To our teachers, colleagues, and students  
To our patients  
and to our families  
Who inspired, questioned, supported, and encouraged

Robert Good, who wrote the foreword for the first edition of this book, and Fred Rosen, a co-author of the chapter on Wiskott Aldrich Syndrome in both the first and second editions, have recently died. Dr. Good and Dr. Rosen were giants in the field of primary immunodeficiencies and their unique heritage dates back to the very beginnings of the recognition and classification of these disorders. We are fortunate to have had such wonderful colleagues and grateful to them for their outstanding contributions to the field and to this book.

# Foreword

The primary immunodeficiency diseases, the first of which were recognized over 50 years ago, are now generally appreciated as major health problems by affected patients, their families, physicians, and even the general public. In 1999, this book was the first comprehensive compendium devoted to primary immunodeficiency diseases. While most are relatively rare, some of these conditions, like IgA deficiency and common variable immunodeficiency, occur with a frequency that makes these patients likely to be seen by most physicians.

The study of patients with these genetically determined immune disorders in conjunction with the study of animal models has led to remarkable progress in our understanding of the interacting components of the complex immune system and how they function in humans. As a consequence, earlier recognition and better treatment options are provided for patients with primary immunodeficiency diseases, as well as for the even larger number of individuals with secondary immune deficiency conditions. This authoritative book, now in its second edition, contains a comprehensive account of currently available information. In the short years since the first publication, the number of known immunodeficiency genes has grown from less than 70 to well over 120, reflecting the tremendous expansion of knowledge in this field. The rich base of information contained in these pages makes it clear that there are few fields in medicine in which laboratory-based research and the study of diseases in patients have been so mutually complementary as for the primary immunodeficiency diseases.

The first immunodeficiency diseases to be identified, namely X-linked agammaglobulinemia, and the more clinically severe congenital lymphopenic syndromes were diseases that are now known to reflect compromised development in the effector limbs of the adaptive immune system. Experimental delineation of the developmentally distinct lineages of lymphocytes, the thymus-dependent population of T cells, and the bone marrow-derived B cells, made possible the recognition of their respective roles in cell-mediated and humoral immunity. Accordingly, the primary immunodeficiency diseases were found to belong to distinct classes, those primarily affecting T cell development, like the thymic underdevelopment seen in the DiGeorge syndrome, and those featuring impaired B cell development and antibody production, as seen in Bruton X-linked agammaglobulinemia. Severe combined immunodeficiency (SCID), recognized first by Glanzmann and Riniker, featured instead a developmental failure of both T and B cells. With the ensuing molecular biology revolution, the pace of the genetic analysis of the immunodeficiency diseases quickened remarkably. As more and more details have been learned about the life history of T and B lineage cells, many of the genetically determined defects in these differentiation

pathways can now be identified quite precisely in genetic and molecular terms.

As is indicated in the contents of this book, we currently have sufficient information about the lymphocyte differentiation pathways to categorize primary immunodeficiency diseases into gene mutations that affect (1) DNA transcription factors; (2) rearrangement and expression of the T cell receptor (TCR) and immunoglobulin genes; (3) signal transducing components of the TCR and B cell receptor (BCR) complexes; (4) essential signaling pathway elements employed by TCR and BCR; (5) coreceptor molecules that are essential for normal function of T and B cells; (6) cytokines and cytokine receptors that promote T and B cell production, proliferation, and differentiation; and (7) cell surface molecules that are necessary for normal lymphocyte homing and intercellular interactions in the peripheral lymphoid tissues, including the spleen, lymph nodes, intestinal Peyer's patches, and appendix. It has also become increasingly evident that the normal function of the effector T and B cell populations depends on other types of cells as well. An especially important cell partner is the dendritic cell, because it responds to potential pathogens by presenting antigen to initiate the T cell response and, in turn, the B cell response. Although few primary immunodeficiency diseases have as yet been attributed to developmental flaws in this cell type, impaired dendritic cell function is an important component of the immunodeficiency caused by gene mutations that prevent CD40 expression or expression of the CD40 ligand on T cells.

The specific adaptive immune responses mediated by T and B cells and their collaborators, although essential, are only a part of the overall host defense strategy. There is an ever-growing awareness that innate immunity is equally important and complex. Disorders of the complement system, abnormal function of phagocytic cells, and deficiencies of the chemokines and chemokine receptors that influence lymphocyte-phagocytic cell interactions can all result in an impaired ability to eliminate pathogens. Natural killer cells with their diverse array of activating and inhibitory receptors are also beginning to be recognized as one of the dysfunctional cell types in some immunodeficiency disorders.

Infections are the major complications of the immunodeficiency diseases, and, as recognized by the late Robert Good, a true giant in the establishment of the field and author of the original foreword to the first edition of this book, the types of infections differ according to the specific gaps in host defense. Primary antibody deficiency states predispose to serious bacterial infections, as do certain complement component and neutrophil deficiencies. Viral and fungal infections are particularly notable in patients with T cell dysfunction. Different infectious disease patterns are seen with other host defense defects. For example, mycobacterial

and salmonella infections are common in patients who have mutations in the genes for IL-12 or the receptors for IL-12 and interferon- $\gamma$ , because these signaling molecules are especially important for normal macrophage activation to kill intracellular pathogens. Characterization of the different patterns of infections has been significantly enhanced by the development of databanks devoted to patients with the relatively rare primary immunodeficiency diseases.

Treatment has advanced in parallel with improved diagnosis of immunodeficiency diseases, understanding of their cellular and molecular basis, and better definition of their clinical consequences. Prophylactic antibiotics can be helpful in reducing the frequency of certain types of infections. Immunoglobulin replacement, employed first by Bruton to treat a boy with congenital agammaglobulinemia, has been refined through the development of safe and efficient preparations of intravenous immunoglobulin. Better ways to perform bone marrow transplantation have made this life-saving mode of cellular engineering safer and

available to more patients with severe combined immunodeficiency disease. Enzyme replacement can benefit SCID patients with adenosine deaminase deficiency. Finally, gene therapy has proven effective for the cure of two types of SCID, albeit presently with an attendant risk of lymphoproliferative disease. For all too many patients with primary immunodeficiency diseases, however, a cure is still not yet possible and will come only with improved knowledge that must be gained through continued study. In the meantime, early diagnosis remains the key for a quality life for many patients with an immunodeficiency disease. Toward this end, this newly updated book provides a remarkably comprehensive and clinically useful source of information about this challenging group of disorders.

## Foreword to the First Edition

Modern immunology can be considered to have been launched in 1952, when Colonel Ogden Bruton described an 8-year old boy who, from 2 years of age, experienced recurrent, life-threatening infections including episodes of bacterial pneumonia and septicemia. Using the newly-introduced technique, serum electrophoresis, Bruton found the boy to be agammaglobulinemic. When challenged with antigens, he failed to produce specific antibodies. Upon treatment by passive immunization with large doses of intramuscularly-injected gammaglobulin, his susceptibility to infections was dramatically terminated. Detailed investigations of similar patients, by Charles Janeway in Boston and my group in Minneapolis, demonstrated many similarly affected children, and proved that agammaglobulinemia was often an X-linked, inherited disorder.

In the course of caring for agammaglobulinemic patients, we realized that they were especially susceptible to encapsulated bacterial pathogens, including *Streptococcus pneumoniae*, *Haemophilus influenzae*, *Streptococcus pyogenes*, *Pseudomonas aeruginosa*, and to a lesser extent, *Staphylococcus aureus*. In contrast however, they could impressively resist infections caused by fungi, coliforms, tuberculosis, bacillus Calmette-Guérin (BCG), and many viruses such as measles, chicken pox, rubella, and vaccinia. Thus, the susceptibility profile of agammaglobulinemic patients bisected the microbial universe. As an experiment of nature, patients with X-linked agammaglobulinemia (XLA) introduced us to additional, crucially important concepts concerning how plasma cells and lymph node germinal centers, which are lacking in agammaglobulinemic patients, must be the source of antibodies providing resistance to encapsulated bacterial pathogens. We reasoned that distinct mechanisms of defense that were intact in agammaglobulinemic patients must have been designed to protect against other types of infections. Lymphocytes in the deep paracortical regions of lymph nodes, which appeared normal in XLA patients, were found to mediate this second type of immune protection, cellular immunity, which was later shown to be dependent on the thymus. This conclusion was partially derived from the study of a different group of patients, those with DiGeorge syndrome, who had congenital absence of the thymus.

Thus, it was evident from the beginning that patients with immunodeficiencies, as experiments of nature, helped us to bisect not only the microbial universe, but also the universe of lymphoid cells and the universe of immunological responses. Further investigations throughout the 1960s, 1970s, and 1980s confirmed that this compartmentalization related to the fundamental lymphocyte dichotomy of B cells versus thymus-dependent T cells. Moreover, patients with different immunodeficiency syndromes helped define the nature and the role in immune responses of

other components of the host defense system, such as phagocytes and complement, and to recognize the diseases that occur when these components are absent or not functional.

Over the last decade, advances in molecular biology have allowed for an even greater understanding of the immune system, and the multitude of molecular pathways that regulate growth, differentiation, communication, and effector functions within and between cells. In 1993, two groups of researchers, led by David Vetrie and Satoshi Tsukada, discovered that the difficulties of Bruton's patient and other patients with XLA were due to many different mutations of an X-linked gene that encodes a B-cell specific tyrosine kinase, Btk. In the few years since that discovery, the molecular genetic universe has expanded phenomenally, so that almost every month there is news of the identification of another immune disease gene.

The present volume, edited by Professors H. D. Ochs, C.I.E. Smith, and J. M. Puck, is the first comprehensive guide to this new molecular genetic universe. Herein, diseases of the immune system are presented and analyzed, both in terms of their clinical features and in the context of the impressive molecular and genetic definitions which can be put forward in 1998. Over 90 well-defined primary diseases of the human immune system are listed in the introductory chapter of this book; specific diseases are discussed in later chapters organized by syndrome (Part II). The current understanding of each disorder is outlined, including discussions of clinical issues and clinical presentation, infections, genetic mutations, protein function, cell biology, and management. Framing these discussions of individual diseases are two equally modern presentations—first, a section of seven chapters outlining the essential concepts of immunology and genetics needed to understand primary immunodeficiency diseases, and at the end, a section covering the most current approaches to assessment and treatment of patients with these conditions. Each authoritative chapter is written by a world leader in the field, or in many cases by a pair or group of immunological specialists with complementary perspectives, to present the most up-to-date and complete information available.

This book is an impressive demonstration of how far we have come. Recent studies of primary immunodeficiency diseases have, perhaps more than any other group of diseases, revealed the power of modern molecular genetics to define diseases in precise molecular terms. This approach has already suggested therapeutic possibilities which have proven successful; it has also set the stage for testing gene therapies meant to cure primary immunodeficiency diseases at the molecular level. Just how disruptions of Btk account for all of the morphological and immunological abnormalities and disease susceptibilities of patients with XLA has not yet been elucidated, but future work will

show how this molecule interacts with other gene products in the B lymphocyte. Studying XLA will continue to reveal fundamental issues in lymphology and immunobiology.

The knowledge of primary immunodeficiency diseases reflected in this volume continues to grow, based on insights derived from the study of individuals with primary immunodeficiency exemplified by Bruton's original agammaglobulinemic patient. Analysis of each of the immune system diseases in its own way represents the molecular interpretation of an informative experiment of nature. In the aggregate, these analyses help us understand more deeply how man can exist free of infection while

living in a veritable sea of microorganisms. This volume constitutes a milestone, marking where we now stand and indicating where we are heading, as we continue to interpret lessons in a most constructive fashion from the greatest teachers of modern immunology: patients with primary immunodeficiency diseases.

# Genetically Determined Immunodeficiency Diseases: A Perspective

C. I. EDVARD SMITH, HANS D. OCHS, and JENNIFER M. PUCK

We are in an era of explosive growth in our understanding of the molecular and genetic basis of immune defects. In the early 1990s, only a handful of genes were known to be associated with these diseases, but now many are recognized and the process of discovering additional immunodeficiency genes is proceeding rapidly. Advances in basic research in immunology, combined with the availability of the DNA sequence of nearly the entire human and mouse genomes plus refined technologies for localizing disease traits, have led to the discovery of the precise molecular basis for 140 or more disorders of human host defenses. A recent example of novel approaches is the discovery of CD3 $\delta$  deficiency through use of microarray technology (Dadi et al., 2003; Chapter 16). The ability to redefine genetic diseases of the immune system in molecular terms has made possible improved diagnosis, appreciation of the spectrum of clinical presentations that can be traced to a given disease gene, genetic counseling and testing, and, most exciting, new therapeutic strategies including gene therapy. Moreover, the discovery of each previously unknown disease gene feeds back into the pool of scientific knowledge of immunology, illuminating and strengthening our evolving models of immune pathways.

This volume contains accounts of gene identification, mutation detection, and clinical and research applications for a wide array of distinct genetic immune disorders. A summary of known inherited immunodeficiencies is provided in Table 1.1. The methods used to identify and understand these disorders constitute a survey of modern molecular genetics and human immunology. The first edition of this book in 1999 marked an historic turning point in the field of immunodeficiencies, demonstrating that many of primary disorders of the immune system could be understood at the molecular level. Seven years later, we are sure that new discoveries will continue to make this collection incomplete even as it is published, but we can also proudly document

an unanticipated fast pace of progress in dissecting the complex immunologic networks responsible for protecting individuals from a hostile environment.

Since the publication of the first edition, the rate of new discoveries in the field has not slowed down. Instead, a flurry of new disease entities has been defined and new treatment regimens have been introduced, the most notable being successful treatment by gene therapy for two genotypes of severe combined immunodeficiency (Chapter 48).

Of great interest is the new identification of human diseases caused by mutations affecting components of the innate immune system. Previously, defects in the complement system pathways (Chapter 42) and the interferon  $\gamma$  (IFN- $\gamma$ ) signaling pathway (Chapter 28) were recognized, and mouse models of innate immune mediators such as the Toll receptors were reported. However, the true function of innate immune pathways in humans could not be fully appreciated until naturally occurring loss-of-function mutations were identified and characterized in human patients. The recent report of patients with bacterial infections who lack the protein IRAK4, mediating signaling downstream from the Toll receptor, provides a new opening for learning the significance of the innate immune system in protecting humans from infections and cancer (Picard et al., 2003).

Important developments during the past 15 years have increased our understanding of disease processes. A majority of the novel primary immunodeficiency disease genes were identified by mapping a familial abnormality to a chromosomal region, followed by the analysis of candidate genes. In some cases the function of the identified gene product had already been studied in detail prior to identification of human disease-causing mutations, but frequently new insights, some quite surprising, have arisen from relating an immune system gene to a clinical phenotype. For example, even though the function of CD45 phosphatase was

**Table 1.1.** Primary Immunodeficiency Diseases

<i>Designation and Gene Name*</i>	<i>Defective Protein, Pathogenesis</i>	<i>Inheritance</i>	<i>Locus</i>	<i>Reference or Book Chapter</i>
<b>A. Combined B and T Cell Immunodeficiencies</b>				
1. Severe combined immunodeficiency (SCID) without T and B cells (T <sup>-</sup> B <sup>-</sup> )				
a. SCID with leukocyte deficiency. Reticular dysgenesis.	Stem cell defect affecting maturation of leukocytes, including all lymphocytes	AR	Unknown	de Waal and Seynhaeve, 1959
b. SCID with radiosensitivity. Artemis deficiency. <i>DCLRE1C</i>	DNA cross-link repair 1C protein/Artemis	AR	10p13	11
c. SCID with RAG1 deficiency <i>RAG1</i>	Recombinase-activating protein 1. Deficient rearrangement of B and T cell receptor genes ( <i>RAG1</i> and <i>RAG2</i> are adjacent genes)	AR	11p13	11
d. SCID with RAG2 deficiency <i>RAG2</i>	Recombinase-activating protein 2. Deficient rearrangement of B and T cell receptor genes	AR	11p13	11
2. SCID with nonfunctional T and B cells				
a. Omenn syndrome with <i>RAG1</i> deficiency <i>RAG1</i>	Recombinase-activation protein 1, partially deficient rearrangement of B and T cell receptor genes	AR	11p13	11
b. Omenn syndrome with <i>RAG2</i> deficiency <i>RAG2</i>	Recombinase-activation protein 2 partially deficient rearrangement of B and T cell receptor genes	AR	11p13	11
c. Omenn syndrome with Artemis deficiency <i>DCLRE1C</i>	DNA cross-link repair 1C protein Artemis	AR	10p13	11
d. Omenn syndrome with IL-7R $\alpha$ deficiency <i>IL-7R</i>	Interleukin-7 receptor $\alpha$ chain	AR	5p13	11
e. DNA ligase deficiency IV <i>LIG4</i>	Ligase IV, ATP-dependent	AR	13q33–34	11,30
f. SCID with microcephaly due to deficiency of non-homologous end-joining factor 1 <i>NHEJ1</i>	DNA repair factor (XRCC4-like factor, Cernunnos) involved in non-homologous end-joining	AR	2q35	11,30
3. SCID without T cells (T <sup>-</sup> B <sup>+</sup> )				
a. X-linked SCID ( $\gamma$ c-chain deficiency) <i>IL2RG</i>	Common $\gamma$ ( $\gamma$ c) chain protein, a component of receptors for cytokines IL-2, -4, -7, -9, -15, and -21.	XL	Xq13.1–13.3	9
b. SCID with Jak3 (Janus kinase 3) deficiency <i>JAK3</i>	Janus-activating kinase 3 (Jak3), a cytoplasmic tyrosine kinase interacting with $\gamma$ c to transmit signals from IL-2, -4, -7, -9, -15, and -21	AR	19p13.1	10
c. SCID with IL-7R $\alpha$ deficiency <i>IL7R</i>	Interleukin-7 receptor $\alpha$ chain	AR	5p13	11
d. SCID with CD45 deficiency <i>PTPRC</i>	Protein tyrosine phosphatase receptor type C	AR	1q31–q32	13
e. SCID with CD3 $\delta$ -chain deficiency <i>CD3D</i>	CD3 $\delta$ component of CD3 antigen receptor complex	AR	11q23	16
f. Human Nude/SCID <i>FOXP1</i>	Forkhead box N1 protein, winged-helix-nude ( <i>Whn</i> ). Transcription factor required for thymus and hair follicle development	AR	17q11–q12	Frank et al., 1999
4. Deficiencies of purine metabolism				
a. SCID with ADA (adenosine deaminase) deficiency <i>ADA</i>	ADA is required for purine metabolism; elevated purine metabolites (primarily dATP) toxic to T and B cells	AR	20q13.2–q13.11	12
b. SCID with PNP (purine nucleoside phosphorylase) deficiency <i>PNP</i>	PNP is required for purine metabolism; elevated purine metabolites (primarily dGTP) toxic to T and B cells	AR	14q13.1	12
5. MHC class II (major histocompatibility complex class II) deficiency secondary to deficiencies of transcription factors for MHCII expression				
a. CIITA (MHCII transactivator) deficiency <i>MHC2TA</i>	MHCII transactivating protein, a non-DNA binding component of the MHCII promoter-binding complex; complementation group A	AR	16p13	17
b. RFXANK deficiency <i>RFXANK</i>	Regulatory factor X-associated ankyrin-containing protein, an MHCII promoter-binding protein; complementation group B	AR	19p12	17

(continued)

**Table 1.1.** (continued)

<i>Designation and Gene Name*</i>	<i>Defective Protein, Pathogenesis</i>	<i>Inheritance</i>	<i>Locus</i>	<i>Reference or Book Chapter</i>
c. RFX-5 deficiency <i>RFX5</i>	MHCII promoter X box regulatory factor 5, an MHCII promoter-binding protein; complementation group C	AR	1q21	17
d. RFXAP deficiency <i>RFXAP</i>	Regulatory factor X-associated protein, an MHCII promoter-binding protein; complementation group D	AR	13q	17
6. MHC class I deficiency				
a. TAP1 deficiency <i>TAP1</i>	Transporter protein associated with antigen presentation 1	AR	6q21.3	18
b. TAP2 deficiency <i>TAP2</i>	Transporter protein associated with antigen presentation 2	AR	6q21.3	18
c. Tapasin deficiency <i>TAPBP</i>	TAP binding protein (tapasin)	AR	6p21.3	18
7. Class-switch recombination defect (hyper-IgM syndromes) affecting both B and T cells; see also B.6.				
a. CD40L deficiency <i>TNFSF5</i>	CD40 ligand (CD154). Tumor necrosis factor superfamily member 5	XL	Xq26	19
b. CD40 deficiency <i>TNFRSF5</i>	CD40. Tumor necrosis factor receptor superfamily member 5	AR	20q12–q.13.2	19
8. Non-SCID CD3 deficiency due to absence of proteins forming the CD3 complex required for T cell receptor signaling See A.2.e for SCID with CD3δ deficiency				
a. CD3ε deficiency <i>CD3E</i>	CD3ε polypeptide	AR	11q23	16
b. CD3γ deficiency <i>CD3G</i>	CD3γ polypeptide	AR	11q23	16
c. CD3ζ-deficiency	CD3ζ polypeptide (TtT3 complex)	AR	1q22–q25	Rieux-Laucat et al., 2006
9. CD8 deficiency <i>CD8A</i>	CD8 antigen, α polypeptide (p32)	AR	2p12	16
10. ZAP-70 deficiency <i>ZAP-70</i>	Cytoplasmic tyrosine kinase ZAP-70 (T-cell receptor ζ-chain associated protein kinase, 70kDa). Signaling from the T-cell receptor during T-lineage development	AR	2q12	14
11. IL-2 R α-chain deficiency <i>IL2RA</i>	IL-2 receptor α-chain is required for regulation and control of autoreactive T cells	AR	10p14–p15	15
12. p56 Lck deficiency <i>LCK</i>	Lymphocyte-specific protein tyrosine kinase. Required for T cell maturation in the thymus	AR	1p34.3	14
<b>B. Deficiencies Predominantly Affecting Antibody Production</b>				
1. Agammaglobulinemia				
a. XLA (X-linked agammaglobulinemia) <i>BTK</i>	Btk (Bruton agammaglobulinemia tyrosine kinase) required for intracellular signaling in B cell development	XL	Xq21.3	21
b. X-linked hypogammaglobulinemia with growth hormone deficiency	Btk not affected; unknown	XL	X	21
c. μ heavy-chain deficiency <i>IGHM</i>	μ heavy-chain. Required for development of B cells from B lineage progenitors	AR	14q32.3	22
d. λ5 surrogate light-chain deficiency <i>IGLL1</i>	λ5 surrogate light-chain. Part of receptor complex on pre-B cells required for B lineage differentiation	AR	22q11.22	22
e. Igα deficiency <i>CD79A</i>	Ig-associated α chain signaling component of pre-B and B cell receptor complex required for B lineage differentiation and B cell signaling	AR	19q13.2	22
f. BLNK deficiency <i>BLNK</i>	B-cell linker/SLP-65/BASH. B cell signaling protein	AR	10q23.2–q23.33	22
g. <i>LRRC8</i> deficiency	Leucine rich repeat containing 8 transmembrane protein	AD	9q34.2	Sawada et al., 2003
2. Selective deficiency of Ig isotypes/subclasses due to isolated or combined deficiencies				
a. IgA deficiency	Failure of IgA B cell differentiation	Complex	—	23
b. α1 subclass deficiency <i>IGHA1</i>	IgA1 is the major IgA subclass	AR	14q32.33	23
c. α2 subclass deficiency <i>IGHA2</i>	IgA2 is mainly found in the gastrointestinal tract	AR	14q32.33	23

(continued)

**Table 1.1.** (continued)

<i>Designation and Gene Name*</i>	<i>Defective Protein, Pathogenesis</i>	<i>Inheritance</i>	<i>Locus</i>	<i>Reference or Book Chapter</i>
d. $\gamma$ 1 subclass deficiency <i>IGHG1</i>	IgG1 constitutes 65% of serum IgG	AR	14q32.33	23
e. $\gamma$ 2 subclass deficiency <i>IGHG2</i>	IgG2 constitutes 25% of serum IgG	AR	14q32.33	23
f. $\gamma$ 3 subclass deficiency (partial) <i>IGHG3</i>	IgG3 constitutes 8% of serum IgG. Partial IgG3 deficiency is associated with the 'g' allotype and caused by reduced isotype switching	AR	14q32.33	Yount et al., 1967
g. $\gamma$ 4 subclass deficiency <i>IGHG4</i>	IgG4 constitutes 4% of serum IgG	AR	14q32.33	23
h. IgG subclass deficiency with or without IgA deficiency	Defect in differentiation of a B lymphocyte subset or in expression of IgG	Unknown	—	23
i. $\epsilon$ isotype deficiency <i>IGHE</i>	IgE is encoded by a single gene	AR	14q32.33	23
3. Light-chain deficiency				
a. $\kappa$ light-chain deficiency <i>IGKC</i>	$\kappa$ light chain binds to a heavy chain to form immunoglobulins	AR	2p11	Stavnezer-Nordgren et al., 1985
4. Common variable immunodeficiency (for WHIM see F8)				
a. Common variable immunodeficiency of unknown origin	Serum IgG low, IgA low or absent, IgM variable. Variable impairment of T cell function	Complex	—	23
b. ICOS (inducible costimulator) deficiency <i>ICOS</i>	ICOS is expressed by activated T cells and interacts with ICOSL (B7RP-1). Deficiency results in late-onset B cell loss	AR	2q33	23
c. CD19 deficiency <i>CD19</i>	CD19 antigen expressed by B cells	AR	16p11.2	23
d. TACI deficiency <i>TNFRSF13B</i>	Tumor necrosis factor receptor super family member 13B	AD, AR	17p11.2	23
e. BAFF receptor deficiency <i>TNFRSF13C</i>	Tumor necrosis factor receptor super family member 13C	AR	22q13.1–q13.3	23
5. Other antibody deficiencies				
a. Antibody deficiency with normal immunoglobulin levels	Defective antigen-specific antibody production	Unknown	—	43
b. Transient hypogammaglobulinemia of infancy	Delayed maturation of T cell helper function	Unknown	—	Gitlin and 1956; Tiller and Buckley, 1978; Kilic et al., 2000
6. Defects of class-switch recombination and somatic hypermutation (hyper-IgM syndromes) affecting B cells; see also A.7.				
a. AID deficiency <i>AICDA</i>	Activation-induced cytidine deaminase	AR	12p13	20
b. UNG deficiency <i>UNG</i>	Uracil-DNA glycosylase	AR	12	20
c. Selective deficiency in Ig class-switch recombination	Defect downstream of AID, normal somatic hypermutation	Unknown	—	20
<i>C. Defects in Lymphocyte Apoptosis</i>				
1. Autoimmune lymphoproliferative syndrome (ALPS); see also D.2.				
a. ALPS type Ia (defective CD95) <i>TNFRSF6</i>	Apoptosis mediator CD95 (Fas/APO-1) required for lymphocyte homeostasis Induces apoptosis via engagement of FasL	AD, AR	10q23–q24.1	24
b. ALPS type Ib (defective CD178) <i>TNFSF6</i>	Fas Ligand (FasL). Inducing apoptosis via engagement of Fas	AD	1q23	24
c. ALPS type IIa (caspase 10 deficiency) <i>CASP10</i>	Caspase 10; apoptosis-related cysteine protease	AR	2q33–q34	24
d. ALPS type IIb (caspase 8 deficiency) <i>CASP8</i>	Caspase 8; apoptosis-related cysteine protease <i>CASP8</i> and <i>CASP10</i> are adjacent genes	AR	2q33–q34	24
<i>D. Other Well-Defined Immunodeficiency Syndromes</i>				
1. Wiskott-Aldrich syndrome, X-linked thrombocytopenia and X-linked neutropenia <i>WASP</i>	Wiskott-Aldrich syndrome protein (WASP), especially important in platelets and T cells	XL	Xp11.22	31

(continued)

**Table 1.1.** (continued)

<i>Designation and Gene Name*</i>	<i>Defective Protein, Pathogenesis</i>	<i>Inheritance</i>	<i>Locus</i>	<i>Reference or Book Chapter</i>
2. Autoimmune disorders; see also C.1.				
a. APECED (autoimmune polyendocrinopathy with candidiasis and ectodermal dystrophy) <i>AIRE</i>	Autoimmune regulator-1 (AIRE-1) or APECED protein. Transcription factor expressed in the thymus	AR	21q22.3	25
b. IPEX (immune deficiency/dysregulation, polyendocrinopathy, enteropathy, X-linked) <i>FOXP3</i>	Forkhead box P3 transcription factor. Expressed by CD4 <sup>+</sup> CD25 <sup>+</sup> regulatory T cells (T reg)	XL	Xp11.23	26
3. X-linked lymphoproliferative syndrome (Duncan disease) <i>SH2D1A</i>	SH2 domain protein 1A (also called SLAM-associated protein, SAP). Involved in intra-cellular signaling of T and NK cells; protects against severe outcome of EBV infection	XL	Xq25–q26	32
4. DiGeorge/velo-cardio-facial syndrome. (22q11.2 deletion syndrome) <i>DGCR</i>	Multiple congenital anomalies most often due to deletion of <i>DGCR</i> (DiGeorge chromosomal region). Developmental defect of thymus. May be associated with congenital heart disease, hypoparathyroidism, and other congenital abnormalities	AD	22q11.2	33
5. CHH (cartilage-hair hypoplasia) <i>RMRP</i>	RNA component of mitochondrial RNA-processing endoribonuclease	AR	9p13	36
6. Hyper-IgE recurrent infection syndrome (Job syndrome)	Unknown	AD, AR, Sporadic	Some cases Chromosome 4	34
7. Chronic mucocutaneous candidiasis	Unknown	AR, AD	2p (AD)	Chilgren et al., 1967; Atkinson et al., 2001
<i>E. Defects of Phagocyte Function</i>				
1. Chronic granulomatous disease caused by defective intracellular oxidative burst required for bacterial and fungal killing.				
a. X-linked CGD <i>CYBB</i>	Cytochrome phagocyte oxidase (phox) gp91 <sup>phox</sup> . Cytochrome b-245 $\beta$ -polypeptide	XL	Xp21.1	37
b. p22 <sup>phox</sup> deficiency <i>CYBA</i>	Cytochrome oxidase p22 <sup>phox</sup>	AR	16q24	37
c. p47 <sup>phox</sup> deficiency <i>NCF1</i>	Cytochrome oxidase p47 <sup>phox</sup>	AR	7q11.23	37
d. p67 <sup>phox</sup> deficiency <i>NCF2</i>	Cytochrome oxidase p67 <sup>phox</sup>	AR	1q25	37
2. Leukocyte adhesion defects (LAD)				
a. LAD1 <i>ITGB2</i>	CD18 cell surface protein. Cell surface adhesion complex (CD11a,b,c/CD18) requires integrin $\beta$ 2 (CD18) to be stably expressed	AR	21q22.3	38
b. LAD2 <i>NAALLAD2</i>	N-acetylated $\alpha$ -linked acidic dipeptidase2. Fucose transporter required for proper carbohydrate addition; patient cells lack sialyl-Lewis X	AR	11q14.3–q21	38
c. LAD3	Defect in G protein-coupled receptor (GPCR)-mediated stimulation of integrins at the endothelial contact. May affect Rap-1 regulation	AR	Unknown	38
d. LAD with RAC2 deficiency <i>RAC2</i>	RAS-related, RHO family small GTP-binding protein RAC2. Predominant in neutrophils, involved in O <sub>2</sub> <sup>-</sup> production, actin cytoskeleton	AR	22q12.13–q13.2	38
3. Chediak-Higashi syndrome <i>LYST</i>	Lysosomal trafficking regulator. Required for formation of lysosomes and cytoplasmic granules	AR	1q42–q43	40
4. Griscelli syndrome				
a. Griscelli syndrome type 1 <i>MYO5A</i>	Myosin-VA (5A). Involved in organelle transport	AR	15q21	41

(continued)

**Table 1.1.** (continued)

<i>Designation and Gene Name*</i>	<i>Defective Protein, Pathogenesis</i>	<i>Inheritance</i>	<i>Locus</i>	<i>Reference or Book Chapter</i>
b. Griscelli syndrome type 2 <i>RAB27A</i>	Rab27A, GTP-binding protein. Regulates cytotoxic granule exocytosis associated with the accelerated phase of Griscelli syndrome. Myosin-VA (5A) and Rab27A are closely linked on chromosome 15q21	AR	15q21	41
5. Glucose 6-phosphate dehydrogenase deficiency <i>G6PD</i>	Granulocyte intracellular killing defect associated with complete absence of G6PD in phagocytes	XL	Xq28	37
6. Myeloperoxidase (MPO) deficiency <i>MPO</i>	MPO is required to convert H <sub>2</sub> O <sub>2</sub> to hypohalous acid. Intracellular killing of fungi is impaired.	AR	17q23.1	Lehrer and Cline, 1969; Nauseef et al., 1994
7. Glycogen storage disease type 1b <i>SLC37A4</i>	Solute carrier family 37 (glycerol-6-phosphate transporter), member 4. Neutropenia, impaired neutrophil migration due to defective glucose 6-phosphate translocase	AR	11q23.3	Hiraiwa et al., 1999
8. Neutropenia				
a. Cyclic neutropenia and severe congenital neutropenias <i>ELA2</i>	Neutrophil elastase 2. Includes Kostmann syndrome	AR (AD)	19p13.3	39
b. Congenital X-linked neutropenia <i>WASP</i>	Wiskott-Aldrich Syndrome Protein (WASP)—see D.1	XL	Xp11.22	31
9. Dyskeratosis congenita <i>DKC1</i>	Dyskeratosis congenita 1, dyskerin. Affected males have epithelial abnormalities, cancer predisposition, bone marrow failure	XL	Xq28	Heiss et al., 1998

studied extensively over several years and known to be essential for lymphocyte activation, no one had predicted that CD45 deficiency would result in human severe combined immunodeficiency (SCID) (Chapter 13). In an even more unexpected development, the identification of a defective RNA component of an endoribonuclease as the cause of cartilage-hair hypoplasia was certainly not anticipated (Chapter 36).

### **Infections, Autoimmunity, and Cancer: Features of Genetic Immunodeficiencies**

The hallmark of primary immunodeficiencies is an increased susceptibility to infections. However, both malignancies and autoimmune disorders are known to occur at high rates, compared to

their incidence in control populations, in patients with certain immunodeficiency syndromes. In this book we have included diseases caused by genes encoding functionally important components of lymphocytes, phagocytes, and proteins in the innate immune system. This means that we have broadened the traditional meaning of the word *immunodeficiency*, which was introduced to describe the lack of a component protecting an individual from infections. The majority of leukocyte abnormalities indeed cause susceptibility to infections. In some diseases the defective component is only expressed in leukocytes, and the defect, therefore, is inherent to this lineage. In other abnormalities, such as ataxia telangiectasia (Chapter 29), Bloom syndrome (Chapter 30), and DiGeorge anomaly (Chapter 33), the gene is expressed outside the hematopoietic lineage and nonimmune

features may even prevail. Among patients with most complement defects and periodic fevers, abnormal susceptibility to infection is less pronounced.

Autoimmunity is often a complex phenomenon involving dysregulation or imbalance in immune pathways and networks. However, discovery of apoptosis defects associated with autoimmunity, such as the mutations in the apoptosis mediator CD95 (Fas) in patients with autoimmune lymphoproliferative syndrome (ALPS), illustrates that mutations in a single gene can have an important effect (Chapter 24). This syndrome is often due to a dominant interfering mutation of CD95 that impairs physiologic apoptosis with the subsequent potential for accumulating self-reactive lymphocytes, which in turn mediate autoimmune responses. More generally, the observation was made many years ago that the incidence of autoimmune disorders is increased in certain primary immunodeficiency diseases, such as common variable immunodeficiency and immunoglobulin A (IgA) deficiency (Chapter 23) and Wiskott-Aldrich syndrome (Chapter 31).

Allergy is recognized as having a genetic component, but at present is not associated with a single-gene primary immunodeficiency. However, high levels of IgE are associated with hypomorphic mutations (i.e., with residual protein activity) in the genes, which cause Omenn syndrome (Chapter 11) and in patients with the Wiskott-Aldrich syndrome or immune dysregulation, polyendocrinopathy, enteropathy with X-linked inheritance (IPEX). In certain hyper-IgE syndromes, which can be inherited as an autosomal dominant or recessive trait, very high levels of IgE are found, but the molecular cause is not yet known (Chapter 34).

Enhanced tumor susceptibility is not a hallmark of all primary immunodeficiencies, but in certain disorders such as Wiskott-Aldrich syndrome (WAS) the frequency of malignancy, particularly lymphoma, is known to be high (Chapter 31). Malignancies in immunocompromised individuals may be secondary to chronic infections, which may induce overstimulation of the immune system and thus increase the risk of transforming mutations associated with cell division. Tumor development in patients with primary immunodeficiencies has also been attributed to defective

“immune surveillance” on the theory that the immune cells, particularly natural killer (NK) cells, are programmed to eliminate transformed cells. Another mechanism contributing to tumor development is impaired eradication of microorganisms with an oncogenic potential such as Epstein Barr virus (EBV); EBV lymphoproliferative disease is seen in several immunodeficiencies, particularly X-linked lymphoproliferative disease (Chapter 32). In some inherited immunodeficiencies with an increased incidence of tumors, however, such as Artemis deficiency and Bloom syndrome, the mutated gene encodes an enzyme affecting DNA breakage and rejoining (Chapters 11, 29, and 30).

### Genetic Immunodeficiencies in the Spectrum of Host Defense Disorders

The immune system is part of the multifaceted general defense system evolved to protect higher organisms from harmful invasion of microorganisms. The first lines of defense against infections are anatomical, mechanical, and chemical barriers. When the skin or mucosa is breached—for instance, by a burn or abnormality involving the skin or respiratory tract (severe eczema, cystic fibrosis, or disorders of ciliary function in respiratory epithelium)—susceptibility to infections is readily apparent. Similarly, the normally low pH of the stomach or vagina and the action of secreted enzymes and antibacterial defensins discourage bacterial invasion. Because small numbers of potentially pathogenic organisms routinely get past these barrier defenses, the reticuloendothelial system, principally the spleen, serves to filter and neutralize invaders in the bloodstream. Thus splenic deficiency, most commonly due to sickling hemoglobinopathies, is a major cause of immune compromise. Phagocytes and lymphocytes and their humoral products constitute a highly specialized and coordinated network responsible for selective recognition and elimination of microorganisms that have passed through the body's outer barriers.

The most common causes of immunodeficiency worldwide are acquired. These are most often malnutrition and immunosup-

**Figure 1.1.** Simplified schematic diagram of mediators of leukocyte activation and interactions between T and B cells, macrophages, and neutrophils. Secreted, membrane-associated, and cytoplasmic proteins are labeled in boldface if primary immunodeficiency disorders are known to result when they are absent or defective. IL-Rc, common chain of IL-2, 4, 7, 9, and 15 receptors; IFN-R, interferon receptor; TCR, T cell receptor; SLeX, S-Lewis X receptor. For other abbreviations, see Table 1.1.

pression secondary to bacterial, fungal, parasitic, and particularly viral infections, not only with human immunodeficiency virus (HIV) but also with other viruses, such as measles and EBV. In developed countries, iatrogenic immunosuppression is also found in settings of cancer therapy, organ transplantation, and chronic steroid administration.

In contrast, diseases for which the primary cause is a heritable defect in an immune system gene are infrequent; the common estimate is around 1 per 10,000 births, but the true incidence is not known. Such rare events might be considered to have limited significance on the global scale. However, an understanding of rare, heritable immunodeficiencies at the molecular level helps physicians diagnose and treat individuals with acquired immune deficits. There is also a long list of additional inherited syndromes that appear related to immune deficiency (Ming et al., 1996). The recent appreciation of the interplay between different combinations of inherited and environmental factors promises to help investigators uncover the molecular etiology of more common disorders with complex inheritance, such as the majority of common variable immunodeficiency and IgA deficiency although also here single gene defects without any known environmental influence have been identified (Chapter 2). On the other hand, a certain genetic makeup may protect an individual from infections; for example, persons lacking the chemokine receptor CCR5 on the surface of their T cells are relatively protected from HIV infection, as this virus uses CCR5 as a coreceptor (Deng et al., 1996; Dragic et al., 1996; Biti et al., 1997).

Although this book's main focus is on the recognizable, single-gene primary immunodeficiency syndromes and their molecular defects, the advances in understanding of these diseases have furthered our knowledge of the normal development and function of each component of the immune system. New insights from primary immunodeficiency demonstrate that efficient protection against microorganisms depends not only on the performance of each individual component but, equally important, on a flawless interdigitation of the innate immune system, neutrophils, and activated T and B lymphocytes.

Figure 1.1 shows a simplified diagram of many major components of the immune system and of gene products that are critical for the development and regulation of immune responses. Each of the molecules highlighted in bold letters has been associated with a primary heritable immunodeficiency. Under normal circumstances, the costimulation of B cells by antigens, antigen-activated T cells, and lymphokines results in the production of antibodies of evolving isotypes from IgM to IgG and with increasingly high affinity. These antibodies form antigen-antibody complexes to opsonize microorganisms, neutralize viruses, and activate the complement cascade. Some of the complement subunits liberated during complement activation are potent chemotactic agents that attract neutrophils and macrophages. To emigrate from the vascular spaces, phagocytic cells need adhesion molecules and a cytoskeletal system that permits movement. To trap antigen for presentation to T cells, macrophages with Fc and complement receptors and also follicular dendritic cells and B cells are strategically distributed throughout the tissues. Before the T- and B-cell-specific responses to invasion can be mobilized, the innate immune system provides significant basic protection.

### Evolution of the Classification of Genetic Immunodeficiencies

The first descriptions of immunodeficiency diseases grew out of clinical observations of patients with recurrent, severe, or un-

usual infections, the common denominator of most genetically determined primary immunodeficiency disorders. The types of pathogenic organisms, the course of the infections, and the effectiveness of available therapies were, over time, recognized to be correlated with the nature of the immune defect. These clinical observations remain the most important tools for suspecting and diagnosing patients with immunodeficiency (see Chapter 43). For example, recurrent sinopulmonary infections might suggest an antibody disorder, while bacterial, viral, and fungal infections, which fail to respond to conventional treatment, suggest T cell or combined defects.

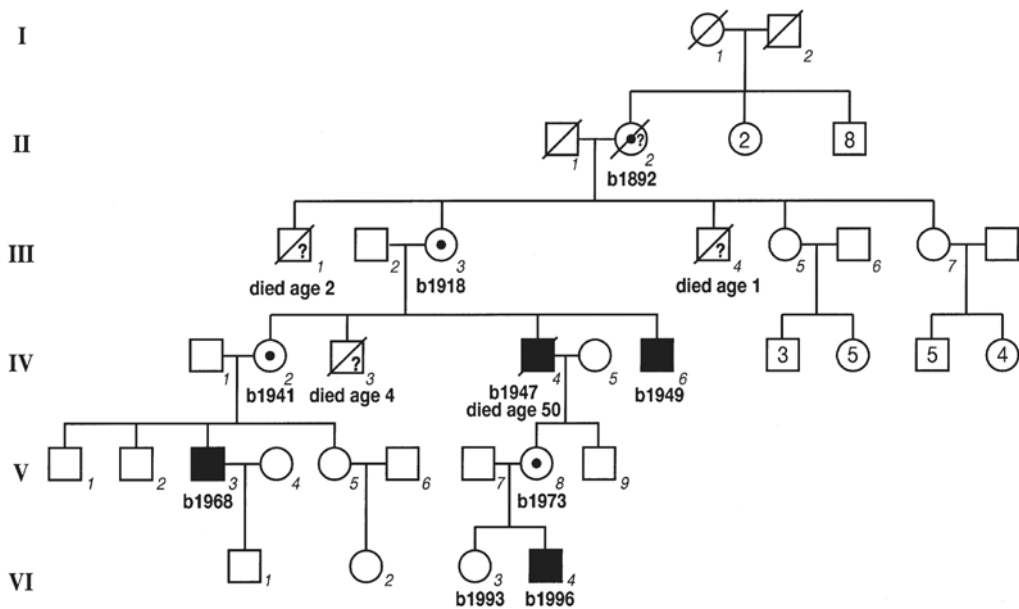

As our appreciation of the different host defense mechanisms has progressed, new immunologic tests have evolved that have improved the diagnostic capability of physicians caring for patients with an abnormal predisposition to infection. From the discovery of agammaglobulinemia and its consequences by Bruton (1952) to the enumeration and phenotyping of B cells, T cells, and T-cell subsets and the functional testing of lymphocytes and phagocytes *in vitro*, we have come a long way in understanding normal immune processes and recognizing specific abnormalities in immunodeficient patients. Classification combining immunological tests and empirical observations has in turn led to improved therapeutic approaches, such as immunoglobulin replacement for patients with agammaglobulinemia.

Grouping of human immunodeficiencies into a series of syndromes by clinical presentation and laboratory findings has made it possible to recognize how dysfunction of each of the distinct branches of the immune system, and in some cases genetically distinct disease entities, can produce a particular pattern of infections and clinical presentations. Such a disease classification system has been composed and periodically updated by the World Health Organization Scientific Group on Primary Immunodeficiency Diseases (WHO Scientific Group, 1995, 1997; Chapel et al., 2003). As new syndromes have been discovered and their associated genes identified, the nomenclature describing primary immunodeficiency disorders has been modified and expanded (Wain et al., 2002, 2004).

Molecular disease classification is now being integrated with ever-more sophisticated and specific *in vitro* testing of immune cell functions. This new level of definition serves to refine further the clinical and laboratory classifications already established, making possible longitudinal clinical follow-up and tailoring of treatments for each genotype. In Table 1.1 a summary of currently recognized primary disorders of the immune system is given and each disorder associated with a known disease gene has the gene name listed along with the disease name. The logical extension of this type of classification is to gather information from large numbers of patients with each specific gene disorder into databases that include clinical presentation, molecular data including specific gene mutations, treatments, outcome, and long-term follow-up. Some attempts in this direction have already been made (Smith and Vihinen, 1996; Levy et al., 1997; Winkelstein et al., 2003); the rarity of each individual disorder dictates that databases of pooled patient information are necessary to provide unprecedented ability to analyze the immunodeficiency diseases.

### Spectrum of Clinical Immunodeficiency Syndromes

How many mutated genes causing primary immunodeficiency diseases are there? Mutations interfering with expression may be irrelevant if the gene product is redundant or nonessential; mutations may escape detection by producing profound abnormalities

**Figure 1.2.** Pedigree of a family with X-linked agammaglobulinemia (XLA), illustrating medical progress in diagnosing and treating affected males. Males, squares; males diagnosed with XLA, filled squares. Females, circles; mutation carriers, circles with filled center. Slash, deceased. Individuals who may have had the XLA mutation are indicated with a question mark. Year of birth (b) and age of death are indicated for selected individuals. Individuals III-1, III-4, and IV-3 died of pneumonia. IV-4 died of pulmonary insufficiency, having suffered many bouts of pneumonia from early childhood until diagnosis at age 7.

incompatible with viability; or mutations may cause a heritable disease with a characteristic phenotype. The total number of genes in humans is estimated to be around 22,000. Estimates based on subtraction experiments suggest that the number of genes primarily involved in leukocyte development and function may be more than 1000. Allowing for some redundancy, somewhat fewer than 1000 single-gene primary immunodeficiencies might be possible, around seven times the number now recognized in Table 1.1.

The more common single-gene immunodeficiency diseases have been studied extensively, but their true frequencies in different populations are still only roughly estimated. The most frequently seen monogenic primary immunodeficiencies are X-linked, requiring only a single mutational event to be manifest. More than 2000 patients with one of five X-linked immunodeficiencies have recently been collectively registered and reported (see Chapter 45). There are far more immunodeficiency disorders that are inherited as autosomal recessive traits. However, because they require loss of function of both copies of a gene on homologous chromosomes, the incidence of these diseases is far lower. If one considers that an estimated number of genetically determined human diseases is around 5000 and over 2300 have been mapped on the human genome (Online Mendelian Inheritance in Man, 2005), it is clear that many potential primary immunodeficiency disorders have so far not been identified as distinct entities. If they have actually occurred, they may have presented as sporadic cases and not been recognized as genetically determined immune deficiencies.

Furthermore, mutations located in different regions of the same gene may cause diseases with different manifestations or phenotypes, referred to as *allelic heterogeneity* (see Chapter 2). This is exemplified by mutations of the WAS gene, some of which tend to present as full-blown WAS, whereas others are more regularly associated with X-linked thrombocytopenia and still others with isolated neutropenia (see Chapter 31).

### Progress in Diagnosis and Treatment

Progress in immunology, genetics, and molecular biology has changed the way we diagnose and treat affected patients. This is illustrated by the histories of families with multiple generations

of affected members. Figure 1.2 represents a kindred now recognized to be carrying X-linked agammaglobulinemia (XLA) (Chapter 21). Inspection of the pedigree reveals that individual III-3, born in 1918, is an obligate carrier of this condition. It is interesting that she had two brothers who died early in life; although definitive information is lacking, they may have been affected with XLA. Her oldest son, IV-3, suffered from recurrent upper and lower respiratory tract infections and died of pneumonia in 1948 at the age of 4 years. Her two younger sons, IV-4 and IV-6, were able to receive the newly available antibiotic penicillin. They survived multiple episodes of pneumonia and were diagnosed with XLA in the mid-1950s, shortly after Bruton's discovery of agammaglobulinemia (Bruton, 1952). By the time intramuscular immunoglobulin treatment was instituted, both boys had developed chronic lung disease and bronchiectasis. IV-4 was one of the first patients treated with high doses of intravenous immunoglobulin (IVIG) for echovirus infection with dermatomyositis, fasciitis, and meningitis (Mease et al., 1981). He died of chronic respiratory failure at the age of 50.

The younger generations of this family have a much more hopeful prognosis. When individual V-3 developed his first pneumonia at the age of 2, he was referred to a university center, where the diagnosis of XLA was confirmed and treatment with immunoglobulin was initiated. He has remained healthy with regular immunoglobulin replacement and presently has a full-time job and no chronic disease. XLA was diagnosed in the youngest member of this kindred, VI-3, at the time of birth by documentation of absent B cells in cord blood. He was immediately started on immunoglobulin treatment and remains completely healthy.

