced cells was attempted twice in this patient, but resulted in only low levels of marking without improvement in immunological status. The reasons for unsatisfactory outcome are not clear, and it is hoped that further investigations in this and additional patients will clarify prospects for gene therapy for JAK3 SCID.

## Preclinical Experiments of Gene Therapy for Other Immunodeficiencies

### Purine Nucleoside Phosphorylase Deficiency

In most cases, the immunologic disorder associated with genetic deficit of purine nucleoside phosphorylase (PNP; EC 2.4.2.1) is restricted to the T cell compartment, whereas B cell functions are generally normal (see Chapter 12). Enzyme replacement therapy, by means of irradiated red blood cells transfusions (Rich et al., 1980), has not been definitively proven beneficial for PNP deficiency, and allogeneic HLA-matched HSCT is the current therapy of choice, although reports indicating its success in patients with PNP deficiency are limited.

The lack of PNP activity leads to the block of the same purine salvage pathway that is affected by the genetic deficit of ADA. Since the biochemical defects of ADA and PNP deficiency are similar, the prospect for successful gene therapy of PNP deficiency also seems likely.

In preclinical studies using retroviral-mediated gene transfer, *in vitro* reconstitution of PNP activity in T lymphocytes derived from PNP-deficient subjects has been described (Nelson et al., 1995). These results suggested that T cells could potentially be used as vehicles for therapeutic PNP gene expression, and a clinical protocol testing this hypothesis has been proposed. Contrary to ADA-SCID, no enzyme replacement treatment is available for this disease. PNP-deficient patients are usually lymphopenic and, for this reason, the possibility remains that PNP-deficient patients will not have a sufficiently developed peripheral T cell repertoire to achieve meaningful immune reconstitution with T lymphocyte-directed gene therapy. The correction of the gene defect at the level of HSC seems a better strategy.

### ZAP-70 Deficiency

Mutations affecting the expression of ZAP-70 protein tyrosine kinase are a rare cause of autosomal recessive SCID characterized by absence of mature circulating CD8<sup>+</sup> T lymphocytes and T cell antigen receptor (TCR) signal transduction defects in peripheral CD4<sup>+</sup> T cells (Arpaia et al., 1994; Chan et al., 1994; Elder et al., 1994) (see Chapter 14). Since ZAP-70-deficient patients have been successfully treated by allogeneic HSCT, this disease is another candidate for stem cell gene correction. The presence of circulating T lymphocytes in these patients has allowed the establishment of HTLV-1-transformed T cell lines that have been used as targets for corrective gene transfer to study the feasibility of a gene therapy approach for this disease. Upon retroviral-mediated gene transduction of the normal ZAP-70 cDNA into T cells from a ZAP-deficient patient, ZAP-70 kinase was expressed that was appropriately tyrosine phosphorylated upon TCR engagement. More importantly, reconstitution of *in vitro* kinase activity of the transduced ZAP-70 and normalization of calcium mobilization after TCR stimulation in gene-corrected cells was demonstrated (Taylor et al., 1996a). More recently, Steinberg and coworkers transferred the ZAP-70 cDNA into primary T lymphocytes from ZAP-70 deficient patients. Upon gene correction, several biological functions were restored in these T cells, including TCR signaling, Ras-mitogen-activated protein kinase (MAPK) activation, and IL-2 secretion. In addition and importantly, selective growth advantage of gene corrected cells was observed after *in vitro* culture of transduced cells (Steinberg et al., 2000), suggesting that the genetic correction of few HSCs and/or lymphoid progenitor cells may generate significant num-

bers of corrected T lymphocytes and restoration of T cell immunodeficiency.

Because of the normally restricted expression of the ZAP-70 protein to specific lymphoid lineages, evaluation of potential deleterious effects of the ectopic expression of ZAP-70 in cell types normally not expressing this protein is a concern. However, gene correction of bone marrow cells of ZAP knockout mice using a retroviral vector expressing the human ZAP-70 gene resulted in the development of mature, polyclonal, and functional T lymphocytes, while expression of the retroviral transgene in B cells did not affect their function (Otsu et al., 2002). Altogether, these data indicate that retroviral-mediated transfer of the ZAP-70 gene may prove to have a therapeutic benefit for patients with ZAP-70 deficiency.