Gene therapy has been pursued in primary immunodeficiencies since the early trials of gene replacement for adenosine deaminase (ADA) deficiency in 1990 (Chapter 48). However, only in 2000 was therapeutic benefit achieved, when patients with X-linked SCID became the first humans to have their disease reversed by gene therapy as their sole treatment (Cavazzana-Calvo et al., 2000). Recent reports of highly effective gene therapy protocols for both X-linked SCID, due to common  $\gamma$ -chain deficiency, and ADA SCID (Aiuti et al., 2003) demonstrate the

promise of correction of known gene defects in hematopoietic stem cells, which can then be self-renewing and capable of differentiating into healthy and functional immune cells. However, the occurrence of a leukemia in three X-linked SCID patients due to insertion of the retroviral gene vector near a T-cell transcription factor, LMO-2 (Hacein-Bey-Abina et al., 2003), indicates that further research into gene therapy will be needed to improve its safety as well as efficacy.

### Genetic Services for Families with Genetic Immunodeficiencies

With an incidence estimated at 1 per 10,000 births and heavy use of medical care services by affected patients, the impact of significant primary immunodeficiency diseases as a whole on health care is considerable. The incidence of immunodeficiencies is lower than that of cystic fibrosis in Caucasians or of congenital hypothyroidism (about 1 per 2500) but comparable to that of phenylketonuria (1 per 10,000) (Scriver et al., 2001). Because of the large number of specific immunodeficiency entities and their widely varying abnormalities, population screening has not yet been implemented for this group of diseases. Therefore, maintaining a high index of suspicion through education of physicians and the public is essential for timely diagnosis.

Precise genetic diagnosis conveys benefits to patients, their families, and the health care system. Because even patients with X-linked immunodeficiencies often have a negative family history, recognition that the condition is genetic is important. Prediction of recurrence risks, genetic counseling, and carrier and prenatal testing are now available for a large number of immunodeficiencies (Chapter 44).

### Genetic Immunodeficiencies and Immunology

The pleiotropy of primary immunodeficiency diseases has become even more evident and reflects the complexity of the human immune system itself. The existence of multiple molecular defects underlying similar phenotypes has helped in elucidating critical immune system components. This is well illustrated by the recent discovery of several new genes (*AID*, *UNG*, *CD40*) related to failure to generate IgG, IgA, and IgE immunoglobulins while making normal or increased levels of IgM, originally named “hyper-IgM syndrome.” In the most common form of this syndrome, the X-linked form, affected individuals carry mutations in the gene for CD40 ligand (*CD40L*) (Chapter 19). Identification of autosomal recessive forms of the syndrome has been crucial for our current understanding of the phenotypic variation among these patients. Thus, the former assembly of patients with “hyper-IgM” into one major group is outdated. Instead, disease-specific criteria have been redefined. In many patients an increased level of IgM is not found; furthermore, the spectrum of infections varies among individuals with mutations in different genes. Thus, in the defects for CD40 ligand and its receptor CD40, cellular immunity is impaired in addition to the humoral defect. Conversely, mutations in the *AID* and *UNG* genes are phenotypically restricted to the B cell lineage. The distinct gene abnormalities produce susceptibility to different classes of infections as well as having different histopathological changes in secondary lymphoid organs. Thus, basic immunology research receives critical clues from humans with immunodeficiencies that cannot always be appreciated, or may not even exist, in animal models.

# Genetic Principles and Technologies in the Study of Immune Disorders

JENNIFER M. PUCK and ROBERT L. NUSSBAUM

Medical genetics is the subspecialty of medicine concerned with the investigation, diagnosis, treatment, counseling, and management of patients and families with inherited disease. Research in medical genetics focuses on identifying the genes involved in human hereditary diseases and the changes in DNA sequence that cause or predispose to these diseases; elucidating disease pathogenesis, including both genetic and environmental factors; understanding the inheritance patterns of diseases in families; developing new treatments or cures for hereditary disorders; and helping patients and families make reproductive decisions and cope with the impact of genetic disorders on the health of family members. Although a complete discussion of medical genetics is beyond the scope of this book and can be reviewed in several texts (Vogel and Motulsky, 1996; Scriver et al., 2001; Nussbaum et al., 2006), it is essential to present here an overview of the terminology, concepts, and methods of modern molecular genetics. This introduction will outline the approaches that have led to the identification of the genes involved in over 140 specific disorders of the immune system. These findings should make possible further revolutionary changes, not only in the discovery of additional disease genes, but also in understanding the pathogenesis of defects in host defenses. Using this understanding, we may create effective new therapies.

The normal complement of 46 chromosomes in a human cell consists of 23 pairs of homologous chromosomes (Fig. 2.1). Twenty-two of the 23 pairs are *autosomes* and are the same in men and women; the remaining pair, the *sex chromosomes*, consist of two X chromosomes in females and one X and one Y (carrying the male-determining genes) in males. The two homologous chromosomes that make up any of the 22 pairs (23 pairs in females) are identical in size, centromere placement, and arrangement of genes.

It is customary in human genetics to refer to the location of a particular gene on a chromosome as the *locus* for that gene. The DNA sequence in and around a gene (such as in introns, flanking regions, or even within coding regions) may be variable among the individuals in the population. The term *allele* is used to describe different DNA sequence variants, and the particular pair of alleles an individual possesses for a given gene is called the *genotype*. Alleles can be rare, deleterious mutations that cause disease, or fairly frequent normal variants of no known clinical significance. If greater than 2% of the population has a DNA sequence that differs from the DNA sequence in other individuals, the variation is called a *polymorphism*. A group of polymorphic alleles at a set of loci close together in a row on a single chromosome is called a *haplotype*. Because the loci are close to each other, recombination between homologous chromosomes will occur only rarely in the region containing these loci and therefore the entire block of alleles contained in a particular haplotype tend to be inherited together.

## Mechanisms of Inheritance

### Mendelian vs. Complex Inheritance

*Mendelian inheritance* is a term used to describe the hereditary patterns seen in diseases caused by DNA mutations in single genes inherited from parents by their offspring. Thus, Mendelian disorders include most of the rare primary immunodeficiency diseases described in this book. An increasing awareness of a genetic contribution to other diseases has led to the designation *non-Mendelian* or *complex inheritance* to refer to instances in which an individual's genetic makeup has a more variable and more complex role in disease causation. Examples of complex

**Figure 2.1.** Normal human metaphase chromosomes from a male, aligned to show the 22 pairs of autosomes, plus one X and one Y. The banding pattern is revealed by Giemsa staining. Giemsa-light regions are particularly rich in genes. (Kindly provided by Amalia Dutra.)

diseases include multifactorial diseases in which one or more gene mutations must interact with each other and/or environmental factors in order for a disease to be manifest.

### Autosomal Recessive Inheritance

In autosomal recessive inheritance (Fig. 2.2), disease usually results when a person inherits two defective copies of the same autosomal gene; the affected individual can be either a homozygote, if two identically defective copies of the same gene are inherited, or a compound heterozygote if there are two different deleterious mutations in the gene. The parents are unaffected heterozygotes who carry one normal copy and one abnormal copy of the gene. By definition, in recessive disease, heterozygous carriers of recessive disorders are not affected because the normal copy of the gene compensates for the defective copy. The typical familial inheritance pattern in autosomal recessive illness is for disease to occur in one or more full brothers and sisters, with both genders affected equally and both parents unaffected. Recessive disorders are seen with increased frequency in children of consanguineous marriages, in which the parents are related to each other (Fig. 2.2), and in genetically isolated populations, because both parents have a greater chance of carrying the same defective gene inherited from a single common ancestor. The genotypes of affected individuals in such instances are expected to show homozygous mutations. A lack of family history is not an argument against autosomal recessive inheritance because, with small sibship sizes typical of many contemporary families, a single affected child born to unaffected parents is the rule rather than the exception.

**Figure 2.2.** Autosomal recessive inheritance. Circles, females; squares, males; filled symbol, affected; symbol with dot, silent carrier. Roman numerals designate generations, with each individual within a generation identified by an integer. This pedigree demonstrates a consanguineous mating, double horizontal line, between cousins III-1 and III-2 (a typical, but not required characteristic of autosomal recessive disease pedigrees). An arrow marks the proband, the first person in the family to come to medical attention. For updated conventions for pedigree drawing, see Bennett et al. (1995).

Recessive illness usually results from loss of function of a gene whose product is normally present in excess so that even a half-normal amount of the gene product is adequate to prevent disease. For example, homozygotes with deletion of the first exon of the gene encoding adenosine deaminase (ADA) have a profound deficiency of the enzyme, resulting in early onset of severe combined immunodeficiency (SCID) (see Chapter 12). In contrast, heterozygotes, with one deleted and one functional copy of the gene, have an amount of enzyme activity intermediate between that found in normals and that in patients with ADA-deficient SCID; but even a small fraction of the normal activity is sufficient to protect them from expressing any immunological defect.

### Autosomal Dominant Inheritance

In autosomal dominant inheritance (Fig. 2.3), an individual needs only one copy of a gene alteration for the disease to occur. The parent from whom the genetic alteration was inherited may himself or herself be affected, or may be a silent, or *nonpenetrant*, carrier. Alternatively, neither parent may harbor the alteration seen in the child if the child's mutation arose spontaneously in one of the two gametes, egg or sperm, from which the child was formed. The typical inheritance pattern in autosomal dominant illness is to see multiple affected individuals, both genders affected equally, with transmission of the disease from one generation to the next. A lack of family history is not a strong argument against autosomal dominant inheritance, however, because a nonpenetrant carrier parent or a new mutation will make the affected individual appear as a sporadic occurrence of the disease in the family.

If a dominantly inherited condition requires the presence of an alteration on only one chromosome, it would seem contradictory that some heterozygotes for the defective gene can show no evidence of the disease (lack of penetrance), as illustrated for individual II-4 in Figure 2.3. However, such lack of penetrance is a well-described phenomenon in autosomal dominant disorders. Incomplete penetrance is seen if the onset of the disorder is age-dependent or if an additional factor or factors, such as a second spontaneous somatic mutation or an environmental agent or influence, must be superimposed on the underlying genetic defect in order for the disease to become clinically evident.

Mutations can cause dominantly inherited diseases through a number of different mechanisms. In the most straightforward situation, abnormal amounts of the gene product may be inadequate or allow accumulation toxic metabolites. For example, deficiency of one copy of a gene or multiple genes contained within microdeletions of chromosome 22 is responsible for DiGeorge

syndrome (see Chapter 33). This model for dominant inheritance is called *haploinsufficiency*. In contrast, more than two copies of a gene may also cause disease inherited in an autosomal dominant manner, as is seen with duplication of the *PMP22* gene in Charcot-Marie-Tooth IA peripheral neuropathy (Boerkel et al., 2002) or triplication of the  $\alpha$ -synuclein gene in familial Parkinson disease (Singleton et al., 2003).

In a second pathogenetic mechanism, a *gain of novel function*, a dominant mutation may cause a new or altered protein to be made that is endowed with a novel or toxic activity not found in the normal gene product. An example is the acute myeloid leukemia M4Eo subtype associated with a somatic (not germline, and thus not inherited from one generation to the next) inversion of chromosome 16 (Liu et al., 1993). This chromosomal rearrangement causes the apposition of the 5' portion of the transcription factor gene *CBFB* with the 3' end of the gene encoding myosin heavy chain, a structural protein of muscle. The result is a chimeric protein that interacts in an abnormal way with other transcription elements to interfere with the normal transcription program of myeloid progenitor cells.

A third type of mutation frequently causing dominant inheritance is *dominant negative* mutation, such as that seen in most patients with an autoimmune lymphoproliferative syndrome (see Chapter 24). Patients with heterozygous mutations in the gene encoding the apoptosis mediator CD95 or Fas have defective programmed cell death through the homotrimeric Fas receptor complex. In vitro studies of the mutated gene products show not only failure of the mutant protein to transmit a death signal itself but also interference by these altered Fas proteins with death signal transmission by coexpressed normal Fas (Fisher et al., 1995). The mutated Fas proteins may produce steric interference when incorporated into the normal trimeric Fas receptor complex.

Finally, a mechanism operating in some dominantly inherited cancer syndromes is that of a *two-hit* process (Knudson, 1971). The first hit is an inherited mutation that inactivates one allele of a tumor-suppressor gene, rendering an individual heterozygous for the mutated gene. One defective allele for this type of inheritance is not in itself sufficient to cause disease. However, an individual who carries only one normal copy of a tumor-suppressor gene is at markedly increased risk for developing cancer. All that is required is that a single somatic cell undergo a second mutation inactivating the remaining normal allele for that one cell to undergo pathologic, unregulated growth and produce a clonal cancer. Second hits are frequently genomic deletions in a single cell as it divides, resulting in *loss of heterozygosity* at the disease locus in the tumor cells.

### X-Linked Inheritance

Mutations in X-linked genes have strikingly different consequences in males and females and cause diseases with a distinctive X-linked pattern of inheritance (Fig. 2.4). This is because of the different number of X chromosomes in males and females and the unique biological properties of the mammalian X chromosome. In a male carrying a defective X-linked gene, clinically apparent abnormality always occurs because his only copy of the gene is disrupted. Male hemizyosity for the X chromosome explains the large number of X-linked immunodeficiencies (Fig. 2.5) and the high proportion of males diagnosed with inherited immunodeficiency. In females with X-linked gene defects, the situation is more complex. In order to provide dosage compensation and to equalize gene expression for X-linked genes in males and females, one of the two X chromosomes in a female's somatic

**Figure 2.3.** Autosomal dominant inheritance. Note male-to-male transmission from subject II-2 to III-4, strongly suggesting dominant inheritance. II-4 is a nonpenetrant carrier. Circles, females; squares, males; filled symbol, affected; symbol with circle, at risk but currently unaffected carrier; arrow, proband.

**Figure 2.4.** X-linked inheritance. Circles, females; squares, males; filled symbol, affected; symbol with dot, silent carrier. Male-to-male transmission is not present.

cells is chosen at random, early in embryonic life, to undergo a near total and irreversible inactivation (Lyon, 1966). Thus, in contrast to the situation with a heterozygote for an autosomal gene mutation, a female heterozygous for an X-linked gene mutation does not have a uniform population of cells, each of which expresses both the normal and abnormal gene. Instead, the somatic tissues of a female are made of a mixture of cells, some of which have an active X chromosome carrying the normal gene, while the rest have an active X carrying the abnormal gene. The relative proportion of cells with one or the other X chromosome active in any one tissue averages 50%, but may differ substantially depending on chance and the number of precursor cells for that tissue that were present in the embryo when X inactivation took place. The fraction of cells in a tissue that have an active X chromosome carrying the normal gene is usually sufficient for normal function of the tissue, so female heterozygotes for X-linked disorders are usually silent carriers. If, however, the cells that

have inactivated the X chromosome carrying the normal gene predominate in a tissue, female heterozygotes may be symptomatic. Thus, the terms *dominant* and *recessive* as applied to autosomal disorders are not strictly applicable to X-linked diseases.

In female carriers of some X-linked conditions, such as X-linked SCID due to defects in the IL-2R $\gamma$  receptor (see Chapter 9) or X-linked agammaglobulinemia (XLA) due to defects in the Btk kinase (see Chapter 21), the expected random X inactivation in the lymphocyte population targeted by the gene defect is not seen (Puck, 1993). In these situations, a female carrier of X-linked SCID (or of XLA) will have no lymphocytes (or in the case of XLA no B cells) whose active X chromosome carries the mutation because the fraction of the lymphocyte precursors that have inactivated the X chromosome carrying the normal version of the gene cannot develop and differentiate normally. As a result, the target lymphocyte population for each disease will show marked “skewing” of X-inactivation. The abnormal X-inactivation pattern seen in X-linked immunodeficiencies is discussed in greater detail in the chapters related to specific diseases and in Chapter 44.

A typical X-linked inheritance pattern (Fig. 2.4) is characterized by multiple affected male siblings and cousins as well as affected males in additional generations, all affected members of the kindred being related through unaffected female relatives. However, a lack of family history does not rule out an X-linked inheritance mechanism for immune deficiency. As with autosomal dominant disorders, a spontaneous new mutation in an X-linked gene can cause the disease to appear in the family, either directly in a male, or by the creation of a silent female carrier who passes the mutation on to her male children. One-third of the cases of X-linked diseases severe enough to prevent reproduction by affected males are expected to be the first manifestation in their pedigree of a new mutation (Haldane, 1935). Because males donate a Y chromosome and not an X chromosome to their sons, documenting male-to-male transmission of any trait in any pedigree rules out X-linked inheritance.

### Heterogeneity

*Genetic heterogeneity* is a broad term used to describe departures from the simple models of “one gene—one enzyme” or “one mutation—one disease.” Diseases can show *allelic heterogeneity*, in which different mutations in the same gene cause disease, as is the rule in single-gene immunodeficiency diseases. *Locus heterogeneity* occurs in diseases such as SCID in which a similar phenotype of opportunistic infections from lack of cellular and humoral immunity can arise from mutations in a number of different genes; the diseases caused by mutations at these different

**Figure 2.5.** Idiogram of human chromosome X, illustrating the major Giemsa bands and conventional cytogenetic nomenclature, including p (short) arm and q (long) arm, integers denoting major bands increasing from centromere to telomere, and additional digits to the right of the decimal point denoting sub-bands. The loci on the X chromosome of known human immune disease genes are indicated.

loci are termed *genocopies*. In contrast, a *phenocopy* is an acquired, not a genetic, disease that resembles genetic forms of the disease.

Still more complicated models of inheritance appear to be operating in disorders such as common variable immune deficiency and IgA deficiency (see Chapter 23) or atopic disease. In these disorders one can observe a clearly increased incidence within families; however, an obvious Mendelian pattern of inheritance is not seen. A genetic contribution to such diseases is suspected when there is greater concordance of the disease in monozygotic (identical) twins than in dizygotic (fraternal) twins and when there is an increased risk for the disease in relatives of affected patients compared to that in the population at large. The risk of a second affected individual in a family is greater the closer the blood relationship with the proband. Such complex inheritance patterns, well described in asthma and insulin-dependent diabetes mellitus, are the result of interactions between genes at different loci combined with unidentified, but substantial environmental effects.

## How to Identify Disease Gene Loci

### Abnormal Protein Products

The first disease genes to be recognized as mutated in immune disorders were identified by defining abnormalities in their protein products. Adenosine deaminase deficiency was originally identified as a purine metabolic defect, and subsequently the absence of ADA enzyme activity was noted in patients who lacked lymphocytes and had immune defects (see Chapter 12; Giblett et al., 1972). This approach was fruitful in ADA-deficient SCID because the enzyme encoded by the disease gene turned out to be a “house-keeping” gene, expressed in all normal cells. It was subsequently appreciated that the amount of ADA protein normally found in lymphocytes is far greater than that in other tissues and that T cells are exquisitely sensitive to elevated levels of its substrates, including deoxyadenosine. These facts help to explain why ADA deficiency is much more harmful to lymphocytes than to other cell types, although effects on organs such as the liver and central nervous system are recognized. The general method of first identifying protein abnormalities in immune disorders and then documenting gene lesions has been less successful for disease genes that have restricted tissue expression or are only active in an early stage of differentiation of the target cell type. For these, positional cloning and testing for mutations in candidate genes have been essential.

### Cytogenetic Abnormalities

When clinical disorders are associated with abnormalities in the number or structure of an individual’s chromosome complement, cytogenetic techniques can lead to the identification of disease genes. Metaphase chromosomes from dividing cells can be stained with Giemsa to reveal segmental banding patterns that uniquely characterize each human chromosome (Fig. 2.1). Cytogenetic analysis involves comparison of each chromosome to the standard karyotype idiogram, as illustrated for the X chromosome in Figure 2.1. Hybridization of labeled DNA probes to denatured chromosomes, known as fluorescent *in situ* hybridization, or FISH (Color Plate 2.1), can pinpoint much smaller regions of the genome to indicate the chromosomal location of a disease-associated microdeletion, duplication, or rearrangement. The example in Plate 2.1 shows hybridization of a fluorescent labeled cosmid containing the Fas-associated death domain (*FADD*) gene to identify its localization to human chromosome 11q13.3 (Kim et al., 1996).

*Aneuploidy*, or abnormal chromosome number, is associated with immune defects. Trisomy 21, or Down syndrome, the most common genetic cause of human mental retardation, is accompanied by depressed *in vitro* immune responses and by increased incidence of autoimmunity and infections, the leading cause of death in Down syndrome (Epstein, 2001).

At the subchromosomal level, *contiguous gene deletion syndromes* are collections of clinical manifestations resulting from consistently observed chromosomal deletions spanning multiple neighboring genes. An example is the chromosome 11p13 deletion syndrome associated with Wilms tumor, aniridia, genitourinary anomalies, and mental retardation (Haber, 2001; Schaffer et al., 2001). Larger deletions produce the complete phenotype, while smaller disruptions involving single genes within the region produce limited phenotypes, such as isolated aniridia. A contiguous gene deletion syndrome in the context of an immunodeficiency has been postulated, but not proven, in DiGeorge syndrome, which is associated with deletions of chromosome 22q11 (see Chapter 33; Schaffer et al., 2001).

Rare or unique chromosomal abnormalities are occasionally found in the context of primary genetic disorders. Coexistence of a chromosomal translocation, duplication, or deletion and an abnormal phenotype in a patient is very unlikely to be a coincidence; rather, the cytogenetic lesion provides direct evidence for the genetic localization of a disease. One of the best examples of chromosomal abnormality leading to gene identification is the contiguous gene deletion syndrome produced by interstitial deletion of chromosome Xp21 in male patients suffering from multiple disorders including chronic granulomatous disease as well as Duchenne muscular dystrophy, retinitis pigmentosa, and McLeod hemolytic anemia (see Chapter 37; Schaffer et al., 2001).

### Disease Gene Localization by Linkage Mapping

#### DNA polymorphisms

Each child inherits one chromosome of each pair of homologous chromosomes from one parent and the other chromosome of the homologous pair from the other parent. The parent of origin of each chromosome in a pair can be identified by tracing the inheritance of *DNA polymorphisms*, small differences in DNA sequence between chromosomes. Polymorphic alleles for linkage analysis were originally detected by different lengths of the DNA segments seen on Southern blots of DNA digested with various restriction endonucleases (restriction fragment length polymorphisms, or RFLPs) (Drayna and White, 1985). By 1990, RFLPs were largely replaced by short tandem repeat polymorphisms (STRPs) composed of stretches of simple dinucleotide, trinucleotide, or tetranucleotide, repeats of variable length, such as CACACACA · · · CA. The number of repeats in an STRP can vary tremendously, with as many as a dozen alleles or more found in populations of healthy subjects. STRPs occur frequently in the genome and can be assayed by the polymerase chain reaction (Litt and Luty, 1989; Weber and May, 1989). More recently, single nucleotide polymorphisms (SNPs) have begun to replace STRPs as useful polymorphisms (Sachidanandam et al., 2001; Holden, 2002). Although SNPs are comprised of only two alleles and, therefore, are less informative than STRPs, they can be analyzed much more inexpensively than STRPs by high-throughput technology. Because SNPs are far more frequent, occurring approximately every 1000 base pairs, SNP variants are dense enough to

be used for association studies (see below). For more information on genetic marker loci, see Chapter 44.

### Meiotic crossing-over

In the absence of abnormal cytogenetic findings to point to the chromosomal locus for a genetic disorder, mapping of a disease gene usually relies on *linkage analysis* in kindreds in which the disorder affects multiple individuals. Gene mapping by linkage analysis is made possible by the normal phenomenon of *meiotic recombination*, or crossing-over during gametogenesis. During the first meiotic division, each pair of homologous chromosomes lines up randomly on the spindle and then separates in the course of the first reduction division of meiosis I. This independent assortment of chromosomes during meiosis I is responsible for randomly distributing one member of each pair of homologous chromosomes into each gamete. It is also in meiosis I that homologous segments of two chromatids form a pair of homologous chromosomes that interchange their genetic material by crossing over at points of contact, known as *chiasmata* (Fig. 2.6). On average, between two and four chiasmata develop between every pair of homologous chromosomes during each meiosis.

Suppose two polymorphic loci are situated at locus 1 and locus 2 on the same chromosome, as shown in Figure 2.6, and there are polymorphic alleles A and a at locus 1 and alleles B and b at locus 2. Also suppose that a parent is heterozygous at both loci (genotype Aa Bb), and, in addition, allele A at locus 1 happens to be on the same chromosome (same DNA molecule) as allele B at locus 2, while alleles a and b are both on the other chromosome. If no crossing-over occurs in the interval between locus 1 and locus 2 during meiosis, each gamete will receive either the chromosome containing alleles A and B or the one carrying alleles a and b (*nonrecombinant*). If, however, a crossing-over event between the two loci in the Aa/Bb individual occurs, the

**Figure 2.6.** Diagram of meiotic crossing-over involving two hypothetical loci, 1 and 2. Alleles at locus 1 are A and a, alleles at locus 2 are B and b. Recombinant gametes are products of a crossover event between locus 1 and locus 2.

resulting gametes will have a chromosome with a new (*recombinant*) combination of alleles, i.e., either alleles A and b or a and B. From a knowledge of the genotypes of parents and their offspring, one can count the number of offspring resulting from a gamete carrying a crossover between locus 1 and locus 2 and determine the observed *recombination frequency* with which crossing-over events happen between the two loci during gametogenesis.

If crossing-over occurs approximately uniformly along a chromosome, then the chance of a crossing-over event should reflect how far apart the two loci are on that chromosome. The further apart the loci are physically, the greater the chance that at least one crossover will occur between them; the closer they are to each other, the smaller the chance of crossing over. It is straightforward to show that if two loci are so far apart that at least one crossover will always occur in the chromosomal interval between locus 1 and 2 during gamete formation, then 50% of all the offspring will have the nonrecombinant and 50% the recombinant genotype (Nussbaum et al., 2006). At the other extreme, when two loci are so close together that crossovers almost never occur, the observed recombination frequency will approach zero. Between these two extremes are *linked* loci on a chromosome. These loci have less than 50% recombination in offspring since recombinants can arise only through a relatively rare crossing-over event that just happens to fall within the short segment of chromosome separating them. For such loci, the frequency of recombinant offspring will be somewhere between 0% and 50%. Thus, in principle one should be able to correlate recombination frequency with the actual distance between two loci. This is the case when two loci are reasonably close, with a recombination frequency less than 10%; recombination frequency then translates directly into a theoretical *genetic distance*, measured in units called *centiMorgans* (cM), where 1% recombination frequency is equal to 1 cM. This relationship does not hold when loci are loosely linked (recombination frequencies >10%–20%) because of the chance that two independent crossovers, rather than just one, will occur between the two loci. A double crossover will not be detected as a recombination between the two markers and, thus, the measured recombination frequency will always be less than the genetic distance in cM.

In physical terms, the average recombination rate across the entire genome is 1.2 cM per megabase (Mb) of DNA, which means that 1 cM of genetic distance represents approximately 830,000 base pairs of DNA (Kong et al., 2002). The correlation between genetic distance and molecular distance, however, can vary with the gender of the individual in whom the meiosis is occurring and the region of the chromosome being examined. Overall, across all 22 autosomes, the recombination rate in males is 0.9 cM per Mb whereas it is 1.5 cM per Mb in females, presumably because of biologic differences in meiosis I in female vs. male gametogenesis. As one looks at smaller and smaller segments of DNA, the average recombination frequency per DNA segment length becomes increasingly inhomogeneous. For example, telomeric regions have threefold higher recombination per unit length of DNA in males than do centromeric regions. At an even finer scale, recombination becomes very nonuniform, with some segments of a few thousand bases showing a 200 times higher recombination rate than that of neighboring segments of equal length (Jeffreys et al., 2001; Gabriel et al., 2002).

### Model-based linkage analysis

Linkage analysis is used to map genes responsible for diseases inherited in a classical Mendelian pattern (Borecki and Suarez, 2001). Affected and unaffected members of families in which the

disease is being inherited are studied by determining their genotypes at a large number of polymorphic genetic marker loci whose positions are known along each chromosome. Recombination events between the disease locus and all of the genetic markers are counted. If the inheritance pattern is known by inspection of the pedigree (model-based analysis), one can score each affected and unaffected individual as either showing or not showing a crossover between the disease locus and each marker locus tested to determine the recombination frequency. For most of the markers, one expects a 50% recombination frequency because they are not linked to the disease locus; indeed, most markers are not even on the same chromosome as the disease locus. If a marker seems to show less than a 50% frequency of offspring carrying chromosomes with a recombination between the marker locus and the disease locus, this marker locus may be linked to the disease locus.

How is the recombination frequency between the disease and particular marker loci actually measured and the significance of any apparent reduced recombination frequency below 50% assessed in a statistically valid manner? The statistical method used to measure the recombination frequency between genetic loci is called the maximum *LOD* (for logarithm-of-odds) score method, and its features are summarized in Table 2.1. The result of a LOD score analysis consists of two parts. The first part, called  $\theta_{\max}$  by convention, is the best estimate (in a statistical sense) of the recombination frequency between the disease locus and a polymorphic marker locus in a set of families. The value of  $\theta_{\max}$  is, therefore, a measure of genetic distance between two loci. The second parameter,  $z_{\max}$ , is a measure of how good that estimate of  $\theta_{\max}$  actually is. When  $z_{\max}$  is greater than 1.5, linkage is strongly suggested. If  $z_{\max}$  is larger than 3, the likelihood that the loci are linked is a thousand times ( $10^3$ ) greater than the likelihood that the linkage data are purely the result of chance. Thus LOD scores with  $z_{\max}$  of 3 or greater are taken as nearly definitive proof that two loci are linked.

LOD score analysis will demonstrate which polymorphic loci of known location are linked to the disease by finding the smallest value of  $\theta_{\max}$  with the largest  $z_{\max}$ , preferably 3 or greater. Linkage of the disease gene to a marker of known location on a chromosome thereby places the disease gene in the same general location as the marker on that chromosome.

Affected relative analysis (model-free linkage analysis)

Model-based linkage works best when one or a few loci of reasonably high penetrance are responsible for a disease and thus

demonstrate a Mendelian inheritance pattern in families. For many disease loci, no Mendelian pattern is discernible because there may be many loci of reduced penetrance as well as gene–gene and gene–environment interactions. In this situation, another approach to mapping disease genes is used, called the *affected-relative method*. This approach makes no assumption about the inheritance pattern of the disease (thus it is “model-free”) but simply relies on the fact that two siblings share half of their alleles, having inherited them from their parents. Or in genetic terms, siblings are identical by descent at half the loci in their genomes. If a particular gene contributes to the development of disease, however, then pairs of siblings who are both affected by the disease will share the alleles at loci linked to the disease gene significantly more frequently than 50% of the time.

The affected-relative method is inherently less powerful than linkage analysis but is more suitable than conventional linkage analysis for detecting a genetic contribution to disease when the disease shows significant lack of penetrance or is inherited as a complex trait. The affected-relative approach has been applied to autoimmune diseases, diabetes, asthma, and atopic disease.

Association Studies

Model-based and model-free linkage analysis both depend on looking in families for linkage between a disease gene and markers distributed throughout the genome. In contrast, association studies are done in populations, not families (Borecki and Suarez, 2001). Suppose a disease-producing or predisposing gene originated many generations ago (Fig. 2.7), in a region of a chromosome with a particular haplotype defined by a particular set of alleles at nearby loci (Todd, 2001). An association between the disease-producing or predisposing gene and this haplotype is likely to be preserved through many generations because the loci containing the alleles that define the haplotype are so close to the disease locus that they are unlikely to recombine during the many meioses that occurred as the disease gene was passed down through the generations (Jorde, 2000). In this case, the disease-causing allele and the alleles making up the haplotype at closely linked markers remain together, a situation known as *linkage disequilibrium*. As a result, the haplotype on which the disease gene originated will be found with increased frequency among affected individuals compared to in the population in general. Such in-

Table 2.1. Characteristics of the LOD Score

1. The LOD score is a measure of the degree of linkage between two genetic markers.
2. The LOD score information comes in two parts: $\theta$ , the recombination fraction $z$ , the logarithm of the odds that the markers are linked, rather than unlinked
3. $\theta$ measures how frequently recombination occurs between two genetic markers. It is a statistical average derived from observing how often a recombination is seen in actual families. <i>The smaller <math>\theta</math> is, the closer two markers are to each other.</i>
4. $z$ is a logarithmic measure of how good the estimate of $\theta$ really is. Every integer increase in $z$ is a 10-fold improvement in certainty that $\theta$ “really” is what it has been measured to be. <i>The higher the <math>z</math>, the more significant the measurement of <math>\theta</math> is.</i>

Figure 2.7. Linkage by descent in a hypothetical population in which a disease mutation can be traced to a founder. Marker alleles very close to the disease gene are unlikely to be separated by crossing over and constitute a disease-associated haplotype, which is preserved over many generations. (Kindly provided by Dennis Drayna.)

**Table 2.2A.** Relative Risk Ratio Analysis

	<i>Disease Present</i>	<i>Disease Absent</i>
Haplotype present	<i>a</i>	<i>b</i>
Haplotype absent	<i>c</i>	<i>d</i>

Relative risk (RR) ratio describes the risk of having a disease with vs. without a given genetic determinant.  $RR\ ratio = [a/(a+b)]/[c/(c+d)]$ .

Increased frequency can be assessed using a case-control study design. An under- or overrepresentation of the haplotype among affected individuals is measured using the *relative risk ratio* (RR ratio) in a two-by-two table (Table 2.2A). The RR ratio is calculated as the proportion of individuals with disease among those with a given haplotype divided by the proportion of individuals with the disease who lack the haplotype. A RR ratio >1 indicates an association between the haplotype and the disease in the population whereas a ratio <1 suggests the haplotype is protective against the disease. The significance of any deviation from 1 must of course be assessed by an appropriate statistical test.

For example, there are mutant alleles of the gene encoding the mannose-binding lectin (MBL), a circulating opsonization factor, that reduce serum levels of this protein to <10% of normal in individuals homozygous for one of these alleles. A study of the frequency of MBL-deficient genotypes in invasive pneumococcal disease (Kronberg and Garred, 2002) revealed the data shown in Table 2.2B. The frequency of homozygotes among individuals with invasive disease was elevated with a RR ratio of 2.1. The elevation was statistically significant ( $p < 0.0001$ ); 95% confidence limits placed the relative risk of invasive pneumococcal disease given an MBL deficient allele at 1.64- to 2.62-fold greater than the risk of healthy control subjects.

Association studies can be powerful tools for identifying alleles that appear to increase or decrease susceptibility to various diseases. However, an association by itself does not prove a causal relationship between the variant alleles and the disease phenotype. For example, all alleles in linkage disequilibrium with a variant found to be associated with a disease will also show an association without being directly causally related, although documentation of linkage of a risk factor to all such alleles (a risk-associated haplotype) would provide important information. For example, the iron-overload disease hemochromatosis and certain alleles at the HLA-A locus are closely associated, but the HLA-A alleles themselves do not actually cause hemochromatosis. Instead, there is significant linkage disequilibrium between particular HLA-A alleles and mutations at the closely linked *HFE* gene that is actually responsible for the disease (Gandon et al., 1996).

Association studies have not been as successful as one might wish, as evidenced by the frequent failure of many follow-up stud-

ies to replicate original reports of association (Hirschhorn et al., 2002). One particular difficulty arises from an artifact known as stratification. A population in which various ethnic subgroups do not freely intermarry is a stratified population. The frequency of particular haplotypes in different ethnic groups may vary because these groups have been geographically separated throughout many thousands of years of human history before they came together into a modern population. If an ethnic group in the population does not intermarry with the general population and happens to have a higher incidence of a particular disease for such historical reasons, any haplotypes whose frequencies in this subgroup differ from those in the general population will appear to be artifactually associated with the disease. Stratification can be managed by proper study design and careful selection of appropriate control groups (Pritchard and Rosenberg, 1999).

### Positional Cloning

The methodologies outlined above provide the means for obtaining information about the location of many disease genes in the human genome. With the localization of disease genes, even prior to specific gene identification and finding mutations, carrier detection and prenatal diagnosis may become possible for the first time. Furthermore, knowing where a disease gene is located can be the first step in discovering what it is. Availability of the entire sequence of the human genome has revolutionized disease gene identification after linkage to a specific genetic region has been established.

### Identification of Candidate Genes

Once a disease gene has been localized to a particular critical region of a chromosome, all the genes located in this region must be evaluated as candidates for alterations responsible for the disease phenotype. The entire complement of genes in any region of human DNA can now be readily ascertained by searching public databases containing the complete human genome sequence deposited by the Human Genome Project (Baxevanis, 2001). In addition to genomic sequence, mRNA sequences from all the expressed genes in a wide variety of tissues are also available (Riggins and Strausberg, 2001).

### Evaluation of Candidate Genes to Define a Disease-causing Gene

Once the set of candidate genes in the critical region of linkage or association is obtained through mining genomic and mRNA sequence databases, candidates can be evaluated to determine which one is the disease gene. Northern blots are used to determine the full length of the transcript and tissue expression pattern and to test patients affected with the disease for alterations in mRNA size or quantity. Finally, sequence comparison must reveal deleterious mutations in the alleles of affected patients that are not present in alleles of healthy controls.

The changes in DNA responsible for causing deleterious mutations in genes are extremely heterogeneous. In some cases, deletion of part or all of the DNA encoding the gene has occurred, resulting in production of no mRNA or a defective mRNA transcript lacking important portions of the gene sequence. Small insertions or deletions of a few base pairs may alter the triplet reading frame and create mRNA carrying incorrect codons and, often, a premature termination downstream of the small insertion or deletion. In other cases, single point mutations can interfere

**Table 2.2B.** Alleles of *MBL* Gene Predispose to Invasive Pneumococcal Disease\*

	<i>Invasive Pneumococcal Disease</i>	<i>Healthy Controls</i>
Homozygous for MBL deficiency alleles	48	61
Not homozygous for MBL deficiency alleles	329	1221

RR ratio =  $[48/(48+61)]/[329/(329+1221)] = 2.075$ .

\*Kronberg and Garred (2002).

with normal RNA processing, such as splicing of exons, resulting in mRNAs that either retain noncoding intronic sequences in the transcript or lack all or part of a coding exon. Some point mutations within coding regions change an amino acid codon into a stop codon (*nonsense mutation*), thereby inserting a premature termination into the mRNA. Still other point mutations may alter a codon from that of one amino acid to another (*missense mutation*). Regardless of which of the above mutation mechanisms has occurred, mutant mRNAs are frequently poorly transcribed or highly unstable; cells carrying such mutations may appear to lack mRNA entirely rather than producing abnormal mRNA.

Mutations that occur over and over again on independent genetic backgrounds are known as *hot-spot mutations*. The most frequent is the alteration of the dinucleotide cytosine-guanine (CG) to thymidine-guanine (TG) either on the coding or anticoding strand. It is believed that the cytosine within a CG dinucleotide is at high risk for undergoing C-to-T transition because such cytosines are frequently covalently modified by methylation at the 5 position of the pyrimidine ring. Spontaneous deamination of a methylcytosine results in a thymidine, which may not be repaired promptly by the cell because it is not recognized as an abnormal base within DNA. Hypotheses for the mechanisms of these mutations and data on their frequency, as well as a lexicon of mutations observed in human genetic disease, have been compiled by Cooper and Krawczak (1995).

The impact of any particular mutation depends on the effect that mutation has on the transcription of the gene into mRNA, the translation of the mRNA into a protein product, and the post-translational processing and stability of any mutant protein that is made. Moreover, functional consequences of mutations also depend on the physiological and environmental context of the cell, tissue, and individual carrying the mutation. In many diseases, a myriad of different mutations can lead to the same final common pathway: the loss of a functional gene product. In the inherited immune disorders as a rule, there are dozens of different mutations that can disrupt function of the gene product and bring about the disease. However, in certain types of genetic disease, a particular mutation may affect the function of a protein in a subtle and unique way and thereby cause a highly specific phenotype. For example, only a few, highly specific missense mutations in the  $\beta$ -globin gene result in a protein with the physicochemical properties that cause the hemoglobin to form crystals under low oxygen conditions, as seen in sickle-cell anemia. Thus the mutation repertoire for sickle-cell disease is severely restricted.

By means of positional cloning, human disease genes have been successfully identified solely on the basis of their genomic location, with little or no knowledge of the nature of the pathophysiological process responsible for the disease. These mutations overwhelmingly affect the coding portions of genes or occur at highly conserved regions of introns immediately adjacent to exons. The coding portions of genes, however, constitute only 4%–5% of sequence of a gene, and thus constitute a mere 1%–2% of the genome. With detailed information on the sequence of the human genome, we are likely to discover other alterations in non-coding regions that contribute to disease, perhaps in ways more subtle than are found with severe, deleterious mutations typical of Mendelian disorders with high penetrance. In such cases, linkage mapping is only the beginning of the study of pathogenesis of genetic disease and correlations between genotype and phenotype. Such variants may be in regulatory or intronic sequences and may alter expression or function only to a limited degree. Variants affecting levels of gene expression are not always adjoining the coding sequence; examples are known of locus control regions,

enhancers, and other sequences altering expression that are 10 to 100 or more kilobases distant from the coding sequences they influence. Finding such alterations and proving they are the cause of disease will be a major challenge to genetics research in the years to come.

### Assets of the Human Genome Project

The Human Genome Project (HGP), first conceptualized in the mid-1980s and officially launched in 1990, had as its stated primary goal the determination of the complete sequence of human DNA. Along the way, the HGP set a number of intermediate goals aimed at developing new tools and biological reagents of outstanding utility and importance for medical genetics research (Green, 2001). An initial goal was creation of a genetic map with highly polymorphic markers spaced approximately every 2–5 cM for genetic mapping. This goal was more than realized, with the identification of nearly 7000 STRPs or microsatellite markers, highly variable DNA segments containing strings of two- to four-nucleotide units detectable by polymerase chain reaction. Microsatellite markers formed the foundation for the first dense genetic linkage map of human DNA that covered over 3600 cM of genetic distance at an average spacing less than 1 cM. Single nucleotide polymorphisms, which are far more frequent than STRPs, have been developed for high-throughput parallel linkage mapping.

As sequencing was scaled up and cost per nucleotide sequenced decreased, the HGP became a dynamic international scientific enterprise. By 2003, a virtually complete, highly accurate sequence of the human genome was freely available in databases accessible through the Internet (International Human Sequencing Consortium, 2001). We are now in an era when the information gained through the HGP is being brought to bear on many aspects of molecular biology, evolutionary studies, and medical practice (Collins et al., 2003). For example, the sequence has provided for the first time a near-complete catalog of human genes and revealed that there are an estimated 20,000 to 25,000 human genes, occupying about 40% of the genome. Such catalogs now form the basis of the powerful new technology known as *expression arrays* (Geschwind, 2003). Sequences corresponding to many or nearly all human transcripts are individually mounted in a two-dimensional array on a glass or silicon wafer. Messenger RNA from two sources (such as normal and cancerous cells from the same tissue) are labeled with two different fluorescent dyes, mixed together, and allowed to hybridize to the array. The intensity of fluorescence from each of the two dyes at each address on the array provides a measure of the relative amount of the transcript of each gene in the two sources from which the mRNA was isolated. The relative amounts of tens of thousands of transcripts can be compared simultaneously, providing a profile of the expression of transcripts in a diseased tissue compared to that in an unaffected standard tissue. Such profiles are not only useful as biomarkers but may also provide crucial insights into disease pathogenesis.

With completion of the human genome sequence, genetic variation can also be investigated in far more detail than before. A complete catalog of all human sequence variation can be compiled along with an assessment of which variants have functional consequences. As of 2003, millions of the estimated total of 10 million SNPs present in the aggregate over all human populations have been identified and catalogued (Sachidanandam et al., 2001; Holden, 2002). These SNPs form the basis for genome-wide population studies designed to identify particular haplotypes that harbor DNA variants that contribute to common, complex diseases.

Shown in Table 2.3 is an annotated list of some of the most important Web sites that hold genome and genetic data of crucial importance in medical genetics research and patient care.

### Ethical Issues in Genetic Testing

There are numerous ethical issues surrounding human genetics as scientific knowledge and medical technology come to grips with the three central tenets of medical ethics: *beneficence* (doing good for the patient), *autonomy* (safeguarding the individual's rights to control his or her medical care and be free of coercion), and *equity* (ensuring that all individuals are treated equally and fairly). A full discussion of these issues is beyond the scope of this chapter, but a few examples arising in immunodeficiency diseases serve to illustrate some of these aspects of medical ethics and genetics.

As more and more genes are identified and found to be involved in human genetic disease, our ability to perform molecular diagnosis will continue to increase dramatically. An inescapable consequence of this rapidly accelerating knowledge is the time lag between acquiring the ability to diagnose genetic disease and developing effective interventions to prevent or treat diseases once they are diagnosed. For the immunodeficiency diseases, recent advances in therapy, from new antibiotics to immunoglobulin replacement to bone marrow transplantation and gene therapy, have placed clinical immunologists at the forefront of developing the tools to close the gap between diagnosis and treatment. How such tools are used and whether they are readily available to all who need them are clearly issues of fairness in the application of scientific knowledge.

An additional aspect of the growth of genetic knowledge is in the area of disease predisposition. Increasingly, molecular tools are allowing clinicians to identify individuals and relatives who

are at risk for disease that may have an onset much later in life than when the molecular testing is being done. Testing healthy individuals for disease predispositions encoded in their genomes has obvious benefits in identifying people at risk who may be able to modify their lifestyles and/or begin appropriate preventive therapy; but it also carries the risk of serious adverse psychological damage, stigmatization in society, and discrimination in insurance and employment. Ethical problems with genetic testing are especially acute when the testing identifies a predisposition for a disorder for which current medical technology provides little or no treatment when clinical disease actually develops. Thus, the issue of beneficence becomes quite central to testing in this setting. Is knowing the result of a genetic test doing more good than harm, or more harm than good?

The ethics of genetic testing is also an acute issue when testing children for the carrier state of diseases, such as X-linked immunodeficiencies that pose no threat to a female child's own health but identify a substantial risk for having affected offspring. The autonomy of children, including their right to make decisions for themselves about learning about their own genetic constitution, must be balanced against the desire of parents to obtain such information and transmit it to their children in the manner they believe best. As the power of genetic diagnoses increases, there is an increasingly greater need to educate health care providers, patients, their families, and society at large to make informed decisions about how to use genetic information wisely and for maximum benefit.

# Mammalian Hematopoietic Development and Function

GERALD J. SPANGRUDE

The origins of the mammalian immune response are found in hematopoiesis. Most of the diseases discussed in this book are mediated by mutations in genes that function during the course of hematopoietic development at the level of the progenitors for specific cell lineages (severe combined immunodeficiencies) or at the level of the expression of signaling molecules that promote differentiation (MHCII deficiency), or at the level of the functional potential of mature effector cells (leukocyte adhesion deficiency, chronic granulomatous disease). The common theme throughout the diseases discussed in this volume is the origin of the cellular components of specific and nonspecific immunity, the hematopoietic stem cell (HSC). While specific mutations in particular genes can result in defects in highly specialized mature cell populations, the resulting immunodeficiencies are distinguished by the biochemical result of the disrupting mutation and not by the developmental origin of the defective cellular response. This presents both an opportunity and a caution in the design of therapies for some of these diseases.

Bone marrow transplantation is one avenue for treatment of some immunodeficiencies, but in the absence of a related, genetically matched donor, the risks inherent in allotransplantation often outweigh the potential benefits. Transplantation of gene-corrected autologous cells can theoretically overcome the allotransplantation issue. While many of the immunodeficiencies might be corrected by genetic therapy, it is important to recognize that alterations in gene expression directed at correcting one developmental defect may be accompanied by an equally disruptive alteration in hematopoietic function as a result of expressing the corrected gene in cell lineages where it is not normally found.

The challenges of genetic therapy for immunodeficiencies are great, and the global effect of correction aimed at one blood lineage on the entire blood-forming system must not be overlooked.

This chapter will give an overview of our current understanding of hematopoiesis, specifically focusing on the transplantable HSC, to provide a basis for considering the common origin of most immunodeficiencies and the prospects for bone marrow transplantation as a therapeutic intervention.

## Overview of Hematopoietic Stem Cells

Because of the relatively short life span of most blood cells, a high rate of production is necessary throughout life to maintain normal numbers. In adult mammals, the major source of blood is the bone marrow. It is here that the HSC is found, represented at a frequency of fewer than 1 cell per  $10^4$  marrow cells (Neben et al., 1993).

The nature and identification of HSC remain somewhat controversial in that isolation of these cells is technically demanding and definitive assays for HSC function are lacking. The HSC is now known to comprise a heterogeneous mixture of cells with various degrees of functional activity in transplants and culture assays. Figure 3.1 depicts three levels of hematopoietic stem and progenitor cells, defined functionally as cells with the potential to differentiate into a variety of lineages of mature cell types. The most primitive of these three populations is the HSC, which is capable of differentiating along all hematopoietic lineages. In addition, this group of cells can be maintained in sufficient numbers to ensure lifelong blood production through a process known as *self-renewal*, which results in replacement of cells in this compartment when they are lost through differentiation.

Various lines of experimental evidence indicate that these primitive HSCs enter the cell cycle only infrequently (Bradford et al., 1997; Cheshier et al., 1999), and they are generally thought of as being metabolically quiescent (Hodgson and Bradley,

**Figure 3.1.** A model of the hierarchy of primitive hematopoietic stem (HSC) and progenitor cells. Quiescent stem cells are representative of the pluripotent HSC, with both self-renewing potential and the ability to differentiate as any type of blood cell. These HSCs occasionally enter the cell cycle and contribute to the expanding multipotent progenitor pool. Retrograde movement back into the quiescent state may explain the process of

self-renewal. Once expansion is under way, the ability to self-renew is lost. The expanding multipotent pool can directly differentiate as lymphoid or myeloerythroid progeny. Commitment to the myeloerythroid lineages results in further expansion of these progenitors during differentiation, and subsequent restriction to specific lineages results in precursor cells with limited proliferative potential.

1984). When one of these cells enters a cycle of cell division, this member of the hematopoietic hierarchy can be thought of as entering the “expanding multipotent progenitor” pool (Fig. 3.1). Although the mechanism of self-renewal is not understood, one possibility is that retrograde movement of at least one daughter cell back into the quiescent pool is responsible for maintenance of adequate numbers of primitive HSCs. The pool of expanding multipotent progenitors retains developmental potential for all hematopoietic lineages but gradually loses the ability to self-renew. After an undefined number of cell divisions, these cells lose their ability to differentiate along the lymphoid lineages and enter the third pool depicted in Figure 3.1, the “committed myeloerythroid progenitors.” These cells then are selected to differentiate as various types of mature cells, depending on the cytokines available in the specific areas of the marrow where they differentiate.