### Major Histocompatibility Complex Class II Deficiency

Deficit of expression of MHC class II molecules can be caused by defects of any of four different MHC class II-specific transcription factors—CIITA, RFX5, RFXAP, and RFXANK. MHC class II deficiency is characterized by severe immunodeficiency with low numbers of CD4<sup>+</sup> lymphocytes (see Chapter 17). Allogeneic HSCT is potentially curative, but its success rate is very low (Huss et al., 1995; Klein et al., 1995). Alternative forms of therapy are therefore needed, and HSC-directed gene therapy could be beneficial for these patients. Exploring this possibility, Bradley et al. (1997) showed that retrovirus-mediated gene transfer of the CIITA factor could restore expression of MHC class II in B lymphoblastoid lines and peripheral blood cells from an MHC class II-deficient patient. Recently, lentiviral vectors that may prove useful for future gene therapy applications have been described that express each of the four MHC class II-specific transcription factors (Matheux et al., 2002). A cautionary note, however, comes from reports indicating that ectopic expression of MHC class II genes can result in pathological hyperactivity of CD4<sup>+</sup> lymphocytes (Bottazzo et al., 1986). Since expression of MHC class II molecules is regulated in such cell types as T lymphocytes, fibroblasts, and endothelial cells, it will be important to determine if tissue-specific expression of the therapeutic gene will be needed for clinical gene therapy.

### Immunodeficiency with Hyper-IgM

The X-linked hyper-IgM syndrome (XHIM) is another rare PID caused by genetic mutations in the CD40 ligand molecule (CD40L) expressed on activated CD4<sup>+</sup> T lymphocytes (see Chapter 19). XHIM patients lack functional CD40L on their T cells and have profound impairment of T cell–B cell interactions. A detailed follow-up of XHIM patients has made it clear that the immunoglobulin substitution used as treatment does not provide an adequate long-term solution to the severe infectious episodes suffered by these boys. Allogeneic HSCT is therefore now considered definitive treatment for this disease, and XHIM is also a potential candidate for gene therapy.

Unfortunately, however, CD40L expression is highly regulated, with expression restricted to activated CD4<sup>+</sup> lymphocytes, thus introducing the need for regulated gene transfer systems. The necessity of strictly regulating the CD40L expression in gene-corrected cells was stressed by Brown et al., who performed transplantation of retrovirally gene-corrected bone marrow or thymic cells into CD40L knockout mice. Humoral and cellular immune responses to influenza virus were partially or

fully restored by this treatment; however, more than 60% of the treated mice developed lymphoproliferative disease in the form of prelymphoma of T-lymphoblastic lymphoma. T cell proliferation was most likely due to enhanced positive selection driven by the constitutive expression of CD40L on developing thymocytes (Brown et al., 1998). Gene transfer systems allowing effective regulation of CD40L will therefore have to be developed before gene correction can be proposed for the treatment of humans with XHIGM. One such approach by Tahara et al. aimed at preserving physiological regulation of CD40L by using spliceosome-mediated RNA *trans*-splicing. Bone marrow from CD40L knockout mice was transduced with a lentiviral vector encoding a pre-*trans*-splicing molecule containing wild-type CD40L exons 2–5 and transplanted into lethally irradiated recipient animals. Corrected CD40L mRNA, regulated CD40L expression in CD4<sup>+</sup> T cells, antigen-specific IgG1 responses, and attenuation of *Pneumocystis carinii* pneumonia were observed in treated mice in the absence of lymphoproliferative complications (Tahara et al., 2004). Although this strategy seems promising, further studies are needed to establish whether the efficacy of RNA *trans*-splicing will be adequate to correct the human phenotype.

Soluble CD40L is available and could represent an alternative form of therapy for XHIGM. If proven beneficial, administration of autologous cells or “pseudo-organs” engineered to produce CD40L that are easily removable could become a more controllable option.

### X-Linked Agammaglobulinemia

Bruton's disease, or X-linked agammaglobulinemia (XLA), is a genetic disorder of B lymphocyte differentiation that results in the absence of mature circulating B cells and undetectable serum immune globulins of all isotypes (Conley et al., 1994; Smith et al., 1994) (see Chapter 21). The molecular defect of XLA has been identified in mutations the gene encoding Bruton's tyrosine kinase (*BTK*) (Tsukada et al., 1993; Vetrie et al., 1993), normally expressed by developing B and myeloid cells, but not plasma cells or T cells. The current management of XLA is to administer immunoglobulin, which is generally efficacious in preventing infections. This treatment, however, is expensive, inconvenient, and, in some cases, insufficient to avoid lethal infections.