### Embryology of Hematopoiesis

Blood cells develop in essentially the same manner in embryos of all mammals. Embryonic mammalian hematopoiesis can be divided into three distinct phases: mesoblastic, hepatic, and myeloid (Wintrobe, 1967). The *mesoblastic phase* (also known as the *vitelline phase* because of the predominance of morphologically recognizable hematopoietic cells in the yolk sac) persists for about 10 weeks in human embryos (about 12 days in the mouse). During this time, the predominant blood cell type observed morphologically is the primitive (nucleated) erythrocyte in the yolk sac, which can be detected as early as 18 days of gestation in humans. During the *hepatic period* (beginning at 6–8 gestational weeks in the human or 10–12 days in the mouse), the fetal liver assumes the major responsibility for blood formation and continues to be hematopoietic until shortly before birth. In humans, a transient period of splenic hematopoiesis precedes the *myeloid*

*phase*, which initiates in marrow cavities at 10–12 weeks of gestation (15–16 days in the mouse), and by 20 weeks the majority of blood formation in human embryos occurs in the bone marrow. While splenic hematopoiesis is only a transient stage during human development, the spleen remains hematopoietically active throughout the adult life of the mouse. In spite of this, the bone marrow remains the primary site of blood formation, as it contains at least 10-fold higher levels of assayable progenitors than those in spleen.

As discussed above, the primary anatomical site where hematopoiesis is first observed in mammalian embryos is extraembryonic, in the numerous blood islands of the yolk sac. The liver primordium is subsequently seeded by migrating HSCs and rapidly becomes the predominant site of embryonic blood production. Recent experimental evidence suggests that a separate origin of hematopoiesis is also present intraembryonically in mammals, as is the case in lower vertebrates. Intraembryonic hematopoiesis in mammals is localized in a specialized splanchnopleural region of mesoderm that includes the dorsal aorta and the mesonephros and genital ridge (AGM region, see Fig. 3.2; Muller et al., 1994). Although morphologically recognizable hematopoietic elements are present only in the yolk sac during early embryogenesis, progenitor assays can detect hematopoietic activity in the AGM region prior to the appearance of progenitors in the fetal liver (Medvinsky and Dzierzak, 1996). It is currently unclear whether the fetal liver is colonized by HSC deriving from the yolk sac, the AGM, or both. However, one series of experiments demonstrated lymphoid and multipotent myeloid generative activity in the region of the dorsal aorta prior to establishment of circulation in the mouse embryo (Cumano et al., 1996). Therefore, it seems clear that mammalian hematopoiesis initiates within the developing embryo as well as in the yolk sac (reviewed in Dzierzak and Medvinsky, 1995).

**Figure 3.2.** Morphology of early mammalian embryogenesis and the origins of the blood-forming cells. The embryo depicted here is human and at the beginning of the fourth week of gestation, just prior to differentiation of the mesonephros and genital ridge from the nephrogenic cord. While morphologically distinct blood cells are already present in the blood islands (not depicted here) of the yolk sac, no blood production is evident in the body of the embryo. Surgical dissection of the AGM region (hatched area in the figure) followed by specific assays for hematopoietic function has demonstrated that primitive hematopoietic stem and progenitor cells are also present in the AGM, even though no morphologically identifiable blood cells can be detected. Adapted from *Illustrated Human Embryology, Volume 1: Embryogenesis*, by Tuchmann-Duplessis et al. (translated by L.S. Hurley), Paris: Masson, 1975. Used with permission.

Transplantation of yolk sac cells into irradiated adult animals does not result in engraftment. However, HSC activity has been demonstrated in early (day 10) mouse yolk sac after transplantation into neonatal recipient animals, possibly because of an obligate localization of these cells in the hematopoietic liver for further maturation into HSCs prior to marrow colonization (Yoder and Hiatt, 1997). It is likely that the yolk sac promotes primarily primitive hematopoiesis (nucleated red cells that transiently function during embryogenesis) while the embryonic source of hematopoiesis is predominantly definitive (the stable, long-term source of hematopoiesis). However, after the onset of blood circulation both types of hematopoietic function are present in both anatomic locations during subsequent development.

The AGM and the yolk sac are both mesodermally derived. The primordial cells that initiate formation of the hematopoietic system migrate to the AGM and yolk sac from the caudal portion of the early primitive streak during gastrulation (Bloom, 1938). The proliferating cells of the blood islands differentiate along two distinct pathways: one to form the endothelial cell boundaries of the first blood vessels at the periphery of the blood islands, and the other to give rise to primitive blood cells in the center of the islands. Thus, the common mesenchymal ancestry of endothelium and blood cells can be traced to a relatively late period during their ontogeny. Within the mammalian embryo, clusters of hematopoietic cells are not observed in the AGM region but rather are seen intravascularly as clumps of cells attached to the aortic endothelium (Dzierzak and Medvinsky, 1995). In birds, the onset of intraembryonic hematopoiesis is morphologically obvious, and for many years this was generally felt to be a fundamental difference between mammalian hematopoiesis and that of lower vertebrates.

## Microenvironments of Hematopoiesis

### Bone Marrow and the Niche

Bone is a calcified extracellular matrix of collagen and glycosaminoglycans that is synthesized by osteoblasts—bone-forming cells. The medullary cavity of bone may be hematopoietically active and contain so-called red marrow, or it may be predominantly inactive and filled with fat cells (white marrow). During the process of aging in humans, the anatomical sites of medullary hematopoiesis are progressively limited, beginning at birth when hematopoietic activity was distributed throughout the skeleton. By 18 years of age, most hematopoietically active marrow is found in central locations such as the pelvis, sternum, and ribs (Amos and Gordon, 1995). The medullary cavity and haversian canals of bone, which house blood vessels, are lined with a membrane called the *endosteum*. Occasional osteoclasts, which destroy bone, are found in the walls of the medullary cavity and are associated with areas of bone resorption.

The endosteum and its associated osteoclasts are of particular interest because the most primitive HSCs for blood formation appear to be localized near the walls of the medullary cavity (Lord et al., 1975; Gong, 1978; Uchida et al., 1994). The process of hematopoiesis depends on HSC in an intimate association with nonhematopoietic tissue cells in the medullary cavity of bone and, in some rodents, in the spleen (reviewed in Testa and Dexter, 1990). These tissue cells are generally termed *stromal cells*, a generic term that may be applied to any of a wide variety of nonmobile cells (reviewed in Dorshkind, 1990). The matrix of the medullary cavity includes structural elements of the blood vascular system, nerve fibers, and a system of reticular cells and fibers. This matrix is established during embryogenesis before the initiation of hematopoiesis. Thus, it provides a specialized microenvironment that supports hematopoietic cells within the parenchyma.

The bone marrow microenvironment probably has several distinct functions with regard to hematopoiesis (Fig. 3.3). First, it must provide conditions to maintain pluripotent HSCs in a primitive state throughout an animal's lifetime, thus ensuring an adequate supply of the seeds of hematopoiesis. Second, it must provide appropriate inductive signals for primitive HSCs to direct regulated development of erythroid, myelomonocytic, and B-lymphoid lineages. The processes of maintenance and differentiation of HSCs must be balanced to sustain a regulated frequency of functionally mature blood cell populations without depleting the HSC pool. The role of regulating the maintenance and differentiation of HSCs is filled by the stromal-cell elements of the marrow microenvironment, although in the case of erythropoiesis the kidney is also intimately involved in an endocrine manner through the production of erythropoietin. In addition to producing cytokines, marrow stromal cells also mediate proliferation and differentiation of hematopoietic progenitors via direct cell-cell interactions, using both common and specialized cell adhesion molecules (Kincade, 1991; Long et al., 1992).

The distinct functions of HSCs and the microenvironments that support them are clearly seen in two mutant mouse strains that were selected after mutations at the "dominant spotting" (W) and "steel" (Sl) loci on chromosomes 5 and 10, respectively (Schultz and Sidman, 1987). The products of these two loci interact to result in normal hematopoietic development and function; the Sl gene product is expressed by the microenvironment, while the W gene product is expressed by the hematopoietic cells (reviewed in Witte, 1990).

**Figure 3.3.** The bone marrow microenvironment includes a complex mixture of parenchymal cells that support maintenance and differentiation of hematopoietic cells by secretion of cytokines as well as via cell–cell interactions. The associations between developing hematopoietic cells and their supportive microenvironment are largely uncharacterized; this diagram is strictly a generalized representation of the notion that interactions with stromal cells are thought to regulate various stages of hematopoietic development in specific manners.

Over the last few years direct evidence for a bone marrow niche critical for HSC has accumulated (Suda et al., 2005). Thus, osteoblasts have been shown to be an integral part of a niche wherein the HSC is believed to reside (Calvi et al., 2003; Zhang et al., 2003). Moreover, the frequency of HSCs seems to be dependent on the number of osteoblasts (Zhang et al., 2003; Visnjic et al., 2004) and parathyroid hormone was reported to increase hematopoiesis by inducing the synthesis of Jagged 1, which serves as a ligand for notch signaling (Calvi et al., 2003). Conversely, osteopontin serves as a negative regulator with defective mice showing increased jagged 1 and angiopoietin 1 expression (Stier et al., 2005). Of particular interest to the field of primary immunodeficiencies, the ATM protein, defective in ataxia telangiectasia, was recently reported to regulate the reconstitutive capacity of HSCs (Ito et al., 2004).

### Spleen

Another example of the importance of HSC–stromal cell interactions in regulating hematopoietic growth is provided by the mouse spleen; in mice hematopoietic activity is maintained in the spleen throughout adult life. Although both the bone marrow and spleen support erythropoiesis and granulopoiesis, the spleen is dominantly erythropoietic, whereas granulopoiesis exceeds erythropoiesis in the bone marrow. Implantation of bone fragments into irradiated spleens allows the two types of microenvironments to exist in juxtaposition. In such cases, individual colonies of hematopoietic cells that arise at the border of the two microenvironments are frequently granulocytic in the vicinity of the bone fragment and erythroid in the splenic area (Wolf and Trentin, 1968). Results from these experiments argue that microenvironmental differences can dictate developmental pathways followed by individual multipotent cells.

Other examples of microenvironments that induce specialized hematopoietic growth include the B and T lymphocyte lineages, which develop predominantly in bone marrow and thymus, respectively. These observations are consistent with an “instructive” role for microenvironments in directing lineage commitment (Metcalf, 1998). An equally compelling case can be made for a stochastic model of hematopoietic differentiation (Enver et al., 1998), and it is likely that both mechanisms function in various lineages and stages of development.

### Hematopoiesis in Culture

The establishment of long-term cultures of bone marrow stromal elements has provided further evidence that specialized stromal cells contribute to microenvironments that support hematopoiesis. In addition, culture systems have been developed that selectively support HSC maintenance with either myeloid and erythroid development (Dexter and Lajtha, 1974), B-cell development (Whitlock and Witte, 1982), or T-cell development (Anderson et al., 1993). These culture systems involve the establishment in vitro of specialized stromal cell monolayers or reaggregation of stromal cells and progenitors into a three-dimensional structure to mimic organ culture of the intact thymus. Stromal cell monolayers may be heterogeneous, consisting of fibroblasts, endothelial cells, adipocytes, and mononuclear-derived macrophages and dendritic cells, or they may be established in vitro as cell lines of clonal origin that have been screened and selected to optimally support hematopoietic development.

Early observations of the myeloid cultures developed by Dexter and colleagues indicated that adipocytes were most closely associated with hematopoiesis in vitro. The subsequent development of stromal cell lines (Hunt et al., 1987; Kodama et al., 1992) has strengthened these findings; the stromal cell lines that support in vitro growth of early lymphoid and myeloid cells and maintain spleen colony-forming cells are adipocyte-like and resemble adventitial reticular cells. These latter cells are fibroblastoid cells that form a cellular network, or reticulum, within the bone marrow cavity. They accumulate neutral lipid deposits under certain conditions and are secretory, producing collagen and other proteins (Hunt et al., 1987). The bone marrow and thymus culture systems promise to provide clues that will clarify the roles of cell–cell interactions and of soluble growth factors in regulating hematopoiesis.

### Isolating Mouse Hematopoietic Stem Cells

Because of the important biological and medical implications inherent in the concept of a rare population of primitive cells being responsible for continuous replenishment of all circulating blood cells, efforts to identify and isolate HSCs date back to the first quantitative assays of hematopoietic development (reviewed in Spangrude, 1989; Visser and Van Bekkum, 1990). After description of the in vivo spleen colony-forming assay (Till

and McCulloch, 1961), development of an in vitro colony assay followed a few years later (Bradley and Metcalf, 1966). Although early efforts to enrich primitive hematopoietic cells relied on these assays, the limitations of the assays in reflecting the self-renewal potential of HSC was recognized early on. Velocity and equilibrium centrifugation studies demonstrated that bone marrow cells with an inherent capacity to produce splenic colonies could be separated from those capable of in vitro colony formation (Worton et al., 1969a, 1969b), and that self-renewal potential, as indicated by the content of splenic colony-forming units (CFU-S) within individual spleen colonies, could be separated from the bulk of the CFU-S in normal bone marrow (Worton et al., 1969a). These observations indicated that CFU-S activity might not directly correlate with self-renewal potential, a problem that has not been conclusively resolved. However, the early separation studies demonstrated that cell separation methods could indeed be applied to dissect the hierarchy of primitive hematopoietic cells.

Mouse HSC can be enriched from adult bone marrow by use of a number of methods. In one approach to the identification and enrichment of mouse HSCs, monoclonal antibodies specific for antigens that characterize cells belonging to specific mature and committed hematomorphoid lineages are used to identify these cells in bone marrow suspensions (Muller-Sieburg et al., 1986). The marked cells can be depleted by a solid-phase immunological method such as panning (Jordan et al., 1990) or use of immunomagnetic particles (Bertoncello et al., 1989; Ikuta et al., 1990). The remaining population of cells, termed *lineage-negative* ( $\text{Lin}^-$ ), contains approximately 5% of the initial number of bone marrow cells and consists of a mixed population of multipotent HSCs, early progenitors, and late progenitors.  $\text{Lin}^-$  cells can be further fractionated with specific monoclonal antibodies that recognize antigens expressed by a variety of hematopoietic and nonhematopoietic cells—for example, Thy-1 (Muller-Sieburg et al., 1986), Ly-6A/E (Spangrude and Brooks, 1992), c-kit (Okada et al., 1991a; de Vries et al., 1992), and major histocompatibility complex class I molecules (Mulder et al., 1984). The lectin wheat germ agglutinin has also been useful in discriminating multipotent HSCs from early- and late-stage progenitors as there is a relatively high number of binding sites for the lectin on multipotent HSCs compared to that on later-stage progenitors (Visser et al., 1984). When combined with a depletion of cells expressing high levels of lineage differentiation antigens, any one of these markers alone or in combination will identify a group of primitive hematopoietic cells in adult bone marrow or fetal liver. This multiparameter approach is necessary because no one cell-surface antigen has been identified that is expressed only by HSCs. Most currently defined HSC markers continue to be expressed as the cells differentiate and new, lineage-specific markers appear.

### Heterogeneity of the Hematopoietic Stem Cell Compartment

Cell populations resulting from antibody selection techniques are heterogeneous in function, suggesting a complex organizational structure within the HSC compartment. The heterogeneity is mostly with respect to self-renewal potential, since a high frequency of cells isolated by antibody enrichment are multipotent for both lymphoid and myeloid lineages (Spangrude and Johnson, 1990). The subset of multipotent cells possessing extensive self-renewal potential is resistant to killing by 5-fluorouracil and other cell cycle-active agents (Hodgson and Bradley, 1979). This

finding suggests that these cells are metabolically quiescent or that they possess elevated levels of a multidrug resistance mechanism (Chaudhary and Roninson, 1991).

Several methods have been used to select for long-term repopulating cells from antibody-enriched HSC populations. The vital mitochondrial dye rhodamine-123 can be used to distinguish cell populations on the basis of metabolic activity, and self-renewing HSCs are predominantly recovered from the group of cells exhibiting low mitochondrial staining (Bertoncello et al., 1985). Rhodamine-123 is also a substrate for multidrug efflux pumps. However, it is likely that the discrimination between the self-renewing and non-self-renewing HSC subsets by rhodamine-123 is due to differences in mitochondrial content and activity (Kim et al., 1998). In a second strategy vital nucleic acid dyes such as Hoescht 33342 are used to identify cells not in cycle (Neben et al., 1991; Wolf et al., 1993).

Finally, specific combinations of antibody markers can select for self-renewing HSCs (Morrison and Weissman, 1994). The combination of cell-surface and metabolic markers allows the recovery of a population of cells capable of long-term repopulation of irradiated animals after transplantation of less than 10 cells (Wolf et al., 1993; Spangrude et al., 1995). In contrast, over  $10^5$  normal bone marrow cells are required to produce a similar level of reconstitution.

The published methods for enriching populations of HSCs from mouse bone marrow and fetal tissues have dramatically improved the ability of researchers to explore the early events in normal mammalian hematopoiesis. As more enriched populations have become available for experimental use, it has become possible to critically test these cells for their ability to respond to recombinant cytokines by proliferating (Li and Johnson, 1992; Sitnicka et al., 1996), to assess the developmental pathways that the cells will follow under defined conditions in vitro (de Vries et al., 1991), and to explore the ability of small numbers of cells to repopulate lethally irradiated animals over long periods of time (Spangrude et al., 1995).

### Characteristics of Human Hematopoietic Stem Cells

The demonstration that the CD34 antigen is expressed by progenitor cells in human bone marrow (Civin et al., 1984) has allowed many investigators to explore the HSC compartment in humans. Applying the same general approach that was successful in the mouse, several groups have combined negative selection for lineage markers; positive selection for CD34 (Andrews et al., 1986), Thy-1 (Baum et al., 1992), or c-kit (Briddell et al., 1992); and selection for low staining with rhodamine-123 (Srouf et al., 1991) to achieve high enrichments of human hematopoietic progenitor cells. Positive selection for CD34 alone has been used as a method to enrich for progenitors prior to bone marrow transplantation after chemotherapy for a number of malignancies (Berenson et al., 1991; Shpall et al., 1994). Highly purified  $\text{CD34}^+ \text{Thy1}^+ \text{Lin}^-$  cells have also been used clinically for transplants after myeloablative chemotherapy (Archimbaud et al., 1996). In allograft transplants for treatment of immunodeficiencies, selection for HSCs by specific antigen expression may decrease the potential for graft-vs.-host disease (Flake et al., 1996). In addition, attempts to introduce normal counterparts of defective endogenous genes into the hematopoietic system for treatment of immunodeficiencies (Mulligan, 1993; Candotti et al., 1996) require that the target population be relatively enriched for self-renewing HSCs. However, in light of a pronounced genetic

variability of HSC phenotype in mice (Spangrude and Brooks, 1992, 1993), caution should be exercised when making the assumption that most HSCs in most human individuals express CD34 or Thy-1. Recently, the existence of human stem cells that lack CD34 has been proposed (Nakauchi, 1998).

In recent years, a great deal of attention has been focused on augmentation and acceleration of engraftment in bone marrow transplant settings by cytokine therapy in the recovery phase, and on the use of peripheral blood-derived stem/progenitor cells as a source of hematopoietic stem cells for human transplantation. While hematopoietic progenitors are rarely found circulating in peripheral blood under normal circumstances (Micklem et al., 1975), cytotoxic drug treatment, the administration of hematopoietic cytokines (Bodine et al., 1993), or both treatments in sequence (Siena et al., 1989) induce a rapid peripheralization of hematopoietic stem/progenitor cells. These cells can be harvested by multiple leukaphoresis sessions over several days, frozen for storage, and infused to mediate hematopoietic recovery following marrow ablative therapy. There is a significant effect of peripheral blood-derived stem and progenitor cells on the kinetics of recovery during the pancytopenic phase, when infection and hemorrhage can result in significant patient morbidity and mortality. A variety of studies have documented dramatic effects on both neutrophil and platelet recovery when peripheral blood stem cells, with or without supplemental cytokines, were used to mediate hematopoietic recovery following high-dose chemotherapy (Benjamin et al., 1995; Bassar et al., 1996). Enrichment of HSCs from normal donor peripheralized blood progenitor products (Weaver et al., 1993; Murray et al., 1995) may enable efficient allotransplantation without graft-vs-host disease in the treatment of many immunodeficiencies (Flake et al., 1996).

Assays for Hematopoietic Stem Cells

A great deal of attention has been focused on the development of assay systems that specifically detect the activity of the most primitive of HSCs for hematopoiesis (Fig. 3.4). One approach to an in vivo clonal assay for long-term repopulation is limiting dilution competitive repopulation to derive a measure of competitive repopulating units (CRUs) (Szilvassy et al., 1990). In this assay, very small numbers of genetically marked cells are transferred into anemic W/W<sup>v</sup> mice (Boggs et al., 1982) or irradiated animals. In the latter case, a radioprotective dose of normal marrow cells is also provided to mediate radioprotection, and the development of donor-derived populations is followed over long periods of time. This approach has been used to estimate the frequency of long-term repopulating cells in normal marrow suspensions (Boggs et al., 1982; Micklem et al., 1987). Enrichment of mouse HSCs from bone marrow resulted in repopulation of recipient animals after transfer of single injected cells (Smith et al., 1991; Spangrude et al., 1995).

Because it is very difficult to determine what the seeding efficiency of this assay is—that is, how frequently an intravenously injected cell seeds to a microenvironment such as the spleen or bone marrow where hematopoiesis is supported—it is not possible to know how frequent the long-term repopulating cell was in the original population; only a minimum frequency can be determined. Further, since there is ample evidence that long-term repopulation is usually quasiclonal in radiation-reconstitution models, the absence of progeny in the long term may indicate that the single injected HSC is one of many in a quiescent state, rather than supporting the idea that the cell was unable to self-renew and give rise to progeny over a long period of time (Van Zant et al., 1992).

**Figure 3.4.** Assays that detect various members of the hematopoietic hierarchy. A number of assays currently used to detect hematopoietic stem and progenitor cells are listed along with the approximate frequency of the normal mouse bone marrow cells detected by these assays and a general indication of the level of the hematopoietic hierarchy detected by each assay. The black and shaded portions of the bars indicate strong and weak activity, respectively, in the indicated assay. The assays are abbreviated as follows: CRU, competitive repopulating unit, a transplantation assay that measures the clonal frequency of cells able to contribute long term to blood formation in a transplant recipient. CAFC, cobblestone- area-forming cell, a cell culture assay that measures the ability of stem and progenitor cells to form within 7–28 days a morphologically distinct colony of cells in association with a monolayer of cul-

tured stromal cells; Radioprotection, the potential of transplanted stem and progenitor cells to mediate hematological rescue of lethally irradiated animals; CFU-S, colony-forming units (spleen), a transplant assay that measures formation of clonally derived colonies of proliferating hematopoietic cells in the spleens of irradiated animals 8 or 12 days after transplant; CFU-C, colony-forming units (culture), a culture assay that measures expansion of clones of cells in a semisolid culture medium in response to soluble growth factor stimulation. This assay can also be performed by seeding single cells into culture wells. The frequency of responding cells in each assay has been taken from Neben et al. (1993) and Szilvassy et al. (1996); these numbers will vary depending specific assay conditions and the age and strain of the donor mouse from which bone marrow cells are obtained.

Unknown seeding efficiencies and the quasiclonal repopulation problems compound the difficulty of measuring the frequency of long-term repopulating cells, even when a remarkable level of enrichment for the activity has been achieved.

Very soon after the description of the CFU-S assay by Till and McCulloch in 1961, the question of whether splenic colonies truly represent the proliferation of primitive HSCs became an important issue. Since the criteria for defining HSCs at that time included multilineage potential and a capacity for self-renewal, it naturally followed that one should be able to demonstrate the presence of new colony-forming cells within spleen colonies. This hypothesis was tested in a double transplant experiment by either excising individual spleen colonies (Siminovitch et al., 1963) or pooling the entire spleen from a CFU-S experiment (Siminovitch et al., 1964) for transplant into secondary irradiated recipients. The results revealed a broad heterogeneity in the ability of splenic colonies to initiate new splenic colonies. Also, when a longer period of time was allowed to elapse prior to harvesting spleen colonies for secondary transplant, the number of colonies containing secondary CFU-S increased. Many more colonies harvested 14 days after injection contained CFU-S compared to colonies harvested after 8 days. While a reasonable interpretation at the time invoked an extended time frame necessary for the self-renewal process within spleen colonies (Lewis and Trobaugh, 1964), later work revealed that the majority of early (day 8) CFU-S disappeared a few days later and that at least half of the late (days 11–13) colonies arose from a separate group of hematopoietic cells (Magli et al., 1982; Wolf and Priestley, 1986). These intrinsic differences in CFU-S hinted at the limited utility of the CFU-S assay to detect HSCs; only after a secondary transplant could one be assured of the self-renewing potential inherent in the original spleen colony.

Refinements in HSC characterization and enrichment have strengthened the concept that many types of hematopoietic cells that form spleen colonies lack the ability to reconstitute long-term hematopoiesis in irradiated animals (Ploemacher and Brons, 1988). Conversely, several groups have demonstrated long-term repopulating potential in the apparent absence of splenic colony-forming potential (Ploemacher and Brons, 1989; Jones et al., 1990; Wolf et al., 1993). While it is not yet clear whether inhibitory cytokines (Graham et al., 1990) or splenic seeding considerations (Spangrude and Johnson, 1990) may explain the failure of certain HSC preparations to form spleen colonies, it is very clear that spleen colony formation is not a unique characteristic of primitive HSCs (Hodgson and Bradley, 1979; Magli et al., 1982). Further, the inability to use such an assay in the investigation of human hematopoiesis, with the possible exception of chimeric human–mouse model systems (McCune et al., 1988), dictates the need to develop specific *in vitro* assays for HSCs.

Many recent attempts to develop specific *in vitro* assays for HSCs have relied on coculture of candidate HSC populations with feeder layers of bone marrow–derived stromal cells. A number of laboratories have used this approach to analyze hematopoiesis with mouse and human models (Ploemacher et al., 1989; Sutherland et al., 1990). In this assay there are two phases: an expansion phase in which the primitive HSC number is increased without a large degree of differentiation, and a detection phase when the products of the initial expansion are read out. In the expansion phase, self-renewal must be favored over differentiation, and the typical approach is to use a stromal cell feeder layer under the conditions originally defined by Dexter and colleagues (Dexter and Lajtha, 1974) to culture HSC populations. In most cases, the second phase of the assay involves harvesting the cells that differenti-

ate in the cultures and testing these progeny cells for the ability to produce macroscopic colonies in semisolid medium under the influence of a variety of cytokines (the culture colony-forming unit, or CFU-C assay). While the readout of colony formation is not an activity uniquely associated with HSCs, the differentiation of HSCs in these stromal cell cocultures is thought to result in the production and thus a net increase in the number of colony-forming cells. The results of such an assay are fairly quantitative, but the assay is not clonal because individual colonies in the second phase of the assay do not reflect single-input HSCs. However, if the coculture is initiated under limiting dilution conditions (Ploemacher et al., 1989; Sutherland et al., 1990), an estimate of the frequency of the HSCs in any given cell population is possible. Furthermore, a higher absolute number of colony-forming cells produced in any one culture is interpreted as an indicator of a more primitive initiating HSC. This culture system, and variants thereof, is usually termed the *long-term culture initiating cell* (LT-CIC) assay.

Cocultures of HSC and supportive bone marrow stroma evolve to generate unique associations between the two cell types. The mobile HSC interdigitates between and beneath the stromal monolayer, resulting in HSCs with a characteristic nonrefractile appearance by phase-contrast microscopy. These stromal-covered cells proliferate to form clusters of tightly packed cells that have been referred to as *cobblestone areas*, and the assay to detect such events is known as the *cobblestone area-forming cell* (CAFC) assay (Ploemacher et al., 1989; Neben et al., 1993). The frequency of formation of cobblestone areas can be correlated to hematopoietic repopulating activity *in vivo*, and the kinetics of cobblestone area formation reflects the relative maturation stage of the initiating cells, with more primitive cells requiring a longer period of time to establish a cobblestone area. These observations have been incorporated into the CAFC assay, which does not rely on a readout of CFU-C, but rather quantitates the frequency of cobblestone areas as a function of time (Ploemacher et al., 1991; Weilbaecher et al., 1991; Neben et al., 1993). There is currently no strong evidence that stromal cell systems effectively reproduce the bone marrow environment in terms of self-renewal of HSCs (Sponcer et al., 1985). The stromal cocultures can produce CFU-C from input HSCs over prolonged periods of time (van der Sluijs et al., 1990), but it is unclear to what extent HSCs can actually self-renew in these cultures relative to the *in vivo* environment.

While some correlation has been made between long-term reconstitution of lethally irradiated animals and some *in vitro* culture systems (Ploemacher et al., 1991), in fact the only definitive method available to define the self-renewing characteristics of HSCs is by transplantation *in vivo* (Orlic and Bodine, 1994). The availability of genetically defined strains of mice that allow easy identification of donor-derived cells in the peripheral blood of recipient animals in an otherwise syngeneic transplant (Harrison, 1980; Spangrude et al., 1988) provides a valuable model system for HSC function that has not yet been entirely duplicated by *in vitro* culture systems (van der Sluijs et al., 1993). The major limitation of the *in vitro* systems is that, in general, the development of only one or a few hematopoietic lineages is supported. Also, sole reliance on long-term culture initiation as an indicator of HSC function ignores the known capacity of mammalian cells to adapt to tissue culture conditions. Recently, immunodeficient strains of mice have been widely used as an *in vivo* model for engraftment of both normal and leukemic hematopoietic cells from human sources (Wang et al., 1998). Although not optimal for analysis of long-term hematopoiesis,

this assay allows detailed study of stem cell homing to bone marrow and multilineage differentiation in the context of a normal microenvironment.

### Colony Stimulating Factors and Hematopoietic Stem Cell Regulation

Although stromal cell cocultures have proved to be a useful model for studying the development of HSCs *in vitro*, ideally one would prefer to identify and characterize the stromal cell-derived cytokines responsible for driving each stage of hematopoiesis. Many hematopoietic cytokines have been identified and purified and have had their genes cloned (reviewed in Metcalf, 1989). However, as single agents, these molecules are primarily involved in later stages of myeloid and lymphoid differentiation. Early hematopoietic progenitors require as many as three cytokines to induce colony formation *in vitro* (Bartelmez et al., 1989), and it is not yet clear whether the most primitive HSCs respond to known cytokines at all (Fig. 3.4). Interleukin (IL)-1 and IL-3, in combination with colony-stimulating factor 1 (macrophage colony-stimulating factor, or M-CSF), are sufficient to drive *in vitro* colony formation by highly enriched populations of HSCs (Kriegler et al., 1990). A similar combination of cytokines, but not single cytokines, was shown to stimulate highly enriched HSCs at a clonal level to differentiate into osteoclasts as well as mature blood cells (Hagenaars et al., 1989). Leukemia inhibitory factor and IL-6 have both been identified as costimulators of primitive HSCs when used in combination with IL-3 (Okada et al., 1991b; Leary et al., 1990). The combination of IL-3 and IL-6 provides the stimulation necessary to achieve retroviral infection of primitive HSCs *in vitro* (Bodine et al., 1990). Finally, several cytokines such as steel factor (Lowry et al., 1992), Flt3 ligand (Shah et al., 1996), thrombopoietin (Broudy et al., 1995; Sitnicka et al., 1996), and basic fibroblast growth factor (Gabbianelli et al., 1990) have been shown to potentiate colony formation by highly enriched progenitor populations in combination with other cytokines. Taken together with numerous reports of negative regulatory influences mediated by macrophage inflammatory protein 1 (Graham et al., 1990), tumor necrosis factor (Rogers and Berman, 1994), and transforming growth factor (Jacobsen et al., 1995), these studies reinforce the concept of synergism and antagonism between the effects of colony-stimulating factors on primitive HSCs (Jacobsen et al., 1994).

### Self-Renewal of Hematopoietic Stem Cells

A major advantage of using a mouse model system to define basic characteristics of the HSC is that, given the paucity of experimental methods, it can be used to demonstrate the most critical of HSC functions, self-renewal. The concept of self-renewal in hematopoiesis can be interpreted in several ways. One possibility is that self-renewal of HSCs occurs at each cell division, which requires that HSCs divide in the complete absence of differentiation. This leads to the conclusion that one HSC may contribute indefinitely to hematopoiesis, a critical assumption for the application of gene therapy protocols in immunodeficiencies. If, however, one envisions a heterogeneous compartment of HSCs, all of which share the ability to initiate development in multiple hematopoietic lineages but differ in ability to give rise to more multipotent cells, the conclusion is consistent with the clonal succession model as proposed by Kay (1965) and there is less optimism for prolonged correction of genetic defects by gene therapy. A supraoptimal number of non-self-renewing multipo-

tent cells, each possessing a high but finite intrinsic proliferative potential, would be adequate to ensure long-term hematopoiesis (Spangrude, 1992). An intermediate situation consisting of essential elements from both extremes produces a further variation.

It will be difficult to prove or disprove the proposal that one HSC can divide to produce progeny of identical proliferative and developmental potential; however, many experiments have demonstrated the reality of clonal succession and of the heterogeneous nature of the HSC compartment. Sequential activation of HSC clones leads to clonal or quasiclonal contributions to hematopoiesis, as demonstrated by transplantation experiments between animals differing at isoenzyme loci (Micklem et al., 1987; Abkowitz et al., 1995) or by transplants of bone marrow cells carrying unique retrovirally induced genetic markers (Jordan and Lemischka, 1990). Serial transplantation of bone marrow, which eventually leads to a loss of repopulating activity (Harrison et al., 1990), can demonstrate two distinct phases of engraftment in recipient animals. The first phase is unsustained, apparently because more committed members of the HSC compartment being unable to maintain hematopoiesis in the long term. The second phase is sustained and is due to very primitive HSCs (Jones et al., 1989). These observations are compatible with clonal succession and with the generation-age hypothesis (Rosendaal et al., 1976), which extends the clonal succession model to predict that the number of generations an HSC is removed from its initial progenitor is inversely proportional to its proliferation potential (and hence hematopoietic-repopulating potential) and directly proportional to its state of activation. This means that the ability of any individual HSC to self-renew is limited, but the compartment of multipotent cells possesses the self-renewing ability of the sum of all individual HSCs.

Application of transplantation pressure in hematopoiesis results in exhaustion of HSCs (Harrison et al., 1990). In a very intriguing study, allophenic chimeras, made by aggregating embryos of two inbred mouse strains, were used to show that HSC exhaustion can be observed under normal developmental pressure (Van Zant et al., 1990). In these experiments, one partner mouse strain (DBA/2) has spleen colony-forming cells, of which 24 are normally in cell cycle, whereas in the other partner strain (C57BL/6) only 2.6 of these cells are in cycle. In allophenic chimeras between these two strains, the DBA/2 HSC population predominated early in life, only to be overtaken and eventually eclipsed by the C57BL/6 population. A similar observation was made after bone marrow transplants from chimeras into irradiated F1 recipients. These experiments bear out basic predictions of the generation-age hypothesis and point to intrinsic differences in the HSC as a factor in the longevity of hematopoiesis and of life span. Do HSCs also self-renew at a cellular level? This question is critical to the concept of gene therapy as a permanent cure for immunodeficiencies. To answer this question definitively we will need more sophisticated techniques of cell culture and analysis.

### Conclusions

The outcome of human bone marrow transplantation may be improved if enriched populations of early progenitors and HSCs are transplanted rather than whole bone marrow or pheresis products. This could be true in allogeneic transplants, where graft-vs.-host disease might be eliminated by T-cell depletion, and also in autotransplants, where residual tumor cells in the graft may contribute to relapse (Gazitt et al., 1995). Application of gene therapy to human immunodeficiency treatments via transplantation will also require HSC enrichment to improve the efficiency of

targeting functional genes to the hematopoietic generative compartment. It is critical that we understand the biology of hematopoiesis and know how to maximize the self-renewing potential of transplanted HSCs. Researchers working in the human system must currently rely on assay systems for long-term repopulation that have not been thoroughly examined for their specific mechanism of detecting the critical (self-renewing) populations of cells. Unraveling of the mysteries of the HSC compartment has been complicated by the difficulty in obtaining native HSCs in any large quantity for classical cell biological studies. This problem is compounded by the observation that HSC biology (phenotype and function) varies among mouse strains, making concrete rules for early hematopoiesis difficult to formulate.

Several recent studies suggest that bone marrow-derived hematopoietic stem cells may have broader developmental potential than originally thought, as examples of differentiation into epithelium, hepatocytes, neurons, and muscle have been reported (Krause et al., 2001; Lagasse et al., 2000). The phenomenon of differentiation across lineage barriers is often referred to as *plasticity*. Furthermore, evidence suggests that multipotent cells capable of generating blood and other tissues exist in many adult tissues (Anderson et al., 2001). Although these new observations may open new avenues to treatment of genetic diseases, this field is still highly controversial, with reports describing both the existence and the essential lack of plasticity (Anderson et al., 2001; Wagers et al., 2002; Goodell, 2003; Raff, 2003; Theise and Wilmot, 2003; Wagers and Weissman, 2004). In some cases fusions between cells have been found as the underlying mechanism (Alvarez-Dolado et al., 2003; Vassilopoulos et al., 2003).

The marked propensity of HSCs to rapidly differentiate in most in vitro culture systems (Rebel et al., 1994) has hampered our ability to investigate under controlled, in vitro conditions the hierarchy of the HSC compartment and to approach the question of how to maintain the essential "stemness" of HSC populations. The possibility that self-renewal in the HSC compartment is limited to a finite number of cell divisions may indicate that even under the best conditions unlimited expansion of true HSCs is an impossible goal to attain. This possibility has an obvious impact on proposals for gene therapy of immunodeficiencies through transplantation, since self-renewal of transduced stem cells is the only vehicle by which this may be accomplished. At the present time, development of better clinical methods for management of the complications of allogeneic transplants may be a more expedient method by which to treat congenital immunodeficiencies.

## T Cell Development

RAE S. M. YEUNG, PAMELA S. OHASHI, MARY E. SAUNDERS,  
and TAK W. MAK

The purpose of this chapter is to give a broad overview of some of the complexities involved in T cell development. T cells are key regulators of specific immunity, and their function is determined by events that occur during an intricate developmental process in the thymus. An understanding of T cell development is thus fundamental to our understanding of immune responses. While a variety of different receptor–ligand interactions are important during T cell development, none are as crucial as those mediated via the T cell antigen receptor (TCR). Although the exact nature of the TCR was not elucidated until the early 1980s (Hedrick et al., 1984; Yanagi et al., 1984), experiments done in the 1970s led to the finding that T cell specificity is linked to proteins encoded by genes in the major histocompatibility complex (MHC) (Shearer, 1974; Zinkernagel and Doherty, 1974). The MHC is known as the H-2 complex in mice and as the HLA (human leukocyte antigen) complex in humans. Unlike B cells, T cells generally do not respond to whole protein or native antigens. Instead, T cells recognize peptide fragments of foreign or self-antigens complexed with MHC molecules. Furthermore, a given T cell recognizes only a particular peptide–MHC complex in a process referred to as *MHC restriction* (Zinkernagel and Doherty, 1979).

The interaction of a developing thymocyte's TCR with peptide presented on self-MHC in the thymus determines the fate of that thymocyte. Only some become the mature T cells that patrol the body's periphery and respond to foreign antigen. The molecular interactions that lead to the elimination of self-reactive thymocytes ("negative selection") and the survival of those that can potentially mount protective immune responses ("positive selection") are complex. Our understanding of thymic ontogeny has been greatly enhanced through the use of genetic tools, particularly mutant animal models. In this context, the use of *transgenic* and *gene-targeted* mice has been especially revealing. We begin

this chapter with a brief description of these technologies and their utility. We then give overviews of the TCR proteins and the genes encoding them, followed by a discussion of the coreceptors CD4 and CD8, which have enormous influence on T cell development. Finally, we describe the stages of T cell development in detail at both the cellular and molecular levels, noting where appropriate the various mutations that have helped to define each stage.

### Transgenic and Gene Targeting Technology

T cell development consists of a sequence of well-coordinated processes in which immature progenitor cells enter the thymus, participate in a complex developmental process, and emerge as mature T cells able to function in host defence. In the past, it was difficult to dissect the unique roles of the multitude of genes involved in thymocyte maturation. Natural mouse mutants existed and furnished much information on immune system development but, in most cases, the identity of the genes mutated in these animals was unknown. With the advent of recombinant DNA technology in the 1970s, it became possible to splice different gene sequences and their control elements together. Subsequent refinements allowed the expression of exogenous genes in experimental animals, an investigative method called *transgenesis*. As is detailed throughout this chapter, the study of transgenic mice bearing genes of relevance to immune responses revealed much about their function (Cantrell, 2002). However, the expression of these genes was necessarily nonphysiologic, and researchers sought a means of eliminating the function of a specific endogenous gene to determine its effects. In 1989, *gene-targeting* technology was developed which allowed researchers to delete a single gene in a whole animal. The study of these genetically modified "knockout" mice has provided us with invaluable data on the

functions of single genes in vivo (Mak et al., 2001). Immunologists readily embraced gene-targeting technology because the loss of many immunological genes is still compatible with normal embryonic development, meaning that a relatively healthy mutant animal can often be recovered and studied.

We will now give a short description of methodologies underlying transgenesis and gene targeting, and the related methodology of RAG complementation.

## Transgenesis

*Transgenesis* is the expression of an exogenous gene of interest in a cell. By placing the transgene of interest under the control of a tissue-specific promoter, the effect of the gene on a specific cell type can be examined. The copy number and location of integration of the transgene in the host cell genome can affect its expression. When and where the transgene's promoter is operational are also relevant, as transgene expression may be activated at different times or at different locations in different cell types. Transgenes are useful for probing the relationship between structure and function of a molecule: the expression of a mutated version of a protein that has been engineered to lack a particular domain may reveal the importance of that domain or protein. Transgenes can also be used to rescue function in gene-deficient mice and thus assess the nature of the original defect. For example, if a mutant in which a developmental process is blocked can be rescued by the overexpression of a molecule known to promote cell survival, it is likely that the original mutation affected a protein with a role in survival. This protein may be quite distinct from the product of the transgene.

A *dominant negative* ( $D^{mN}$ ) transgene can be used to interfere with the expression of an endogenous protein. Often the protein derived from a  $D^{mN}$  transgene is a catalytically inactive version of the molecule of interest, the theory being that large quantities of such a protein (5- to 10-fold excess) will compete with the endogenous protein for essential substrates or cofactors. It should be ensured that the promoter used to drive  $D^{mN}$  transgene expression is capable of achieving the necessary high level of expression. It is also essential to determine how much interference is required to completely inactivate the endogenous protein, and how specific an inhibitor the  $D^{mN}$  molecule truly is. It is not unusual for a  $D^{mN}$  inhibitor to sequester molecular intermediates needed by more than one endogenous enzyme or pathway. This latter characteristic can be an advantage when one wants to overcome redundancy of function and simultaneously disable all isoforms of a protein of interest.

*Constitutively active* transgenes can also be constructed to overcome natural control mechanisms within a cell. Mutations of residues in negative control sequences or enzymatic catalytic sites can result in constitutive activation of a protein. A difficulty with these types of mutants is that nonphysiological expression of the gene in question occurs by definition: the molecule is likely not produced at either the normal location, time, or concentration, forcing a guarded interpretation of results. Temporal control of transgenes can be exerted by placing them under the control of promoters engineered to be regulated by the addition of the antibiotic tetracycline (Gossen et al., 1995) or the synthetic estrogen tamoxifen (Littlewood et al., 1995). Transgenes encoding bacterial toxins are valuable tools because of their specificity and high potency at low concentration. For example, transgenes encoding the bacterial cholera, botulism, and pertussis toxins have been used as inhibitors to determine the roles of G proteins in various intracellular signaling pathways (Chaffin and Perlmutter, 1991; Henning et al., 1997).

With respect to studying T-cell development, transgenes have been placed under the control of various promoters that restrict expression of the genes they regulate primarily to the T lineage. Such promoters include the proximal promoter of the gene encoding the Src family protein tyrosine kinase  $p56^{Lck}$  (Lck) (Allan et al., 1992), the promoters of the genes encoding the CD4 and CD8 coreceptors (Ellmeier et al., 1999), and a modified CD2 promoter (Zhumabekov et al., 1995). These promoters are expressed both in thymocytes and in peripheral T cells but at different stages of development. For example, the expression of transgenes under the control of the Lck promoter can be detected in the earliest thymocytes, whereas the CD2 promoter is generally not activated until a later stage.

While "standard" transgenesis as described above is undeniably a powerful and useful technology, it has the disadvantage of random integration of the transgene. Knock-in technology rectifies this defect because the transgene is introduced into a precise location in the genome by homologous recombination—that is, the transgene is designed such that sequences flanking the gene of interest are homologous in sequence to the endogenous locus and thus ensure that the transgene integrates in its natural position. The natural transcription controls of the gene of interest are thus preserved (unlike standard transgenesis) and the danger of overexpression artefacts is reduced. Knock-in mutations can be used to introduce reporter constructs to facilitate detection of a hard-to-monitor gene, or regulatory constructs can be added to alter expression patterns. For example, to investigate control of IL-4 expression in vivo, a reporter gene was "knocked into" the IL-4 locus (Pannetier et al., 1999). This study led to the generation of much useful information on the regulation of effector T-cell differentiation (Hu-Li et al., 2001).

## Gene Targeting

The basic principle of gene targeting is replacement of the gene of interest via homologous recombination between exogenous DNA (a targeting vector or knock-out construct) and its endogenous chromosomal homologue (Capecchi, 1989; reviewed in Koller and Smithies, 1992) (Fig. 4.1). The targeting vector contains flanking sequences that are identical to endogenous DNA sequences, ensuring that the endogenous gene is replaced with the mutated version. The homologous recombination event yields an insertion, replacement, or deletion of the targeted genomic locus, depending on the design of the knockout construct. It was shown in the early 1980s that multipotent embryonic stem (ES) cells from mouse embryos could be cultured and manipulated in vitro and then reintegrated back into a wild-type mouse blastocyst. When returned to the embryonic environment, the manipulated ES cells resumed normal development and contributed to all cell lineages including germ cells. By combining gene-targeting technology with the transfection and culture of murine ES cells, mice with mutations in a single gene can be generated. To create a knockout mouse, murine ES cells are injected in vitro with the targeting vector. To enrich for those rare ES cells that have undergone homologous recombination, a selectable marker gene, such as that encoding neomycin resistance, is usually included in the targeting construct. A negative selection marker (such as a toxic gene) may also be included in the flanking region of the construct to kill cells in which random integration of the targeting construct has occurred (Yagi et al., 1990; Hasty et al., 1991). Embryonic stem cells that have undergone homologous recombination are detected by polymerase chain reaction (PCR) assays and confirmed by genomic Southern blot analysis (Capecchi,

**Figure 4.1.** The classical approach to gene targeting in embryonic stem (ES) cells. Gene targeting is carried out in wild-type mouse ES cells cultured for manipulation. A targeting construct is engineered in which the gene of interest is disrupted by the insertion of the *neo* gene. The thymidine kinase *Hsv-tk* gene can be placed outside the target gene as a negative selection marker. The construct is transfected into the cultured ES cells, usually by electroporation. If homologous recombination occurs, only the *neo*/target gene sequences will be inserted into the chromosomal DNA of the ES cells. Selection with the neomycin-like drug G418 will kill any nonrecombinant ES cells. Selection with gancyclovir will kill any nonhomologous recombinants carrying the *Hsv-tk* gene. ES cells heterozygous for the targeted mutation as confirmed by polymerase chain reaction (PCR) and Southern blotting are injected into a mouse blastocyst. The chimeric blastocyst is then implanted into a pseudo-pregnant female. Homozygosity for the targeted mutation is achieved by subsequent breeding steps.

1989). The recombinant cells are microinjected into a mouse blastocyst which is then implanted into a pseudopregnant female. The resulting chimeric mice transmit the knockout genes to their offspring (Robertson et al., 1986). The progeny are analyzed for presence of the knockout mutation and interbred to achieve homozygosity. The phenotype of the null-mutant mouse is then assessed to obtain knowledge of the gene's function.

While gene knockouts are extremely useful for deducing the functions of many genes, there are some caveats to their use. Unanticipated alternative or aberrant splicing of exons or the synthesis of truncated translation products can complicate interpretation of the data. In addition, an engineered mutation in one gene may have an unexpected effect on a neighboring gene, making it difficult to distinguish the true source of the observed phenotype. Mutations that affect the architecture of an organ may indirectly influence the differentiation or behavior of the cells of interest within it. Genetic background can have a huge influence on expression of the phenotype of the mutant mouse, and redundancy in molecular systems may mean that the function of missing gene may be compensated for by the function of another gene. Finally, if the gene in question has a double function in the immune system and in embryonic development, embryonic or perinatal lethality may preclude analysis of the gene's function in adult tissues.

Some of these problems can be circumvented by the Cre-LoxP and FLP-FRT recombination systems that allow tissue- or stage-specific gene expression (Metzger and Chambon, 2001). In the former, Cre recombinase from bacteriophage P1 recognizes bacterial LoxP sequences flanking the mammalian genomic DNA to be deleted. Cre-mediated recombination of two loxP sites in *cis* orientation results in the deletion of all DNA between them (Sternberg et al., 1986). FLP-recombinase from yeast carries out the same function by recombining flanking FRT sequences (O'Gorman et al., 1991). Transgenic expression of Cre or FLP by use of a tissue-specific promoter thus allows the generation of tissue-specific knockouts. For example, constructs in which Cre expression is controlled by the T cell-specific promoter of the *Lck* gene can be used to induce the deletion of loxP-flanked genes only in T cells (Fig. 4.2). Inducible knockout of a gene can be achieved by placing Cre under the control of tetracycline transactivation systems, insect hormones, or analogues of mammalian steroid hormones (Kuhn et al., 1995; Rajewsky et al., 1996). A caveat with respect to the use of Cre recombinase (in particular) is that the efficiency of gene deletion in a tissue will depend on the efficiency of transgenic Cre expression in that tissue, a highly variable parameter.

A specific mutation of a gene of interest can also be generated using the knock-in approach. For example, a knock-in construct

**Figure 4.2.** Cre/loxP-mediated gene targeting. Genetic manipulation of ES cells produces a mouse in which the gene of interest is “floxed,” or flanked by two *loxP* sites. The floxed mouse is then crossed with a transgenic mouse expressing *Cre* recombinase under the control of a tissue-specific promoter; in this case, the  $p56^{lck}$  promoter which is active only in T cells. Cre expressed in the thymus of the double transgenic progeny of this cross recombines adjacent *loxP* sites and deletes the gene of interest only in T cells.

was created in which the dimerization domain of the key hematopoietic signaling phosphatase CD45 was disrupted by a point mutation. Analyses of transgenic animals expressing this mutated gene showed that CD45 activity was lost in the absence of the dimerization function and that control of lymphocyte proliferation was compromised (Majeti et al., 2000).

### RAG Complementation

RAG complementation provides a system in which to test the role of a particular gene in lymphocyte development and function. The recombination activation genes (*Rag1* and *Rag2*) are essential for V(D)J rearrangement of the antigen receptor genes in B and T cells (Schatz et al., 1989). Mice lacking either RAG1 or RAG2 are viable but lack mature T and B cells (Shinkai et al., 1992, 1993; Mombaerts et al., 1992b). When ES cells homozygous for a knockout mutation are microinjected into blastocysts of RAG-deficient mice, all lymphocytes developing in these chimeric animals are necessarily derived from the RAG<sup>+</sup> knockout ES cells (Chen et al., 1994) (Fig. 4.3). The effect of the knockout mutation on specific immunity can then be analyzed. RAG complementation is particularly useful when the homozygous knockout phenotype is embryonic lethal.

### TCR/CD3 Complex

We now return to the T cell itself, first examining the structure of its antigen receptor. The TCR is responsible for the recognition of both foreign and self antigens, and thus is central to both T-cell development and the mounting of specific immune responses. Inability to recognize foreign antigen can lead to overwhelming infection, while inappropriate recognition of self-antigen can result in autoimmunity.

TCRs are heterodimeric proteins composed of either TCR $\alpha$  and  $\beta$  chains, or TCR $\gamma$  and  $\delta$  chains. Thymocytes and the majority of peripheral T cells bear  $\alpha\beta$  TCRs but about 5%–10% of all T cells bear  $\gamma\delta$  TCRs. All TCR $\alpha\beta$  heterodimers recognize peptides complexed with MHC molecules, but some TCR $\gamma\delta$  molecules recognize nonpeptide antigens either directly or bound to the MHC-like molecule CD1. For both  $\alpha\beta$  and  $\gamma\delta$  TCRs, recognition of the antigen depends on the binding site formed by portions of the  $\alpha\beta$  or  $\gamma\delta$  chains. However, surface expression of the TCR and antigen-specific T-cell signaling and activation depend on the association of the TCR with the CD3 complex. The CD3

**Figure 4.3.** RAG-deficient blastocyst complementation. Mice deficient for either RAG1 or RAG2 are viable but lack mature T and B lymphocytes. To examine lymphocyte development and behavior in the absence of a gene of interest (gene X), wild-type embryonic stem (ES) cells homozygous for deletion of gene X (RAG<sup>+/+</sup>; gene X<sup>-/-</sup>) are injected into RAG-deficient blastocysts. The chimeric blastocysts are implanted in pseudopregnant females where they develop into pups in which any lymphocytes present are necessarily derived from the gene X<sup>-/-</sup> ES cells. Because the gene deletion in this system is somatic, RAG complementation is particularly useful for examining the function in lymphocyte development of genes that are embryonic lethal when deleted in the germ line.

**Figure 4.4.**  $\alpha\beta$ TCR/CD3 on the cell surface. Schematic drawing of the  $\alpha\beta$ TCR/CD3 complex in the T-cell membrane. The TCR $\alpha\beta$  heterodimer is associated with three other CD3 dimers: CD3 $\epsilon\delta$ , CD3 $\gamma\epsilon$ , and (most often) CD3 $\zeta\zeta$ . The CD3 $\epsilon$ ,  $\delta$ , and  $\gamma$  chains each contain one immunoreceptor tyrosine-based activation motif (ITAM) sequence (black rectangles) important for signal transduction, while the CD3 $\zeta$  chain contains three ITAMs. The TCR $\alpha\beta$  heterodimer is responsible for antigen recognition, whereas the CD3 chains convey intracellular signals via activation of kinases associated with their cytoplasmic tails (see Fig. 4.6).

complex consists of at least five distinct membrane proteins, CD3 $\gamma$ ,  $\delta$ ,  $\epsilon$ ,  $\zeta$ , and  $\eta$ , which are noncovalently associated both with each other and the TCR heterodimer (Weiss and Littman, 1994). The CD3 $\gamma$ ,  $\delta$ , and  $\epsilon$  chains are found as  $\gamma\epsilon$  and  $\delta\epsilon$  subunits within the TCR/CD3 complex (Blumberg et al., 1990; Malissen and Malissen, 1996), whereas the  $\zeta$  chain is found as a homodimer (in 90% of TCRs) or as a  $\zeta\eta$  heterodimer (~10% of TCRs). The CD3 $\zeta$  and  $\eta$  chains are splice variants derived from the same gene. Other splice variants encoded by the CD3 $\zeta$  gene have been described, such as CD3 $\theta$  and CD3 $\iota$  (Malissen and Malissen, 1996). The minimal stoichiometry of the most common  $\alpha\beta$  TCRs is TCR $\alpha\beta$ : CD3 $\gamma\epsilon$ CD3 $\delta\epsilon$ CD3 $\zeta\zeta$  (Fig. 4.4). All CD3 chains contain at least one of the tyrosine-rich immunoreceptor tyrosine-based activation motifs (ITAMs) essential for initiating intracellular signaling following antigen binding to the TCR.

### TCR Genes

An  $\alpha\beta$  TCR binds to peptide–MHC via its variable (V) region located at the extracellular N-terminus of the heterodimer. The V region is linked to an invariable extracellular region, a transmembrane domain, and a short intracellular domain at the carboxyl terminus of the protein. These latter elements are encoded by the constant (C) region exons of the TCR loci (Davis and Bjorkman, 1988). The V regions of both component TCR chains contribute to the antigen binding site, and each chain's V region is encoded by a V exon. Analogous to the immunoglobulin (Ig) light-chain gene, the TCR $\alpha$  and  $\gamma$  V exons contain a V (variable) and a J (joining) gene segment, while, like the Ig heavy-chain gene, the TCR $\beta$  and  $\delta$  V exons contain a V, a D (diversity), and a J gene segment. In each developing thymocyte, the V and J or V, D, and J gene segments forming the V exons are randomly chosen from the huge array of multiple V, D, and J gene segments present in germline TCR loci. In a process known as *somatic gene rearrangement*, the site-specific RAG1/2 recombinases initiate the joining of the chosen V, D, and J gene segments at the DNA level (Schatz et al., 1989; Chen et al., 1994). The double-stranded DNA protein kinase (dsDNA-PK) catalyzes the ligation of the rearranged gene segments to form a complete and

unique V exon for each TCR chain in each developing thymocyte (Kirchgesner et al., 1995). The V exon sequences are then joined to the C exon sequences by conventional RNA splicing prior to translation of both chains and heterodimer assembly. It is the random rearrangement of V(D)J gene segments that generates most of the enormous diversity of TCRs expressed on mature T cells (Toyonaga et al., 1985; Davis and Bjorkman, 1998). Additional diversity is introduced at V-D-J junctions through the introduction of template-independent (or N) nucleotides during V(D)J rearrangement. N-nucleotide addition is mediated by the enzyme terminal deoxynucleotidyl transferase (TdT) (Tonegawa, 1983).

### The Coreceptors

While the TCR antigen binding site is responsible for the recognition of specific peptide in the binding groove of an MHC molecule, the CD8 and CD4 molecules function as coreceptors by binding to nonpolymorphic regions of the MHC class I and class II molecules, respectively. The coreceptors facilitate TCR signal transduction because the cytoplasmic domains of both CD4 and CD8 are physically associated (with differing stoichiometry) with Lck tyrosine kinase (see below; Veillette et al., 1988; Turner et al., 1990; Weiss and Littman, 1994). Both CD4 and CD8 have important roles in the ontogeny and selection of thymocytes and in the activation of mature T cells resident in peripheral lymphatic organs (Wallace et al., 1993).

#### CD8 and MHC Class I

CD8 is a cell surface glycoprotein expressed on MHC class I-restricted T cells. In mice, thymocytes and peripheral T cells generally express CD8 as heterodimers of CD8 $\alpha$  (Lyt-2) and CD8 $\beta$  (Lyt-3). On human T cells, CD8 is composed of homodimers of a single subunit, the homologue of murine CD8 $\alpha$ . The greatest sequence similarity between human and murine CD8 $\alpha$  is located in the transmembrane (79%) and cytoplasmic (5%) domains (Littman, 1987). The MHC class I molecule to which CD8 binds is a heterodimer composed of an MHC class I  $\alpha$  chain noncovalently associated with the invariant  $\beta$ 2-microglobulin ( $\beta$ 2M) chain. The corresponding gene symbol is *B2m*.  $\beta$ 2M is crucial for the expression of the MHC class I molecule on the cell surface. The peptides associated with MHC class I molecules are generally derived from endogenous proteins degraded by proteasomes in the cytosol. The peptides are translocated into the endoplasmic reticulum (ER) by a heterodimeric transmembrane transporter complex with structural similarity to ATP binding cassette transporters (Spies and DeMars, 1991). The TAP1 (transporter associated with antigen processing-1) and TAP2 subunits of this transporter complex are encoded by the *Tap1* and *Tap2* genes which map to the MHC class II region (Deverson et al., 1990; Monaco et al., 1990). Once in the ER lumen, the endogenous peptides are immediately loaded into the binding grooves of newly synthesized MHC class I molecules (Androlewicz and Cresswell, 1996).

Since interaction with peptide-loaded MHC class I is required for CD8<sup>+</sup> T-cell development, disruptions in either the *B2m* gene or the *Tap* genes have severe effects on the mature CD8<sup>+</sup> T-cell population. For example, a drastic reduction in the number of CD8<sup>+</sup> T cells is observed in gene-targeted  $\beta$ 2M-deficient mice (Koller et al., 1990; Zijlstra et al., 1990), and a similar phenotype is observed in animals in which the *Tap1* gene has been deleted (Van Kaer et al., 1992). Cytotoxic T-cell functions are severely impaired in these mutant mouse strains because they lack CD8<sup>+</sup>

T cells; however, T-helper activities mediated by CD4<sup>+</sup> lymphocytes are normal.

### CD4 and MHC Class II

CD4 (L3T4 in the mouse) is a 55 kDa single-chain glycoprotein with four Ig-like extracellular domains (D1–D4), a transmembrane region, and a cytoplasmic domain (Littman, 1987). Comparison of the human and mouse CD4 amino acid sequences reveals 55% similarity, with the greatest homology shared between the cytoplasmic domains. CD4 molecules interact with MHC class II molecules in both functional studies and binding assays (Greenstein et al., 1984; Doyle and Strominger, 1987). The two most distal extracellular domains of CD4 bind to the nonpolymorphic  $\beta$ 2 domain of MHC class II molecules. The intracellular domain of CD4 is associated with large quantities of Lck, making it particularly important for the initiation of the complex TCR signaling cascade (Glaichenhaus et al., 1991). The majority of T helper functions, which consist primarily of the secretion of cytokines required for the complete activation of B cells and cytotoxic T cells, are carried out by CD4<sup>+</sup> T cells.

The MHC class II molecule to which CD4 binds is a heterodimer composed of an MHC class II  $\alpha$  chain noncovalently associated with an MHC class II  $\beta$  chain. MHC class II molecules generally present peptides from exogenous sources. Because both MHC class I and II molecules are assembled in the ER, and both are capable of binding peptides, a mechanism must exist in the ER to protect the peptide-binding groove of class II molecules from occupancy with endogenous peptides (Neeffjes and Ploegh, 1992). The invariant chain (Ii) is coordinately expressed with MHC class II in the ER and associates with newly synthesized MHC class II molecules such that the binding of peptide in the MHC class II groove is blocked. As the MHC class II–Ii complexes traverse the increasingly acidic intracellular antigen-processing compartments, Ii undergoes stepwise degradation by cathepsin-like proteases until only a fragment of Ii, called *CLIP* (class II–associated invariant chain peptide), remains in the binding groove (Roche, 1995). CLIP peptides were initially discovered by examination of mutant antigen-presenting cell (APC) lines that exhibited unstable MHC class II molecules (Mellins et al., 1990). These APCs were able to present exogenous peptide fragments but could not process whole protein antigens or present peptides derived from them to T cells. Further study showed that these mutant cell lines had mutations in the HLA-DM gene that maps to the class II region of MHC between HLA-DP and HLA-DQ (Fling et al., 1994; Morris et al., 1994). The murine homologue of HLA-DM is H2-M. Both HLA-DM and H2-M are heterodimers with low homology to conventional MHC class II proteins (Roche, 1995). HLA-DM/H-2M colocalizes with MHC class II molecules in an endolysosomal compartment called the *MHC class II compartment* (MIIC) (Roche, 1995) and functions as a peptide exchanger. HLA-DM/H-2M catalyzes the release of CLIP peptides from the MHC class II groove and the subsequent loading of processed exogenous peptides (Denzin and Cresswell, 1995; Sherman et al., 1995). Accordingly, HLA-DM/H-2M is most effective at pH 4.5–6, the pH range prevalent in later antigen-processing compartments. Once the MHC class II molecule is loaded with peptide, HLA-DM/H-2M is released and the peptide–MHC complex makes its way to the APC surface.

The functions of many molecules involved in the exogenous antigen processing pathway have been clarified through studies of knockout mice. The development and function of CD4<sup>+</sup> T cells are disturbed in mice lacking Ii, confirming the crucial

role of this protein in normal MHC class II antigen presentation (Viville et al., 1993). In H2-M-deficient mice, normal amounts of MHC class II molecules are present on the cell surface but the majority of them are associated with CLIP rather than exogenous peptide (Fung-Leung et al., 1996; Martin et al., 1996; Miyazaki et al., 1996). Unexpectedly, positive selection of MHC class II–restricted CD4<sup>+</sup> T cells appeared intact in these animals and they possessed large numbers of CD4<sup>+</sup> T cells that responded vigorously to antigens presented by normal APCs. However, APCs from H2-M-deficient mice were unable to stimulate syngeneic or allogeneic T lymphocytes to respond against self-antigens or foreign antigens (Fung-Leung et al., 1996). In MHC class II–deficient mice (Cosgrove et al., 1991; Grusby et al., 1991; Kontgen et al., 1993), thymocyte development is blocked at an early stage and CD4<sup>+</sup> lymphocytes are virtually absent in peripheral lymphoid organs. However, the development and functions of peripheral CD8<sup>+</sup> cytotoxic T cells are normal. Surprisingly, there were significant numbers of CD4<sup>+</sup> T cells in the thymus of MHC class II–deficient mice, although these cells were not of a mature phenotype. A subset of these unusual CD4<sup>+</sup> cells was found to be restricted to MHC class I–like CD1 molecules (Cardell et al., 1995).

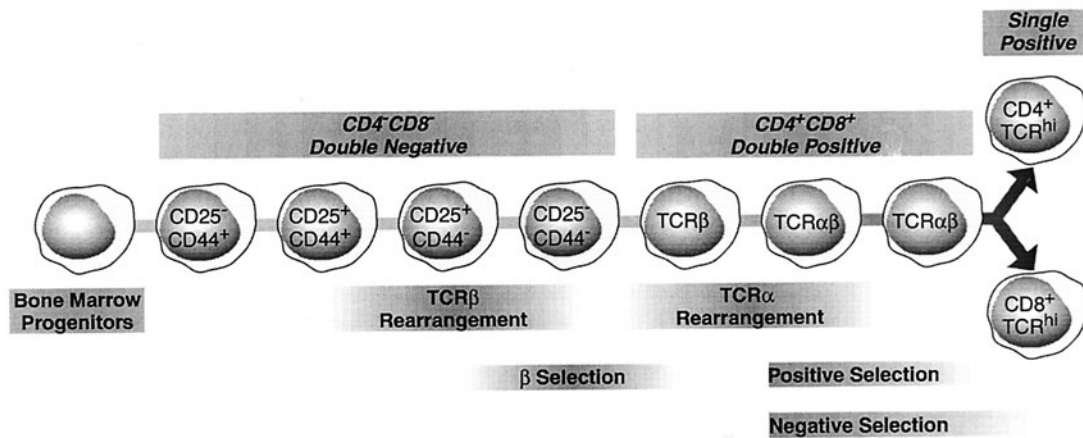

## Overview of T Cell Development and TCR Signaling

In this section, we present brief overviews of the stages of thymocyte development and introduce the signaling pathways vital to this process. It is hoped that the reader will then have a better understanding of the in-depth discussion of thymocyte selection processes that follows.

### Stages of T Cell Development

T cell development takes place in the thymus in a well-defined process during which precursor thymocytes divide, rearrange their antigen receptor DNA, and express functional TCRs and coreceptors. Thymic ontogeny can be divided into three major stages distinguished by the expression of certain cell surface receptors (Sebzda et al., 1999) (Fig. 4.5). The first major stage is the triple negative (TN) stage, in which neither the TCR, CD4, nor CD8 is expressed. Some immunologists refer to this stage as the double negative (DN) or CD4<sup>–</sup>CD8<sup>–</sup> stage. It is during the third phase of this stage (DN3; see below) that rearrangement of the VDJ segments of the TCR $\beta$  (but not TCR $\alpha$ ) locus commences. The TCR $\beta$  chain pairs with an invariant TCR $\alpha$ -like chain known as the pre-T $\alpha$  chain (or the TCRV $\alpha$  chain or gp33) to form a pre-TCR complex on the cell surface. In the second major stage of development, thymocytes commence expression of both coreceptors and are known as double positive (DP) or CD4<sup>+</sup>CD8<sup>+</sup> thymocytes. Rearrangement of the TCR $\alpha$  locus occurs, expression of pre-T $\alpha$  is extinguished, and true TCR $\alpha\beta$  heterodimers are expressed on the surfaces of DP thymocytes. It is at this point that positive and negative selection of DP thymocytes occur. In the third major stage of thymocyte development, DP cells that have been positively selected up-regulate expression of the TCR/CD3 complex. Recognition of MHC class I molecules by the TCR leads to the down-regulation of the expression of CD4 and the maturation of single positive (SP) CD8<sup>+</sup> thymocytes. Conversely, the interaction of a TCR with MHC class II results in the cessation of CD8 expression and the maturation of SP CD4<sup>+</sup> T thymocytes. Mature CD4<sup>+</sup> and CD8<sup>+</sup> T cells then emerge from the thymus and take up residence in the periphery, ready to detect foreign antigens.

**Figure 4.5.** Overview of thymocyte development. Simplified scheme of thymocyte development based on the expression of the markers CD25 and CD44, the TCR, and the coreceptors CD4 and CD8. As bone marrow-derived hematopoietic progenitors differentiate, three broad stages of thymocyte development can be distinguished: the double negative (DN) stage (no expression of CD4 or CD8; also no expression of a mature TCR); the double positive (DP) stage (expression of both CD4 and CD8; eventual expression of a mature TCR); and the single positive (SP) stage (expression of either CD4 or CD8 and a mature TCR). During the DN stage, the TCR $\beta$  gene undergoes somatic recombination and thymocytes that express a functional TCR $\beta$  chain are allowed to mature fur-

ther. This process is called  $\beta$ -selection. During the DP stage, the TCR $\alpha$  gene undergoes somatic recombination to generate a functional TCR $\alpha$  chain that combines with the TCR $\beta$  chain to form a functional heterodimer. Double positive thymocytes expressing TCR $\alpha\beta$  heterodimers are then subjected to negative selection to remove cells expressing TCRs that strongly recognize self-peptide/MHC complexes (potentially autoreactive cells), and positive selection to ensure the maturation of cells expressing TCRs that only weakly recognize self-peptide/MHC complexes. It is these latter cells that enter the SP stage and become mature CD4<sup>+</sup> and CD8<sup>+</sup> T cells capable of mounting immune responses to pathogens in the periphery.

Two major events occur during thymocyte development to ensure that an optimal T cell repertoire is generated. Negative thymic selection refers to the deletion by induced apoptosis of potentially self-reactive thymocytes—that is, those cells that strongly recognize self-peptide presented on self-MHC by thymic stromal cells. *Positive selection* refers to the differentiation of thymocytes that only weakly recognize self-peptide presented on self-MHC (those cells that are more likely to recognize foreign peptide presented on self-MHC). Positive selection thus generates a T cell repertoire that is restricted to self-MHC (Bevan, 1977; Zinkernagel et al., 1978; Zinkernagel and Doherty, 1979), and negative selection ensures that that repertoire is self-tolerant (Kappler et al., 1987a, 1987b, 1988; MacDonald et al., 1988). Immunologists call the outcome of these processes the establishment of *central tolerance*. T cell clones that recognize self-antigens but escape deletion or inactivation in the thymus are functionally inactivated in the periphery by mechanisms of *peripheral tolerance*.

### TCR Signaling Cascade

The binding of TCR/CD3 and a coreceptor to peptide-MHC triggers a signaling cascade that conveys information from the T cell surface to its nucleus. The transcription of a variety of new genes is induced while that of other genes is inhibited. Cellular responses are mediated through mobilization of the actin cytoskeleton, and a multimolecular structure called the *immunological synapse* (IS) or *supramolecular activation cluster* (SMAC) forms at the interface of the T cell and the APC (Bromley et al., 2001). Immunologists are still in the throes of elucidating all the players in this cascade, the means by which they interact with each other, and how their activities lead to T cell responses. Studies of the structure of SMACs in mature T cells and thymocytes have turned up some intriguing differences. In mature T cells activated by engagement of their TCRs by antigen, a central SMAC forms in which a ring of the adhesion binding partners LFA-1 and ICAM-1 surrounds

an inner cluster of TCR/peptide-MHC complexes (Monks et al., 1998). However, in thymocytes, a decentralized SMAC is formed in which multiple TCR/peptide-MHC complexes accumulate in areas of ICAM-1 exclusion (Hailman et al., 2002).

As noted above, the antigen binding subunits of the TCR cannot transduce signals themselves and depend on the ITAM-bearing CD3 chains for this function. The CD3 proteins do not possess intrinsic enzymatic activity but are coupled to cytoplasmic tyrosine kinases that interact with a host of other kinases, adaptor proteins, and transcription factors to bring about the downstream effects of antigen recognition (Hermiston et al., 2002) (Fig. 4.6). Among those membrane-bound kinases responsible for the earliest events in TCR-induced signal transduction are the Src family protein tyrosine kinases (PTKs) Lck and p59<sup>fyn</sup> (Fyn). Lck interacts noncovalently with cysteine residues in the cytoplasmic tails of both CD4 and CD8 (Yamaguchi and Hendrickson, 1996), whereas Fyn associates directly with the CD3 chains of the TCR/CD3 complex. In a resting cell, phosphorylation of regulatory C-terminal residues by p50<sup>csk</sup> kinase (Csk) renders Lck and Fyn catalytically inactive. Antigen receptor binding in both T and B lymphocytes activates CD45, a transmembrane phosphotyrosine phosphatase (PTPase) expressed in all nucleated hematopoietic cells. In T cells, the intracellular domain of CD45 dephosphorylates the negative regulatory tyrosine residues of Lck and Fyn, thereby up-regulating their activities.

Once activated by CD45 dephosphorylation, Lck and Fyn phosphorylate ITAMs found within the CD3 complex. Phosphorylated ITAMs in CD3 $\zeta$  chains recruit the kinase ZAP70 to the TCR complex, and this enzyme in turn recruits and activates the molecular adaptor proteins SLP76, LAT, and GADS. These adaptors recruit additional mediators such as Vav1, Itk, and Grb2 and subsequently key mid-stream transducers such as Rho GTPases, phosphatidylinositol 3-kinase (PI3K), phospholipase C- $\gamma$ 1 (PLC $\gamma$ 1), and Ras. Vav1 is expressed in all hematopoietic cells, contains SH2 and SH3 signaling domains, and functions

**Figure 4.6.** TCR signaling pathways. A schematic drawing of some of the signaling molecules involved in TCR signaling that influence thymocyte selection, based on gene targeting studies. See text for descriptions of molecular activities and interactions. [ $\text{Ca}^{2+}_i$ , intracellular calcium; DAG, diacylglycerol; ERK, extracellular signal-regulated kinase; IP<sub>3</sub>, inositol 1, 4, 5-triphosphate; LAT, linker for activation of T cells; MEK, mitogen-activated protein kinase (MAPK)/ERK kinase; MHC, major histocompatibility complex; MKK, MAPK kinase; PI3K, phosphatidylinositol 3-kinase; PIP<sub>2</sub>, phosphatidylinositol 4,5 bisphosphate; PKC, protein kinase C; PLC- $\gamma$ , phospholipase C $\gamma$ ; RasGRP, Ras guanyl-releasing protein; ZAP70, (CD3) zeta-associated kinase.

as a guanine nucleotide exchange factor for the Rac and Rho GTPases. These GTPases in turn promote thymocyte survival and differentiation as well as reorganization of the T cell actin cytoskeleton. Transgenic mice in which Rho function was genetically inactivated in the thymus showed a striking decrease in thymic cellularity and in levels of peripheral T cells that were due to a defect in thymocyte expansion (Henning et al., 1997). Studies of Vav1-deficient mice have confirmed that Vav1 is vital for the actin cap formation that supports SMAC assembly (Fischer et al., 1998; Holsinger et al., 1998; Wulfig, 2000). Actin cytoskeleton reorganization also requires the function of the Vav target gene *WASP*, which encodes the protein defective in Wiskott-Aldrich syndrome (Snapper et al., 1998; J. Zhang et al., 1999). In addition to cytoskeletal reorganization, Vav1-driven Rho family GTPases induce activation of the important transcription factor NFAT. Transcription of genes driven by NFAT is vital for the completion of T-cell activation and proliferation and cytokine production.

A second signaling pathway induced following ZAP70 activation depends on PLC $\gamma$ 1. PLC $\gamma$ 1 interacts with both LAT and Itk and mediates the hydrolysis of phosphatidylinositol 4,5 bisphosphate (PIP<sub>2</sub>) into diacylglycerol (DAG) and inositol 1,4,5-triphosphate (IP<sub>3</sub>). DAG production leads to activation of protein kinase C  $\theta$  (PKC $\theta$ ) and the recruitment of this isoform to the SMAC. PKC $\theta$  activation is also associated with the formation and recruitment of a protein complex containing the adaptors Bcl10 and MALT1. Bcl10 is specifically required for the activation of the transcription factor NF- $\kappa$ B following antigen receptor engagement (Rüland et al., 2001) but the precise role of MALT1 is not yet known. The second product of PLC $\gamma$ 1 action, IP<sub>3</sub>, induces an increase in the concentration of free cytoplasmic  $\text{Ca}^{2+}$  by binding to and opening insP<sub>3</sub>-regulated receptors in the ER

(Klausner and Samelson, 1991). This increase in intracellular calcium activates calcineurin, a serine/threonine phosphatase required for the activation of NFAT.

A third set of signaling pathways induced following TCR-mediated ZAP70 activation involves the MAPK (mitogen-activated protein kinase) family of signal transducers, particularly ERK (extracellular signal-regulated kinase). MAPK signaling cascades generally function in the proliferation and differentiation of hematopoietic cells (Rincon, 2001). Grb2, a molecule acting downstream of LAT, mediates the transduction of signals between the TCR and Sos, a guanine nucleotide exchange factor. Sos assists in Ras GTP exchange, resulting in the activation of Ras. Activated Ras in turn recruits the serine/threonine kinase Raf to the plasma membrane and activates it. Activated Raf phosphorylates MEK (MAPK/ERK kinase), which in turn phosphorylates ERK. Phosphorylated ERK induces transcription leading to the production of cytokines that support T cell differentiation. Other MAPK pathways are also triggered upon TCR engagement. Both the JNK/SAPK (jun kinase/stress-activated kinase) and p38 signaling pathways have been implicated in T cell activation and apoptosis. There is also extensive cross-talk between TCR signaling pathways. For example, DAG production can promote Ras activation because DAG interacts with the upstream Ras activator Ras guanyl-releasing protein (RasGRP).

### Thymocyte Ontogeny

With this background in T cell development and TCR signaling molecules, we are ready to examine thymocyte ontogeny in detail. As we follow hematopoietic precursor cells on their journey from progenitors to thymocytes to mature T cells, we will discuss

the effects on this process of various genes as demonstrated by the phenotypes of gene-targeted mice (Mak et al., 2001; Yeung et al., 1994). These animals have been of key importance in establishing that T cells mature through multiple genetic checkpoints (Fig. 4.7). For example, deletion of the TCR $\beta$  locus leads to a much earlier block in thymocyte development than the deletion of the TCR $\alpha$  locus (Mombaerts et al., 1992a). This unexpected result defined two distinct points at which TCR gene rearrangement takes place. Another surprise arose from the phenotype of Lck-deficient mice (Molina et al., 1992), which were found to have the same defects as TCR $\beta$ -deficient animals. Lck signaling function had not been expected to be important at so early a stage because it was generally assumed that the TCR was not expressed on early thymocytes. The door was thus opened to the discovery of the

pre-TCR signaling complex and a key checkpoint in T lymphopoiesis (reviewed in von Boehmer et al., 1999).

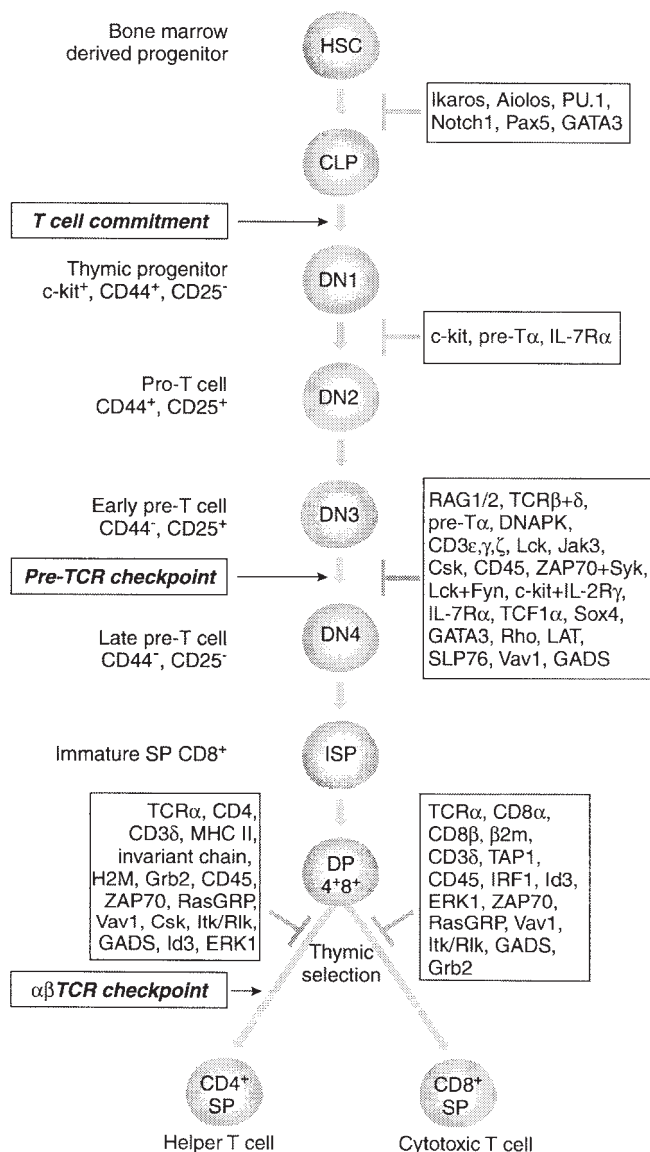

## The Double Negative Stage

### T Cell Development in the Bone Marrow

Hematopoietic cells originate in the fetal liver during embryonic development and in the bone marrow in adulthood. According to the most widely accepted model of murine hematopoiesis, a pluripotent hematopoietic stem cell (HSC) resident in the bone marrow differentiates into an HSC expressing the tyrosine kinase Flt3, and then into two early multipotent progenitors: the common myeloid progenitor (CMP) and the common lymphoid progenitor (CLP) (Borowski et al., 2002). Hematopoietic stem cells are capable of indefinite self-renewal *in vivo* and can reconstitute the complete spectrum of hematopoietic cells. Common myeloid progenitors and CLPs retain some self-renewal capacity and are able to differentiate into the full complement of either myeloid cells or lymphoid cells, respectively. It is still not entirely clear whether all CLPs remain in the bone marrow, or whether some can migrate to the thymus and differentiate into T cells in that location. *In vitro* experiments in adult mice have identified progeny of CMPs and CLPs that are more restricted in their potential. For example, cells giving rise only to neutrophils or monocytes have been isolated, as well as intermediates such as a B/T/natural killer (NK) precursor and an NK/T precursor, and still other cells limited to producing granulocytes, erythrocytes, monocytes, or macrophages.

Multiple growth factors, cytokines, and transcription factors play roles in initiating and maintaining lymphopoiesis (Berg and Kang, 2001). Function of the transcription factor PU.1 is essential for the development and maturation of both CLPs and CMPs. PU.1 controls the transcription of cytokine receptors needed to receive developmental signals such that PU.1<sup>-/-</sup> mice lack T cells, B cells, neutrophils, and macrophages. The level of PU.1 in a hematopoietic progenitor controls its destiny: low levels of PU.1 induce IL-7R expression and lymphoid development, whereas high levels of PU.1 suppress IL-7R expression and promote the expression of receptors for cytokines favoring myeloid development. IL-7, along with Flt3 ligand and c-kit ligand (growth factors derived from bone marrow stromal cells), is essential for the survival of the earliest committed T cell progenitors, and IL-7 is crucial for the maturation of these progenitors to lymphocytes. Mice with disruptions of the genes encoding either IL-7 or the IL-7R subunits have defects in cell cycle progression and thus exhibit impaired thymocyte development. If a transgene encoding the anti-apoptotic protein Bcl-2 is introduced into IL-7- or IL-7R-deficient mice, T cell development can be rescued (Akashi et al., 1997; Maraskovsky et al., 1997; von Freuden-Jeffry et al., 1997). This result implies that a primary function of IL-7 is to maintain thymocyte survival. Interestingly, signaling delivered through IL-7R is more important for  $\gamma\delta$  T-cell than for  $\alpha\beta$  T-cell development. IL-7R<sup>-/-</sup> mice have decreased numbers of  $\alpha\beta$  T cells but a complete absence of  $\gamma\delta$  T cells because of a failure in TCR $\gamma$  locus rearrangement. Introduction of an already rearranged TCR $\gamma$  transgene can rescue  $\gamma\delta$  T cell development in these animals (Kang et al., 1999). It is thought that signals initiated by IL-7 binding to IL-7R and transduced via the intermediaries Jak and STAT trigger changes to the accessibility of the TCR $\gamma$  locus that are required for RAG recombinase binding (Schlissel et al., 2000).

Ikaros is a transcription factor acting slightly later than PU.1 that is also required for the development of CLP and its progeny (reviewed in Rothenberg and Anderson, 2002). Ikaros is thought

**Figure 4.7.** Checkpoints in thymocyte development as indicated by gene-targeting studies. Examination of the phenotypes of gene-targeted mice has allowed researchers to define specific genetic checkpoints during thymocyte development. Molecules whose functions are required at or around these checkpoints are indicated. See text for detailed descriptions of various stages. DN, double negative stage; DP, double positive stage; ISP, intermediate single positive stage; SP, single positive stage; +, double knockout mutant.

to repress the transcription of “lineage-inappropriate” genes by recruiting histone deacetylases that reduce the chromatin accessibility of a locus (Georgopoulos, 2002). For example, CD19 (a B cell-specific gene) is repressed in T/B progenitors destined to become T cells, while CD4 and CD8 expression is repressed in those precursors destined to become B cells. A related transcription factor called Aiolos interacts with Ikaros to help establish T lineage commitment and thymocyte expansion. Mice with reduced levels of Ikaros or Aiolos fail to activate expression of the CD8 $\alpha$  gene, leading to an apparent increase in immature T cells expressing CD4. Another important transcription factor involved in the divergence of T cell progenitors from B cell progenitors is GATA-3. GATA3 $^{-/-}$  mice can produce B cells but not even the earliest of thymocyte populations.

There is now a considerable body of evidence that supports a role for the cell fate determination protein Notch-1 in T cell lineage commitment (Robey, 1999). The Notch proteins are a family of highly conserved transmembrane receptors that control binary cell fate decisions in diverse organisms. The Notch proteins regulate transcription directly by associating with nuclear factors (Artavanis-Tsakonas et al., 1999). Interaction between Notch-1 and one of its several ligands results in proteolytic cleavage of Notch-1 and the release of its intracellular domain (IC). The Notch-1 IC translocates to the nucleus and interacts with the CBF1 transcription factor, converting it from a repressor to an activator of genes involved in cell fate decisions (Hsieh et al., 1996; Struhl and Adachi, 1998). Among these are the HES genes, transcriptional repressors that act as downstream effectors in the Notch-1 signaling pathway. HES $^{-/-}$  mice either lack a thymus or have a small organ that is completely deficient in mature  $\alpha\beta$  and  $\gamma\delta$  T cells (B and NK cells are normal). Commitment to the T lineage results from the interaction of Notch-1 with Delta-1 (but not an alternative ligand, Jagged-1) (Jaleco et al., 2001). Indeed, in vitro, Delta-1 expressed ectopically by a bone marrow stromal cell line induces the differentiation of hematopoietic progenitors into both  $\alpha\beta$  and  $\gamma\delta$  T cells but not B cells (Schmitt and Zúñiga-Pflücker, 2002). The production of NK cells is independent of Delta-1 expression. This study thus shows that the lymphopoietic function of the thymic microenvironment, which had been difficult to replicate in vitro, is largely to supply ligands to induce Notch-1 signaling. In the absence of Notch signaling, V-to-DJ recombination in the TCR $\beta$  locus is impaired and thymocyte development is halted at this stage (Wolfer et al., 2002). Notch-1 also interferes with the activity of the E2A transcription factor that facilitates transcription of B cell-specific genes, blocking development down the B-cell path. Consistent with these findings, loss-of-function mutations of Notch-1 in newborn mice or in bone marrow stem cells result in a severe early block in T cell development and the appearance of ectopic B cells in the thymus (Radtko et al., 1999; Wilson et al., 2001). In addition, Notch-1 function can be manipulated to favor the development of B cells in the thymus (Koch et al., 2001; Izon et al., 2002). Conversely, expression of a constitutively active form of Notch-1 in bone marrow stem cells results in the ectopic development of precursor T cells outside the thymus (Pui et al., 1999; Allman et al., 2001).

Early lymphopoiesis is also influenced by signal transduction molecules. As mentioned above, Csk kinase negatively regulates Src family kinases in resting hematopoietic cells by phosphorylating specific tyrosine residues. Genetic disruption of the *Csk* gene causes multiple defects in organ development such that embryonic lethality occurs at days 9–10 of gestation (Imamoto and Soriano, 1993; Nada et al., 1993). Phosphorylation of the negative regulatory tyrosine residues of Fyn, Src, and p53/p56<sup>lyn</sup> (Lyn, an-

other member of the Src family that is predominantly expressed in B cells) was greatly reduced, but not absent, in *Csk* $^{-/-}$  mice. Consequently, the catalytic activity of these Src family kinases was enhanced in in vitro assays, and various hyperphosphorylated proteins were detected in *Csk* $^{-/-}$  embryos. Studies of *Csk* $^{-/-}$  ES cells and *Csk* $^{-/-}$  RAG $^{-/-}$  reconstituted mice showed that *Csk* $^{-/-}$  hematopoietic precursors could colonize the bone marrow and thymus but that there was an early block in differentiation prior to the T-cell commitment stage (Gross et al., 1995). A conditional *Csk* knockout mutation specifically confined to the T lineage allowed the development of mature CD4 $^{+}$  T cells in a RAG-deficient background (Schmedt et al., 1998; Schmedt and Tarakhovsky, 2001).

### T-Cell Development in the Thymus

The earliest precursor T cells that can be found within the thymus itself are the DN1 subset, characterized as HSA $^{+}$  (heat-stable antigen; CD24) CD3 $^{-}$ CD4 $^{-}$ CD8 $^{-}$  and also c-kit $^{+}$ CD44 $^{+}$ CD25 $^{-}$ . These cells, which constitute approximately 2%–5% of all thymocytes, have the ability to home directly to the thymus after intravenous transfer into a host animal (Shortman, 1992). DN1 cells subsequently up-regulate expression of CD25 to become DN2 or pro-T cells with a surface phenotype of CD44 $^{+}$ CD25 $^{+}$ . The pre-T $\alpha$  chain is also expressed in these cells. When DN2 thymocytes become DN3 or early pre-T cells, they down-regulate expression of CD25 again to become CD44 $^{+}$ CD25 $^{-}$  cells. It is at this point that an obvious commitment to the  $\alpha\beta$  or  $\gamma\delta$  T lineage is made. Thymocytes at the DN3 stage commence somatic recombination in the TCR $\beta$ ,  $\gamma$ , and  $\delta$  loci, with rearrangement of the  $\gamma$  and  $\delta$  gene segments preceding that of the  $\beta$  gene segments (Raulet et al., 1985). While only rearrangement of the TCR $\beta$  locus is required to initiate  $\alpha\beta$  T-cell maturation, both TCR $\gamma$  and TCR $\delta$  must be productively rearranged to generate functional  $\gamma\delta$  T cells. Since the somatic recombinases RAG1/2 have been shown to be essential for the rearrangement of all TCR genes (Schatz et al., 1989), it is not surprising that mice deficient for either of these molecules have very early defects in lymphocyte development (Mombaerts et al., 1992b; Shinkai et al., 1992, 1993). The thymic RAG1- or RAG2-deficient mice contain a decreased number of thymocytes (approximately  $3 \times 10^6$  compared to about  $1 \times 10^8$  thymocytes in normal mice) and T-cell development is arrested at the early DN2 stage. Similarly, mice with a natural mutation in the dsDNA-PK (*Prkdc*) gene show normal initiation of gene segment recombination but fail to ligate the segments together, resulting in a lack of mature T and B cells (Kirchgessner et al., 1995). In contrast, mice with a mutation in the *Tdt* gene responsible for N-nucleotide addition do not show altered T-cell development (Gilfillan et al., 1993; Komori et al., 1993).

The TCR $\alpha$  locus does not initiate rearrangement until considerably later than the other three loci. Instead, in thymocytes destined to become  $\alpha\beta$  T cells, newly synthesized TCR $\beta$  chains pair with pre-T $\alpha$  chains to form pre-TCRs. Pre-TCRs undergo testing to determine whether the TCR $\beta$  chain can function in a signaling complex. Thus, disruption of the pre-T $\alpha$  gene leads to an arrest in TCR $\alpha\beta$  thymocyte development at a phenotypic stage similar to that in TCR $\beta$ -deficient mice (Fehling et al., 1995). Introduction of various transgenes encoding mutated versions of pre-T $\alpha$  has demonstrated that the cytoplasmic domain of the pre-T $\alpha$  chain is not required for pre-TCR function (Fehling et al., 1997) and that pre-TCR signaling does not require a ligand (Irving et al., 1998; Wiest et al., 1999). As long as the pre-T $\alpha$  chain associates successfully with a functional TCR $\beta$  chain, exits the Golgi, and assembles with the CD3 complex in the plasma membrane

microdomains, thymocyte development proceeds normally (O'Shea et al., 1997). Interestingly, pre-T $\alpha$ -deficient mice exhibit normal development of  $\gamma\delta$  T cells, indicating that the  $\gamma\delta$  T lineage diverges from the  $\alpha\beta$  T lineage at the point of pre-TCR expression (Fehling et al., 1995; Malissen and Malissen, 1996). It is thought that pre-TCR signaling may "instruct" T precursors to divert down the  $\alpha\beta$  differentiation path. Indeed, the pre-TCR and  $\gamma\delta$  TCR differ in their signal initiation mechanisms. Unlike the pre-TCR, the  $\gamma\delta$  TCR does not associate with lipid microdomains in the plasma membrane and does not associate with CD3 $\epsilon$  (Saint-Ruf et al., 2000). Further confirmation of this difference can be found in the phenotype of mice with a targeted disruption of the TCR C $\delta$  exon. These animals have no detectable cell surface expression of any  $\gamma\delta$  TCR components but  $\alpha\beta$  T cell development is normal (Itohara et al., 1993). TCR $\delta$  knockout mice are also able to mount normal antibody responses after immunization with ovalbumin, indicating that  $\alpha\beta$  T helper cell function remains intact (Itohara et al., 1993). Conversely, development of  $\gamma\delta$  cells is unaffected by either *Tcra* or *Tcrb* mutations (Mombaerts et al., 1992a). Initial studies reported a role for Notch-1 in  $\alpha\beta/\gamma\delta$  T cell lineage commitment (Washburn et al., 1997), but it now appears that Notch-1 signaling supports the differentiation of both T-cell types (Schmitt and Zúñiga-Pflücker, 2002).

Only DN3 pre-T cells that have rearranged the TCR $\beta$  locus in-frame and have successfully combined it with the pre-T $\alpha$  chain to form a functional pre-TCR on the thymocyte surface receive a signal permitting further development, a process called  *$\beta$  selection*. Pre-TCR signaling leads to activation of the transcription factor NF- $\kappa$ B, which controls the expression of numerous genes needed for survival and proliferation (Voll et al., 2000). Cells that have rearranged the TCR $\beta$  locus out-of-frame do not receive the survival signal and are induced to undergo apoptosis (Malissen and Malissen, 1996). As the  $\beta$ -selected thymocytes further evolve into DN4 or late pre-T cells, expression of CD44 is lost and the cells are phenotypically CD44<sup>-</sup>CD25<sup>-</sup>. These cells undergo a dramatic expansion that requires the activities of the transcription factors Tcf-1 and Sox4. Mice deficient for either of these molecules lack DP cells and have pre-T cells that fail to proliferate (Schilham and Clevers, 1998). DN4 cells that expand successfully pass through an immature single positive (ISP) stage in which CD8 is transiently expressed on the cell surface but a mature TCR is not yet present. The transition is then made to the DP stage in which both CD4 and CD8 are expressed, rearrangement of the TCR $\alpha$  locus occurs, and a complete TCR $\alpha\beta$  heterodimer is finally expressed on the thymocyte surface. DP cells are then subjected to positive and negative thymic selection.

The importance of functional TCR $\beta$  chain rearrangement and pre-T $\alpha$ /TCR $\beta$  expression for the transition from DN to DP thymocytes and for expansion of  $\beta$ -selected thymocytes is clearly demonstrated in the phenotype of TCR $\beta$ -deficient mice (Mombaerts et al., 1992a). These animals have a small thymus because of an early block in T cell development at the DN3 stage. The reduced numbers of cells making up the TCR $\beta$ <sup>-/-</sup> thymus are present in equal proportions of DN and DP cells. Both these thymocyte populations lack detectable rearrangements of *Tcrb* genes and TCR $\alpha\beta$  expression (Mombaerts et al., 1992a). However, recombination did occur at the TCR $\alpha$  locus, suggesting that TCR $\beta$  rearrangement and expression are not an absolute prerequisite for TCR $\alpha$  rearrangement.

Pre-TCR signaling also requires intact function of components of the CD3 complex, signal transduction molecules, and adaptor molecules further downstream. For example, CD3 $\epsilon$ <sup>-/-</sup> thymocytes, although still able to express rearranged TCR $\beta$  transcripts, are

blocked at the DN3 stage (Malissen et al., 1995). These findings imply that CD3 $\epsilon$  expression is important for monitoring the productivity of TCR $\beta$  rearrangement by testing for pre-TCR signal transduction. Consistent with the association between pre-TCR signaling and  $\alpha\beta$  T commitment, rearrangements of TCR $\gamma$  (*Tcrg*) and  $\delta$  (*Tcrd*) gene segments are normal in CD3 $\epsilon$ <sup>-/-</sup> mice. Mice deficient for CD3 $\zeta$  show a profound reduction in the amount of surface TCRs on DP cells as well as a reduced number of thymocytes (Liu et al., 1993; Love et al., 1993; Malissen et al., 1993; Ohno et al., 1993; Shores et al., 1998). In the peripheral lymphoid organs of double-mutant CD3 $\zeta\eta$ <sup>-/-</sup> mice, unusual CD4<sup>+</sup>CD8<sup>+</sup>TCR $\alpha\beta$ <sup>+</sup> and CD4<sup>+</sup>CD8<sup>+</sup>TCR $\alpha\beta$ <sup>+</sup> cells were present that were positive for Thy-1 and CD44 surface expression but did not stain with anti-CD3 $\epsilon$  or anti-HSA antibodies. Interestingly, the development of thymus-independent intestinal intraepithelial lymphocytes (IELs) occurred normally in these mice, and IELs expressed TCRs complexed with the Fc $\epsilon$ RL $\gamma$  chain in the absence of CD3 $\zeta\eta$  (Love et al., 1993; Malissen et al., 1993).

Mice deficient for Lck kinase exhibit a small thymus because of an early block in the maturation of both TCR $\alpha\beta$  and TCR $\gamma\delta$  thymocytes (Molina et al., 1992). Mice transgenic for a dominant negative Lck mutation (Levin et al., 1993) have a phenotype similar to that of Lck<sup>-/-</sup> mice. Conversely, a transgene encoding a constitutively active form of Lck can fully replace defective pre-TCR signaling in RAG1-deficient mice (Mombaerts et al., 1994). These results indicate that the catalytic activity of Lck is crucial for the maturation of all early thymocyte precursors. These results were confirmed using RAG complementation studies in which Lck was shown to be critical for signaling pathways activated by gamma-irradiation and CD3 $\epsilon$  engagement in RAG-1<sup>-/-</sup> immature thymocytes (Wu et al., 1996). The maturation of transgenic TCR $\gamma\delta$  T cells was followed in Lck<sup>-/-</sup> mice and found to be blocked at an early stage (Penninger et al., 1993). However, the development of these transgenic  $\gamma\delta$  T cells did not require the coexpression of CD4 or CD8, indicating that the Lck/CD4 and Lck/CD8 associations observed in normal T cells are not essential for thymocyte development (Penninger et al., 1993). Surprisingly, as was true for CD3 $\zeta\eta$ -deficient mice, intestinal TCR $\gamma\delta$  T cells appeared to be unaffected by the Lck mutation (Penninger et al., 1993), indicating that Lck-mediated signal transduction may be differentially regulated in thymocytes, depending on the antigen recognized or the anatomical site of development.