XLA patients therefore could benefit from development of gene therapy. The generation of retroviral vectors expressing *BTK* has been attempted since the mid-1990s, but several laboratories failed to produce high-titer retroviral-producing cell lines. These difficulties were explained by the demonstration that expression of *BTK* can mediate apoptosis (Islam et al., 2000). Thus high levels of *BTK* expression in target cells may induce toxic effects, and vector selection could be critical for the development of successful gene therapy for XLA. Progress in vector design and production has made possible preclinical experiments of genetic correction in the X-linked immunodeficiency (Xid) mouse, in which *btk* is mutated. Preliminary results show that gene transfer into *Xid* bone marrow cells can reconstitute B cell development and production of IgM and IgG<sub>3</sub> antibodies (Conley et al., 2000; Yu et al., 2000). In addition, BTK-expressing B cell progenitors were found to have a selective advantage over BTK-negative progenitors (Rohrer and Conley, 1999). Mice deficient in both *Btk* and the related kinase Tec have been corrected by retroviral-mediated gene therapy with a human *BTK* vector (Yu et al., 2004). Treated mice showed restoration of both primary and peripheral B-lineage development, correction of serum IgM and IgG<sub>3</sub> levels, and restoration of T-independent immunity and

B cell–proliferative responses. Together, these data support the concept of therapeutic *BTK* gene transfer and hold promise for future gene therapy for XLA.

### RAG-2 Deficiency

Patients with mutations of the recombination activating genes *RAG1* or *RAG2* suffer from a form of SCID characterized by the lack of both T and B lymphocytes. HSCT is currently the only curative treatment, which, however, is only partially successful in the absence of an HLA-identical familial donor. Exploring the potential of gene therapy for this disease is therefore justified. Recently, Rag-2-deficient mice were used to test a retroviral-mediated gene therapy approach. Genetic correction and transplantation of HSC into Rag-2 knockout mice could provide long-term correction of the immunologic deficiency in treated animals. T cell and B cell development was accompanied by diverse T cell repertoire, normal proliferative responses to mitogens and alloantigens, and humoral responses to antigenic challenge. A selective advantage for transduced lymphoid cells was demonstrated by comparative provirus quantification in of RAG-2 lymphoid and myeloid cells, while there was no evidence of toxicity due to constitutive expression (Yates et al., 2002). Altogether, these preliminary experiments demonstrate the feasibility of gene therapy for RAG-2 deficiency and encourage the further development of preclinical protocols for this disease.

### Wiskott-Aldrich Syndrome

The Wiskott-Aldrich syndrome (WAS) is characterized by eczema, thrombocytopenia, recurrent infections, autoimmune disorders, and a high incidence of lymphomas (Fischer, 1993; Sullivan et al., 1994). The breadth and severity of WAS symptoms make management of this disease a complex problem (Mullen et al., 1993). The WAS gene encodes a highly proline-rich protein, WASP (Derry et al., 1994), that has been implicated in actin organization in the cytoskeleton (see Chapter 31). The unsatisfactory results of haploidentical BMT in WAS patients (Antoine et al., 2003) justify efforts to test the safety and efficacy of gene therapy for this disease.

Studies in WAS lymphoblastoid B cell lines (Candotti et al., 1999; Huang et al., 2000) as well as T cell lines and primary T lymphocytes (Dupre et al., 2002; Wada et al., 2002; Strom et al., 2003) have shown that retroviral-mediated gene transfer can correct the phenotype of WAS cells. More recent experiments have shown that WASP gene transfer using lentiviral vectors can provide functional correction of WAS patients' T cells with higher efficacy (Dupre et al., 2004). More importantly, in vivo models of gene therapy using knockout mice have shown that T cell numbers and responses can be improved in animals treated with both retroviral and lentiviral WASP gene transfer, albeit at reduced levels compared to wild-type animals (Strom et al., 2002; Klein et al., 2003; Charrier et al., 2004). Interestingly, competitive repopulation experiments have also documented a selective advantage of wild-type over WASP knockout cells, thus suggesting that gene-corrected lymphocytes could similarly have a selective advantage over unmodified populations after gene therapy. These observations are in line with the reports of somatic reversion of WASP mutations in T lymphocyte progenitors of WAS patients; somatic reversion resulted in significant numbers of WASP-expressing circulating T lymphocytes that had selective survival advantage in vivo over WASP-negative cells (Wada et al., 2001, 2003, 2004).