Mice deficient for Fyn kinase do not display any overt phenotypic changes in T-cell development (Appleby et al., 1992; Stein et al., 1992), although they do display brain-associated defects (Grant et al., 1992; Stein et al., 1992). The proliferative responses of thymocytes and splenic T cells from Fyn-deficient mice were only slightly decreased after TCR/CD3 activation or stimulation with allogenic spleen cells, lectins, or bacterial superantigens. At the molecular level, a defect in Fyn expression resulted in altered patterns of tyrosine phosphorylation and decreased Ca<sup>2+</sup> flux. However, double-mutant Lck/Fyn-deficient mice show a profound block at the DN3 stage of thymocyte differentiation that was more pronounced than that observed in Lck-deficient animals. These results indicate that Fyn can functionally compensate for Lck during early thymocyte development and pre-TCR signal transduction (Groves et al., 1996; van Oers, 1996).

Interestingly, mice lacking ZAP70 have a later block in thymopoiesis than that of Vav1-deficient mice, even though Vav1 functions downstream of ZAP70. It has been shown through RAG complementation that mice lacking Vav1 have only a small number of mature T cells because of a block at the DN3 stage. These mutant T cells proved to be hyporeactive to TCR/CD3

stimulation, and  $\text{Ca}^{2+}$  signaling was impaired (Fischer et al., 1995; Tarakhovsky et al., 1995; Zhang et al., 1995). In contrast, ZAP70-deficient mice have DP thymocytes but these cells do not progress to mature  $\text{CD4}^+$  or  $\text{CD8}^+$  SP cells. A block in positive and negative T-cell selection of DP thymocytes has been demonstrated in ZAP70 $^{-/-}$  thymocytes (Negishi et al., 1995). Why the discrepancy between the phenotypes of Vav $^{-/-}$  and ZAP70 $^{-/-}$  mice? SYK, a kinase related to ZAP70, is highly expressed in DP thymocytes (A.C. Chan et al., 1994). SYK $^{-/-}$  mice show impaired differentiation of B-lineage cells due to disruption of pre-BCR complex signaling but have no apparent block in the development of TCR $\alpha\beta$  thymocytes (Cheng et al., 1995; Turner et al., 1995). (These animals apparently do have a defect in the maturation of  $\gamma\delta$  T cells.) However, double-mutant mice lacking both ZAP70 and SYK show a complete block in thymocyte development at the DN3 stage (just like Vav1-deficient mice), which implies that ZAP70 and SYK can compensate for each other's activity for pre-TCR signaling but not for thymic selection (Cheng et al., 1997).

Downstream of ZAP70, the molecular adaptors SLP-76 (Clements et al., 1998; Pivniouk et al., 1998), LAT (W. Zhang et al., 1999), and Gads (Yoder et al., 2001) are all essential for pre-TCR signaling and DN3 thymocyte maturation. Transgenic studies have shown that constitutively active Rac-1 can induce differentiation of pre-T cells but not proliferation (Gomez et al., 2000). In particular, constitutively active Rac-1 rescues functions missing in the absence of Vav and allows Vav1-deficient thymocytes to complete  $\beta$ -selection. A constitutively active Raf-1 transgene promotes thymocyte proliferation and differentiation but not allelic exclusion (Iritani et al., 1999). Other studies have suggested that allelic exclusion of the TCR $\beta$  locus requires SLP-76 (Aifantis et al., 1999) and PKC $\theta$  activity (Michie et al., 2001).

There have been some reports implicating Notch-1 in the DN-to-DP transition. Immature outer cortical DN thymocytes express high levels of Notch-1, whereas DP thymocytes express little or no Notch-1, and the most mature SP thymocytes express an intermediate level of Notch-1. It was proposed that Notch-1 down-regulation might be required for the maturation of cortical thymocytes (Hasserjian et al., 1996). Felli et al. (1999) further demonstrated a differential expression of different Notch isoforms (Notch-1, 2, and 3) and their ligands (Jagged-1 and 2) in the thymus, suggesting that thymocyte development is regulated by the interactions between different members of the Notch family and their cognate ligands in different thymic cell compartments.

## The Double Positive Stage

### The Coreceptors

$\text{CD44-CD25}^+$  late pre-T cells (DN4) differentiate into  $\text{CD4}^+\text{CD8}^+$  DP thymocytes that rearrange the TCR $\alpha$  (*Tcra*) locus to generate a functional TCR $\alpha\beta$  heterodimer. Mice with a disruption in the *Tcra* locus consequently show a later block in development than do TCR $\beta$ -deficient mice. TCR $\alpha$ -deficient animals have a normal-sized thymus and a marked absence only of  $\text{CD4}^+$  and  $\text{CD8}^+$  SP cells (Mombaerts et al., 1992a; Philpott et al., 1992). Interestingly, normal numbers of both DN and DP thymocytes expressing TCR $\beta$  chains but not heterodimeric  $\alpha\beta$  TCRs exist in TCR $\alpha$  $^{-/-}$  animals. In older TCR $\alpha$ -deficient mice, an unusual  $\text{CD4}^+\text{TCR}\beta^{\text{dull}}$  lymphocyte population can be observed in the periphery that is even more apparent after the introduction of a TCR $\beta$  transgene (Philpott et al., 1992). These data indicate that,

while TCR $\alpha$  is not required for the DN-to-DP transition and the subsequent expansion of the DP thymocyte pool, its expression (along with that of TCR $\beta$ ) is required for the DP-to-SP transition. The TCR $\alpha$  locus does not undergo allelic exclusion like the TCR $\beta$  locus and  $\text{V}\alpha\text{J}\alpha$  rearrangements may continue within a given cell such that two TCRs containing different TCR $\alpha$  chains may be expressed on the surface (Heath et al., 1995). More recently, it has been noted that progression of  $\text{V}\alpha\text{J}\alpha$  rearrangement is controlled by thymocyte survival in a way that regulates the T cell repertoire (Guo et al., 2002). It has been suggested that TCRs, like BCRs, may undergo secondary rearrangement in the form of receptor editing (McGargill et al., 2000).

As might be expected, the coreceptors CD4 and CD8 are crucial for DP thymocyte maturation. The CD8 $\alpha$  chain is required for the surface expression of both CD8 $\alpha$  and CD8 $\beta$ . Thus, in mice with a disrupted *Cd8a* gene there is a total absence of CD8 expression on T cell surface (Fung-Leung et al., 1991a, 1993). The vast majority of T cells in the periphery of these mutants are  $\text{CD4}^+$  T cells whose maturation appears to be normal. Cytotoxic responses to alloantigens were partly impaired whereas cytotoxic responses to virus infections were severely inhibited. Studies of CD8 $\alpha$  $^{-/-}$  mice transgenic for a CD8 $\alpha$  chain bearing point mutations of the Lck binding domain showed that the Lck-associative function of CD8 is not essential for thymic selection (I.T. Chan, 1993). Nevertheless, an absence of most of the CD8 $\alpha$  cytoplasmic domain did have an inhibitory effect on the positive selection of cytotoxic cells (Fung-Leung et al., 1991b).

In mice with a disrupted *Cd8b* gene, the CD8 $\alpha^+$  T-cell population in the thymus and in most peripheral lymphoid organs is reduced to 20%–30% of normal, and CD8 $\alpha$  expression on thymocytes is decreased to approximately 50% of normal (Fung-Leung et al., 1994). This defect does not extend to IELs, cells that express a CD8 $\alpha\alpha$  homodimer and develop extrathymically (Guy-Grand et al., 1991). Thus, CD8 $\beta$  is important only for thymically derived CD8 $^+$  T cells. The absence of CD8 $\beta$  reduces but does not completely abolish thymic maturation of CD8 $^+$  T cells. Moreover, peripheral T cells in CD8 $\beta$  $^{-/-}$  mice display effective cytotoxic activity against virus infections, a finding suggesting that CD8 $\beta$  is not essential for cytotoxic effector functions of CD8 $^+$  T cells (Fung-Leung et al., 1994).

Mice with a disruption in the *Cd4* gene have markedly decreased T helper cell activity but normal development and function of CD8 $^+$  T cells. These results indicate that expression of CD4 on progenitor cells and on DP thymocytes is not obligatory for the differentiation of CD8 $^+$  cytotoxic effectors (Rahemtulla et al., 1991; Killeen et al., 1993). Curiously, CD4 $^{-/-}$  mice are still able to mount detectable T-helper cell responses. This residual T helper activity has been attributed to a population of TCR $\alpha\beta^+\text{CD4}^-8^-$  T cells present in peripheral lymphatic organs (Locksley et al., 1993; Rahemtulla et al., 1994).

### Mechanisms of Positive and Negative Thymic Selection

Positive selection of DP thymocytes results in the generation of mature  $\text{CD4}^+$  TCR $^{\text{high}}$  helper or  $\text{CD8}^+$  TCR $^{\text{high}}$  cytotoxic SP T cells that are able to react to non-self, whereas negative selection eliminates potentially harmful self-reactive T cells (von Boehmer et al., 1989b; Sebzdka et al., 1999). The mechanisms governing positive and negative selection are dependent on physical interactions between the antigen-specific TCR expressed on developing thymocytes and peptide-MHC complexes expressed on surrounding thymic stromal cells. More than 80% of developing

thymocytes express a TCR that does not recognize any self-peptide/self-MHC combination. These cells undergo apoptosis and are said to “die of neglect” or “die by non-selection default.”

There were originally several models put forward to explain how the interaction of the TCR with thymic ligands could result in nonselection, positive selection, or negative selection. However, the preponderance of the most recent evidence gained from studies of animal models supports the “affinity/avidity model” of thymic selection (Sprent et al., 1988; Sebzda et al., 1999). This model proposes that the type of selection a thymocyte undergoes depends on the strength of the interaction between its TCR and its peptide-MHC thymic ligand (Fig. 4.8). According to this model, thymocytes with TCRs of low affinity or avidity for self-MHC do not receive any type of signal and undergo programmed cell death by default. However, thymocytes expressing TCRs with intermediate affinity or avidity for self-MHC receive a survival signal and are positively selected. These TCRs are those most likely to recognize foreign peptides presented in the context of self-MHC and thus may be useful in host defence against pathogen infections. In contrast, thymocytes expressing TCRs with high affinity or avidity for self-peptide/self-MHC receive a signal that induces them to undergo either clonal deletion or clonal inactivation. This negative selection of thymocyte clones removes potentially self-reactive cells. To test the affinity/avidity model, the outcome of thymic selection has been experimentally manipulated in fetal thymic organ cultures (FTOC) by titrating the density of specific peptide-MHC complexes. A low concentration of the peptide antigen recognized by a transgenic TCR resulted in positive selection, whereas a high concentration of the peptide antigen resulted in negative selection and immunological tolerance (Ashton-Rickardt et al., 1994; Hogquist et al., 1994; Sebzda et al., 1994). Bolstering the density hypothesis is the observation that negative selection is associated with maximal internalization of the engaged TCR, whereas fewer TCRs are internalized during positive selection (Mariathasan et al., 1998). As is discussed in more detail below, internalization

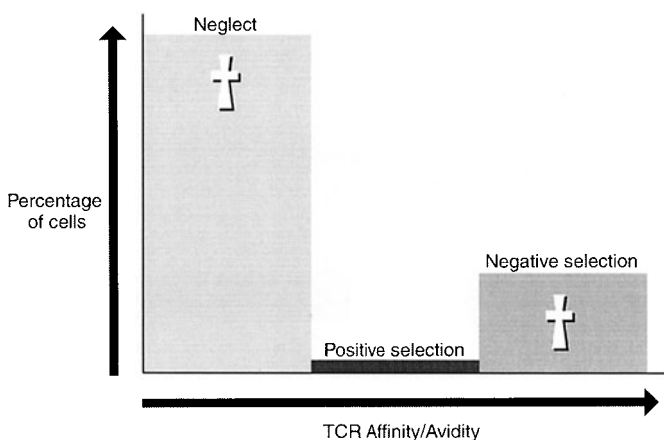

of TCRs has been linked to modulation of downstream signal transduction.

### Stromal Cell Involvement in Thymic Selection

Although it has been clear for some time that negative selection of autoreactive thymocytes occurs in the thymus (Ramsdell et al., 1989; Speiser et al., 1992), it has been less obvious which cell types are responsible for presenting the selecting ligands. Both bone marrow-derived cells and stromal cells in the thymus have been implicated, but comparatively few studies have been done to specifically identify the cell types involved. Peptides derived from ubiquitously expressed “housekeeping” proteins can be presented by thymic stromal cells and thus contribute to both positive and negative selection of thymocytes. However, until very recently, it was believed that T cells recognizing tissue-specific self-proteins were generally inactivated by peripheral tolerance mechanisms, since, by definition, tissue-specific proteins should not appear in the thymus. There was also some evidence that tissue-specific proteins shed into the circulation by the tissue in question could be taken up by recirculating APCs able to access the thymus (Heath and Carbone, 2001). However, despite sporadic reports that expression of tissue-specific proteins such as myelin and cytokeratin could be detected in the thymus itself (Heid et al., 1988; Jolicoeur et al., 1994; Pribyl et al., 1996; Smith et al., 1997), thymic expression of tissue-specific proteins was not fully appreciated (Hanahan, 1998). Experiments with transgenic mice expressing genes under the control of tissue-specific promoters often showed expression in the thymus as well as in the tissue of interest (Klein et al., 1995), but it remained possible that the promoters were displaying leaky expression because of their site of integration.

Recent studies have identified a population of medullary thymic epithelial cells (mTECs) located in the thymus that may play a key role in the establishment of central tolerance to tissue-specific proteins. Medullary TECs can transiently express a wide range of these molecules, allowing the deletion of reactive T-cell clones before their release to the periphery (Kyewski et al., 2002). Also, mTECs have been shown to express RNAs encoding hormones, secreted proteins, membrane proteins, and transcription factors, among other molecules. Experiments in transgenic and nontransgenic mice have confirmed that ectopic expression of a protein in mTECs leads to peripheral tolerance of that protein (Anderson et al., 2000; Klein et al., 2000; Derbinski et al., 2001). It has yet to be determined whether all mTEC clones can express all tissue-specific proteins or whether individual mTEC clones express different subsets of tissue-specific proteins. The latter situation would enable an individual mTEC cell to express a greater percentage of its cell surface proteins as the tissue-specific protein in question, increasing epitope density and the likelihood of a sufficiently strong TCR signal being delivered to the T cell to induce negative selection (Kyewski, 2002). Some have speculated that mTECs may also be involved in the differentiation of regulatory T cells that suppress autoimmune responses (Sakaguchi, 2000; Seddon and Mason, 2000).

It is not yet clear whether expression of tissue-specific genes in mTECs is the result of random derepression of transcription or a more directed activation process. Similarly, the influence of external factors on mTEC gene expression remains a mystery. However, new evidence has implicated a transcription factor called AIRE (autoimmune regulator) in mTEC-induced central tolerance (Anderson et al., 2002). Both humans and mice deficient for AIRE suffer from autoimmune symptoms that affect multiple

**Figure 4.8.** Affinity/avidity model of thymocyte selection. Schematic diagram of the relationship between the affinity and avidity of TCRs for peptide/self-MHC ligands (pMHC) presented in the thymus and the percentage of thymocytes directed toward the indicated cell fate. Thymocytes whose TCRs have low affinity or avidity (>80% of thymocytes) do not recognize pMHC and do not receive survival signals; they are not selected and die of neglect. Thymocytes with high affinity for pMHC (18%) receive signals inducing apoptosis; these cells are negatively selected. Thymocytes with intermediate affinity for pMHC (<1%–2%) receive signals allowing them to survive, expand, and differentiate into mature T cells; these cells are positively selected.

organs (Bjorses et al., 1998; Anderson et al., 2002; Ramsey et al., 2002). (See Chapter 25). Analyses of transcription by cells of AIRE-deficient mice showed that mTEC expression of several tissue-specific proteins associated with various autoimmune symptoms was reduced in the absence of AIRE. Furthermore, although the highest levels of AIRE expression occurred in mTECs, AIRE was not required for the differentiation or antigen-presenting function of mTECs. Studies of chimeric animals in which AIRE expression was missing either from hematopoietic cells or from stromal cells showed that peripheral autoimmunity was present only in the latter situation. AIRE is known to interact with the transcriptional coactivator CREB-binding protein (Pitkanen et al., 2000), and it has been suggested that AIRE may participate in a multisubunit complex in mTECs that activates the transcription of multiple genes encoding tissue-specific proteins. Both AIRE-dependent and independent promiscuous expression of tissue-restricted self antigens in the thymus seems to occur (Derbinski et al., 2005). In the absence of AIRE, negative selection of T cells recognizing these proteins does not appear to occur, and tissue-reactive T cell clones escape to the periphery.

Several other molecules have been identified as being important for thymic stromal cell development and/or function. GHLF, Whn, Pax1, and Hox3a are all transcription or differentiation factors important for TEC development and the establishment of a normal thymic microenvironment (Nehls et al., 1994, 1996; Panigada et al., 1999; Su and Manley, 2000). "Sonic hedgehog" is a maturation factor produced by thymic stromal cells that acts on DN thymocytes to hold them at this stage of development (Outram et al., 2000). The transition to DP cells cannot occur until an unknown mechanism blocks sonic hedgehog signaling by thymic stromal cells.

### Role of Signaling Molecules and Transcription Factors in Thymic Selection

Receptor proximal signaling elements such as components of the CD3 complex, CD45, Lck, and Vav influence thymic selection. While other CD3 chains are important for DN stages of thymocyte differentiation, CD3 $\delta$  appears to act at a later stage such that  $\gamma\delta$  T cells are normal in CD3 $\delta$ -deficient mice (Dave et al., 1997). Analysis of these mutant animals has shown that they have specific defects in  $\alpha\beta$  DP positive selection, and point to CD3 $\delta$  as the link between TCR engagement and ERK pathway activation during positive selection (Delgado et al., 2000; see below).

It is perhaps surprising that the phosphatase CD45, which functions to dephosphorylate Src family PTKs, is not essential for early thymocyte development. Strains of gene-targeted mice lacking the alternatively spliced exon 6 (Kishihara et al., 1993) or exon 9 (Byth et al., 1996) of CD45 have been generated. Myeloid lineage development is normal in these mutants, and B-cell development is normal until a stage of differentiation that correlates with BCR-dependent positive and negative selection (Cyster et al., 1996). Similarly, T cell development in CD45-deficient animals is blocked only at the transition of DP to mature CD4<sup>+</sup> and CD8<sup>+</sup> SP cells (Kishihara et al., 1993; Byth et al., 1996). Taken together, these results point to an important role for CD45 in T- and B-lymphocyte selection.

Lck and Vav1 have dual roles in thymocyte development. As well as being important for the DN-to-DP transition, Lck and Vav are required for the DP-to-SP transition. Genetic data have indicated that, although Lck is not required for superantigen-driven cell death of CD4<sup>+</sup> T helper cells, it is involved in the

proximal signaling pathways necessary for the TCR-mediated clonal deletion underlying negative selection (Penninger et al., 1996). Similar studies have shown that Vav1 regulates peptide-specific apoptosis in thymocytes and is required for both positive and negative selection (Turner et al., 1997; Kong et al., 1998).

Attempts have been made to find molecules and/or pathways that are exclusively involved in either positive or negative selection. For example, D<sup>m</sup>N transgenes have been used to inhibit various molecules within the MAPK pathways, including Ras and MEK (Alberola-Ila et al., 1995, 1996; Swan et al., 1995; O'Shea et al., 1996; Genot and Cantrell, 2000). Positive selection is blocked in these mutants and there are significant reductions in numbers of mature SP thymocytes. These results have been confirmed in mice genetically deficient for ERK1 (Pages et al., 1999) or its upstream mediator RasGRP (Dower et al., 2000). Other evidence suggests that the level of ERK signaling as induced by TCR affinity or avidity for the peptide-MHC complex in question determines positive vs. negative selection (Bommhardt et al., 2000; Mariathasan et al., 2000; Hogquist, 2001). In situations of negative thymocyte selection, ERK activation is vigorous but short-lived, while positive selection generates weak ERK signaling that is sustained (Werlen et al., 2000). It is speculated that ligands with low affinity for a TCR (positively selecting) do not trigger receptor internalization, allowing them to continue to trigger TCR signaling and to sustain moderate ERK activation. In contrast, high-affinity ligands (negatively selecting) induce vigorous ERK activation that is rapidly extinguished by TCR internalization. As mentioned above, ERK signaling leading to positive selection is also dependent on the extracellular transmembrane domain of CD3 $\delta$ , which is required for association with LAT and the subsequent activation of other downstream transducers in the MAPK pathway (Delgado et al., 2000).

The Tec family kinases may also be involved in selection. Several members of the Tec family, including Itk and Rlk, have been shown to be important in setting the signaling thresholds for positive and negative selection (Liao and Littman, 1995; Schaeffer et al., 2000). Id3, a nuclear helix-loop-helix protein regulated by Itk, also appears to be involved in positive selection (Rivera et al., 2000; Bain et al., 2001). Genes specifically associated with negative selection have been harder to identify, although many have been implicated (reviewed in Sebzda et al., 1999). The engagement of costimulatory molecules such as CD28 by binding partners on thymic stromal APCs has been shown to promote negative selection (Page et al., 1993; Punt et al., 1994; Amsen and Kruisbeek, 1996). Interestingly, mice heterozygous for a null Grb2 mutation express subnormal levels of this adaptor and show impaired negative thymocyte selection (Gong et al., 2001). Positive selection is normal in these mutants. On the basis of the above findings, it has been proposed that negative selection may proceed to ERK activation via Grb2, but that positive selection takes a different route to ERK through Ras-GRP (Hogquist, 2001).

In contrast to the MAPK pathways, the phospholipid signaling pathway activated following TCR engagement does not appear to be important for thymic selection of DP cells. Analysis of mice deficient for PKC $\theta$ , the isoform of PKC that preferentially associates with the SMAC, has suggested that PKC $\theta$  does not play an essential role in either positive or negative selection (Sun et al., 2000a). It also remains controversial whether calcineurin is important for either positive or negative selection (Kane and Hedrick, 1996; Hayden-Martinez et al., 2000; Chan et al., 2002).

Interestingly, mice with a targeted disruption of the interferon regulatory factor-1 (IRF-1) gene have a block specifically in the development of DP cells into CD8 SP thymocytes as well as a profound reduction in mature CD8<sup>+</sup> T cells (Matsuyama et al., 1993). The development of CD4<sup>+</sup> T cells is normal. IRF-1 controls the expression of the *Tap* and other genes required for MHC class I loading, which explains part of the reduction in CD8<sup>+</sup> T cells (White et al., 1996). However, there also appears to be a defect in selection that is intrinsic to CD8<sup>+</sup> thymocytes (Penninger et al., 1997). IRF-2 binds the same promotor sequences as IRF-1 and acts as a transcriptional repressor. While IRF-2<sup>-/-</sup> mice have a defect in B-cell development, T-cell development is normal (Matsuyama et al., 1993).

Molecules that promote thymocyte survival can influence thymic selection in several ways. Without the induction and maintenance of thymocyte survival pathways, the window of opportunity for positive and negative selection would rapidly close. Studies of transgenic and knockout mice have shown that the genes encoding the antiapoptotic protein Bcl-X<sub>L</sub>, RhoA GTPase, the transcription factors NFAT and c-Myb, the retinoid-related orphan receptor (RORγ), and members of the E family of regulatory proteins are important for DP thymocyte survival (Ma et al., 1995; Motoyama et al., 1995; Taylor et al., 1996; Oukka et al., 1998; Bain et al., 1999; Costello et al., 2000; Pearson and Weston, 2000; Sun et al., 2000b). Similarly, studies of mice transgenic for mutant NF-κB regulatory proteins that act as inhibitors have shown that this transcription factor is crucial for pre-T-cell survival and positive selection (Kuo and Leiden, 1999; Hettmann and Leiden, 2000; Voll et al., 2000). CD8<sup>+</sup> T cells do not develop in the absence of NF-κB, whereas CD4<sup>+</sup> T cells are more dependent on CREB.

### The Single Positive Stage

The engagement of MHC class I or II during the positive selection of a DP thymocyte spurs it to proliferate and differentiate into mature CD8<sup>+</sup> or CD4<sup>+</sup> SP cells, respectively. This process is called *CD4/CD8 lineage commitment*.

Precisely how a DP cell determines that it should become a CD4<sup>+</sup> SP or a CD8<sup>+</sup> SP cell has yet to be completely elucidated. Models proposed to account for CD4/CD8 lineage commitment fall into two camps: those based on an instructive mechanism and those based on a stochastic (random choice) mechanism. The original instructive model proposed that differentiation into a CD4 or a CD8 cell was determined by engagement of the αβTCR plus CD4 or CD8 by either MHC class II or class I, respectively (von Boehmer et al., 1989a). In other words, thymocytes recognizing MHC class I were instructed to differentiate into CD8<sup>+</sup> T cells, while thymocytes expressing TCRs with affinity for MHC class II were instructed to become CD4<sup>+</sup> T cells. Although initial results using TCR transgenic mice were consistent with this model, later analyses of various mutant mouse strains and of additional TCR transgenic mice favored a stochastic mechanism (Kaye et al., 1989; S.H. Chan et al., 1993; Davis et al., 1993; Itano et al., 1994; Robey et al., 1994; van Meerwijk et al., 1995; von Boehmer, 1996). Subsets of CD4<sup>+</sup>8<sup>lo</sup> and CD4<sup>lo</sup>8<sup>+</sup> T cells expressing intermediate levels of CD4 and CD8 were identified in different MHC-deficient mutant mouse strains, consistent with the idea that DP thymocytes randomly down-regulate the expression of one or the other coreceptor as they move toward becoming mature CD4<sup>+</sup>8<sup>-</sup> and CD4<sup>-</sup>8<sup>+</sup> SP cells. This hypothesis was supported by findings that transgenic expression of

CD4 in thymocytes could mediate development of CD4<sup>+</sup>8<sup>+</sup> TCR transgenic cells in class I-deficient mice, and that transgenic expression of CD8 molecules could mediate development of CD4<sup>+</sup>8<sup>-</sup> TCR Tg cells in class II-deficient mice (Baron et al., 1994; S.H. Chan et al., 1994; Robey et al., 1994; van Meerwijk et al., 1995; von Boehmer, 1996).

More recent studies have continued to generate opposing bodies of evidence. Brugnera and colleagues have proposed a "coreceptor reversal" model that is at least partly instructive (Brugnera et al., 2000). This model posits that CD8 expression is first down-regulated in all DP thymocytes regardless of their MHC restriction, so that all thymocytes initially become CD4<sup>+</sup> cells. Those thymocytes that subsequently receive both an IL-7 signal and a weak signal delivered by binding to MHC class I resume CD8 expression and down-regulate CD4 expression, effectively "reversing" their prior CD4<sup>+</sup> phenotype to a CD8<sup>+</sup> phenotype. However, those thymocytes that receive a signal through MHC class II maintain their CD4 expression and do not resume CD8 expression. The stochastic mechanism of CD4/CD8 commitment is supported by a study examining the deletion of a regulatory motif functioning as a silencer of CD4 expression (Leung et al., 2001). β2M-deficient mice, which usually have only very low numbers of CD8<sup>+</sup> T cells, were transfected with a transgene conferring constant expression of CD4 due to the absence of the silencer. These mice contained mature T cells that expressed both CD4 and CD8 and exhibited MHC class II restriction. These cells developed into cytotoxic effectors after antigen stimulation.

Lck signaling has also been proposed as a mechanism of CD4/CD8 commitment because Lck associates with the cytoplasmic tails of both coreceptors (Turner et al., 1990). The model holds that strong Lck signaling favors the differentiation of DP cells into CD4<sup>+</sup> SP cells, while little or no signaling results in CD8<sup>+</sup> SP cells (Berg and Kang, 2001). The amount of Lck signaling is determined by the MHC restriction of the TCR: MHC class I-restricted TCRs bind to CD8, which is associated with low levels of Lck activity, whereas MHC class II-restricted TCRs bind to CD4, which is associated with about 20-fold higher levels of Lck activity. Experiments in which mutated CD8 molecules capable of binding different amounts of Lck were compared showed that the greater the amount of Lck bound to CD8, the more CD4<sup>+</sup> T cells emerged from the DP population (Salmon et al., 1999). Yasutomo and colleagues (2000) devised an in vitro culture system that allowed them to monitor SP development following the binding of a TCR to either wild-type MHC class II (fully capable of binding Lck) or mutated MHC class II lacking the CD4 binding site (decreased Lck binding). In the absence of significant Lck binding, thymocyte differentiation was skewed to CD8<sup>+</sup>. The authors interpreted their data to mean that the duration of antigen signaling as transduced by Lck determines CD4/CD8 commitment. Additional evidence supporting a commitment model based on quantitative differences in Lck signaling has come out of transgenic studies in which constitutively active or D<sup>mn</sup> mutants of Lck were used (Hernandez-Hoyos et al., 2000). Overexpression of Lck induced MHC class I-restricted thymocytes to develop into CD4<sup>+</sup> T cells, whereas reduced levels of Lck drove MHC class II-restricted thymocytes down the CD8<sup>+</sup> path. Confirmation of these results has been obtained by the introduction of a transgene specifying tetracycline-inducible Lck expression into Lck<sup>-/-</sup> cells (Legname et al., 2000). Induced expression of Lck resulted in high levels of Lck activity and the exclusive differentiation of CD4<sup>+</sup> T cells.

There is some evidence supporting a role for ERK signaling in CD4/CD8 lineage commitment. In one study, high levels of ERK signaling appeared to favor CD4<sup>+</sup> over CD8<sup>+</sup> SP development. Transfection of mice with a transgene encoding a constitutively active form of ERK resulted in increased numbers of CD4<sup>+</sup> thymocytes but decreased numbers of CD8<sup>+</sup> cells (Sharp et al., 1997). Consistent with this result, CD4 maturation was blocked by inhibition of ERK signaling whereas CD8 development was enhanced (Bommhardt et al., 1999; Sharp and Hedrick, 1999). However, other studies have shown that CD8 differentiation can be blocked by deletion, inhibition, or interference with ERK activity (Alberola-Ila et al., 1995; Pages et al., 1999; Mariathasan et al., 2000).

Finally, some investigators have suggested that Notch-1 may contribute to CD4/CD8 lineage commitment, although its involvement is still the subject of much debate (Osborne and Miele, 1999; Robey, 1999; Deftos and Bevan, 2000; von Boehmer, 2001). Robey et al. demonstrated that expression of an active form of Notch-1 in developing T cells resulted in an increase in CD8<sup>+</sup> lineage cells and a decrease in CD4<sup>+</sup> lineage cells, even if MHC class I was absent (Robey et al., 1996; Robey, 1999). In addition, when Notch-1 signaling was blocked with antibodies, CD8<sup>+</sup> SP development was favored (Yasutomo et al., 2000). Complementary studies revealed that the CD4 silencer that prevents CD4 expression in DN and CD8 SP thymocytes has an HES-1 binding site (Kim and Siu, 1998), and HES genes are known to be regulated by Notch-1. However, other data have suggested that rather than promoting only the development of CD8<sup>+</sup> SP cells, Notch-1 signaling is involved in the maturation of both CD4 and CD8 SP thymocytes (Deftos et al., 1998, 2000). Still others believe that Notch-1 may exert its effect indirectly, by reducing the strength of signal delivered through the TCR (Anderson et al., 2001; Izon et al., 2001). Cells receiving high Notch-1 signals would have reduced signaling through the TCR and would consequently adopt the CD8 cell fate, whereas cells receiving lower Notch-1 signals would have stronger TCR signals and become CD4 cells.

### Concluding Remarks

T cell development is coordinated by the concerted actions of a variety of surface receptors, signal transduction molecules, and transcription factors. Genetic engineering technology has provided valuable tools for the dissection of the complex multitude of genes and gene products involved in thymocyte ontogeny and T cell function. The use of mutant animals has been central to the identification of several important genetic checkpoints in thymic development. Overlapping gene functions have emphasized the enormous plasticity of the immune system, enabling the animal to adapt to changes and compensate for loss of key molecules. A greater understanding of T cell development will assist us in designing rational therapeutics for the treatment of cancer, autoimmunity, and chronic inflammatory diseases.

## Molecular Mechanisms Guiding B Cell Development

ANTONIUS G. ROLINK, JAN ANDERSSON, ULF GRAWUNDER,  
and FRITZ MELCHERS

B lymphocytes develop from hematopoietic stem cells. In the mouse, B cell development takes place at different sites in the body during ontogeny, starting at day 8–8.5 of gestation in yolk sac and fetal aorta (Cumano et al., 1993; Godin et al., 1993, 1995; Cumano and Godin, 2001; Ling and Dzierzak, 2002). When circulation of blood begins at day 9 of gestation, B cell precursors can still be found in the yolk sac and fetal aorta, and later—around days 10–11—in the liver, spleen, and omentum (Ogawa et al., 1988; Rolink and Melchers, 1991; Solvason et al., 1992; Melchers and Rolink, 1999; Cumano and Godin, 2001). From days 15 to 16 of gestation, B cell precursors are also found in the bone marrow. After birth, the bone marrow becomes the major site for B lymphopoiesis (Hardy et al., 1991; Rolink and Melchers, 1991; Rolink et al., 1993, 1994; Osmond et al., 1998; Melchers and Rolink, 1999; Hardy and Hayakawa, 2001). B cell development in mouse and human bone marrow from progenitor (pro) and precursor (pre) B cells to immature and mature sIg-positive B cells is characterized by changes in (1) rearrangement of immunoglobulin (Ig) heavy (H) and light (L) chain genes; (2) the expression of surface-bound and intracellular markers; (3) cell cycle status; (4) *in vitro* growth properties; and (5) life expectancy *in vivo*.

In this chapter we will use this nomenclature for the different stages of B cell development. Table 5.1 provides a comparison with the widely used “Philadelphia” nomenclature (Hardy et al., 1991; Hardy and Hayakawa, 2001) for early B cell stages. The table also shows the Ig rearrangement status of various developmental stages. Figure 5.1 summarizes the different early stages of B cell development in mouse and the markers expressed at these various stages. In Figure 5.2 presents a similar summary of the late stages of B cell development in mouse.

We have described in detail normal B cell development elsewhere (Rolink and Melchers, 1991; Ghia et al., 1998; Osmond

et al., 1998; Melchers and Rolink, 1999). Briefly, the first identifiable cell within the B cell lineage, the pro-B cell, expresses low levels of CD45R (B220) together with c-kit, Flt3/FLK-2, and CD43, but does not yet express the lineage-specific marker CD19 (Rolink et al., 1996; Ogawa et al., 2000; Hardy and Hayakawa, 2001). The Ig heavy (IgH) chain loci in these cells are predominantly in (nonrearranged) germ-line configuration.

pre-BI cells following the earlier pro-B stage carry both IgH chain alleles DJ rearranged, with the exception of those found in rearrangement-deficient or defective mice, such as RAG1<sup>-/-</sup>, RAG2<sup>-/-</sup>, severe combined immunodeficiency (SCID), or J<sub>H</sub>-deficient mice (Bosma et al., 1988; Mombaerts et al., 1992; Shinkai et al., 1992; Chen et al., 1993). The pre-BI cells express CD45R (B220), CD19, CD43, and c-kit on their surface, whereas TdT, RAG1, and RAG2 are expressed intracellularly (Rolink et al., 1991a, 1991b, 1993, 1994; Grawunder et al., 1995). Moreover, pre-BI cells express the two components of the surrogate light (SL) chain,  $\lambda_5$  and V<sub>preB</sub> (Karasuyama et al., 1993, 1996). They have lost Flt3/FLK-2 expression (Ogawa et al., 2000) and do not yet express CD25 (Rolink et al., 1994). About 30%–40% of pre-BI cells are in the S, G<sub>2</sub>–M phase of the cell cycle. pre-BI cells can also proliferate long term on stromal cells in the presence of IL-7 *in vitro* (Rolink et al., 1991a).

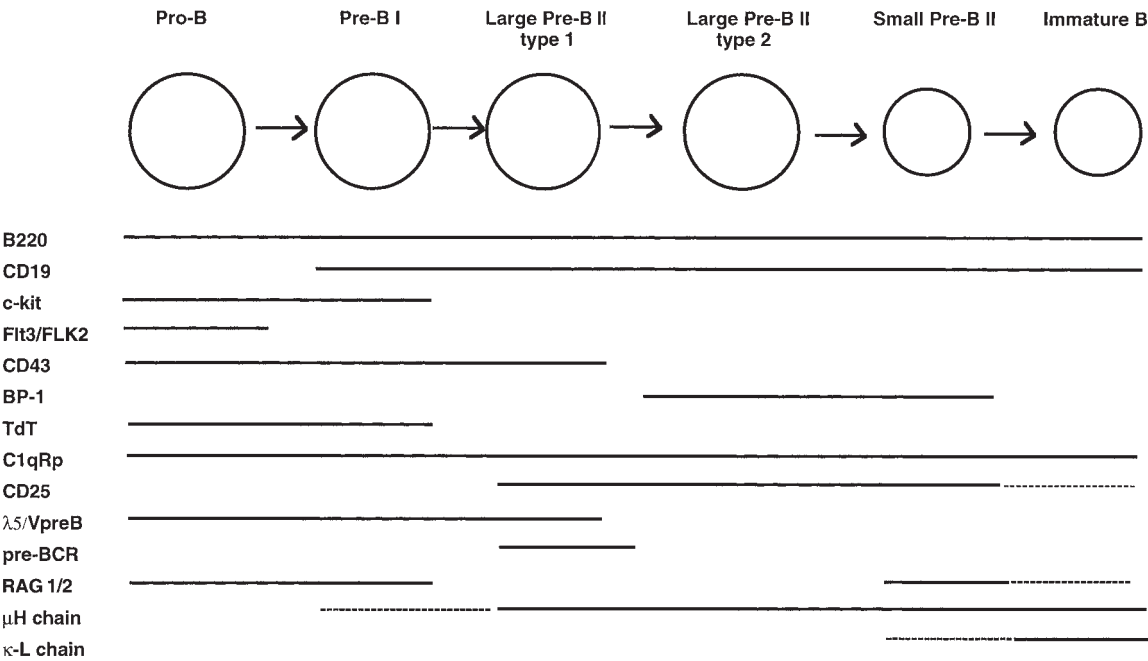

Pre-B-II cells have VDJ-rearranged IgH chain loci and can be subdivided by expression of SL chain and size into three populations (Rolink et al., 1994; Grawunder et al., 1995; Ghia et al., 1998; Osmond et al., 1998; Melchers and Rolink, 1999). All pre-B-II cells have lost c-kit and TdT but gained CD25 (TAC) surface expression (Rolink et al., 1994). Moreover,  $\mu$ H chain expression in the cytoplasm can be detected in over 95% of these cells (Rolink et al., 1994), thus indicating that the pre-B-II compartment is selected for those cells that have undergone productive V<sub>H</sub>D<sub>H</sub>J<sub>H</sub> rearrangement. Pre-B-II cells express intermediate

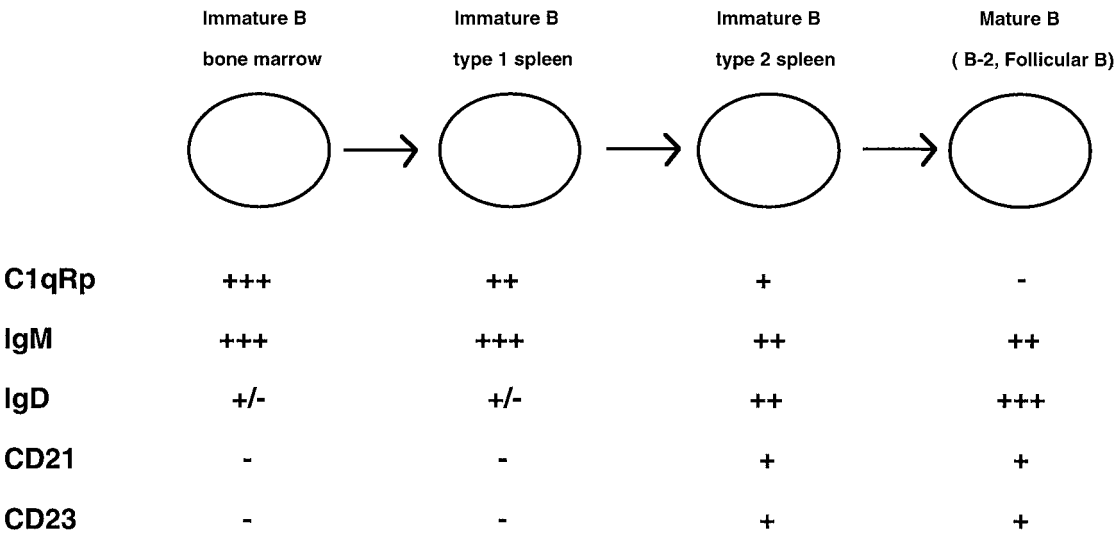

**Table 5.1.** Nomenclature and Immunoglobulin Rearrangement Status of Early Stages of Mouse B Cell Development

gH, immunoglobulin heavy chain; IgL, immunoglobulin light chain.

**Figure 5.1.** Markers used to identify early stages of mouse B cell development. Solid lines indicate that all cells express the marker, whereas broken lines indicate weak expression or only a fraction of the cells expressing the marker. Large circles represent cells that are cycling; small circles indicate resting cells.

**Figure 5.2.** Markers used to identify late stages of mouse B cell development. Surface markers indicated are evaluated for staining intensities in FACS analyses.

levels of CD45R (B220) and CD19. All pre-B-II cells have lost the capacity to proliferate on stromal cells plus IL-7. About 15%–20% of pre-B-II cells are large, and 70%–80% of these are in the S, G<sub>2</sub>–M phase of the cell cycle. Approximately 25% of these express the SL chain in complex with a  $\mu$ H chain on their surface (Rolink et al., 1994).

The noncycling, small pre-B-II population has also lost SL expression. Single-cell polymerase chain reaction (PCR) analysis (ten Boekel et al., 1995; Yamagami et al., 1999a, 1999b) has shown that these cells are in the process of L-chain rearrangement and are therefore the direct precursors of *immature* sIgM<sup>+</sup>sIgD<sup>+</sup> B cells. Some of the immature B cells formed in the bone marrow migrate to the spleen. Here they can be distinguished from their mature counterparts by expression of the C1qRp protein, recognized by the monoclonal antibodies (MAbs) 493 and AA4.1 (Rolink et al., 1998, 1999a, 2001; Norsworthy et al., 1999; Petrenko et al., 1999; Allman et al., 2001), and by their short life span (4 days vs. more than 6 weeks). The immature B cells in spleen can be subdivided into type 1 and type 2 (transitional cells), based on the differential expression of CD21, CD23, IgM, and IgD, as depicted in Figure 5.2 (Loder et al., 1999; Rolink et al., 2001). Both types of immature splenic B cells are very sensitive to anti-IgM-induced apoptosis *in vitro*.

In this chapter, we will summarize recent experimental evidence that further defines different cellular stages of B cell development. Special attention will be paid to mutant mice in which B cell development is impaired at various stages.

## B Lineage Commitment

The differentiation of hematopoietic stem cells (HSCs) into the various hematopoietic lineages is usually pictured in a hierarchical fashion: these cells develop first into progenitors and then into precursors, with decreasing pluripotency and increasing commitment to single differentiation pathways (Weissman, 2000). Mice deficient for the basic helix-loop-helix proteins encoded by the *E2A* gene and early B cell factor (EBF) show an arrest of B cell development at the earliest stage prior to rearrangement of the IgH locus (Bain et al., 1994; Busslinger, 2004; Zhuang et al., 1994; Lin and Grosschedl, 1995; Matthias & Rolink, 2005). These findings, together with those showing that forced expression of *E2A* and *EBF* in hematopoietic precursors induce the transcription of several B lymphoid-specific genes (Kee and Murre, 1998; O’Riordan and Grosschedl, 1999; Romanow et al., 2000; Goebel et al., 2001), have implicated these two transcription factors in the control of B lineage commitment. However, this idea was recently challenged by findings made with mice deficient for the transcription factor Pax5.

Pax5-deficient mice exhibit a block in B cell development at the transition from D<sub>H</sub>J<sub>H</sub>-rearranged pre-BI to V<sub>H</sub>D<sub>H</sub>J<sub>H</sub>-rearranged pre-B-II cells (Urbánek et al., 1994; Nutt et al., 1997). Pax5<sup>−/−</sup> pre-BI cells express various lymphoid and B cell-specific genes, including RAG-1, RAG-2, TdT,  $\lambda_5$ , V<sub>preB</sub>, Ig $\alpha$ , Ig $\beta$ , *E2A*, and *EBF*, similar to wild-type pre-BI cells (Nutt et al., 1997, 1998; Schebesta et al., 2002). Moreover, like wild-type cells, Pax5<sup>−/−</sup> pre-B-I cells have the long-term capacity to grow *in vitro* on stromal cells in the presence of IL-7 (Nutt et al., 1997, 1998; Schebesta et al., 2002). However, and in marked contrast to wild-type pre-BI cells, Pax5-deficient B cell precursors can undergo appropriate *in vitro* conditions develop into macrophages, granulocytes, osteoclasts, dendritic cells, and natural killer (NK) cells (Nutt et al., 1999; Schebesta et al., 2002; Busslinger, 2004).

Upon transplantation into an irradiated host, Pax5<sup>−/−</sup> pre-BI cells can differentiate into T cells, macrophages, granulocytes,

osteoclasts, dendritic cells, NK cells, and, in rare cases, even into erythrocytes (Nutt et al., 1999; Rolink et al., 1999b; Schebesta et al., 2002; Schaniel et al., 2002a). Furthermore, Pax5<sup>−/−</sup> pre-BI cells home to the bone marrow where they retain their phenotype and original differentiation state. These cells can then be re-cloned *in vitro* on stromal cells and IL-7. Upon retransplantation these cells again populate the bone marrow and also give rise to the various hematopoietic cells mentioned before (Rolink et al., 1999b; Schaniel et al., 2002b). Recently Schaniel et al. (2002b) showed that at least five serial transplantations can be performed with these Pax5<sup>−/−</sup> pre-BI cells without losing their hematopoietic multipotency and self-renewing capacity. Thus, Pax5<sup>−/−</sup> pre-BI cells exhibit features of pluripotent HSCs. Moreover, this unexpected *in vitro* and *in vivo* plasticity of Pax5<sup>−/−</sup> pre-BI cells in hematopoietic development strongly suggests that Pax5 expression determines B cell commitment.

Pax5 is known to both activate and repress transcription depending on the regulatory sequence context of the target gene (Nutt et al., 1999; Schebesta et al., 2002). This dual function of Pax5 is compatible with its role in B lineage commitment. On the one hand, Pax5 further activates B lymphoid-specific gene expression, as best illustrated by the induction of CD19 expression in Pax5<sup>−/−</sup> pre-BI cells after reconstitution with a Pax5-expressing recombinant retrovirus (Nutt et al., 1999). On the other hand, Pax5 represses the transcription of lineage-inappropriate genes, e.g., the macrophage colony-stimulating factor receptor (M-CSF-R) gene, thus rendering these pre-BI cells unresponsive to M-CSF and interfering with their capacity to differentiate into macrophages.

## Pro-B Cells

The earliest fraction of B cell progenitors in the scheme of Hardy and colleagues (Hardy et al., 1991; Hardy and Hayakawa, 2001) is fraction A. The cells in this fraction are characterized by the expression of B220 and CD43 and the absence of heat-stable antigen (HSA) and BP-1. They constitute approximately 3% of the total nucleated bone marrow cells. It has been shown that, in contrast to all other stages of B cell development, these cells do not express CD19 (Rolink et al., 1996). In fact, it has been demonstrated that the vast majority of these cells do not belong to the B cell lineage. About 30% of these cells are precursors of NK cells: they express NK cell markers and, after stimulation with IL-2 *in vitro*, gain the ability to lyse NK cell targets very efficiently (Rolink et al., 1996). Another 30%–40% of the cells in this fraction coexpress CD4 at levels comparable to those found on T cells. However, these cells are not T lineage cells because they do not express components of the T cell receptor and are found in similar numbers in RAG1- and RAG2-deficient animals. Furthermore, these cells were unable to proliferate in an *in vitro* stromal cell/IL-7 culture system that enables the growth of pro- and pre-BI cells (Rolink et al., 1991a), thus these B220<sup>+</sup>CD4<sup>+</sup> cells are not progenitors of the B cell lineage. In addition, transplantation of these cells into RAG2<sup>−/−</sup> (gene name: *Rag2*) mice did not result in development of a detectable number of B cells or any other cell type of hematopoietic lineage. Several groups (Asselin-Paturel et al., 2001; Nakano et al., 2001; Nikolic et al., 2002) have recently indicated that these CD4<sup>+</sup> cells might be the murine counterparts of the so-called plasmacytoid dendritic cells of humans (Cella et al., 1999).

Within the population of B220<sup>+</sup>, CD19<sup>−</sup>, NK1.1<sup>−</sup>, CD4<sup>−</sup> cells, a small subpopulation can be identified that expresses c-kit, Flt3/FLK-2, C1qRp, and  $\lambda_5$  and exhibits B cell progenitor activity (Rolink et al., 1996; Ogawa et al., 2000). These cells can be

grown on stromal cells in the presence of IL-7 and can differentiate into CD19<sup>+</sup> B lineage cells. However, whether these cells are already committed to the B cell lineage remains unknown. Transplantation of such cells grown for 2 weeks in vitro into RAG2-deficient mice results in the reconstitution of both B and T cell compartments (Rolink et al., unpublished observation).

### pre-BI Cells

The next stage in B cell development relates to the so-called pre-BI cells. These cells have gained CD19 expression and lost Flt3/FLK-2 expression—i.e., they are B220<sup>+</sup>, CD19<sup>+</sup>, c-kit<sup>+</sup>, CD43<sup>+</sup>, SL<sup>+</sup>, and C1qR<sup>+</sup> and express TdT, RAG1, and RAG2 in the nucleus (Rolink et al., 1993, 1994, 1996; Ghia et al., 1998; Osmond et al., 1998; Ogawa et al., 2000). The L chain gene loci in these cells are in germ-line configuration and are transcriptionally still inactive (Grawunder et al., 1995; ten Boekel et al., 1995). Development at this stage is blocked in mice with deficiencies in the rearrangement machinery (Bosma et al., 1988; Mombaerts et al., 1992; Shinkai et al., 1992) and in mice harboring a deletion of the J<sub>H</sub> gene segment (Chen et al., 1993). This results in pre-BI cells with IgH chain loci in germ-line configuration. In contrast, the vast majority of pre-BI cells found in other strains of mice (rearrangement competent) have both IgH alleles DJ rearranged (Rolink et al., 1991a; ten Boekel et al., 1995).