### CD3 $\gamma$ Deficiency

The T cell antigen receptor (TcR) is constituted by a glycoprotein heterodimeric complex containing TcR $\alpha$  and TcR $\beta$ , or TcR $\gamma$  and TcR $\delta$  chains that associate with the CD3 complex composed of CD3 $\gamma$ , CD3 $\delta$ , CD3 $\epsilon$ , and CD3 $\zeta$  (or CD3 $\eta$ ) polypeptides. Selective defects of the expression of CD3 $\gamma$  have been reported in humans, resulting in only partial disorders of cellular immunity (Arnaiz-Villena et al., 1992) (see Chapter 16). Because of the presence of circulating T lymphocytes in these patients, a T lymphocyte-directed gene therapy approach could be developed. Retroviral-mediated expression of CD3 $\gamma$  in mutant Jurkat T cells resulted in normalization of IL-2 production after TCR/CD3 engagement and TCR/CD3 down-modulation in response to phorbol myristate acetate (Sun et al., 1997). Similarly, CD3 $\gamma$  introduction into peripheral blood T lymphocytes from CD3 $\gamma$ -deficient patients corrected the TCR/CD3 expression and down-regulation defects, but unfortunately also induced constitutive IL-2 synthesis, causing death of nontransduced T lymphocytes. CD3 $\gamma$  gene transfer into post-thymic lymphocytes therefore can become detrimental to the host, and regulated expression will be necessary if gene therapy is to be developed this disease.

### X-Linked Lymphoproliferative Syndrome

Mutations or deletions in *SH2D1A*, or *SAP*, gene result in the X-linked lymphoproliferative disease (XLP), a combined immunodeficiency associated with severe or fatal outcome after EBV infection (see Chapter 32). The SAP protein is primarily expressed in T and NK cells (Parolini et al., 2000; Czar et al., 2001; Wu et al., 2001). Among T lymphocytes, cytotoxic T cells (CTL<sub>s</sub>) play a crucial role in the immune response to EBV. CTL from XLP patients are characterized by reduced IFN- $\gamma$  production in response to EBV-mediated stimulation and decreased cytotoxic activity against autologous lymphocytoid cell lines. These defects were restored using retroviral-mediated *SAP* gene transfer, thus opening the way to approaches for corrective gene transfer into CTL as potential form of therapy for this disease (Sharifi et al., 2004).

### Conclusions

Primary immunodeficiency diseases fully meet the definition of "experiments of nature" as proposed by Garrod in 1924: they provide unique examples of what are the real consequences of genetic defects in humans, thus shedding light on the physiological role of the missing gene product(s) (Garrod, 1924). For this important characteristic, the highly heterogeneous group of extremely rare PID diseases has been the focus of extensive clinical and molecular studies, and has often been the object of innovative therapeutic approaches.

The first demonstration that allogeneic HSCT could be successfully applied to clinical practice was reported in 1968 following the treatment of children with XSCID and WAS (Bach et al., 1968; Gatti et al., 1968); similarly, successful enzyme replacement therapy was first achieved in a case of ADA deficient SCID (Pahwa et al., 1989). Finally, XSCID was also the first disease to be successfully treated by gene therapy (Cavazzana-Calvo et al., 2000). With the first clear clinical benefits, the first serious potential complications of gene therapy have unfortunately also become evident (Hacein-Bey-Abina et al., 2003b) and sparked a revision of the assessment of risks and benefits that will be critical for future development of gene therapy approaches for all PIDs and other genetic disorders.

As HSCT has subsequently emerged as an essential form of treatment for a wide variety of clinical applications, it is likely that the experience acquired from the pioneering gene therapy experiments for immunodeficient patients will constitute a guide for developing and applying gene therapy strategies to an increasing number of congenital and acquired genetic conditions in which conventional therapies have failed or are not a satisfactory long-term option.