A small segment (10%–20%) of the pre-BI cells have completed IgH chain rearrangements and express a  $\mu$ H chain in the cytoplasm (ten Boekel et al., 1997, 1998). Surprisingly, 50% of  $\mu$ H chains found in pre-BI cells are unable to pair with the SL components  $\lambda_5$  and V<sub>preB</sub>, and thus cannot make a precursor B cell antigen receptor (pre-BCR) (ten Boekel et al., 1997, 1998; see below). Also surprising was the finding that about 20% of these  $\mu$ H chains use the most D-proximal V<sub>H</sub> element V<sub>H</sub>81X (ten Boekel et al., 1997). None of these V<sub>H</sub>81X  $\mu$ H chains analyzed was able to form a pre-BCR. This might also explain why V<sub>H</sub>81X  $\mu$ H chains are very rarely found in mature B cells (Decker et al., 1991; Carlsson et al., 1992; Huetz et al., 1993). The biological meaning of this biased V<sub>H</sub>81X usage in pre-BI cells is still unclear.

In vitro, pre-BI cells can be propagated on stromal cells in the presence of IL-3, IL-7, or thymic stromal-derived lymphopoietin (TSLP) (Rolink et al., 1991a; Winkler et al., 1995a; Ray et al., 1996).

As mentioned above, an arrest in B cell development at the pre-BI stage is also found in Pax5<sup>-/-</sup> mice. However, the target genes of Pax5 that are responsible for this arrest have not yet been identified. Moreover, a block in B lymphopoiesis at this stage is also observed in animals that cannot form a pre-BCR—for example, mice deficient for  $\lambda_5$  (Kitamura et al., 1992), V<sub>preB1</sub>, and V<sub>preB2</sub> (Mundt et al., 2001), and membrane deposition of  $\mu$ H ( $\mu$ H<sup>-/-</sup> mice) (Kitamura et al., 1991) and Ig $\beta$  (Gong and Nussenzweig, 1996). This block also occurs in mice that have a defect in pre-BCR signaling due to mutations of Syk (Cheng et al., 1995; Turner et al., 1995) and B cell linker protein (BLNK) (Jumaa et al., 1999; Pappu et al., 1999; Hayashi et al., 2000). A block at the pre-BI cell stage of development is also observed in IL-7- and IL-7R-deficient mice—i.e., IL-7<sup>-/-</sup>, IL-7R $\alpha$ <sup>-/-</sup>, and IL-2R $\gamma$ <sup>-/-</sup> mice (Peschon et al., 1994; DiSanto et al., 1995; von Freuden-Jeffry et al., 1995). The block observed in membrane  $\mu$ H<sup>-/-</sup>, Ig $\beta$ <sup>-/-</sup>, Ig $\alpha$ <sup>-/-</sup>, and Pax5<sup>-/-</sup> mice is absolute, whereas in other mice, later stages, including mature B cells, are found in the bone marrow and in peripheral lymphoid organs, although in far lower numbers than in wild-type mice.

### Pre-B-II Cells

The next developmental stage along in B lineage is characterized by cytoplasmic  $\mu$ H chain expression, which defines the pre-B-II cell stage. These typical pre-B cells have lost the expression of c-kit and TdT, and most of them do not express CD43 (Rolink et al., 1994). In addition to  $\mu$ H chain expression, these cells have gained the expression of CD25 (Rolink et al., 1994).

The pre-B-II compartment can be subdivided into three different developmental subsets. The first stage contains large and actively cycling cells. On the surface, they express the pre-BCR consisting of the SL chain in association with the  $\mu$ H chain (Rolink et al., 1994; Winkler et al., 1995b; Karasuyama et al., 1996). These cells do not express RAG1 and RAG2 and carry their IgL chain loci still in germ-line configuration (Grawunder et al., 1995; ten Boekel et al., 1995). It is exactly at this stage of development that the allelic exclusion of the second H chain allele is likely to be established; a transient down-regulation of the VDJ rearrangement machinery might be involved in this process (Grawunder et al., 1995). At this stage the L chain loci are not yet transcriptionally active. The H chain locus might be rendered inaccessible for further rearrangements in ways that need to be clarified.

The importance of this stage, especially the membrane deposition of the pre-B receptor ensuring normal B cell development, is best illustrated in mutants unable to produce this receptor. In mice with a deletion in the transmembrane portion of their  $\mu$ H chain and mice with a deletion in the  $\lambda_5$  part or the V<sub>preB1</sub> and V<sub>preB2</sub> part of the SL-encoding genes, large cycling pre-B-II cells are not detected. This results in a reduced number of small pre-B cells (Kitamura et al., 1991, 1992; Mundt et al., 2001). A similar phenotype is found in mice with a deletion in the genes encoding Ig $\beta$  (Gong and Nussenzweig, 1996), indicating that the association between the pre-BCR and Ig $\beta$  and Ig $\alpha$  and consequent signaling via surface pre-BCR is required for the transition from pre-BI to pre-B-II cells.

In line with this, tyrosine kinase Syk-deficient mice and mice defective for the adapter protein BLNK display a block at this early stage of B cell development. This finding indicates a key role for Syk and BLNK in pre-BCR signaling (Cheng et al., 1995; Turner et al., 1995; Jumaa et al., 1999; Pappu et al., 1999; Hayashi et al., 2000).

The importance of the pre-BCR is also indicated in experiments in which RAG1<sup>-/-</sup> or RAG2<sup>-/-</sup> mice are supplemented with a transgenic  $\mu$ H chain (Rolink et al., 1994; Spanopoulou et al., 1994; Young et al., 1994). As discussed above, RAG1<sup>-/-</sup> and RAG2<sup>-/-</sup> mice are blocked at the pre-BI cell stage. However, supplementation with a rearranged  $\mu$ H gene, which allows them to express a pre-BCR, results in progression of B cell development in these mice up to the stage of small pre-B-II cells. Thus, expression of the pre-BCR ensures proliferative expansion that constitutes a positive selection for pre-B cells with a productive VDJ rearrangement that can lead to formation of a pre-BCR.

We have shown that this pre-BCR-mediated selection and expansion can be mimicked in vitro. Sorted pre-BI cells of wild-type mice cultured in plain medium (no cytokines added) expanded (Rolink et al., 2000) were selected for productive VDJ rearrangement. By day 5 of culture, 70%–80% of the cells recovered expressed IgM on their surface. No expansion and/or selection was observed in pre-BI cells of  $\lambda_5$ <sup>-/-</sup> mice—i.e., pre-BI cells that cannot form a pre-BCR. Single-cell experiments with wild-type pre-BI cells indicated that approximately 15% of them undergo this expansion and selection. Moreover, it was found that

single ex vivo isolated pre-BI cells proliferate to different clone sizes in vitro. This finding may indicate that pre-BCRs with different fitness of pairing with the SL chain allow different numbers of divisions. Overall, these in vitro data suggest that pre-BCR exerts its function in a ligand-independent fashion. There is further evidence that IL-7 can enhance the efficiency of pre-BCR-mediated expansion (Stoddart et al., 2000).

It has been shown that the transmembrane form of the  $\mu$ H chain is necessary for IgH chain allelic exclusion. Thus, around 15% of the peripheral B cells expressing sIgM in F1 mice carrying a wild-type and a transmembrane-deficient  $\mu$ H chain allele express the deficient allele in the cytoplasm (Kitamura and Rajewsky, 1992). On the basis of this finding and the fact that pre-BCR expressing pre-B-II cells have down-modulated RAG1 and RAG2 expression (Grawunder et al., 1995), it has been suggested that the pre-BCR also mediates allelic exclusion. However,  $\lambda_5^{-/-}$  and  $V_{preB1}$  and  $RAG2^{-/-}$  mice that cannot form a pre-BCR still exhibit allelic exclusion, which indicates that a complete pre-BCR is not needed for this process (ten Boekel et al., 1997, 1998; Mundt et al., 2001).

In all likelihood, the next developmental stage following the pre-BCR-positive cells is the large, cycling pre-B-II cell stage, in which expression of the SL chain is lost (Rolink et al., 1994; Winkler et al., 1995b; Karasuyama et al., 1996). Unlike the pre-BCR-positive pre-B-II cells, the large, cycling pre-B-II cells express RAG1 and RAG2 at the RNA but not yet at the protein level (Grawunder et al., 1995). Moreover, sterile transcripts from the  $\kappa$ L chain gene locus become detectable, although the L chain gene loci in these cells are still in germ-line configuration (ten Boekel et al., 1995). When the large, cycling pre-B-II cells become resting and small, a large proportion of the cells carry rearranged L chain genes (ten Boekel et al., 1995; Yamagami et al., 1999a, 1999b). Already at this stage, the  $\kappa$ L and  $\lambda$ L chain loci are rearranged in the characteristic 10:1 ratio. Experiments by Engel et al. (1999) and Goldmit et al. (2005) suggest that chromatin structural changes rendering Ig gene loci accessible for V(D)J recombination occur earlier within the  $\kappa$ L chain gene locus than within the  $\lambda$ L chain gene. This may explain the high frequency of  $\kappa$ L chain-containing immunoglobulins in the mouse.

In wild-type mice, about half of the sIg<sup>+</sup> B cells have rearranged only one allele at the  $\kappa$ L chain locus. Most of these cells show only a single rearrangement, preferentially to J $\kappa$ 1, the most V proximal of the functional J segments. In marked contrast, small pre-B-II cells show a dramatically increased frequency of multiple  $\kappa$ L chain rearrangements (Yamagami et al., 1999a, 1999b). Moreover, about 20% of small pre-B-II cells express a  $\kappa$ L chain protein in the cytoplasm but not on the cell surface, although half of these cells have productively rearranged V $\kappa$ J $\kappa$  segments. Although over 95% of all pre-B-II cells express  $\mu$ H chains in their cytoplasm, these  $\mu$ H- $\kappa$ L chain combinations are not expressed on the surface.

Two possible scenarios might account for the lack of surface expression of the  $\mu$ H- $\kappa$ L chain pairs. First, it is conceivable that certain  $\mu$ H- $\kappa$ L chain combinations may not be able to form an IgM molecule. Since the peripheral sIgM<sup>+</sup> B cell pool should contain only pairing combinations, the small pre-B-II pool may be enriched for those that do not fit together. Second, a given  $\mu$ H- $\kappa$ L chain combination may have paired properly and been deposited on the surface. However, if this IgM is autoreactive and encounters autoantigen in the bone marrow environment, this might lead to down-regulation of these autoreactive receptors from the cell surface. Both scenarios are by no means mutually exclusive.

Nemazee and colleagues (Tiegs et al., 1993; Nemazee, 2000) and Weigert and coworkers (Gay et al., 1993; Radic et al., 1993) have shown that recognition of autoantigen by immature B cells induces secondary rearrangements at the L chain loci and thus can change the cells' receptor specificity from self to non-self. In humans, a similar type of BCR editing has been observed (Dorner et al., 1998). Recently, Casellas et al. (2001) showed that the contribution of B cells that have undergone receptor editing to the total peripheral B cell repertoire is about 25%. However, mice deficient for the expression of  $\kappa$ L chains due to a deletion of the constant  $\kappa$ L region display patterns of  $\kappa$ L chain gene rearrangements in small pre-B-II cells similar to those in wild-type mice. This finding would argue against the notion that most of the receptor editing is autoantigen recognition driven (Yamagami et al., 1999a, 1999b).

When autoreactive Ig transgenes are bred onto a rearrangement-deficient background—i.e., a situation where receptor editing is impossible—an absolute block at the transition from small, pre-B-II to immature B cells is observed (Andersson et al., 1995). For instance,  $RAG2^{-/-}$  mice carrying the Sp6 anti-TNP IgM transgene display this absolute block in differentiation at the transition from small pre-B-II to immature B cells. It is assumed that this block in differentiation results from the cross-reaction of Sp6 anti-TNP IgM with dsDNA, an apparently abundant autoantigen in the bone marrow environment where extensive cell apoptosis occurs. However, injection of Sp6 transgenic  $RAG2^{-/-}$  mice with the T cell-independent antigen TNP-Ficoll elicits a strong antibody response within 5 days. Hence, cross-reactive T cell-independent antigens might be able to overcome negative selection and clonal deletion of autoreactive B cells. This raises the possibility that T-independent antigens may be involved in the initiation of autoimmune diseases.

### Immature B Cells

Osmond and colleagues (reviewed in Osmond, 1993) have determined that mice produce roughly  $2 \times 10^7$  immature B cells per day in the bone marrow. These immature B cells then migrate through the terminal branches of central arterioles into the spleen. At this site, these immature B cells, which display life spans of about 4 days, differentiate into mature B cells with life spans of around 15 weeks (Rolink et al., 1998, 2001). In the spleen the immature B cells can be distinguished from their mature counterparts by the cell surface expression of the C1qRp protein recognized by MAbs 493 and AA4.1 (Rolink et al., 1998, 1999a, 2001; Petrenko et al., 1999). Based on the expression of CD21 and CD23, immature B cells in the spleen can be subdivided into two populations (transitional cells); CD21<sup>-</sup> CD23<sup>-</sup> and CD21<sup>+</sup> CD23<sup>+</sup> (Loder et al., 1999) (Fig. 5.2).

In the transition from bone marrow to the spleen, about 90% of immature B cells are lost. A large part of this loss can probably be explained by the deletion of autoreactive B cells in the bone marrow, and signaling through the BCR appears to play a key role for this process. Thus both Syk-deficient mice and mice expressing an Ig $\alpha$  lacking the cytoplasmic tail (Ig $\alpha^{\Delta c/\Delta c}$ ) show a much more marked loss of B cells at this transition (Turner et al., 1995; Torres et al., 1996). Interestingly, immature B cells in Ig $\alpha^{\Delta c/\Delta c}$  mice have increased levels of tyrosine phosphorylation and expression of activation antigen (Torres and Hafen, 1999). This suggests that the intensity of signaling may be very critical for B cells passing this checkpoint. Similar findings were evident in Ig $\alpha^{\Delta c/\Delta c}$  mice carrying a soluble hen egg lysozyme (HEL) and an anti-HEL immunoglobulin transgene (Kraus et al., 1999). The

finding that in  $CD45^{-/-}$  mice more immature B cells enter the spleen might indicate that the phosphatase CD45 is critically involved in signaling thresholds (Rolink et al., 1999a, 2001).

Mice deficient for the transcriptional coactivator OBF (also called OCA-B or Bob-1) show a severe reduction of immature B cells in the spleen (Schubart et al., 1996). This reduction is even more dramatic in OBF/Oct-2 (Schubart et al., 2001) and OBF/Btk (Bruton's tyrosine kinase) (Schubart et al., 2000) double-mutant mice. The molecular mechanisms underlying these defects are still unclear. However, a Bcl-2 transgene expressed in the B lineage rescues this defect to a large extent in OBF/Btk double-mutant mice, a finding suggesting that life spans of immature B cells may play a role in this transition (A.G. Rolink, unpublished data).

Cross-linking of the BCR on the two immature B cell populations found in the spleen (Fig. 5.2) leads to the induction of apoptosis (Rolink et al., 1998; King and Monroe, 2000), which indicates that these cells are still sensitive for undergoing negative selection. Nevertheless, in wild-type mice, most immature splenic B cells enter the pool of long-lived mature B cells (Rolink et al., 1998). The finding that apoptosis induced by BCR cross-linking can be blocked by anti-CD40 and IL-4 (Rolink et al., 1998; King and Monroe, 2000) may indicate that these molecules are involved in the transition from immature to mature B cells. CD40- and IL-4-deficient mice, however, have normal numbers of mature B cells (Kopf et al., 1993; Kawabe et al., 1994).

Recently it has been shown that mice deficient for the tumor necrosis factor (TNF) family member BAFF (also termed TALL-1, THANK, Blys, and zTNF4 (Moore et al., 1999; Mukhopadhyay et al., 1999; Schneider et al., 1999; Shu et al., 1999; Gross et al., 2000) or its receptor BAFF-R (Thompson et al., 2001) are blocked in B cell development at the  $CD21^{-} CD23^{-}$  stage in the spleen—i.e., at the type 1 immature B cell stage (Fig. 5.2). Moreover, immature splenic B cells treated with BAFF in vitro acquire a mature phenotype and become resistant to BCR cross-linking-induced apoptosis (Batten et al., 2000; Rolink et al., 2002). Taken together, these findings strongly suggest that the interaction between BAFF and BAFF-R plays a crucial role in the transition from immature to mature B cells.

Other mutant mice with defects in the transition from immature to mature B cells have also been described. For instance, Btk-defective mice have normal numbers of immature splenic B cells; however, their number of mature B cells is reduced about fivefold. Because the life span of mature B cells in  $Btk^{-/-}$  mice is indistinguishable from that found for wild-type B cells, the defect most probably reflects a reduced efficiency of  $Btk^{-/-}$  immature splenic B cells in entering the mature compartment (Rolink et al., 1999a). The finding that a Bcl-2 transgene expressed in B cells can rescue this defect suggests that the Btk molecule might be involved in induction of survival.

Major histocompatibility complex (MHC) class II has also been implicated in the transition from immature to mature B cells in the spleen. Thus, mice deficient in the invariant chain ( $Ii^{-/-}$ ) (Shachar and Flavell, 1996) and MHC class II $\alpha^{-/-}$  mice (Rolink et al., 1999a) display a severely reduced mature B cell compartment. In fact, the mature B cell pool is completely absent in  $Btk/A\alpha$  double-mutant mice. The defect in  $A\alpha^{-/-}$  mice appears to be intrinsic to the B cells and may be due to a four- to fivefold reduced life span of mature B cells (Rolink et al., 1999a). The molecular mechanisms underlying these defects are still unclear. In particular, the finding that  $CTIIA^{-/-}$  (Chang et al., 1996) and  $A\beta^{-/-}$  (Cosgrove et al., 1991; Markowitz et al., 1993) mice, as

well as mice lacking all conventional MHC class II genes (Madsen et al., 1999), do not show such a defect makes the role of MHC class II in this transition very puzzling.

## Mature B Cells

The peripheral mature B cell compartment can be subdivided into three subpopulations: B-1, B-2, and marginal zone B cells, which can be distinguished by the differential expression of various cell surface markers (Table 5.2). Thus, B-1 cells are characterized by the high expression of IgM and the low expression of IgD and B220. Moreover, these cells express CD11b/Mac-1 and part of them expresses CD5, but they do not express CD21 and CD23. B-2 cells express intermediate levels of IgM and high levels of IgD and B220. Moreover, these cells express intermediate levels of CD21 and CD23 and do not express CD11b/Mac-1 or CD5. Marginal zone (MZ) B cells, by contrast, express high levels of IgM and CD21 but no or very little IgD and CD23. B220 expression levels are intermediate, whereas CD11b/Mac-1 and CD5 expression cannot be detected in these cells.

In addition to their different surface marker phenotype, these three subpopulations of mature B cells preferentially localize in different parts of the body. Thus B-1 cells are primarily found in the peritoneal cavity and some in the spleen (Hardy and Hayakawa, 2001). B-2 cells are mainly found in the circulation and in the primary lymphoid follicles of secondary lymphoid organs. Marginal zone B cells localize in the spleen to a region that surrounds the primary lymphoid follicles (Dammers et al., 1999; Oliver et al., 1999; Martin et al., 2001).

B-1 cells have a self-renewing capacity and are mainly derived from fetal liver stem cells. These cells contribute to a large extent to T-independent antibody responses. Many B1 cells carry a BCR that has low affinity for self-antigens, and recent evidence shows that their development depends on BCR-derived positive selection signals (Hayakawa et al., 1999; for review see Hardy and Hayakawa, 2001).

Marginal zone B cells show an activated phenotype and respond better and faster than B-2 cells to low concentrations of mitogens such as lipopolysaccharide (LPS) (Oliver et al., 1999; Martin et al., 2001). These cells can rapidly differentiate into plasma cells when activated, primarily by T-independent antigens, although they may also respond to T-dependent antigens. Like B-1 cells, MZ B cells have been shown to be generated by a positive selection process (Martin and Kearney, 2000; Wellmann et al., 2001).

The vast majority of B2 cells in the mouse are small and resting, i.e., not activated. They are primarily responsible for T-dependent immune responses and thus are also the precursors of the memory B cell compartment. It is probable that, like B-1 and MZ B cells, the B-2 cell compartment is generated via positive

**Table 5.2.** Markers Used to Distinguish Different Mature B Cell Subpopulations

	<i>B1</i>	<i>B2/follicular B</i>	<i>Marginal Zone B</i>

B220	+	+++	++
CD21	+/-	++	+++
CD23	+/-	++	+/-
CD5	+/-	—	—
CD11b/Mac-1	++	—	—

selection, although direct experimental evidence for this is not yet available.

It is now well established that the formation of all three mature B cell subpopulations requires the expression of a functional BCR (Lam et al., 1997)—i.e., a BCR with signaling properties. The numerous mutant mice created in the last couple of years, however, have indicated that the BCR signal strength needed for the formation of these three subpopulations might be different (for reviews see Hardy and Hayakawa, 2001; Cariappa and Pil-lai, 2002). These studies showed that mutations causing a weakening of the BCR signal strength affect formation of the B-1 compartment but not that of the B-2 and MZ B cell compartments. In addition to BCR signaling, non-BCR-related molecular interactions are also differentially required for the formation of the three mature B cell subpopulations.

In this respect, BAFF- and BAFF-R-deficient mice lack the B-2 and the MZ B cell compartment but display a normal B-1 compartment (Moore et al., 1999; Mukhopadhyay et al., 1999; Schneider et al., 1999; Shu et al., 1999; Gross et al., 2000; Thompson et al., 2001). In addition, mutations affecting the microarchitecture of secondary lymphoid organs, especially of the spleen, as well as those disturbing the migration and homing of cells can influence the generation of the different mature B cell compartments (Futterer et al., 1998; Guinamard et al., 2000; Lipp et al., 2000; Fukui et al., 2001; Girkontaite et al., 2001; Reif et al., 2002).

### Human B Cell Development

B cell development in human bone marrow is very similar to that in the mouse, but the expression of various cell surface markers characterizing murine differentiation stages is different (Gougeon et al., 1990; Ghia et al., 1996). A summary of markers used to identify early stages of human B cell development is given in Table 5.3. Cells at the earliest stage of B cell development in human bone marrow corresponding to the mouse pro/pre-BI compartment are CD19<sup>+</sup> CD10<sup>+</sup> CD34<sup>+</sup>. They express TdT and RAG intracellularly, but not  $\mu$ H chains. On the surface these cells also express the SL chain. The proteins associated with the SL chain at this stage of differentiation have not yet been identified. Like their murine counterparts, these cells actively undergo cell division. However, in contrast to the murine system, it has not yet been possible to define conditions that allow long-term proliferation of human pre-B cells in vitro. At this point, we do not know whether the inability to grow these pro/pre-B cells is due to the lack of a proper stromal cell or to the appropriate cytokines not yet being identified. It is also noteworthy that IL-7 seems to be far less important in human than in mouse B cell development.

This is based on the finding that patients with an inactive IL-2R $\gamma$  chain (also called common  $\gamma$ -chain, which is part of the IL-7 receptor) appear to have normal B cell development (Gougeon et al., 1990; Noguchi et al., 1993), whereas IL-2R $\gamma^{-/-}$  mice have a major block in B cell development during the transition from pre-BI to pre-B-II cells (DiSanto et al., 1995).

A human equivalent to the mouse pre-BCR-positive pre-B-II cells has been identified. These cells are characterized as CD19<sup>+</sup>, CD10<sup>+</sup>, CD34<sup>-</sup> TdT<sup>-</sup>, RAG1<sup>-</sup>, pre-B cell receptor-positive large, cycling cells. They carry productively V<sub>H</sub>D<sub>H</sub>J<sub>H</sub>-rearranged IgH chain loci, while their L chain gene loci, as in the mouse, are still in germ-line configuration. Mutations inactivating the expression and/or signaling of the pre-BCR (Minegishi et al., 1998, 1999; Conley et al., 2000) indicate that this receptor plays a role in human B cell development similar to that in mice—namely, selection and proliferative expansion of VDJ in-frame rearranged pre-B cells. This assumption is based on the fact that the vast majority of precursor B cells in human bone marrow also express  $\mu$ H chains in the cytoplasm.

Analogous to B cell development in the mouse, the next B lineage differentiation stage is defined by pre-BCR-negative pre-B-II cells that are CD19<sup>+</sup>, CD10<sup>+</sup>, CD34<sup>-</sup>, TdT<sup>-</sup>, RAG1<sup>+/+</sup>,  $\mu$ c<sup>+</sup>. However, some minor differences between the phenotypes of these cells in mouse and humans are also apparent at this stage of differentiation. For instance, a small but significant number of the large pre-BCR-negative human pre-B-II have undergone L chain rearrangements. Furthermore, low levels of V<sub>preB</sub> mRNA, but not of protein, are still detectable in these cells.

When the large and cycling pre-BCR-negative human pre-B-II cells become quiescent, they up-regulate RAG expression and lose the expression of V<sub>preB</sub>. Single-cell PCR analysis has shown that most of these cells have rearranged their IgL chain loci. Therefore, these cells are comparable to small, resting pre-B-II cells in mouse.

Collectively, these results indicate that the different stages of B cell development in human bone marrow are very similar to those found in mouse. Their relative sizes of the different pre-B cell compartments in young mice and young humans are also comparable. The identification of patients with impaired B cell development at a certain stage of differentiation might help us to elucidate mouse/human parallels and differences in transcription factors, cell surface receptors, and signaling molecules in B cell development, to name a few important components.

# Signal Transduction by T and B Lymphocyte Antigen Receptors

NEETU GUPTA, ANTHONY L. DEFRANCO, and ARTHUR WEISS

Considerable progress has been made during the past several years toward our understanding of the processes by which T and B lymphocytes become activated. Antigen-specific activation of these quiescent cells involves the triggering of antigen receptors to induce signal transduction events that can lead to both the cell cycle progression and differentiation of T and B cells. A remarkable synergy has resulted from a convergence of studies of the most fundamental processes involved in T and B cell activation and those involving clinical and experimental immunodeficiency syndromes. Clinical and experimental immunodeficiency states often result when the functions of T and B cell antigen receptors (TCRs and BCRs) or critical components in the pathways regulated by these receptors are interrupted.

An increasing number of cell surface receptors on T and B cells contribute to the activation of these cells. However, the specificity of the response to antigen dictates that the antigen receptors on these cells play the central role. Although the forms of antigens recognized and the effector functions mediated by these two cell types are quite distinct, the mechanisms by which the antigen receptors transduce signals and the ensuing molecular events are remarkably similar. Stimulation of the TCR and BCR induces the protein tyrosine phosphorylation of a large number of proteins implicated in signal transduction processes that contribute to cellular activation. Here, we will focus on the means by which the TCR and BCR induce protein tyrosine phosphorylation and the consequences of these phosphorylation events.

## Antigen Receptors on T and B Lymphocytes

The TCR and BCR are both oligomeric complexes that contain subunits responsible for antigen recognition and other subunits involved in signal transduction (Fig. 6.1A). The repertoires of the clonally distributed ligand binding subunits of these receptors

are entrusted with the responsibility of recognizing the vast array of antigens or peptides that may be encountered through interactions with pathogens. In the case of the TCR, the antigen- or ligand-binding subunit consists of productively rearranged  $\alpha\beta$  or  $\gamma\delta$  heterodimers. The antigen-binding subunit of the BCR consists of the heavy and light chains of membrane immunoglobulin (Ig). Whereas these subunits have all of the information necessary for specific antigen recognition, their short cytoplasmic domains do not contain sufficient information to interact with cytoplasmic molecules involved in signal transduction.

In the case of the TCR, the  $\alpha\beta$  or  $\gamma\delta$  heterodimers assemble with the invariant CD3  $\gamma$ ,  $\delta$ , and  $\epsilon$  chains and a homo- or heterodimer of  $\zeta$  and/or Fc $\gamma$  chains. The precise stoichiometry of the assembly, which occurs in the endoplasmic reticulum, is not known, but there is evidence for CD3  $\epsilon$  chains forming noncovalent dimers with CD3 $\delta$  or CD3 $\gamma$  (Blumberg et al., 1990; Kappes and Tonegawa, 1991). The assembly of all of the components is necessary for efficient expression on the plasma membrane. Human or murine immune deficiency syndromes characterized by T cell developmental arrests or functional defects and lower TCR expression have been associated with CD3 $\gamma$  or  $\epsilon$  mutations (Perez-Aciego et al., 1991; Tanaka et al., 1995; see Chapter 16). Studies in T cell lines and heterologous cells show that most incomplete complexes are retained in the endoplasmic reticulum or golgi and shunted toward a degradative pathway (Klausner et al., 1990). Unusually placed transmembrane acidic and basic residues appear to play an important role in the interaction of these chains. The CD3 and  $\zeta$  chain dimers are responsible for signal transduction function of the receptor.

Membrane Ig also assembles with invariant chains, Ig $\alpha$  and Ig $\beta$  involved in signal transduction. Like the CD3 chains, Ig $\alpha$  and Ig $\beta$  form heterodimers and each chain has a single extracellular Ig-like domain and intracellular domains with signaling

**Figure 6.1.** A. Schematic representation of the T cell antigen receptor (TCR) and B cell antigen receptor (BCR). B. Immunoreceptor tyrosine-based activation motifs present in hematopoietic receptors involved in antigen recognition and in viruses that infect T or B cells. h, human; r, rat; m, mouse; BLV, bovine leukemia virus; EBV, Epstein-Barr virus; SIV, simian immunodeficiency virus; KSHV, Kaposi's sarcoma-associated herpes virus.

function (Reth, 1992). The number of Ig $\alpha$ /Ig $\beta$  dimers associated with a membrane Ig tetramer unit has not been definitively established. Efficient cell surface expression of membrane Ig requires association with Ig $\alpha$  and Ig $\beta$ . Although charged amino acid residues are not present in the transmembrane domains of BCR subunits, these domains do interact with each other and this interaction is necessary for assembly (Venkitaraman et al., 1991). Thus, the BCR and TCR are both obligate multisubunit complexes in which antigen-binding functions and signal transduction functions are provided by distinct chains.

In addition to the antigen receptors found on mature lymphocytes, related receptors are found on pre-B cells in the bone marrow and on CD4<sup>+</sup>/CD8<sup>-</sup> thymocytes (Roth and DeFranco, 1995; von Boehmer and Fehling, 1997). These receptors contain only one of the two antigen-binding chains, the one that is generated by recombination first during development of the cell, in combination with a surrogate for the second chain. In B cells, this "pre-BCR" contains the Ig  $\mu$  heavy chain together with the  $\lambda_5$  and V<sub>preB</sub> proteins, each of which is thought to mimic one-half of the Ig light chain of the BCR. This pre-BCR also contains Ig $\alpha$ /Ig $\beta$

heterodimers. Similarly, the pre-TCR contains a complex of the TCR $\beta$  chain with an  $\alpha$  chain surrogate called pre-T $\alpha$  associated with CD3 and  $\zeta$  chains. In both cases, these receptors play critical roles in allowing developing lymphocytes to sense the successful rearrangement of the first antigen receptor gene and pass through a developmental checkpoint, after which rearrangement at that locus ceases and rearrangement of the Ig light-chain gene or the TCR $\alpha$  gene increases.

The CD3 and  $\zeta$  chains of the TCR and the Ig $\alpha$  and Ig $\beta$  chains of the BCR have substantial cytoplasmic domains containing sequences responsible for the signal transduction function of these receptors. These signal transduction functions were most definitively established through the use of chimeric receptors in which the cytoplasmic domains of several of these proteins were linked to the extracellular and transmembrane domains of heterologous proteins (Irving and Weiss, 1991; Romeo and Seed, 1991). Although these cytoplasmic domains do not encode enzymatic functions, they can confer TCR and BCR signal transduction functions to heterologous receptors. This signal transduction function is encoded in a sequence motif, termed *ITAM* (for immunoreceptor tyrosine-based activation motif), which is present as a single copy in all of the CD3 chains and the Ig $\alpha$  and Ig $\beta$  chains, and as three copies in the  $\zeta$  chain (Fig. 6.1B). The ITAMs are also present and functionally active in the cytoplasmic domains of the nonligand-binding subunits of the high-affinity IgE Fc receptor, the phagocytic Fc $\gamma$  receptors on macrophages, and the DAP-12 chain that associates with natural killer (NK) cell-activating receptors (Lanier, 2001). Interestingly, the ITAM sequence motif, D/ExxYxxL(x)6–8YxxL, in many of these chains is encoded by two exons with similar organization, suggesting a common evolutionary origin (Wegener et al., 1992). This also suggests that these antigen receptors use similar mechanisms to transduce signals. Mutagenesis studies have shown that both tyrosines and both leucines are critical for the ability of ITAMs to transfer signal transduction function to heterologous receptors (Sefton and Taddie, 1994). The residues surrounding the conserved tyrosines and leucines can be quite variable. A major question that arises and remains unsettled is whether ITAMs, which contain such variable sequences, have equivalent functions or whether part of their functions are distinctive. Some investigations have suggested that multiple ITAMs are present in TCRs and BCRs to recruit distinct signaling molecules (Frank et al., 1990; Clark et al., 1992; Siemasko and Clark, 2001). Others have suggested that the presence of multiple ITAMs may play a role in signal amplification (Irving et al., 1993; Law et al., 1993; Lin et al., 1996; Donnadieu et al., 2000; Love and Shores, 2000). In mouse experiments involving genetic deletion of all or part of the CD3 $\zeta$  ITAMs, it was shown that the CD3 $\gamma$ ,  $\delta$ ,  $\epsilon$  subunits are sufficient for normal TCR signaling events and effector functions and that the CD3 $\zeta$  ITAMs do not play any exclusive role (Ardouin et al., 1999). Mice containing mutations of the ITAM tyrosines in Ig $\alpha$  did not exhibit any major defects in the development of B-2 cells, whereas there was a reduction in B-1 and marginal zone B cells. Combining the Ig $\alpha$  mutation with a truncation in Ig $\beta$  resulted in a dramatic arrest in B cell development at the pro-B cell stage demonstrating the requirement for functional ITAMs on at least one of the signal transducing chains of the BCR for progression through early development. Mice carrying a truncation in the cytoplasmic tail of Ig $\beta$  alone progress to the immature stage and respond normally to BCR ligation; however, they are arrested at this stage in the bone marrow and die by apoptosis. These observations indicate that Ig $\alpha$  and Ig $\beta$  might have distinct biologic activities in vivo (Kraus et al., 2001; Reichlin et al., 2001).

As in other situations where pathogens have usurped or targeted normal cellular machinery to their benefit, at least four viruses that infect T or B cells encode ITAMs that appear to play an important role in their pathogenesis. The bovine leukemia virus, which can transform B cells, contains an ITAM in the cytoplasmic domain of the gp30 envelope glycoprotein that is critically important for viral infection and/or replication (Willems et al., 1995). An ITAM is also present in the latent membrane protein 2 (LMP2) of the Epstein Barr virus (EBV) and has been implicated in maintaining a state of viral latency in transformed B cell lines (Miller et al., 1995). Recent studies suggest that LMP2 serves to recruit E3 protein ubiquitin ligases that target BCR-activated protein kinases, thereby down-regulating BCR signaling (Winberg et al., 2000). In addition, SLP-65/BLNK, a signaling adaptor molecule that will be discussed later, was recently identified as a downstream effector of LMP2A. In EBV-infected B cells, one of the SLP-65 isoforms was found to be constitutively tyrosine phosphorylated, resulting in complex formation with CrkL and subsequent phosphorylation of Cbl and C3G (Engels et al., 2001a,b). In contrast, phospholipase C  $\gamma$ 2 (PLC $\gamma$ 2) activation was completely blocked. Thus, during latent EBV infection, LMP2 has contrasting effects on SLP-65-regulated pathways. A rare mutation of the Nef protein of the simian immunodeficiency virus results in the creation of an ITAM sequence (Du et al., 1995). This mutation is associated with the unusual ability of this viral isolate to infect and replicate in primary resting T cells and cause a fulminant viral infection. Finally, human herpesvirus 8 (HHV8; also known as Kaposi's sarcoma [KS]-associated herpesvirus, or KSHV) which causes Kaposi's sarcoma, primary effusion lymphoma, and multicentric Castleman's disease, encodes the K1 gene product that contains an ITAM-like sequence in the C-terminal cytoplasmic tail. Expression of this protein leads to ligand-independent signaling in B cells that is abrogated upon mutation of the ITAMs (Lagunoff et al., 1999). Thus, the ITAM plays a critical role in normal T and B cell antigen receptor function and some pathogens have capitalized on this function.

### ITAMs of T and B Cell Antigen Receptors Interact with Distinct Families of Protein Tyrosine Kinases

Stimulation of the TCR and BCR leads to the activation of protein tyrosine kinases (PTKs) that are critical for lymphocyte responses to antigen. Two families of cytoplasmic PTKs, members of the Src and Syk/ZAP-70 families, have been implicated in the most proximal signaling events induced by these receptors. Indeed, considerable evidence has accumulated to suggest a model in which the TCR and BCR ITAMs interact with these two families of PTKs in a sequential and coordinated manner (Fig. 6.2). Whereas the members of the families of the PTKs that are expressed in T and B cells differ, they appear to subserve similar functions.

In B cells and in T cell lines and T cell clones, the earliest event associated with antigen receptor stimulation is the tyrosine phosphorylation of ITAMs (Law et al., 1993; Iwashima et al., 1994). In contrast, in ex vivo T cells, phosphorylation of the ITAM tyrosines is present in the basal state (van Oers et al., 1993). Both the inducible and basal phosphorylation of ITAM tyrosines depends on members of the Src family (Iwashima et al., 1994; Richards et al., 1996; van Oers et al., 1996a). Src family kinases expressed in T cells are Lck, Fyn, and Yes and those expressed in B cells are primarily Lyn, Fyn, and Blk. These kinases are peripheral membrane proteins characterized by the following: (1) a unique N-terminal domain that is myristylated in all family

**Figure 6.2.** Model for sequential interaction of Src and Syk/ZAP-70 protein tyrosine kinases with an ITAM. Note that the subsequent interaction of the Src kinase, involving its SH2 domain, with the phosphorylated Syk or ZAP-70 kinase is not depicted.

members and also may be palmitoylated; (2) an SH3 domain involved in mediating protein–protein interactions by binding to proline-rich sequences; (3) an SH2 domain involved in mediating protein–protein interactions by binding phosphorylated tyrosine residues in the context of particular neighboring amino acid residues; (4) a catalytic domain; and, (5) a carboxy-terminal domain that contains a negative regulatory site of tyrosine phosphorylation.

In T cells, the functions of Lck and/or Fyn are critical for TCR signal transduction. Lck and Fyn both coimmunoprecipitate with the TCR complex and can interact with an ITAM (Samelson et al., 1990; Beyers et al., 1992), but genetic studies with cell lines and mice have indicated a more important role for Lck in the phosphorylation of the ITAMs (Iwashima et al., 1994; van Oers et al., 1996a). However, in the absence of Lck, or when Lck function might be limiting, Fyn may be able to play a compensatory role. This view is consistent with the developmental phenotypes seen in mice deficient in one or both of these kinases: mice deficient in Fyn have no developmental abnormality of conventional  $\alpha\beta$  T cells but they lack NK1.1<sup>+</sup> T (NKT) cells (Appleby et al., 1992; Stein et al., 1992; Eberl et al., 1999), whereas the loss of Lck is associated with a severe but incomplete arrest in T cell development (Molina et al., 1992). The residual development seen in thymocytes lacking Lck is completely absent in thymocytes from mice deficient in both kinases (van Oers et al., 1996b). These thymocytes exhibit a complete developmental block at a stage where the function of the pre-TCR is important (Fehling et al., 1995). Presumably, this reflects the inability of the pre-TCR to transduce signals in the absence of Lck or Fyn.

A unique feature of Lck is the ability of its N-terminal region to associate with the cytoplasmic tails of the CD4 and CD8 coreceptors (Chow and Veillette, 1995). A primary role for Lck function in the initiation of TCR signaling is also consistent with its association with CD4 and CD8. The colocalization of CD4 or CD8 with the TCR during antigen recognition may serve to lo-

calize Lck in close proximity with the TCR, facilitating its participation in early signaling events.

In B cells the Src family kinases are also believed to be responsible for ITAM phosphorylation, although Syk may contribute as well. For example, in a chicken B cell line, DT-40, Lyn is apparently the only Src family kinase expressed. Disruption of the Lyn gene in these cells decreased anti-IgM-induced tyrosine phosphorylation of Ig $\alpha$  and Ig $\beta$ , but did not eliminate it (Takata et al., 1994). Moreover, subsequent signaling events were decreased but not eliminated. Conversely, when the BCR was expressed in the AtT-20 rat pituitary cell line following the introduction of cDNA expression vectors, BCR stimulation led to strong tyrosine phosphorylation of Ig $\alpha$  and Ig $\beta$  but minimal downstream signaling. These cells express Fyn but not Syk, Lyn, or Blk. Introduction of Syk restored some downstream signaling events and also boosted the stimulation-dependent phosphorylation of Ig $\alpha$  and Ig $\beta$  (Richards et al., 1996). In murine splenic B cells, Lyn is the most abundant Src family member present, although substantial amounts of Blk and Fyn are also detectable. B cells from mice rendered deficient in Lyn by targeted gene disruption exhibit significantly delayed tyrosine phosphorylation of Ig $\alpha$  after BCR stimulation (Nishizumi et al., 1995; Chan et al., 1997), indicating that Lyn is important but not essential for Ig $\alpha$  phosphorylation. Thus, the situation is a bit more complex than in T cells, but again, Src family kinases are primarily responsible for phosphorylation of Ig $\alpha$  and Ig $\beta$  ITAM tyrosines.

In the absence of coreceptor involvement, the low stoichiometry of the documented interactions of the Src family members with the TCR and BCR, as well as the apparent redundancy in some functions among these PTKs, raises questions about how TCR and BCR stimulation induces these kinases to phosphorylate the ITAMs. One point worth noting is that the stoichiometry of ITAM phosphorylation is low, even in systems where receptor stimulation is maximal. The basis for such interactions could be relatively nonspecific and involve ligand-induced association of receptors with membrane microdomains ("lipid rafts") where

these Src kinases are concentrated. Alternatively, the association of the receptor and kinase could be based on an interaction between the SH2 domain of the Src family PTK and a small percentage of ITAMs that may be tyrosine phosphorylated in the basal state. The recruitment of Src family PTKs to phosphorylated ITAMs is attractive in view of studies suggesting that the tyrosine phosphorylated YEEL sequence, similar to the YXXL sequences in ITAMs, is a preferred binding site for the SH2 domains of Src kinases (Songyang et al., 1993). Most ITAMs have at least one negatively charged amino acid residue between the tyrosines and leucines (Fig. 6.1B). Indeed, cross-linking of chimeric transmembrane proteins with Ig $\alpha$  or Ig $\beta$  ITAMs leads to induced association of Lyn (Law et al., 1993). Moreover, the inducible phosphorylation of  $\zeta$  chain ITAMs requires the function of the Lck SH2 domain (Straus et al., 1996). This could reflect a positive feedback loop whereby once a few ITAM tyrosines are phosphorylated, Lck binds and then phosphorylates other ITAMs of neighboring receptors aggregated by the triggering stimulus. While there are alternative explanations for the interactions of the Src PTKs with the TCR or BCR, receptor ligation does appear to increase the catalytic activity of these PTKs (Saouaf et al., 1994; Tsygankov et al., 1994).

Both tyrosines of an ITAM are necessary for its signal transduction function (Sefton and Taddie, 1994). The explanation for this dependency on both tyrosines is likely to reflect the requirement for tyrosine phosphorylation of both sites for high-affinity binding of a second type of PTK, ZAP-70 and/or Syk. ZAP-70 and Syk have a similar overall structure. They contain N-terminal tandem SH2 domains and a C-terminal catalytic domain. ZAP-70 is expressed exclusively in T cells and NK cells. Syk is more broadly expressed within the hematopoietic lineages. ZAP-70 and Syk bind to doubly phosphorylated ITAMs with relatively high affinity via an interaction that depends on both of their SH2 domains (Wange et al., 1993; Iwashima et al., 1994; Bu et al., 1995). The crystal structure of the ZAP-70 tandem SH2 domains bound to a doubly phosphorylated TCR $\zeta$  ITAM peptide confirms that both SH2 domains interact with a single, doubly phosphorylated ITAM and helps explain their cooperative binding (Hatada et al., 1995). Similar data have been obtained for the crystal structure of Syk bound to an ITAM (Fütterer et al., 1998). Thus, inducible phosphorylation of ITAMs results in recruitment of ZAP-70 or Syk to the stimulated-receptor complex. If ITAMs are phosphorylated in the basal state, as has been observed in ex vivo thymocytes and peripheral T cells, ZAP-70 and/or Syk are bound and poised to respond to receptor stimulation (van Oers et al., 1994, 1996a).

The induction of PTK activity following Syk/ZAP-70 recruitment to the receptor complexes likely involves additional interactions between the Src and Syk/ZAP-70 PTKs. In vitro studies suggest that the binding of Syk, but not ZAP-70, to ITAMs can lead to its activation (Shiue et al., 1995). However, simple binding of Syk and ZAP-70 to ITAMs in vivo is probably not sufficient for stimulation of their kinase activity and subsequent signal transduction, since Syk and ZAP-70 bound to the ITAMs in ex vivo thymocytes are not activated (van Oers et al., 1994, 1996a). Rather, both Syk and ZAP-70 kinase activities are regulated primarily by phosphorylation of tyrosine residues within a regulatory loop of their catalytic domains (Chan et al., 1995; Wange et al., 1995). In the case of ZAP-70, this key phosphorylation event can be performed by Lck or Fyn but not by ZAP-70 itself (Chan et al., 1992, 1995; Wange et al., 1995). In contrast, Syk can activate itself, and this is seen in overexpression studies in Cos cells or upon cross-linking of a chimeric protein in which

Syk has been fused to the cytoplasmic domain of a transmembrane protein (Kolanus et al., 1993; Couture et al., 1994). Syk can probably also be activated by Src family PTKs such as Lyn. Thus, the Src kinases can play a critical role in Syk and ZAP-70 catalytic activation by phosphorylating the regulatory tyrosines. In addition to the tyrosines in the activation loop, there is evidence that other tyrosines are phosphorylated and are involved either in negative regulatory functions, i.e., Y292 in ZAP-70 (Chan et al., 1995; Wange et al., 1995; Kong et al., 1996; Zhao and Weiss, 1996; Magnan et al., 2001), or in positive regulatory functions, i.e., Y315 and Y319 in ZAP-70 (Gong et al., 2001b; Magnan et al., 2001). These phosphorylation sites are involved in recruitment of substrates that may contain SH2 domains with specificity for specifically phosphorylated sequence motifs, in a manner analogous to that observed with PTK growth factor receptors. Proteins that have been reported to bind to either Syk or ZAP-70 include Lck (Thome et al., 1995; Straus et al., 1996), Lyn (Law et al., 1996), Shc (Nagai et al., 1995), Vav (Katzav et al., 1994), PLC $\gamma$ 1 (Law et al., 1996), SHIP (an inositol 5-phosphatase) (Crowley et al., 1996), and Cbl (Fournel et al., 1996). The functions of some of these signaling components will be discussed in a later section.

A stable complex of Lck and ZAP-70 or Syk has been observed following TCR stimulation (Thome et al., 1995; Straus et al., 1996). The interaction appears to depend on the binding of the Lck SH2 domain to tyrosine phosphorylated residues in the interdomain B region of ZAP-70 (Y319) or Syk (Pelosi et al., 1999). A Y319F mutant of ZAP-70 retains full tyrosine kinase activity but is unable to reconstitute TCR-dependent Ca<sup>2+</sup> mobilization, Ras activation, CD69 expression, and NFAT-dependent transcription in ZAP-70-deficient Jurkat cells. This functional defect may reflect the inability of the mutant ZAP-70 to interact with Lck, although other explanations are possible. For example, phosphorylation of Tyr319 also promotes the association of ZAP-70 with the SH2 domain of PLC $\gamma$ 1. Accordingly, ZAP-70-deficient cells reconstituted with Y319F mutant ZAP-70 show reduced tyrosine phosphorylation of PLC $\gamma$ 1 and the LAT adapter protein (Williams et al., 1998).

The relative contribution of the two families of PTKs toward phosphorylation of downstream substrates has not been clearly assessed. However, activation of Lck alone by cross-linking CD4 or CD8 fails to mimic TCR stimulation (Ledbetter et al., 1990). This suggests a critical function provided by Syk and ZAP-70 in later signal transduction events. Successful reconstitution of Syk-deficient B cells or ZAP-70-deficient T cells with ZAP-70 or Syk depends on the catalytic functions of these PTKs and the presence of the activating tyrosine of the kinase domain (Y518, Y519 for Syk, and Y493 for ZAP-70) (Kurosaki et al., 1995; Kong et al., 1996; Williams et al., 1998). Thus, a contribution of both Src and Syk/ZAP-70 kinases is likely to be important for effective downstream signaling events.

Both ZAP-70 and Syk play critical roles in lymphocyte development, presumably because signal transduction through immature and mature antigen receptors is critical for transition through certain developmental checkpoints. Mice and humans deficient in ZAP-70 exhibit distinct developmental arrests and marked impairment in TCR signal transduction function (Arpaia et al., 1994; Chan et al., 1994b; Elder et al., 1994; Negishi et al., 1995; see Chapter 14). A profound B cell developmental arrest and bleeding diathesis are the most prominent features of mice deficient in Syk (Cheng et al., 1995; Turner et al., 1995). Bleeding may be secondary to a collagen receptor signaling defect in platelets (Poole et al., 1997). The B cell developmental arrest in

these mice occurs at the same stage as seen with mutations that prevent expression of the membrane-bound form of the Ig $\mu$  heavy chain. Thus, it is thought that the developmental block results from impaired pre-BCR function. This interpretation is consistent with the impaired BCR signal transduction function observed in an avian B cell line deficient in Syk (Takata et al., 1994). Thus, the Syk and ZAP-70 PTKs play critically important roles in TCR and BCR signal transduction function.

In some systems it has been suggested that Syk and ZAP-70 may be interchangeable (Gelfand et al., 1995; Kong et al., 1995). One clear difference is that Syk appears to be less dependent on interactions with Src kinases than is ZAP-70 (Kolanus et al., 1993; Chu et al., 1996). It is not yet clear whether Syk and ZAP-70 are completely functionally redundant with regard to activation of downstream signaling events. It is likely that these kinases do have unique functions in T cells. For instance, the  $\alpha\beta$  T cell lineage is primarily affected in mice made deficient in ZAP-70 (Negishi et al., 1995), whereas the  $\gamma\delta$  lineage of T cells in epithelial tissues is defective in Syk deficient mice (Mallick-Wood et al., 1996). Thus, many of the functions of these PTKs overlap, but they appear to have unique functions as well.

## Regulation of Antigen Receptor Signal Transduction

### Coreceptors on T Cells

The great sensitivity of the immune system has evolved to allow immune responses to be initiated early upon infection with pathogens. While receptors with high affinity exist within the derived repertoire of antigen receptors on T and B cells, the immune system has also developed mechanisms to increase the sensitivity of responsiveness until the clonal expansion of cells with high-affinity receptors can take place. T and B cells both have distinct coreceptor molecules that function in concert with antigen receptors to recognize antigen and induce signaling events. Here we will restrict our use of the term *coreceptors* to refer to molecules that recognize the molecular complex containing intact antigen or peptide antigen along with the antigen receptor.

The positive selection of most  $\alpha\beta$  thymocytes and the primary response of  $\alpha\beta$  T cells to antigen usually depend on the functional contributions of the coreceptors CD4 and CD8. The

CD4 and CD8 molecules are integral membrane glycoproteins whose extracellular domains bind to the  $\beta 2$  domain of class II - major histocompatibility complex (MHC) molecules or the  $\alpha 3$  domain of class I MHC molecules, respectively, on antigen-presenting cells (Janeway, 1992; Robey and Fowlkes, 1994). These interactions are of relatively low affinity and may depend on the simultaneous binding of the TCR as well. In fact, some evidence suggests that a TCR-initiated signaling event may be required for the recruitment and effective participation of the CD4 coreceptor (Xu and Littman, 1993). An alternative but not mutually exclusive view is that the CD4 or CD8 participation stabilizes the low-affinity TCR-MHC/peptide interaction and also potentiates TCR signal transduction by delivering Lck to the TCR complex (Fig. 6.3).

The cytoplasmic domains of CD4 and CD8 bind to the unique N-terminal region of Lck through a cysteine-containing motif shared by CD4 and CD8 (Chow and Veillette, 1995). This interaction is important but not absolutely essential for TCR signal transduction during development or at low antigen concentrations (Killeen and Littman, 1993). Several functional consequences may result from the interaction of Lck with the CD4 and CD8 coreceptors. In T cell clones or lines, if CD4 or CD8 delivers Lck to the TCR complex through colocalization driven by the interaction of the coreceptors with the MHC/peptide complex, the phosphorylation of ITAMs by Lck would be facilitated and subsequent interactions involving the phosphorylation and activation of ZAP-70 or Syk could be potentiated (Weiss, 1993). A similar interaction of the coreceptors of T cells *in vivo* would lead to the delivery of Lck into close proximity with ITAM-bound ZAP-70 or Syk, again potentiating their phosphorylation and activation. In addition to this initiating function of Lck in TCR signal transduction, Lck appears to contribute to T cell activation in a second way in which a CD4-bound Lck molecule binds to phosphorylated ZAP-70 or Syk via its SH2 domain, thereby stabilizing the interaction of the coreceptor with the TCR-MHC/peptide complex (Xu and Littman, 1993; Thome et al., 1995; Straus et al., 1996).

The ligation of coreceptors in the absence of TCR engagement has been reported to induce negative signals. Ligation of CD4 with anti-CD4 monoclonal antibodies primes the T cells for subsequent apoptosis when the TCR is stimulated (Newell et al., 1990). *In vivo*, this may be relevant to interactions of the HIV

**Figure 6.3.** Models of coreceptor/antigen receptor engagement on T and B cells. APC, antigen-presenting cell; MHC, major histocompatibility complex.

gp120 protein with CD4, which can lead to apoptosis if the TCR is subsequently stimulated (Banda et al., 1992). The mechanisms underlying such coreceptor-induced inhibitory signals have not been clarified.

Mature CD4 or CD8 T cells are derived from thymocyte precursors that express both of these coreceptors. Evidence suggests that these two coreceptors play an active role in the decision process regarding lineage commitment (von Boehmer and Kisielow, 1993). Moreover, T cells that express CD4 or CD8, in addition to recognizing peptide antigens on distinct classes of MHC molecules, generally have distinct effector functions, helper or cytolytic functions, respectively. To explain this linkage of coreceptor expression to differentiated phenotype, it has been proposed that the engagement of the TCR with each of these coreceptors leads to distinct signaling events (Ratcliffe et al., 1992; von Boehmer and Kisielow, 1993; Itano et al., 1996). The identity of such specialized events remains unknown. Since the interaction of CD4 with Lck appears to be more avid than that of CD8 with Lck (Wiest et al., 1993), it is possible that there are quantitative and qualitative effects that should be considered.

### Coreceptors on B Cells

The concept of coreceptors in B cell antigen recognition is a newly emerging concept, in part because a coreceptor involved in the recognition of native antigen is not often considered. However, recent studies suggest that complement fixed to soluble or particulate antigen may serve to colocalize complement receptors with the BCR and greatly potentiate BCR signaling and B cell activation (Fearon and Carter, 1995). Antigen/complement complexes or fusion proteins are much more potent inducers of B cells than native antigen. These observations suggest that coligation of the complement receptor and the BCR increases the sensitivity of the B cell response to antigen, analogous to the role of coreceptors in T cell activation.

The complement receptor that functions as coreceptor is CD21. It is part of a molecular complex formed by CD19, CD21 (complement receptor 2, CR2), and TAPA-1 (CD81) (Fig. 6.3). CD21 binds the complement proteolytic product C3dg. Ligands for CD19 and TAPA-1 have not been identified, although TAPA-1 serves as the receptor for infection by hepatitis C virus (Pileri et al., 1998). Coligation of CR2 or CD19 with the BCR lowers the effective concentration of anti-Ig required to induce early signal transduction events or B cell proliferation (Fearon and Carter, 1995). Similar observations have been made with a soluble antigen/complement fusion protein (Dempsey et al., 1996), suggesting that such synergy in coligation of these complexes is physiologically relevant. Interestingly, preligation of CD19 inhibits IgM-mediated B cell proliferation in a manner that is remarkably similar to the properties of the T cell coreceptors, CD4 and CD8.

The precise mechanism by which the CD19/CD21/TAPA-1 complex functions as a coreceptor is not clear. Stabilization of the extracellular ligand interactions is one possible mechanism. Src kinases, including Lyn, have been detected in CD19 immunoprecipitates (van Noesel et al., 1993), which suggests that the B cell coreceptor complex could bring these kinases into proximity of the BCR ITAMs or recruited kinases. In addition, the inducible phosphorylation of CD19 by BCR stimulation leads to the recruitment of a number of signaling molecules that could contribute to the initial events in BCR activation or could recruit potential substrates or signaling molecules (Fearon and Carter, 1995). The best-characterized interaction is with the p85

subunit of phosphatidylinositol 3-kinase (PI3K) (Tuveson et al., 1993). This results from the interaction of the p85 SH2 domains with phosphorylated CD19 residues containing the consensus motif YXXM. Activation of PI3K follows BCR stimulation and it participates in downstream signaling events as described later. CD19 also binds the signaling component Vav (see below) and this likely contributes to B cell activation as well. The positive role of CD19 in B cell activation is illustrated by the striking effects of altering CD19 expression genetically. B cells with elevated levels of CD19 are highly activated, whereas those with decreased levels are poorly stimulated by antigen (Sato et al., 1997).

### Receptors with Inhibitory Functions

Recent studies have identified several receptors that appear to function in negatively regulating signal transduction by the TCR (the killer inhibitory receptors, KIRs; and CTLA-4) (Waterhouse et al., 1995; Yokoyama, 1995; Marengere et al., 1996) and the BCR (FcγRIIB, CD72, and PIR-B) (Brauweiler et al., 2000; Parnes and Pan, 2000; Takai and Ono, 2001). These receptors inhibit signal transduction by the TCR or BCR by recruiting from the cytoplasm inhibitory signaling proteins to the plasma membrane in close proximity to the stimulated antigen receptor. Among the proteins recruited to the membrane by these receptors are the cytoplasmic protein tyrosine phosphatases SHP-1 and SHP-2 and the inositol phosphatase SHIP-1. The mechanisms by which these proteins inhibit signal transduction by the TCR and BCR are beginning to be characterized.

The best characterized of these inhibitory receptors is FcγRIIB. Coligation of this receptor with the BCR inhibits B cell proliferative responses and promotes B cell apoptosis. Physiologically, coligation is likely to occur during the binding of antigen-antibody complexes to antigen-specific B cells. The presence of IgG bound to the antigen reflects the presence of specific antibody, so inhibition of further B cell activation is a mechanism for down-regulating antibody production late in an immune response. Indeed, mice made deficient in FcγRIIB have heightened B cell responses to BCR stimulation (Takai et al., 1996). Coligation of the BCR with FcγRIIB leads to FcγRIIB tyrosine phosphorylation (Muta et al., 1994). The major inhibitory function of this receptor maps to a single tyrosine residue in its cytoplasmic domain that is in the context of an immunoreceptor tyrosine-based inhibitory motif (ITIM) with a consensus sequence I/LVXYXXL. Phosphorylation of this tyrosine residue in the ITIM leads to the recruitment of the SHP-1 and SHP-2 protein tyrosine phosphatases (PTPs) and also the SHIP-1 inositol 5-phosphatase via their SH2 domains (D'Ambrosio et al., 1995; Chacko et al., 1996). The significance of SHP-1 and SHP-2 binding to FcγRIIB remains unclear. SHIP-1 is the primary effector of FcγRIIB and is thought to modulate its signaling function by hydrolysis of phosphatidylinositol 3,4,5 triphosphate (PIP<sub>3</sub>), a key molecule involved in the translocation and assembly of a signaling complex consisting of PLCγ2 and Btk. These are required for PIP<sub>2</sub> hydrolysis and Ca<sup>2+</sup> mobilization (see below; Gupta et al., 1997; Okada et al., 1998; Scharenberg et al., 1998; Hashimoto et al., 1999). FcγRIIB ligation also results in the inhibition of BCR-mediated Ras activation. In addition, SHIP forms a complex with another adaptor protein, p62<sup>dok</sup>, which becomes strongly tyrosine phosphorylated upon BCR-FcγRIIB co-cross-linking and recruits RasGAP, a suppressor of Ras activity (Tamir et al., 2000; Yamanishi et al., 2000).

The related Ig superfamily members, paired immunoglobulin-like receptors (PIRs), have also been shown to modulate BCR

signaling. These receptors are expressed not only on B cells but also macrophages, neutrophils, mast cells, and dendritic cells. These are type I transmembrane glycoproteins with six Ig-like domains related to human Fc $\alpha$ R and bovine Fc $\gamma$ 2R, with the activating (PIR-A) and inhibitory (PIR-B) forms being expressed in a pairwise fashion. The ligand for these receptors is unknown, although co-cross-linking PIR-B with the BCR or the Fc receptor for IgE (Fc $\epsilon$ RI) results in inhibition of antigen receptor- or Fc receptor-mediated activation through the ITIMs present in the cytoplasmic tail. On B cells, PIR-B is constitutively tyrosine phosphorylated and associated with the tyrosine phosphatase SHP-1. PIR-A, by contrast, requires association with the Fc receptor common  $\gamma$  chain for its membrane expression and activation function (Kubagawa et al., 1999; Maeda et al., 1998, 1999). The functions of these proteins are not yet understood.

CD72 is the third receptor that negatively regulates B cell function. CD72 is a type II transmembrane protein belonging to the C-type lectin superfamily. It is expressed on the surface of B cells throughout their development and is thought to be a regulator of different stages of B cell development (Parnes and Pan, 2000; Kumanogoh and Kikutani, 2001). Absence of CD72 is associated with a significant increase in the number of IgM-IgD<sup>+</sup> pre-B cells in the bone marrow whereas the mature IgM<sup>+</sup>IgD<sup>+</sup> B cells are fewer in number. These findings indicate that CD72 may be required for the efficient transition from the pre-B cell to the immature B cell and/or from the immature to the mature B cell stage. CD72-deficient mice also have increased numbers of splenic B-1 cells and marginal zone B cells (Pan et al., 1999). This change in the relative distribution of B-1 and conventional B-2 cells has also been observed in mice that have been gene targeted for other negative regulators of BCR signaling—e.g., Lyn, SHP-1, and CD22. Interestingly, the cytoplasmic domain of CD72 contains two ITIMs, one of which has been shown to recruit SHP-1. Accordingly, the B cells from CD72-deficient mice are hyperresponsive to suboptimal doses of antigenic and mitogenic stimulation (Pan et al., 1999; Adachi et al., 2000).

### Receptors with Dual Effects on Antigen Receptor Signaling

Another cell surface protein that influences the outcome of signaling via the BCR is CD22, a transmembrane glycoprotein that belongs to the family of Siglecs (sialic acid binding Ig-like lectins) and is expressed exclusively on B cells. The sialic acid binding activity of CD22 is largely undetectable in resting B cells; however, activation of the B cell results in CD22 binding to  $\alpha$ 2,6 sialylated

ligands, probably because of unmasking of the ligand binding domains (Nitschke et al., 2001). Upon BCR engagement, the cytoplasmic tail of CD22 is phosphorylated by the Src family kinase Lyn on six tyrosine residues. Three of these are in the context of ITIMs, which suggests a negative regulatory role for CD22. Lyn-deficient mice lack BCR-induced tyrosine phosphorylation of CD22, and this might contribute to the hyperactive state of B cells derived from these mice (Chan et al., 1998; Cornall et al., 1999).

There is also evidence that CD22 can signal positively. For example, the cytoplasmic tail of CD22 has been shown to recruit several signaling molecules including Lyn, Syk, PLC $\gamma$ 2, PI3K, Grb2, and Shc (Fearon and Carroll, 2000). In addition, B cells from CD22-deficient mice exhibit decreased overall tyrosine phosphorylation and proliferation, consistent with a positive signaling function of CD22. Further studies will be needed to better define the role of CD22 in B cell regulation. At the same time, CD22 also binds the tyrosine phosphatase SHP-1 and the inositol phosphatase SHIP, both of which are involved in the negative regulation of B cell activation. Accordingly, CD22-deficient B cells show augmented calcium responses which are regulated by membrane recruitment of SHP-1 and SHIP (Sato et al., 1996; Nitschke et al., 1997; Poe et al., 2000). Similarly, sequestering CD22 away from the BCR by preincubation with anti-CD22-coated beads leads to robust mitogen-activated protein kinase (MAPK) activation upon BCR stimulation, whereas coligating BCR with CD22 suppresses MAPK activation. It has been suggested that the *cis* binding of CD22 to the cell surface glycans could keep it sequestered away from the BCR and could thus prevent it from exerting a negative influence (Smith and Fearon, 2000).

### Regulation by CD45 and Csk

The steady-state level of protein tyrosine phosphorylation is the result of a dynamic equilibrium involving the opposing actions of kinases and phosphatases. The function of Src PTKs is tightly regulated by tyrosine phosphorylation (Cooper and Howell, 1993). Phosphorylation of a tyrosine near the catalytic loop of the kinase domain is associated with the activated state of these kinases. In addition, the C-terminal regulatory region of the Src kinases contains a tyrosine residue whose phosphorylation negatively regulates their activity. In T and B cells, the phosphorylation of this negative regulatory site in Src PTKs appears to be regulated by the opposing actions of the transmembrane PTP CD45 and the cytoplasmic Csk PTK (Fig. 6.4) (Chan et al., 1994a; Chow and Veillette, 1995). The regulation of Lck in T cells by CD45 and Csk has been most thoroughly studied.

**Figure 6.4.** Dynamic regulation of Src family kinases by Csk and tyrosine phosphatases, CD45 and PEP, in plasma membrane microdomains (lipid rafts).

Various isoforms of CD45, derived by alternative splicing of exons 4–6, which encode portions of the extracellular domain, are expressed in a cell type- and activation-specific manner on all nucleated cells of the hematopoietic lineage (Trowbridge and Thomas, 1994). Although the regulated expression of specific isoforms of CD45 suggests that CD45 may be regulated by extracellular ligands, definitive identification of such ligands has not yet been achieved. It is also possible that the extracellular domain of CD45 interacts laterally with other molecules present in the same plasma membrane, thereby delivering the phosphatase domains to their targets. Some evidence of this has been obtained for interaction of the low-molecular weight isoforms of CD45 with CD4 and the TCR (Leitenberg et al., 1996). Like most transmembrane PTPases, CD45 contains two tandem PTP homology domains in its cytoplasmic domain. Only the membrane proximal PTP domain clearly has catalytic phosphatase function, although the membrane distal domain may play an important regulatory function as it appears to be necessary for PTP activity of CD45 (Johnson et al., 1992; Desai et al., 1994).

CD45 expression is required for normal T cell development in mice (Kishihara et al., 1993; Byth et al., 1996). Interestingly, B cell development is not dependent on CD45, although the B cells that do develop show functional defects. In peripheral mature T and B cells as well as cell lines and clones, CD45 is required for TCR- and BCR-induced signal transduction (Chan et al., 1994a; Trowbridge and Thomas, 1994). The PTP catalytic function of CD45 is required for TCR signal transduction (Desai et al., 1994). In its absence, the earliest phosphorylation of ITAMs or recruitment of ZAP-70 does not occur (Chu et al., 1996). In CD45-deficient T cell lines, although there is not an substantial increase in basal tyrosine phosphorylation of most proteins, the negative regulatory tyrosine phosphorylation sites of Lck and Fyn are hyperphosphorylated (Ostergaard et al., 1989; Hurley et al., 1993; McFarland et al., 1993; Desai et al., 1994). Phosphorylation of this site results in an inactive state of these PTKs because of a conformational constraint imposed by an intramolecular interaction between the C-terminal phosphotyrosine and the SH2 domain of the kinase (Sicheri and Kuriyan, 1997; Young et al., 2001). The observations made in CD45-deficient cells are consistent with the notion that the phosphotyrosine in the C-terminal region is a physiologic substrate of CD45 and the Lck and Fyn kinases are inactive in CD45-deficient cells. The greatly decreased activity of Lck and Fyn can account for the defect in TCR signal transduction function. Thus, in normal resting cells where these kinases are dephosphorylated at the C-terminal-negative regulatory sites, CD45 maintains the Src kinases in a TCR-responsive but not active state. Activation of Src family kinases involves the phosphorylation of a critical tyrosine within the regulatory loop of the kinase domain in addition to the lack of phosphorylation of the negative regulatory site.

Observations of isoform-specific effects of CD45 in reconstituted T cell hybridoma systems are suggestive of specific functions for the different isoforms (Novak et al., 1994; McKenney et al., 1995). Studies with an epidermal growth factor receptor-CD45 chimera suggest that ligand-induced dimerization may negatively regulate the phosphatase function of CD45 (Desai et al., 1993). Inactivation by dimerization of CD45 appears to be mediated by a putative wedge-like structure in the juxtamembrane region that blocks the catalytic site of the partner molecule during dimerization (Majeti et al., 1998). Disruption of the wedge function in mice leads to lymphoproliferation and autoimmunity (Majeti et al., 2000). These studies strongly suggest

that dimerization of CD45 regulates its activity and thereby restrains lymphocyte activation.

The PTK responsible for the phosphorylation of the negative regulatory sites of Src PTKs is Csk, a widely expressed PTK that contains SH2 and SH3 domains (Chow and Veillette, 1995). In the basal state, Csk and CD45 are presumably in equilibrium, maintaining the C-terminal tyrosines of Src family protein kinases primarily in the unphosphorylated form. Overexpression of Csk can inhibit TCR-induced protein tyrosine phosphorylation and interleukin-2 (IL-2) production, but does not lead to the hyperphosphorylation of the negative regulatory site in the basal state (Chow et al., 1993). Regulation of Csk occurs by its differential distribution between the cytosol and lipid raft fraction of the plasma membrane during lymphocyte activation (Fig. 6.4). The lipid raft resident transmembrane adaptor protein Cbp/PAG-85 was identified as a binding partner for Csk in resting T cells. Cbp is constitutively tyrosine phosphorylated in resting T cells and binds to Csk via the SH2 domain of the latter. According to one model, upon TCR cross-linking, Cbp is dephosphorylated by an unknown tyrosine phosphatase, thereby releasing Csk, which relocalizes to the cytosol, allowing the balance to be shifted in the favor of Src family kinase activation. Later, Cbp gets rephosphorylated and recruits Csk back to the lipid microdomains where it can exert its negative regulatory effect on Lck and Fyn once again (Penninger et al., 2001). In addition, an intracellular protein tyrosine phosphatase, proline-enriched phosphatase (PEP), which is expressed in hematopoietic cells, has been found to associate with Csk via the SH3 domain of Csk. Substrate-trapping experiments using mutant PEP identified Zap-70 and FynT as two proximal targets of PEP-mediated inhibition and the site of dephosphorylation on FynT was mapped to the positive regulatory tyrosine 417. Thus, a complex of Csk-PEP acts synergistically to interfere with TCR signaling by phosphorylating the C-terminal negative regulatory tyrosine and dephosphorylating the activating tyrosine of Src family kinases (Cloutier and Veillette, 1999). In addition, two other members of the PEP family, PTP-PEST and PTP-HSCF, have been reported to cooperate with Csk in the regulation of antigen receptor signaling in T cells (Davidson and Veillette, 2001; Wang et al., 2001). Whether PEP, PTP-PEST, and PTP-HSCF all act redundantly or uniquely is currently unknown.

In Csk-deficient chicken B cells, Lyn was found to be highly phosphorylated at the autophosphorylation site and constitutively active. In addition, Syk was also constitutively activated, to an extent similar to that observed upon BCR stimulation. However, BCR cross-linking was still required for other cellular proteins to be tyrosine phosphorylated and for calcium mobilization and inositol 1,4,5-triphosphate (IP<sub>3</sub>) generation (Hata et al., 1994). Homozygous mutant mice with a disruption in the Csk gene were found to have neural tube defects, were embryonic lethal, and died during gestation at days 9–10. The embryonic cells exhibited an increase in the activity of Src, Fyn, and Lyn kinases, which suggests that Csk regulates the activity of these kinases; this may be essential during embryogenesis (Imamoto and Soriano, 1993; Nada et al., 1993). The role of Csk in lymphocyte development was studied by conditionally inactivating Csk in immature thymocytes. Lack of Csk was found to override the requirement for pre-TCR,  $\alpha\beta$  TCR, and MHC class II for the development of CD4<sup>+</sup>CD8<sup>+</sup> double-positive and CD4<sup>+</sup> single-positive thymocytes as well as peripheral CD4  $\alpha\beta$  T-lineage cells (Schmedt et al., 1998). Thus, Csk and its substrates, the Src family kinases, mediate the effect of pre-TCR and  $\alpha\beta$  TCR on the development of  $\alpha\beta$  T cells. Triple knockout mice lacking Csk,

Lck, and Fyn show a block in the development of  $\alpha\beta$  T cells, indicating that Lck and Fyn are specific substrates for Csk during T cell development. Furthermore, Csk was shown to play a differential role in positive and negative selection during development (Schmedt and Tarakhovsky, 2001).

**Signaling Pathways Activated by Antigen Receptor-Induced Tyrosine Phosphorylation**

The stimulation of the TCR and BCR induces the tyrosine phosphorylation of many intracellular proteins and sets into motion a number of signaling pathways. A list of many of the proteins that are inducibly tyrosine phosphorylated is presented in Table 6.1. In the following sections, we will focus on some of the better-understood TCR- and BCR-regulated signaling pathways and discuss the involvement of some of these proteins in lymphocyte activation.

**Role of Adaptor Proteins**

Signal transduction via the TCR and BCR flows from the membrane proximal tyrosine kinases to downstream signaling reactions such as activation of Ras, MAPKs, actin rearrangement, and calcium-dependent pathways. The transmission of these signals requires the formation of multimolecular complexes consisting of adaptor proteins and signaling components (Table 6.1). The adaptor proteins lack enzymatic or transcriptional activity but are comprised of modular domains such as the SH2, SH3, PTB, PDZ, or PH domains or simply multiple tyrosines or prolines that can act as docking sites for some of the above domains (Pawson, 1995; Pawson and Nash, 2000).

Some adaptors are membrane proteins whereas others are cytosolic in unstimulated cells and are recruited to the plasma membrane by initial receptor signaling events. In the former category are the transmembrane adaptors LAT, which is required for TCR signaling, and CD19, which is a major coreceptor in B cells. Both proteins contain multiple tyrosine residues that are phosphorylated upon receptor ligation and form docking sites for

other downstream adaptors and signaling enzymes and therefore serve to nucleate the formation of multimeric signaling complexes, or “signalosomes.” B cells likely contain an additional protein of this type as genetic ablation of CD19 decreases B cell activation but does not abolish it. In T cells, phosphorylated LAT recruits the cytosolic adaptor SLP-76 (Jackman et al., 1995) via the latter’s C-terminal SH2 domain. SLP-76 also interacts with the adaptor Gads and with the signaling component Vav, whose function is described below. A close relative of SLP-76 expressed in B cells is B cell linker protein (BLNK) (Fu et al., 1998), also known as BASH (Goitsuka et al., 1998) or SLP-65 (Wienands et al., 1998). SLP-76 and BLNK have similar domain structures and recruit many of the same signaling molecules in T and B cells. Both SLP-76 and BLNK have a single C-terminal SH2 domain, acidic, basic, and proline-rich regions, and multiple tyrosines that get phosphorylated upon stimulation. They bind PLC $\gamma$ , Nck, Vav, and Cbl (Jackman et al., 1995; Fu et al., 1998).

In cells lacking SLP76 or BLNK, proximal receptor engagement is uncoupled from distal events such as calcium flux and IL-2 activation (Clements et al., 1998; Yablonski et al., 1998; Pappu et al., 1999). Deficiency of SLP-76 or BLNK in mice leads to strong defects in T and B cell development, respectively (Clements et al., 1998; Pappu et al., 1999; Hayashi et al., 2000). However, despite the obvious parallels in the structure and function of SLP-76 and BLNK, B cells lacking BLNK could not be functionally complemented by SLP-76 alone. Reconstitution also required the addition of the adaptors LAT and Gads, which form a complex with SLP-76 (Ishiai et al., 2000). Presumably this reflects the formation of distinct but analogous complexes of adaptor proteins in B cells and T cells. The additional components of this complex in B cells are not yet defined. Recently, BLNK was shown to bind directly with the Ig $\alpha$  chain of the BCR upon B cell stimulation. The interaction was mediated by the SH2 domain of BLNK and Y204 of Ig $\alpha$ , which is located distal to and outside the ITAM (Engels et al., 2001b). Thus, it is possible that in B cells Ig $\alpha$  plays a role similar to that of LAT in TCR signaling.

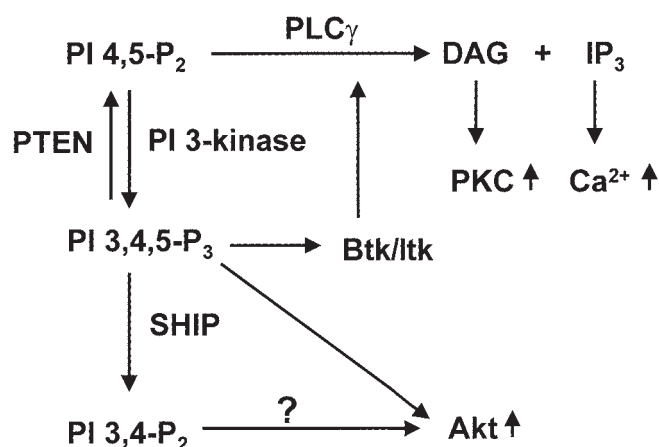

**The Phosphatidylinositol Second Messenger Pathway**

TCR or BCR stimulation results in the tyrosine phosphorylation and activation of PLC $\gamma$ 1 or PLC $\gamma$ 2 (Carter et al., 1991; Park et al., 1991; Weiss et al., 1991). PLC $\gamma$ 2 is preferentially expressed in B cells whereas PLC $\gamma$ 1 is preferentially expressed in T cells. The PLC $\gamma$  isozymes are responsible for the hydrolysis of PI 4,5-bisphosphate yielding IP $_3$  and diacylglycerol (DAG), which lead to increases in cytoplasmic free calcium ([Ca $^{2+}$ ] $_i$ ) and activation of protein kinase C (PKC) isozymes, respectively (Majerus et al., 1990) (Fig. 6.5). The critical role of PLC $\gamma$  in regulating these events in antigen receptor stimulation is supported by observations in an avian B cell line in which the PLC $\gamma$ 2 gene was inactivated (Takata et al., 1995) and PLC $\gamma$ 2 knockout mice (Hashimoto et al., 2000; Wang et al., 2000). The increase in [Ca $^{2+}$ ] $_i$  and activation of PKC have been shown to contribute to a variety of cellular responses in T and B cells.

Following TCR or BCR stimulation, PLC $\gamma$  isozymes translocate to the membrane, where they become tyrosine phosphorylated on critical tyrosine residues (Todderud et al., 1990; DeBell et al., 1999; Rodriguez et al., 2001; Veri et al., 2001). This activates their catalytic activity (Nishibe et al., 1990). This translocation involves the recruitment of PLC $\gamma$  isozymes via their SH2 domains to phosphorylated tyrosine residues on LAT in T cells and BLNK in B cells. In addition, some data suggest that the

SH2 domain of PLC $\gamma$ 1 and  $\gamma$ 2 may directly interact with tyrosine-phosphorylated Syk (Sillman and Monroe, 1995; Law et al., 1996). Moreover, the SH3 domain of PLC $\gamma$ 1 interacts with a proline-rich motif in SLP-76, which may explain the requirement of this adaptor for PLC activation (Yablonski et al., 1998, 2001). Whether the two PLC $\gamma$  isoforms are differentially regulated remains to be determined.

Stimulation of the TCR and BCR results in a rapid and sustained increase in  $[Ca^{2+}]_i$  (Gardner, 1989; Lewis and Cahalan, 1989). A requirement for this sustained increase for biological responses has often been observed (Goldsmith and Weiss, 1988). The immediate increase in  $[Ca^{2+}]_i$  is the result of the release of intracellular stores of calcium through the action of IP $_3$  on the IP $_3$  receptor (Taylor and Marshall, 1992; Kurosaki et al., 2000). This release of the intracellular stores of calcium, however, results only in a transient rise in  $[Ca^{2+}]_i$ . The sustained increase requires an inward transmembrane flux of extracellular calcium, which occurs through mechanisms and channels that remain ill defined but may be a consequence of the emptying of the intracellular stores, a mechanism referred to as *capacitative calcium entry* (Bootman and Berridge, 1995). Both soluble mediators and tyrosine phosphorylation have been implicated in this capacitative flux of extracellular calcium (Parekh et al., 1993; Bootman and Berridge, 1995; Jayaraman et al., 1996).

The increase in  $[Ca^{2+}]_i$  has effects on several downstream events, including the activation of calcium/calmodulin-dependent kinase II and calcineurin, a calcium/calmodulin-regulated protein serine/threonine phosphatase (also called PP2B). Although the activation of calcium/calmodulin-dependent kinase II has been implicated in T cell anergy (Nghlem et al., 1994), the regulation and function of calcineurin has received considerably greater attention. Calcineurin function has been implicated in T and B cell responses that depend on TCR and BCR functions in a wide variety of experimental systems. This connection was made possible through the use of the immunosuppressives cyclosporin A and FK506, which, when bound to their cellular receptors (cyclophilin and FKBP, respectively), function as specific inhibitors of calcineurin (Schreiber and Crabtree, 1992). Among the best examples illustrating the importance of calcineurin in lymphocyte responses are the studies of its role in the activation of a family of transcriptional factors, nuclear factor of activated T cells (NFAT), which plays an important role in the regulation of several lymphokine genes, including IL-2. Calcineurin catalytic function

has been shown to be required for the transformation of inactive cytoplasmic NFAT into active nuclear NFAT, where it interacts with AP-1 transcription factors (made up of Fos and Jun family members) at composite elements in the upstream IL-2 regulatory region (Flanagan et al., 1991). This requirement probably involves the dephosphorylation of the inactive cytoplasmic NFAT (Jain et al., 1993; Macian et al., 2001). In addition to its contribution to regulating transcriptional events, calcineurin has many other functions in response to antigen receptor activation, including a role in triggering the degranulation of cytolytic T cells.

The elevations of DAG following TCR or BCR stimulation of the phosphatidylinositol pathway results in the activation of PKC isoforms. There are several PKC isoforms expressed in T and B cells. Most are calcium- and phospholipid-dependent enzymes (PKC $\alpha$ ,  $\beta$ 1, and  $\beta$ 2); some are calcium-independent (PKC $\epsilon$ ,  $\delta$ ,  $\eta$ , and  $\theta$ ) (Nishizuka, 1988). These isoforms can also be activated by phorbol esters as well as DAG. The functions of the individual isoforms are not clear. Approaches using activated forms of  $\alpha$ ,  $\beta$ ,  $\epsilon$ , and  $\theta$  have suggested that all four isoforms may be able to regulate various transcription factors in T cells (i.e., AP-1 and NF- $\kappa$ B), but there may be some level of isozyme specificity on these factors (Genot et al., 1995). Inactivation of PKC $\theta$  results in defects of TCR-mediated activation of NF- $\kappa$ B (Sun et al., 2000). In contrast, inactivation of PKC $\beta$  has effects on B cell development that are reminiscent of Btk deficiency (Leitges et al., 1996). PKC activation has also been implicated in many other events, including CD4 and TCR down-regulation, Ras activation, and cytolytic granule exocytosis. These pleiomorphic effects suggest that PKC isoforms may be involved in many separate downstream events.

A remarkable synergy is observed in inducing T cell or B cell activation by the combined actions of calcium ionophores (to elevate  $[Ca^{2+}]_i$ ) and phorbol esters (to activate PKC isoforms). This suggests that the pathways downstream of these events intersect at critical nodal points. These critical events are not established. However, there are candidates that would be responsive to both events, including calcium-dependent isoforms of PKC, an upstream regulator of the c-Jun N-terminal kinase (Su et al., 1994), or NFAT. The identification of molecules whose function depends on both of these events is likely to lead to critical new insights into the processes governing lymphocyte activation.

### Ras Activation in T and B Cells

Ras proteins have been implicated in a wide variety of growth and differentiation responses (McCormick, 1993; Bar-Sagi and Hall, 2000). The activation of Ras proteins following antigen receptor stimulation has been shown to be a critical event in lymphocyte development and activation. The Ras proteins are a small family of 21 kDa GTP-binding proteins with GTPase activity. The activation state of Ras is determined by the form of guanine nucleotide bound to it: GTP-bound Ras is active and GDP-bound Ras is inactive. GDP-bound Ras becomes activated by interacting with guanine nucleotide exchange proteins (GEFs) which cause it to release GDP, allowing it to bind GTP. Conversely, GTP-bound Ras is inactivated by hydrolyzing the GTP to form GDP and PO $_4$ , a reaction stimulated by GTPase activating proteins (GAPs). Thus, the activation of Ras could be a consequence of GEF stimulation, GAP inhibition, or a combination of both. The activation of Ras can lead to a variety of downstream events, including (1) the activation of the Erk MAPK pathway; (2) the activation of PI3K; and, (3) the activation of

other small molecular-weight, GTP-binding proteins such as Rac and CDC42 (McCormick and Wittinghofer, 1996).

Initial studies of growth factor receptor PTKs in *Drosophila*, *C. elegans*, and mammalian fibroblasts identified an adaptor molecule called Drk, Sem 5, or Grb2, respectively, in the different species, that interacts with both the stimulated receptors and with a guanine nucleotide exchange factor called SOS (son of sevenless) (Schlessinger, 1993). Subsequently, in some systems another adaptor, called Shc, was found to function in linking Grb/SOS to the activated receptor PTKs. Genetic and biochemical studies indicate that Grb2/SOS proteins couple the stimulated PTK receptors to the activation of Ras. Currently it is thought that SOS action on Ras is primarily regulated by intracellular localization: receptor signaling induces a translocation of Grb2/SOS from the cytosol to the plasma membrane by virtue of the binding of Grb2 to tyrosine phosphorylated sites on the receptor itself or on adaptor proteins such as Shc (Aronheim et al., 1994). Shc phosphorylation and interaction with Grb2/SOS has been observed after TCR or BCR stimulation (Ravichandran et al., 1993; Saxton et al., 1994; Crowley et al., 1996), although its importance for activation of Ras in these cells is unclear.

The mechanisms by which antigen receptors activate Ras are not yet well established. Stimulation of the TCR and BCR induces activation of Ras (Downward et al., 1992) and the Erk MAPK. In lymphocytes, phorbol esters induce strong activation of Ras. This has generally been interpreted to reflect a role for PKC in the activation of Ras, but other interpretations are possible (see below). Initial studies of the mechanism by which phorbol esters activate Ras implicated a PKC-dependent inhibitory effect on GAP (Downward et al., 1990), but this has not been confirmed. GAP is tyrosine phosphorylated following BCR stimulation and to a lesser extent following TCR stimulation (Gold et al., 1993). In B cells, it is recruited to the membrane via the negative coreceptor Fc $\gamma$ RIIB, SHIP, and the adaptor protein p62<sup>dok</sup>, so it appears to function to limit Ras activation at least in this context.

Regulation of GEF function is probably more directly responsible for the positive activation of Ras by the TCR and BCR (Ravichandran et al., 1993). In some T cells, Grb2/SOS associate with the TCR-induced phosphorylated LAT, which would serve to translocate these complexes to the membrane and presumably stimulate Ras activation (Wange, 2000). Alternately, Ras activation may be a consequence of PLC $\gamma$ 1 activation. In this regard, the GEF RasGRP was recently identified in T cells (Dower et al., 2000; Ebinu et al., 2000). This protein has calcium-binding EF hands and, more importantly, a DAG-binding domain. Thus, the activity of PLC $\gamma$ 1 may be directly translated into Ras activation through the recruitment of RasGRP. The EF hands may also bind phorbol esters, thereby explaining the ability of PMA to activate Ras (Izquierdo et al., 1992).

Some studies have implicated c-Cbl, an antigen receptor-inducible phosphoprotein, as a negative regulator of the interaction of Grb2 with SOS (Donovan et al., 1994; Yoon et al., 1995). Cbl also interacts with BLNK, a critical adaptor molecule required for the activation of PLC $\gamma$ 2, and exerts a negative regulatory effect on BCR signaling, possibly by inhibiting the binding of BLNK to PLC $\gamma$ 2. Accordingly, it was shown that BCR-mediated PLC $\gamma$ 2 activation is enhanced in DT40 cells deficient in Cbl (Yasuda et al., 2000). Clearly, these interactions are complex and much more needs to be learned about them.

Ras plays a critical role in lymphocyte activation. Dominant negative mutants of Ras can partially block IL-2 gene activation in T cells and completely block NFAT-based transcription (Cantrell,

1996). This is probably explained by the involvement of Ras in regulating the AP-1 components involved. An activated form of Ras, which cannot hydrolyze GTP, can synergize with calcium ionophores to induce NFAT-directed transcription. Similarly, BCR-induced transcription of the *egr-1* early response gene is mediated by Ras (McMahon and Monroe, 1995). *Egr-1* appears to be important for BCR-induced up-regulation of ICAM-1 and CD44 expression (McMahon and Monroe, 1996). Ras also plays an important role in T cell development. For example, expression of activated Ras as a transgene can promote early T cell developmental transitions in recombina-activating gene (RAG)-deficient mice, which cannot express the pre-TCR (Swat et al., 1996). Similarly, blockade of the Ras pathway with inactivating mutants can interrupt normal thymic development (Alberola-Ila et al., 1995; Crompton et al., 1996). Thus, a variety of observations position the activation of Ras as a critical event in antigen receptor signal transduction pathways.

As listed above, there are several reported downstream effectors of Ras. The effectors responsible for Ras function in different systems are not fully established and no single effector can usually substitute for the activated form of Ras in experimental models. The best-characterized Ras effector is the Raf-1 kinase. GTP-bound Ras interacts directly with the serine/threonine kinase Raf-1, translocating it to the membrane (Moodie et al., 1993; Van Aelst et al., 1993; Vojtek et al., 1993). The translocation of Raf-1 to the membrane can increase its activity, although other mechanisms have been implicated in Raf activation, including its tyrosine phosphorylation and transphosphorylation by dimerization (Marshall, 1996). The translocation to the membrane by Ras may simply concentrate Raf-1 there and allow it to dimerize and transphosphorylate. In any case, Raf-1 is activated in T and B cells in response to TCR and BCR stimulation or phorbol ester stimulation, corresponding to signals activating Ras (Cantrell, 1996). The activation of Raf-1 leads to its direct interaction and activation of a dual specific tyrosine/serine/threonine kinase, MEK-1, that in turn activates the Erk1/Erk2 MAP kinases.

MAP kinases have numerous functions including the phosphorylation and activation of transcription factors such as serum response factor, which can regulate c-fos and *Egr-1* transcription. Thus, this antigen receptor-regulated cascade of events ending in MAP kinase activation can function to regulate transcriptional events leading to lymphocyte differentiation and activation. Specific inhibition of the Erk MAPK by using pharmacologic inhibitors of MEK1 and MEK2 blocked BCR-induced proliferation of mature B cells, but did not block apoptotic responses of immature B cells and an immature B cell line, indicating that Erk MAPK mediate some effects of BCR signaling but not others (Richards et al., 2001). Similarly, changes in activation of the three MAPK families, Erk, Jnk, and p38, were found to perturb development. Thus, genetically reduced expression of the adaptor protein Grb2 results in weaker Jnk and p38 activation but does not affect Erk, which, in turn, selectively decreases the ability of thymocytes to undergo negative but not positive selection (Gong et al., 2001a).

### Vav Phosphorylation and Function in T and B Cells

Among the many TCR- and BCR-induced tyrosine phosphoproteins is the protooncogene *Vav* (Bustelo and Barbacid, 1992; Margolis et al., 1992). *Vav* is expressed exclusively in hematopoietic cells and trophoblasts, although two closely related family

**Table 6.2.** T and B Cell Defects in Vav-Deficient Mice

Event	Deficiency In:		
	Vav-1	Vav-2	Vav-1 and Vav-2

T-independent type 2 antibody response	Normal or ↓	↓	↓↓
T-dependent antibody response	↓	↓	ND

Results are based on data presented in (Turner, 1997; Fisher et al., 1998; Doody et al., 2001; Tedford et al., 2001). Entries with "or" reflect somewhat different results obtained in two different studies. ↓↓, more severe defect; ↓, moderate defect, especially upon suboptimal stimulation of TCR or BCR; ND, not determined.

members (Vav-2 and Vav-3) are now known and are expressed more widely. The original cellular Vav is now called Vav-1. It contains multiple distinct domains including a leucine-rich domain, a domain related to GEF domains of Rho-family GTPases, a pleckstrin homology (PH) domain, a zinc finger domain, two SH3 domains, and an SH2 domain. Deletion of the N-terminal 65 residues of Vav leads to a protein with transforming ability in NIH 3T3 fibroblasts (Katzav et al., 1991). Genetic experiments demonstrate that Vav plays an important role in antigen responses of T cells and B cells, but how it does so is not clear (DeFranco, 2001).

The importance of Vav in T cell signaling is underscored by the phenotype of Vav-1<sup>-/-</sup> mice, which are severely compromised in T cell function (Fischer et al., 1995; Tarakhovsky et al., 1995). These mice show defects in thymic cellularity, thymocyte positive and negative selection, peripheral T cell numbers, and peripheral T cell responses. While the deficiency of Vav-1 does not have any serious defects in the B cell compartment other than loss of the B-1 subtype of B cells, recent evidence from genetic knockouts of the Vav-2 gene alone or both Vav-1 and -2 together shows that Vav-1 and Vav-2 have both unique and redundant roles in BCR-mediated signaling (Doody et al., 2001; Tedford et al., 2001). The development of T and B cells in Vav-2-deficient mice is largely unaffected; however, these mice show a decrease in antibody responses to T-independent type 2 antigens and also a partial defect in T-dependent IgG production. Suboptimal stimulation of the BCR revealed defects in BCR responses such as calcium flux and proliferation in these mice. Vav-1 and Vav-2 double knockout mice, by contrast, had impaired B cell development and greatly diminished BCR responses, similar to the drastic effects of the Vav-1 knockout on T cells (Table 6.2).

Vav-1 appears to be a direct substrate for the ZAP-70, and possibly Syk, PTKs. Its SH2 domain has a consensus binding specificity for the sequence adjacent to Y315 (YESP) in ZAP-70 (Songyang et al., 1994). A homologous sequence is present in Syk. The binding of the SH2 domain of Vav-1 and Vav-1 tyrosine phosphorylation depends on this site in ZAP-70 (Wu et al., 1997). Moreover, the functional activity of ZAP-70 is markedly reduced by mutation of this site in a reconstitution system where NFAT activity is assessed. These results suggest that the interaction of ZAP-70 with Vav is an important event in antigen receptor signal transduction.

The function of Vav in TCR or BCR signaling pathways is not completely understood. On the basis of sequence homology and overexpression experiments in fibroblasts, it is likely that Vav regulates Rho, Rac, or Cdc 42 GTP-binding proteins (Adams et al., 1992; Bustelo et al., 1994). In one model system, overexpression of Vav in Jurkat T cells led to potentiation of TCR-mediated IL-2- and NFAT-regulated reporter constructs (Wu et al., 1995). This functional activity, which depends on TCR-specific signals, is also dependent on Ras, Lck, and calcineurin function. This suggests that Vav may function very proximally within the TCR pathway or in an alternate signaling pathway which, together with Ras and calcineurin regulated pathways, contributes to IL-2 gene expression. This is most likely to involve increased Rac and Cdc42 activity as evidenced by studies of Vav-deficient cells. The most prominent signaling defect in these cells is a failure of actin polymerization and antigen receptor clustering or cap formation (Fischer et al., 1998; Holsinger et al., 1998). As a consequence, there is inefficient immunological synapse formation (Wulfig et al., 2000). These effects suggest that the regulation of Rac and Cdc42 by Vav GEF function is a critical event in TCR signal transduction.

Surprisingly, biochemical defects in TCR signaling in Vav-1-deficient T cells include defects in phospholipase C tyrosine phosphorylation and Ca<sup>2+</sup> mobilization (Fischer et al., 1995). This global effect of Vav deficiency suggests that Vav may have roles in T cell activation beyond Rac or Cdc42 activation. In this regard, it should be noted that Vav interacts with the TCR- and BCR-induced adaptors, SLP-76 (Jackman et al., 1995; Wu et al., 1996), and BLNK (Fu et al., 1998). The Vav SH2 domain is required for these interactions. As has been seen with Vav, overexpression of SLP-76 markedly potentiates TCR-mediated IL-2 promoter and NFAT-driven gene expression (Motto et al., 1996). Furthermore, overexpression of both Vav and SLP-76 synergistically induced basal and TCR-stimulated NFAT activity (Wu et al., 1996). These results suggest that a signaling complex containing Vav and SLP-76 plays an important but as yet undefined role in T lymphocyte activation. At least part of this function may be GEF-independent and may relate to an adaptor function of Vav (Kuhne et al., 2000).

### Other Signaling Events

It is not our intention to be exhaustive in reviewing signaling events that occur following TCR and BCR stimulation, but two other events deserve brief mention. A prominent substrate of antigen receptor-induced tyrosine phosphorylation is the protein HS-1 (Kitamura et al., 1995). The function of HS-1 is not established, but lymphocyte antigen responses in mice deficient in HS-1 are partially defective (Taniuchi et al., 1995), demonstrating the importance of HS-1. Finally, antigen receptors also activate PI3K (Gold et al., 1992; Ward et al., 1992). The p85 subunit of PI3K is recruited to the membrane by binding of its SH2 domains to the consensus YXXM motif in the cytoplasmic tail of CD19 (Chalupny et al., 1995). Alternatively, it was shown that BCAP, an adaptor protein that is tyrosine phosphorylated by Syk and Btk, could recruit the p85 subunit of PI3K. DT40 B cells deficient in BCAP were unable to generate PIP<sub>3</sub> in response to BCR ligation and exhibited an impaired Akt response (Okada et al., 2000).

The main reaction catalyzed by PI3K is phosphorylation of PI 4,5-bisphosphate to generate PI 3,4,5-trisphosphate (see Fig. 6.5). This compound is a membrane-bound second messenger that recruits signaling molecules to the plasma membrane via their PH

domains. Key signaling molecules attracted to the plasma membrane by  $\text{PIP}_3$  are the Tec family of tyrosine kinases, Btk and Itk. These kinases have a PH domain followed by a Tec homology (TH), an SH3, an SH2, and a kinase domain (Smith et al. 2001). These molecules play an important role in phosphorylation and activation of  $\text{PLC}\gamma$ . Mutations in Btk are responsible for the pathogenesis of the heritable immunodeficiency disorder X-linked agammaglobulinemia (XLA) in humans and X-linked immunodeficiency (Xid) in mice (Chapter 21; for review see Conley et al., 2000; also Conley et al., 1994; Lindvall et al., 2005). The disease is characterized by a severe block in the transition of B cell progenitors into mature B lymphocytes, resulting in a complete absence of B and plasma cells and undetectable immunoglobulins (Vihinen et al., 2000). A similar phenotype was observed in mice lacking the  $\text{p85}\alpha$  subunit, and its splice variants  $\text{p55}\alpha$  and  $\text{p50}\alpha$ . These mice had reduced peripheral mature B cell numbers and serum immunoglobulin corresponding to the somewhat less severe phenotype seen in mice with Btk deficiency (Fruman et al., 1999). Interestingly,  $\text{PIP}_3$  is the substrate for SHIP, described above as one of the proteins that binds to  $\text{Fc}\gamma\text{RIIB}$  when it is co-engaged with the BCR. The product of the combined action of PI3K and SHIP is PI 3,4-bisphosphate. SHIP is tyrosine phosphorylated in BCR-stimulated B cells, but this is enhanced by co-engagement with  $\text{Fc}\gamma\text{RIIB}$  (Chacko et al., 1996). The relative amount of PI 3,4-bisphosphate may be controlled by  $\text{Fc}\gamma\text{RIIB}$  and possibly by other receptors on the B cell surface. Future studies may clarify the biological significance of these reactions.

In addition to SHIP, which removes the 5' phosphate from  $\text{PIP}_3$  there is a second phosphatase that acts on  $\text{PIP}_3$ , PTEN, which removes the 3' phosphate (Fig. 6.5). PTEN is a prominent tumor suppressor and is frequently mutated in tumor cells (Mae-hama and Dixon, 1999). Interestingly, the Jurkat T cell line has a defective PTEN (Shan et al., 2000).

CD28 plays a critical costimulatory function in T cells by binding CD80 and CD86 (B7-1 and B7-2) on antigen-presenting cells. CD28 costimulation can lead to increased lymphokine production, enhanced proliferation, and diminished apoptosis in TCR-mediated responses (Salomon and Bluestone, 2001). CD28 has a consensus PI3K SH2 domain binding site and this site is phosphorylated following CD28 stimulation. The importance of CD28-mediated PI3K activation is at best controversial. Experiments in Jurkat cells often find a functional role of CD28 that is independent of the PI3K docking site. As mentioned above, Jurkat cells lack the  $\text{PIP}_3$  phosphatase PTEN, so they may understate the importance of  $\text{PIP}_3$  for CD28 function and emphasize the other signaling functions of CD28. In any case, at least one downstream effector of this pathway, the Akt serine/threonine kinase, can partially substitute for CD28 signals in T cell lines and in CD28-deficient T cells (Kane et al., 2001). Akt has a PH

domain that binds  $\text{PIP}_3$ , which allows Akt to be recruited to the membrane in response to  $\text{PIP}_3$  elevations—i.e., following CD28 stimulation. Once at the membrane, Akt is activated by a second kinase, PDK-1. The consequences of Akt activation are numerous and include antiapoptotic effects via Bad phosphorylation as well as transcriptional effects that may be mediated by Forkhead and NF- $\kappa\text{B}$ . Activation of Akt by CD28 has thus been linked to NF- $\kappa\text{B}$  pathways that regulate IL-2 and IFN- $\gamma$  pathways. Akt is also activated in B cells following BCR ligation in a PI3K-dependent manner. This activity is inhibited upon BCR coligation with  $\text{Fc}\gamma\text{RIIB}1$ , a finding suggesting a functional role for SHIP-1 in this regulation and also explaining the increased apoptosis of B cells in these conditions (Aman et al., 1998; Gupta et al., 1999).

### Compartmentalization of T and B Antigen Receptor Signaling

Signaling via the antigen receptors and recruitment of various signaling molecules into a “signalosome” is increasingly being viewed in the cell biological context. The spatial arrangement of various participants is seen as one of the key determinants in the regulation and outcome of signaling.

#### Formation of the Immunological Synapse

Efficient T cell activation requires sustained interaction between the TCR and MHCpeptide complex. Recent imaging studies of regions of contact between T cells and antigen-presenting cells have described the following sequence of events occurring at the plasma membrane: T cell polarization, initial adhesion, immunological synapse (IS) formation (early signaling), and IS maturation (sustained signaling). This involves the formation of a bull's-eye arrangement of molecules at the point of cell–cell contact with the TCR and MHCpeptide complexes clustering in the center (central supramolecular activation clusters, c-SMACs) and the adhesion molecules, LFA-1 and ICAM-1, forming a ring around the periphery (p-SMACs) (Fig. 6.6) (Bromley et al., 2001). Consistent with its role as a positive regulator of Src family kinase activation, CD45, which was initially thought to be excluded from the IS because of topological constraints, was recently shown to localize with the TCR in the c-SMAC. In addition, within the c-SMAC, CD45 was found to occupy a distinct sub-domain separate from the TCR (Johnson et al., 2000). Recently, an IS similar to the one described above was reported to form between B cells and follicular dendritic cells (FDCs) (Batista et al., 2001). It was shown that the BCR could acquire intact antigen from the FDCs through the synapse and, after processing it, present the antigenic peptides to T cells expressing the specific TCR, thus resembling an “immunological relay race.”

**Figure 6.7.** A schematic view of the organization of phospholipids and modified proteins in lipid rafts. GPI, glycosyl-phosphatidylinositol.

### A Role for Plasma Membrane Microdomains in Signal Transduction

Another feature of the molecular reorganization that occurs upon antigen receptor ligation is the translocation of the TCR and BCR to membrane microdomains known as “lipid rafts” (Fig. 6.7). These are subdomains of the plasma membrane rich in cholesterol, sphingomyelin, and glycosphingolipids, that are resistant to extraction by nonionic detergents and can be biochemically purified on sucrose density gradients. Lipid rafts are home to glycosyl-phosphatidylinositol (GPI)-anchored proteins, members of the Src kinase family, heterotrimeric G proteins, and Ras family small G proteins, and contain bound actin (Harder and Simons, 1997; Brown and London, 1998). Several key participants of the antigen receptor signaling pathways are enriched in lipid rafts, including the coreceptors CD4 and CD8, the Src family kinases, Lck, Lyn, Fyn, the C-terminal Src-like kinase Csk, Cbp/PAG, and LAT (Cherukuri et al., 2001a). Cross-linking of the TCR and BCR induces association of these receptors with lipid rafts and also aggregation of lipid rafts into large patches on the cell surface, which may serve to hold multimolecular signaling complexes in close proximity for efficient signal transduction (Figs. 6.4 and 6.8) (Hoessli et al., 2000). In B cells, the raft components were demonstrated to internalize along with the receptor into the antigen-processing compartment (Cheng et al., 1999). Functional evidence for the significance of lipid rafts in antigen receptor signaling comes from experiments in which rafts were disrupted. Treatment of B or T cells with a variety of agents that disrupt rafts, such as methyl  $\beta$ -cyclodextrin, filipin, nystatin, or

polyunsaturated fatty acids, leads to loss of activation-induced calcium flux in both T and B cells. This finding suggests that the assembly of signaling molecules on lipid raft platforms is crucial for the outcome of activation (Aman et al., 2001; Awasthi-Kalia et al., 2001). In addition, the palmitoylation of LAT that directs its localization to lipid rafts is necessary for it to become efficiently tyrosine phosphorylated upon TCR engagement (Lin et al., 1999). Moreover, the presence of LAT in lipid rafts is absolutely required for coupling TCR engagement to activation of the Ras signaling pathway, increases in intracellular  $\text{Ca}^{2+}$ , and induction of the transcription factor NFAT (Finco et al., 1998; Zhang et al., 1998).

Interestingly, the developmental stage of B and T cells influences the ability of the BCR or TCR to enter lipid rafts and the outcome of signaling through the receptor. A fraction of the pre-BCR was found to be constitutively associated with lipid rafts, which may reflect constitutive signaling that promotes the developmental transition to the pre-B cell stage. Upon receptor cross-linking, additional pre-BCR molecules translocated to lipid rafts, where they were found to assemble a signaling complex consisting of tyrosine phosphorylated Lyn, Syk, Btk, PI3K, BLNK, Vav, and  $\text{PLC}\gamma 2$ , all of which have been identified genetically as important for the cell to make the decision to progress to the next stage in its development (Guo et al., 2000). On the other hand, the BCR does not redistribute to lipid rafts upon receptor engagement in immature B cells, and this may contribute to the difference between the outcome of signaling in immature (deletion or anergy) and mature (activation) B cells (Sproul et al., 2000; Chung et al., 2001). Similarly, while the pre-TCR constitutively associates with lipid rafts, where it signals in a ligand-independent manner, the TCR in  $\text{CD4}^+\text{CD8}^+$  immature thymocytes does not translocate to these domains upon ligation (Ebert et al., 2000).

Differences in BCR translocation to lipid rafts also correlate with the functional state of mature B cells. In this regard, tolerant B cells from double transgenic mice expressing both anti-hen egg lysozyme (HEL) Ig and soluble HEL failed to translocate their BCRs into a detergent-insoluble fraction compared to B cells from wild-type mice (Weintraub et al., 2000). Whether this reflects a defect in translocation to lipid rafts or a defect in attachment to the actin cytoskeleton is unclear. In addition, cross-linked BCR fails to enter lipid raft fractions in EBV-infected human B cells because of expression of the latent membrane protein LMP2A (Dykstra et al., 2001). These cells exhibit greatly

**Figure 6.8.** Proximal signaling events that occur in B cell lipid rafts upon antigen receptor ligation. Note that relative dimensions of BCR and lipid rafts are not to scale; however, antigen stimulation induces movement of the BCR into lipid rafts and congregation of the lipid rafts into larger structures.

diminished BCR signaling, although other mechanisms likely contribute to this functional effect. LMP2A causes degradation of Lyn and Syk via a E3 ubiquitin ligase mechanism. In contrast, CD19/CD21 coreceptors reduce the threshold for B cell activation, and this correlates with their ability to enhance the retention of the BCR in lipid rafts, thus retarding its internalization and degradation (Cherukuri et al., 2001a, b).

Lipid rafts may also form a link between the antigen receptors and the actin cytoskeleton. Cross-linking induces association of TCR $\zeta$  to the cytoskeleton and this association is dependent on lipid raft integrity (Xavier et al., 1998). Actin-rich rings were found to organize around the contact area upon TCR ligation with coverslips coated with anti-TCR antibodies. Sustained contact required the presence of the lipid raft localized adaptor LAT (Bunnell et al., 2001). TCR-dependent actin remodeling is impaired by the inhibition of the binding between the Ena/VASP family of proteins and the fyb/SLAP adaptor protein. This result suggests that these proteins provide a crucial link between TCR signaling and the actin cytoskeleton (Krause et al., 2000). The motor forces that drive actin cytoskeletal rearrangement and lipid raft aggregation still remain largely unidentified.

## Conclusions

Although T and B cells use distinct receptors to recognize completely different forms of antigens, the signal transduction machinery regulated by their antigen receptors functions remarkably similarly. This signaling machinery includes lymphocyte-specific components that interact with signaling components more ubiquitously expressed and used in a wide variety of systems. Lymphocyte function may be impaired by interruption of any of the critical components in these signaling cascades. However, discrete immune deficiency states are likely to affect the critical known and unknown components that are lymphoid-specific.

# Lymphoid Organ Development, Cell Trafficking, and Lymphocyte Responses

SIRPA JALKANEN and MARKO SALMI

A productive interaction between a lymphocyte and its cognate antigen is required to trigger an adequate immune response. Thus, it is not only the defects in the production and maturation of lymphocytes or in the activation machinery that can result in immunodeficiencies, but the same outcome can be seen if otherwise normal cells do not migrate properly within the body in search of foreign antigens. The best-known examples of this class of diseases are leukocyte adhesion deficiencies 1 and 2 (LAD1 and 2, see Chapter 38). The impact of proper lymphocyte recirculation between blood and different tissues and within the tissue stroma for eliciting an immune response already becomes evident by looking at the physical dimensions of our immune system.

Humans have approximately  $10^{12}$  lymphocytes, each of which normally expresses receptors for only one antigen. Thus, for most antigens only some 100–1000 specific lymphocytes reside anywhere in the body. Moreover, at any moment only about 1% of these lymphocytes are in blood circulation whereas the rest are in tissues. The freely mobile cells in the blood travel at high velocity for their size. Even in small-caliber venules, where the extravasation takes place, an 8  $\mu\text{m}$ -diameter cell moves about 500  $\mu\text{m}/\text{sec}$  in the blood flow. Moreover, the total length of the circulatory tree has been estimated to exceed 100,000 km in an adult. These constraints make it very challenging for a specific cell to leave the blood at a desired site. At the same time, enormously large body surfaces are exposed to antigen invasion. The total area of the principal entry ports for antigens is about 2  $\text{m}^2$  in the skin, 400  $\text{m}^2$  in the gut, and 100  $\text{m}^2$  in the respiratory system. The antigens can be minute particles such as viruses or short foreign peptides. Thus it is clear that a highly efficient, adaptive immune response cannot rely on chance for random contact between the antigen and a specific lymphocyte anywhere in the body.

An elaborate system of lymphocyte recirculation has evolved to address these challenges (Carlos and Harlan, 1994; Springer,

1994; Butcher and Picker, 1996; Salmi and Jalkanen, 1997). Different functions of the immune system are compartmentalized to specific organs and tissues, and these units are then interconnected by lymphocyte trafficking via trees of vascular and lymphatic vessels (Fig. 7.1). Thus, primary lymphoid organs are specialized for production of huge numbers of lymphocytes. The specificity of a lymphocyte is also determined in these organs. The mature but antigenically inexperienced cells are then released into the circulation. These naive cells extravasate from the blood into secondary lymphoid organs (such as peripheral lymph nodes, Peyer's patches of gut). Simultaneously, antigens are concentrated into these very same organs from large epithelial surfaces (via an afferent lymphatic system to peripheral lymph nodes and via M cells into Peyer's patches). The secondary lymphoid organs are thus designed to collect and concentrate lymphocytes on the one hand and antigens on the other and to provide an optimal microenvironment for launching a productive immune response. Finally, the effector lymphocytes leave the secondary lymphoid organs, equipped with a capacity to migrate to the peripheral sites of inflammation. All the rest of the organs and tissues in the body can be regarded as tertiary immune tissues, which harbor significant numbers of lymphocytes only during an active immune response.

## Lymphocyte Migration to Primary Lymphatic Organs

Lymphocyte trafficking first takes place during early ontogeny, when lymphoid precursor cells populate the lymphocyte-forming organs (Weissman, 2000). Initially, precursor cells from the yolk sac and/or aorta–gonad–mesonephros area migrate to fetal liver. Later, bone marrow becomes the main target for these precursor cells. After this stage the fate of B and T lymphocytes differs.

**Figure 7.1.** Lymphocytes recirculate between the blood and lymphoid organs. Most lymphocytes enter the peripheral lymph nodes or organized lymphoid tissues of the gut (Peyer's patches [PP] and appendix) via high endothelial venules. A low-level, continuous migration of lymphocytes from vascular beds such as skin to lymph nodes takes place via afferent lymphatics. The incoming lymphocytes migrate through the tissue parenchyma, enter the lymphatics, and are then carried within the efferent lymphatics back to the systemic blood circulation. Most of the venous circulation has been omitted for clarity. (Reproduced with permission from Salmi and Jalkanen, 1997).

B lymphocytes undergo their entire development in the cavity of bone marrow in contact with stromal cells. T cell precursors, by contrast, move further on to the thymus. They enter the thymus through cortical vessels and gradually migrate toward the medulla during the maturation processes. Finally, immunocompetent but naive B and T lymphocytes join the circulating pool of lymphocytes in the blood. Although these early migratory events are crucial for the development of the immune system, most of the molecular determinants involved in the trafficking remain to be elucidated.

Development of the lymphoid organs and their population of lymphocytes is regulated in a highly time-dependent manner (Bailey and Weiss, 1975; Bofill et al., 1985; Spencer et al., 1986; Campana et al., 1989). In humans, first CD3-positive thymocytes are found by week 10 of gestation. Anlage of secondary lymphoid organs have already started to develop earlier. Peripheral lymph nodes developing from a lymphatic plexus become recognizable around week 10, but development of high endothelial venule (HEV)-like vessels (the specialized vessels for lymphocyte recruitment, see below) and accumulation of early lymphocytes in these nodes can be seen only in 15- to 18-week old fetuses. In gut, mucosal villi appear around weeks 9–10 of gestation. By week 14, clusters of lymphocytes can be detected in the lamina propria and by 19 weeks well-organized Peyer's patches appear. The 12-week-old fetal spleen contains few lymphocytes, but at 14 weeks T and B cells are scattered throughout the organ. The early seeding of lymphocytes takes place in the absence of any external antigenic stimulation.

It is intriguing that the endothelial adhesion molecules, which govern lymphocyte trafficking in the adult, are expressed in a functional form very early during human development but in a remarkably different manner in terms of tissue specificity (Salmi et al., 2001). The gut addressin MADCAM-1 (see below) is widely expressed in fetuses already at week 7. In fetuses, it is not only crucial for lymphocyte adhesion to vessels in gut, but it is also

the most important determinant for lymphocyte binding to HEV in peripheral lymph nodes. Although the adult peripheral node addressin, PNA<sub>d</sub> (see below), is expressed in humans at week 15, it only gradually starts to dominate in mediating lymphocyte trafficking to peripheral lymph nodes during early childhood. On the basis of these findings it is likely that efficient lymphocyte recirculation takes place already in utero.

### Trafficking of Lymphocytes to Secondary Lymphoid Organs

Peripheral lymph nodes, Peyer's patches, and spleen are the prime target organs for naive lymphocytes. In lymph nodes, a specialized vessel type called *high endothelial venule* (HEV), based on the characteristic cuboidal morphology of endothelial cells, allows efficient recruitment of blood-borne lymphocytes (Bjerknes et al., 1986; Kraal and Mebius, 1997). In these postcapillary venules, the shear stress is relatively low, and the endothelial surfaces protruding into the lumen of the vessels are rich in specific molecules needed for efficient adhesion. Moreover, the junctions between endothelial cells in these vessels are not typical tight junctions, rather, a flap-valve-like mechanism is operative at this site, which also facilitates cellular transmigration. Consequently, when the lymphocytes flow into HEV they undergo the different steps of the classical extravasation cascade very efficiently. It has been estimated that up to 50% of incoming lymphocytes make contacts with HEV lining in Peyer's patches and that even one cell in four can ultimately extravasate in these specialized organs (Bjerknes et al., 1986). On the basis of calculations in sheep, up to 15,000 lymphocytes can be expected to be transmigrating through HEV in a single lymph node every second (Girard and Springer, 1995).

Antigens are concentrated to lymph nodes through the other vessel system draining into these organs (Cella et al., 1997; Banchereau and Steinman, 1998). Free antigens or antigens taken

up by dendritic cells enter lymph nodes from the periphery via afferent lymphatic vessels. These vessels empty into the subcapsular sinuses, from which cells and antigens can penetrate into the lymphoid areas while flowing through the fine lymphatic channels within the tissue. The dual vessel supply bringing in lymphocytes by blood and antigens by lymph maximizes the likelihood for lymphocyte–antigen contacts in lymph nodes.

When lymphocytes enter the lymphoid tissue they are further guided by chemotactic gradients into specific intraorgan locations. Most notably, different chemokines secreted by many cell types help to segregate lymphocytes into discrete T and B cell areas within the lymph node (Cyster, 1999; 2005). Thus B cells preferentially accumulate into cortical B cell follicles, whereas T cells are recruited into more diffuse subcortical T cell areas. While percolating through the tissue stroma the lymphocytes constantly search for their cognate antigens presented by different types of professional antigen-presenting cells also concentrated in lymph nodes. If they fail to find a specific antigen in the lymph node, they enter the lymphatic sinuses and leave the organ via efferent lymphatic vessels. These cells are then carried back to the blood system, since the main lymphatic trunks (such as ductus thoracicus) open into the major veins near the heart. Then these cells are free to move on in the circulation and to enter any other lymphoid tissue in the body during their continuous recirculation (Gowans and Knight, 1964). One cycle from the blood back to the blood takes about 1 day, hence any single lymphocyte has time to percolate through hundreds of lymph nodes until it dies. This patrolling behavior of a lymphocyte is only interrupted and retargeted if it encounters its specific antigen within a lymphoid tissue (see below).

Lymphocyte recirculation through the spleen is profoundly different from that in the lymph nodes (Pabst, 1988). Notably, HEV are absent from the spleen and lymphocytes enter the white pulp via marginal zone sinuses, where macrophage-like cells surrounding the endothelial cells may be important for recruitment. In the splenic parenchyma, lymphocytes again migrate toward specific guidance molecules. However, here T cells migrate into confined T cell areas around the central arteriole, whereas B cells remain scattered in the corona. Splenic lymphocytes also seem to leave the organ via the splenic vein rather than via lymphatics. Although the spleen contains more lymphocytes than all the lymph nodes together, the migratory pathways in this organ specialized for concentrating blood-derived antigens remain rather poorly characterized.

### **Tissue-Selective Homing of Activated Lymphocytes**

When a lymphocyte meets its cognate antigen in lymph nodes, its migratory properties change profoundly (Gowans and Knight, 1964; Watson and Bradley, 1998). The activated lymphocyte undergoes proliferation and differentiation in the lymph node. Thereafter, its progeny cells leave the node via the efferent lymphatics together with other naive lymphocytes. However, upon rearrival into the circulation, the antigen-activated effector cells no longer randomly recirculate to other lymph nodes. Instead, they have become imprinted so that they can preferentially traffic into the peripheral epithelial tissues through which the inciting antigen penetrated the body surfaces. This reprogramming involves at least changes in the expression profile of adhesion molecules and receptors for chemokines. These effector cells can leave the blood via the normal flat-walled postcapillary venules in the periphery and navigate into areas of microbial or other in-

flammatory stimuli. Hence, the effector cells are efficiently targeted to those locations where they can do the most good to defend the body.

A small population of effector cells ultimately turns into memory cells. These cells have the unique capacity to patrol the tertiary lymphoid tissues, mainly epithelial surfaces. Should the same antigenic exposure reoccur, the memory cells can evoke a rapid response against it. Again, the phenotypic changes in memory cells affect their recirculation potential. These cells (and effector lymphocytes) have profoundly decreased ability to immigrate into lymph nodes via HEV, thus they drain mainly into the local lymph nodes via the afferent lymphatics together with the antigen-presenting cells and antigens (Sallusto et al., 1999).

Under physiological conditions, two main recirculation routes for activated lymphocytes can be distinguished (Fig. 7.1) (reviewed in Carlos and Harlan, 1994; Springer, 1994; Butcher and Picker, 1996; Salmi and Jalkanen, 1997). Immunoblasts activated in peripheral lymph nodes preferentially migrate into the skin, whereas those responding to gut-derived antigens in Peyer's patches tend to return to the gut-associated lymphatic tissues (Butcher, 1999; Robert and Kupper, 1999). The gut-seeking immunoblasts enter mainly the intestine in the lamina propria, which is the body's largest nonorganized lymphoid tissue. These cells may also have the capacity to migrate into the respiratory and genitourinary tract, which have traditionally been included in the common gut-associated lymphoid system (Brandtzaeg et al., 1999). Thus, under normal conditions, the gut and non-mucosal lymphoid organs share the total pool of naive cells with all possible antigenic specificities, but upon activation, the subsequent migratory route sharpens the immune response into the affected tissue.

During pathologic inflammation there are characteristic changes in leukocyte trafficking (Carlos and Harlan, 1994; Springer, 1994; Butcher and Picker, 1996; Salmi and Jalkanen, 1997; Cines et al., 1998). First, in acute inflammation, polymorphonuclear leukocytes invade the affected site very rapidly, and only later are waves of monocyte and lymphocyte influx seen. In a primary challenge it takes about 3 days before antigen-specific immunoblasts enter the peripheral lesion, but during a secondary response the influx of memory-derived cells occurs much faster. Second, the exposure of flat-walled venules to proinflammatory mediators at a site of acute inflammation makes them much more adhesive toward different classes of leukocytes. Bathing of the affected tissue in inflammatory cytokines, microbial products, and other proadhesive compounds results in the rapid synthesis of many endothelial adhesion molecules that are absent from noninflamed vessels or only expressed at low levels. In chronic inflammation, even an HEV-like transformation of vessels in peripheral tissues is common and is quite often associated with notably lymphoid follicles in these nonlymphoid organs.

Different types of inflammation have typical features that also affect lymphocyte trafficking (Carlos and Harlan, 1994; Springer, 1994; Butcher and Picker, 1996; Salmi and Jalkanen, 1997; Butcher, 1999; Robert and Kupper, 1999). In general, both CD8 T-killer cells and CD4-positive Th1 and Th2 cells can infiltrate to sites of inflammation, but their relative proportions vary according to the underlying cause. The inflammatory stimulus and/or anatomic location results in a characteristic, although partially overlapping, pattern of expression and/or activation of adhesion molecules and chemotactic systems on both lymphocytes and endothelial cells, which translates into apparently tissue-selective migration patterns into inflamed tertiary sites.

For example, inflamed synovial membrane in rheumatoid arthritis displays features of lymphocyte homing, which are clearly distinct from those in peripheral lymph nodes, skin, and gut. In fact, restricted expression of homing-associated molecules on Th1 vs. Th2 CD4 lymphocytes may explain the preponderance of Th1 cells in certain inflammatory lesions (Syrbe et al., 1999; D'Ambrosio et al., 2000).

## Molecular Mechanisms in Leukocyte Extravasation

### The Multistep Adhesion Cascade

Lymphocytes and other leukocytes leave the blood in a multistep process that can be visualized both *in vitro* and *in vivo* as tethering, rolling, firm adhesion, and transmigration (Fig. 7.2) (Butcher, 1991; Springer, 1994; Carman and Springer, 2004). Tethering and rolling phases are mainly mediated by selectins and their sialomucin ligands. Transient and weak interactions between lymphocytes and endothelial cells formed by these molecular pairs lead to triggering of an activation step involving chemokines and their receptors. Activation is required for optimal adhesive behavior of leukocyte integrins that are inactive when cells are freely flowing in the bloodstream. However, engagement of other types of molecules, such as glycosyl-phosphatidylinositol (GPI)-linked proteins, on lymphocyte surface can result in integrin activation. During activation and firm adhesion, leukocytes change their shape and then start to transmigrate. Molecular mechanisms functioning at the transmigration step are poorly known but include metalloproteinases that help lymphocytes to penetrate the basement membrane. The path used by a transmigrating lymphocyte is rapidly closed by unknown repair mechanisms. Movement and final localization of a lymphocyte within the tissue is largely dependent on chemokine receptors and molecules binding to extracellular matrix proteins on its surface (Cyster, 1999; 2005).

**Figure 7.2.** The multistep adhesion cascade of lymphocyte extravasation. The freely flowing, blood-borne lymphocyte starts the interaction with vascular endothelium by tethering and rolling that then proceeds to an activation step. Activation is followed by firm adhesion. Thereafter, the lymphocyte seeks an interendothelial junction, through which it penetrates into the tissue. The contribution of major molecular families at each step is illustrated.

The complexity of the multistep cascade functioning in leukocyte extravasation is comparable to blood clotting and complement-mediated killing, in which each step has to be executed correctly to achieve the goal. The extravasation cascade is made more complex by the fact that vascular beds in different organs and inflammatory conditions express some unique homing-associated molecules, and each leukocyte subset displays partially distinct homing-molecules on their surface. Because the lymphocyte can enter a particular tissue only if it is equipped by a set of molecules matching the ligands presented on vascular endothelium of this tissue, the composition of lymphocytic infiltration in each tissue is tightly controlled (Butcher, 1991; Springer, 1994; Salmi and Jalkanen, 1997).

The most relevant homing-related molecules (illustrated in Fig. 7.3) are presented below in more detail and in the order of their principal place in the adhesion cascade. It should be emphasized here, however, that functions of these molecules overlap *in vivo* and may depend on the characteristics of the vascular bed, where the interactions take place. For example, integrins are able to mediate rolling under low shear, and in narrow capillaries they may act without a clear preceding, selectin-mediated rolling phase (Springer, 1994; Salmi and Jalkanen, 1997).

### Tethering and Rolling

#### Selectin and their sialomucin ligands

Selectins and their sialomucin ligands are the key players in tethering and rolling steps, because the lectin-carbohydrate bonds between these receptor-ligand pairs allow formation of rapid but transient and weak interactions typical of rolling behavior. There are three members of the selectin family that have been named, based on their main site of expression: L-selectin (CD62L) is present on different types of leukocytes, E-selectin (CD62E) is on endothelium, and P-selectin (CD62P) is on platelets and endothelium (Rosen, 1999; Vestweber and Blanks, 1999; Ley, 2001).

The common structural feature of these molecules is the N-terminal lectin domain, which is of fundamental importance in binding to sialyl Lewis X (sLeX) carbohydrate present on the sialomucin ligands of selectins (Fukuda et al., 1999; Rosen, 1999; Vestweber and Blanks, 1999; Ley, 2001). The ligand structures for L-selectin are presented by PNAd on HEV in peripheral lymph nodes, thus PNAd is fundamental to guiding L-selectin-positive lymphocytes into peripheral lymph nodes. PNAd consists of at least six different proteins, all decorated by a sulfated and fucosylated sLeX. Only four of them have been molecularly defined: glycosylation-dependent cell adhesion molecule-1 (GlyCAM-1), CD34, podocalyxin, and mucosal addressin cell adhesion molecule (MAdCAM-1). Interestingly, MAdCAM-1 has the proper glycosylation for L-selectin recognition only in organized lymphoid areas of the gut such as Peyer's patches but not in lamina propria vessels, allowing to a certain extent L-selectin-dependent entrance of cells to mucosal sites.

The importance of most homing-related molecules *in vivo* has been demonstrated by creating knockout mice (Table 7.1). Among the first were L-selectin-deficient mice that exhibit severely impaired lymphocyte homing to peripheral lymph nodes. In contrast, GlyCAM-1 knockout mice only have enlarged lymph nodes, a result suggesting a regulatory role for the soluble GlyCAM-1 molecule in lymphocyte homing. CD34 knockout mice are seemingly healthy despite defective eosinophil migration. Also, the genes important for proper post-translational modifications of the selectin ligands are disrupted. For example,

**Figure 7.3.** Homing-associated molecules involved in lymphocyte traffic. The most relevant lymphocyte surface molecules and their counter-receptors on vascular endothelium are depicted.

fucosyltransferase VII (Fuc-TVII)-deficient mice are not able to add the critical fucose moiety to the sLeX structure. Hence, they do not glycosylate L-selectin ligands properly and exhibit severe impairment in lymphocyte homing and leukocyte extravasation to sites of inflammation (Lowe, 1997). Lack of a highly HEV-specific sulfotransferase (GlcNAc6ST) leads to inefficient or absent sulfation of the sLeX motif, concomitant disappearance of L-selectin ligand activity, and decreased lymphocyte homing (Hemmerich et al., 2001).

Expression of both P- and E-selectin are induced at sites of inflammation. However, their expression kinetics differs remarkably. P-selectin is released within minutes from intracellular storage granules, Weibel-Palade bodies, and is translocated to the endothelial cell surface, whereas E-selectin requires new protein synthesis and its maximal expression is seen 4 hours after the induction of inflammation. The primary ligand for P-selectin is correctly tyrosine-sulfated P-selectin glycoprotein ligand-1 (PSGL), which is present on most leukocytes (McEver and Cummings, 1997). Depending on its glycosylation profile it can also bind to E-selectin, which has high affinity particularly toward cutaneous lymphocyte antigen (CLA), a specific glycoform of PSGL-1. CLA-E-selectin interaction appears to be important in directing lymphocytes to skin inflammations. In addition, E-selectin binds to a non-mucin-like E-selectin ligand-1 (ESL-1) on leukocytes (Vestweber and Blanks, 1999).

E-selectin knockout mice are apparently healthy, but their leukocytes roll faster than in normal mice, indicating that E-selectin is an important molecular brake at early steps of leukocyte-endothelial cell interactions. P-selectin-defective mice are also viable and fertile. They show neutrophilia due to a longer half-life of neutrophils. After induction of inflammation, leukocyte rolling is impaired for less than 2 hours in these mice. This finding suggests that P-selectin is indispensable only at early phases of inflammation (Frenette and Wagner, 1997). PSGL-1

knockout mice largely resemble P-selectin-deficient mice, thus confirming the importance of PSGL-1 at the rolling step (Yang et al., 1999). Mice deficient for both E- and P-selectin have also been generated. These mice exhibit much more profound defects than those of single knockouts, indicating that E- and P-selectin have overlapping functions and that they compensate each other (Frenette and Wagner, 1997). Furthermore, mice whose core 2β 1,6-N-acetylglucosaminyl transferase (C2-β-GlcNAcT) gene has been disrupted have a defect in the early step of branching of LeX oligosaccharide and therefore lose proper glycosylation of their E- and P-selectin ligands. These mice show normal lymphocyte homing to lymph nodes but their leukocytes cannot efficiently enter the sites of inflammation (Etzioni et al., 1999; Vestweber and Blanks, 1999). A human immunodeficiency disease, leukocyte adhesion defect 2 (LAD2), resembles characteristics of these knockout animals: LAD2 patients do not have functional selectin ligands because of a glycosylation defect. Leukocytes of these patients have decreased rolling capacity, although in static conditions leukocytes adhere efficiently to endothelial cells. Patients with LAD2 suffer from recurrent bacterial infections and also have other developmental abnormalities (Etzioni et al., 1999). This disease is presented in detail in Chapter 38.

#### CD43, CD44, and vascular adhesion protein-1

Other (nonselectin) molecules have also been shown to directly mediate rolling or tethering or to indirectly regulate this step. An example of a regulatory molecule is CD43, a long and negatively charged glycoprotein on lymphocytes that inhibits engagement of L-selectin, thus blocking the homing of lymphocytes. Its role is clearly demonstrated in CD43-deficient animals, which show enhanced lymphocyte homing to secondary lymphoid organs (Stockton et al., 1998). CD44 is a multifunctional member of the proteoglycan family that can mediate rolling of lymphocytes

**Table 7.1.** Phenotype of Gene-Targeted Mice Made Deficient for Individual Homing-Associated Molecule

<i>Molecule</i>	<i>Main Abnormalities in Leukocyte Trafficking</i>
L-selectin	Impaired lymphocyte homing to peripheral lymph nodes
E-selectin	Increased velocity of rolling leukocytes
P-selectin	Decreased leukocyte rolling at early stages of inflammation
GlyCAM-1	Enlarged lymph nodes
CD34	Impaired eosinophil accumulation in allergen-induced lung inflammation
PSGL-1	Decreased leukocyte rolling at early stages of inflammation
Fuc-TVII	Reduced leukocyte migration to sites of inflammation Reduced lymphocyte homing to peripheral lymph nodes
C2β GlcNAcT	Reduced leukocyte emigration to sites of inflammation
GlcNAc6ST	Decreased lymphocyte homing
ICAM-1	Impaired neutrophil migration to sites of inflammation
ICAM-2	Delayed eosinophil accumulation in the airway lumen in allergy
VCAM-1	Embryonic lethal
CD31	Deficient migration through basement membrane
CD11a	Reduced lymphocyte trafficking to peripheral lymph nodes and to Peyer's patches Decreased leukocyte trafficking to sites of inflammation
CD11b	Decreased neutrophil emigration in ischemia/reperfusion injury
β2-integrin	No neutrophil emigration into the skin, normal emigration into inflamed peritoneum, and increased migration into inflamed lung
α4-integrin	Embryonic lethal, chimeric mice have reduced lymphocyte homing into Peyer's patches
β7-integrin	Impaired lymphocyte migration to Peyer's patches
CD43	Increased lymphocyte homing to secondary lymphoid organs
CD44	Decreased lymphocyte migration to peripheral lymph nodes and thymus
CCR4	No obvious defects in leukocyte trafficking
CCR7	Defective lymphocyte entry to lymph nodes and formation of T cell areas
CXCR5	Defect in formation of follicles in lymph nodes
CX3CL1	No obvious defects in leukocyte trafficking

on endothelial hyaluronan (Siegelman et al., 1999). In addition, triggering of CD44 activates lymphocyte function-associated antigen-1 (LFA-1), which may strengthen lymphocyte adhesion to endothelium. In vivo experiments using function-blocking antibodies suggest that CD44 is important in lymphocyte trafficking to sites of inflammation. Moreover, lymphocytes of CD44-deficient mice show impaired lymphocyte homing to peripheral lymph nodes and thymus (Protin et al., 1999).

Vascular adhesion protein-1 (VAP-1) is a unique member among the homing-related molecules, because in addition to its adhesive function at an early phase of the multistep cascade it possesses intrinsic enzymatic activity. The end products of the reaction catalyzed by this amine oxidase are aldehyde, ammonium, and hydrogen peroxide. All of them are potent compounds that may regulate the entire scene of inflammation by, for instance, aberrantly glycosylating endothelial proteins (aldehydes) or by up-regulating other adhesion proteins and metalloproteinases and inducing apoptosis (hydrogen peroxide). Regulation of VAP-1 function appears to involve its sequestration into intracellular granules, from which it is rapidly translocated to the endothelial surface upon induction of inflammation (Jalkanen and Salmi, 2001; Salmi and Jalkanen, 2001).

## Activation

### Chemokines and their receptors

Certain endothelial chemokines and their interaction with the seven pass transmembrane receptors on leukocytes are considered to be of fundamental importance at the activation step of the adhesion cascade. *Chemokines* are small molecules divided into the following families on the basis of their structural cysteine motifs: C, CC, CXC, and CX3C, where C is cysteine and X is any amino acid residue.

Chemokines are typically heparin-binding soluble molecules and many of them are not even produced by endothelial cells. How these molecules can exert their function at the luminal surface of endothelial cells where blood constantly flushes away any soluble gradients remains an enigma. The answer appears to be in the good diffusibility of these molecules, possibly via a specialized reticular conduit, through the lymph node to the abluminal side of the vessels. They can then be transcytosed to the luminal side of the endothelial cell, where they become immobilized by an avid binding to surface-expressed glycosaminoglycans. Chemokines injected subcutaneously can find their way to the luminal surface of HEV in the draining lymph nodes, and hence selectively enhance lymphocyte recruitment to the draining node (Middleton et al., 1997; Gretz et al., 2000). After chemokine binding, activation signals are transduced from the serpentine receptors via guanine nucleotide-binding (G) proteins via still poorly defined signaling routes that eventually result in affinity/avidity changes of leukocyte integrins (Mantovani, 1999; Zlotnik et al., 1999; Baggiolini, 2001; Gerard and Rollins, 2001; Mackay, 2001).

Different leukocyte subsets possess alternative sets of chemokine receptors that determine whether they are allowed to exit from the blood—for example, at HEV in peripheral lymph nodes or vasculature at sites of inflammation. For instance, T cells bearing CCR7 receptor become recruited to peripheral lymph nodes and mucosal sites where its ligand CCL21 (secondary lymphoid chemokine, SLC) is expressed on HEV. CCR7 also binds to CCL19 (EBV-induced molecule 1 ligand chemokine, ELC) present on HEV. B cells, by contrast, bind efficiently to areas of HEV devoid of CCL21 with a currently unknown receptor. They may also use CCL13 (B cell-attracting chemokine, BCA-1) in follicular vessels and directly enter the follicles using CXCR5 (Moser and Loetscher, 2001). CX3CL1 (Fractalkine) is structurally very different from other endothelial chemokines, because in addition to a soluble form it has a transmembrane form with a long stalk of sialomucin-like structure. CX3CL1 has a strong affinity toward T cells (Mackay, 2001). Tissue selectivity among chemokines has been demonstrated to exist at least in the skin, where endothelial CCL17 (thymus and activation-regulated chemokine, TARC) attracts CCR4-bearing lymphocytes (Campbell et al., 1999).

CCR7 knockout mice demonstrate the importance of this chemokine in lymphocyte trafficking, as these mice have defective T cell entry to lymph nodes (Cyster, 1999; 2005). In contrast, no obvious homing defects have been found in CX3CL1 and CCR4 knockout mice. The only abnormality discovered in CX3CL1<sup>−/−</sup> mice is the diminished number of cells belonging to the monocyte/macrophage lineage in the blood (Cook et al., 2001). The same population was diminished in CCR4<sup>−/−</sup> mice in the peritoneal cavity (Chvatchko et al., 2000), a finding suggesting that the function of these two chemokines can be compensated for by other molecules.

### Other molecules

Engagement of several other leukocyte surface molecules can lead to activation of LFA-1, CD11a/CD18. However, only a few of them have been directly shown to result in increased leukocyte binding to endothelium. One of the molecules having this property is CD73, a GPI-linked molecule that has ectonucleotidase activity catalyzing conversion of extracellular AMP to adenosine (Resta et al., 1998; Airas et al., 2000). Adenosine regulates both E-selectin and integrin function and endothelial permeability (Cronstein and Weissmann, 1993; Cronstein, 1997). Interestingly, lack or diminished expression of CD73 is linked to a variety of immunodeficiency diseases, such as Wiskott-Aldrich syndrome, severe combined immunodeficiency, common variable immunodeficiency, primary hypogammaglobulinemia, selective IgA deficiency, and Omenn syndrome.

### Firm Adhesion

#### Integrins and their immunoglobulin superfamily ligands

Certain integrins participate effectively in the arrest of leukocytes on endothelium through use of members belonging to the immunoglobulin superfamily as their vascular ligands. They can also function at the earlier steps of the cascade, even during rolling. Typical for integrins is that they are heterodimers consisting of  $\alpha$  and  $\beta$  chains (Shimizu et al., 1999). Important integrins for leukocyte extravasation are  $\alpha 4\beta 7$ , LFA-1, and  $\alpha 4\beta 1$ .  $\alpha 4\beta 7$  is a principal homing receptor for MAdCAM-1 and directs lymphocytes to mucosa-associated lymphatic tissues (Butcher, 1999). Its role as a mucosal homing receptor has been clearly demonstrated by  $\beta 7$  knockout animals. They have rudimentary Peyer's patches and their lymphocyte homing to mucosal sites is severely impaired. In contrast, lymphocyte homing to peripheral lymph nodes in these mice is intact (Wagner and Müller, 1998).

$\alpha 4\beta 1$ , by contrast, exerts its role mainly at inflammatory sites, where it binds to its ligand, vascular cell adhesion molecule-1 (VCAM-1, CD106). Both VCAM-1 and  $\alpha 4$  knockout animals are embryonically lethal, indicating that besides homing they have more fundamental roles in embryonic development. Mice that are chimeric regarding the deletion of  $\alpha 4$  show diminished lymphocyte trafficking to Peyer's patches but not to other secondary lymphatic organs, a finding compatible with the phenotype of  $\beta 7$  knockouts (Wagner and Müller, 1998).

LFA-1 (CD11a/CD18) is a member of the group of four leukocyte integrins sharing the same  $\beta$  chain,  $\beta 2$  (CD18), while having unique  $\alpha$  chains (CD11a, b, c, and d). LFA-1 is present on practically all leukocytes and mediates their binding to intercellular adhesion molecules 1 and 2 (ICAM-1 [CD54] and ICAM-2 [CD102]) in its active form (Wang and Springer, 1998; Shimizu et al., 1999; Hogg and Leitinger, 2001). Mac-1 (CD11b/CD18) also participates in leukocyte migration, but its role is heavily overshadowed by LFA-1. The role of leukocyte integrins in leukocyte trafficking is evident through the dramatic defects in leukocyte extravasation in patients suffering from LAD1 or its alternative form. These patients lack the normal  $\beta 2$  chain, consequently surface expression of all leukocyte  $\alpha$  chains is prevented as well, or they express LFA-1 in a nonfunctional form (Etzioni et al., 1999). This deficiency is presented in more detail in Chapter 38 in this book.

Mice deficient in CD18 do not show as dramatic defects as those of LAD1 patients. Their neutrophils do not migrate into

the skin but traffic normally to peritoneum and increased homing takes place in inflamed lung. CD11a $^{-/-}$  mice have impaired lymphocyte homing to both peripheral lymph nodes and Peyer's patches, a finding in keeping with the role of LFA-1 as a non-organ-specific homing molecule. In CD11b-negative mice, reduced neutrophil binding to endothelium is observed. Mice lacking ICAM-1 have a relatively mild phenotype compared to findings obtained from studies using function-blocking antibodies. These mice have decreased neutrophil migration to tissues in some inflammatory models. Lack of ICAM-2 normally constitutively present on endothelium does not cause any obvious defects in lymphocyte recirculation (Etzioni et al., 1999).

### Transmigration

Transmigration is the least-analyzed phase in leukocyte extravasation process although recent progress has been made (Carman and Spring, 2004). Studies using function blocking antibodies have shown that CD31 is intimately involved in transmigration. CD31 belongs to the immunoglobulin superfamily and is expressed by several leukocyte subsets and continuous endothelium of all vessel types (Newman, 1997). On vascular endothelium its expression is concentrated on intercellular junctions. Unexpectedly, CD31-deficient mice show a normal overall transmigration capacity. However, the polymorphonuclear leukocytes are arrested between the endothelium and basement membrane, demonstrating that CD31 is needed in migration through the basement membrane (Duncan et al., 1999). Other molecules such as junctional adhesion molecule (JAM), LFA-1, and the ICAMs have been implicated in transmigration (Faveeuw et al., 2000; Dejana et al., 2001). Matrix metalloproteinase-2 (MMP-2), which is induced in T cells upon binding to endothelium, also plays a role in this invasive process.

### Intraorgan Localization of Lymphocytes

Subsequent to entry into the lymphoid organs, lymphocytes start their voyage within the organs. For the migration, lymphocytes need balanced function of adhesion molecules capable of binding to extracellular matrix molecules (ECM), such as fibronectin, laminins, and collagens, and mechanisms to detach from the anchorage to ECM (Gretz et al., 1996).  $\beta 1$ -integrins are essential for binding to various ECM, and lymphocytes can use CD44 to bind to fibronectin and collagens. Detaching mechanisms are poorly understood. Controlled and directional migration also needs proper chemokine receptors on the lymphocyte surface that respond to chemokines secreted by different cell types within the tissues. These interactions are important both in early phases of lymphocyte maturation, for example, in thymus and later during physiological lymphocyte recirculation and leukocyte movement at sites of inflammation (Mantovani, 1999; Zlotnik et al., 1999; Baggiolini, 2001; Gerard and Rollins, 2001; Mackay, 2001). During normal recirculation, CCL21 and CCL19 guide T cells to interfollicular areas within the nodes, whereas CCL13 produced by follicular dendritic cells attracts B cells expressing CXCR5 into the follicles (Fig. 7.4).

In addition to cell surface molecules mediating adhesion-de-adhesion steps in the intraorgan movement of lymphocytes, the pathways that transduce these surface signals into the locomotory machinery are important for proper localization (Sánchez-Madrid and del Pozo, 1999). Hence, specific receptors are clustered at the leading edge and trailing edge of the crawling lymphocyte. Via still incompletely understood mecha-

**Figure 7.4.** Chemokines contribute to both entrance and intraorgan localization of lymphocytes. CCL19 and CCL21 are involved in T lymphocyte entrance via high endothelial venules (HEV) into the node. They also guide T cells to the interfollicular areas in the lymph node. CCL13, by contrast, directs B lymphocytes into the follicles.

nisms, these molecules signal to the actomyosin and microtubuli networks within the cell, and translate the surface signals into polarized cell crawling. Just one example of the importance of these steps for proper immune defense is Wiskott-Aldrich syndrome, in which a defect in one of these effector signaling proteins leads to a severe immunodeficiency (Thrasher et al., 1998).

Dendritic cells entering the lymph nodes via afferent lymph and bringing antigens are key players in the immune response as antigen-presenting cells. CCL21 expressed in lymphatic endothelium assists dendritic cell entrance into the T cell areas allowing these two cell types to interact with each other. B cell collaboration with T cells is ensured by up-regulation of CXCR5 on a subset of T cells and CCR7 on B cells. This makes it possible for B and T cells to move to the boundary of the B and T cell zones and interact with each other. A spontaneously mutant mouse strain, *plt*, which has decreased expression of both CCL21 and CCL19, demonstrates the importance of these chemokines in intraorgan localization (and entry) of lymphocytes, as these mice have defective organization of T cell areas within lymph nodes. The phenotype of these mice is thus comparable to that of mice lacking the receptor for these chemokines (CCR7). In contrast, in CXCR5-negative mice development of B cell follicles is defective—again, in keeping with the function of this chemokine in B cell localization (Cyster, 1999).

Intraorgan localization also shows remarkable tissue specificity, best exemplified in the gut. Practically all lymphocytes in the small intestine have CCR9 whereas in the colon these cells are less frequent. Importantly, lymphocytes in several other tissues (excluding thymus) are CCR9 negative. The ligand for CCR9 is CCL25 (thymus-expressed chemokine, TECK), which is produced by gut epithelial cells and thus expected to guide CCR9-positive lymphocytes, especially to small intestine (Kunkel

et al., 2000). Whether CCL25–CCR9 interaction plays a role at the entrance phase to small intestine has not been directly demonstrated.

## Conclusions

Optimal lymphocyte entry to primary lymphoid organs during development and to secondary lymphoid organs during recirculation, and efficient leukocyte trafficking to sites of inflammation are the key elements in adequate functioning of the immune system. Molecular mechanisms mediating lymphocyte contacts with the vascular wall are relatively well known. Knowledge of the network of chemokines and receptors needed for leukocyte entrance and intraorgan localization is increasing exponentially. In contrast, the mechanisms functioning during diapedesis through the vascular wall, leukocyte entry to afferent lymphatics at different vascular beds, and lymphocyte exit via efferent lymphatics within the lymphoid organs remain to be elucidated. The importance of leukocyte trafficking to the pathophysiology of human disease is reflected in the numerous attempts worldwide at manipulating the trafficking mechanisms of leukocytes to combat harmful inflammations.

Thus far, the number of patients diagnosed as having a defect in any of the molecules involved in leukocyte migration has been very small. One reason for this small number may be that many of the defects are not compatible with life. The tools for diagnosing patients who suffer from defective leukocyte trafficking are continuously being developed and may help to reveal many new disease entities. One example of recent advances is a study in which CXCR1 (receptor for IL-8) expression levels in neutrophils of normal and pyelonephritis-prone children were compared. Patients suffering from recurrent pyelonephritis had significantly lower CXCR1 levels than those of healthy controls, providing an explanation for these recurrences (Freundt et al., 2000). Analogous findings can be expected to emerge from other disease groups in the near future.

Over the past few years, we have gained increasing insight into the salient molecular and physiological mechanisms guiding lymphocyte recirculation from the blood into the tissues and back to the circulation. In terms of our immune defense, this continuous patrolling process is important for guaranteeing maximal efficacy of a lymphocyte meeting its cognate antigen. Failure of this process inevitably leads to some form of immunodeficiency. Thus, a detailed understanding of the multifaceted extravasation cascade will help us to develop new strategies for guiding and redirecting lymphocyte trafficking into locations where lymphocytes are needed in immunodeficiency patients, where the system has gone awry for one reason or another.

## Phagocytic System

KUENDER D. YANG, PAUL G. QUIE, and HARRY R. HILL

Phagocytes were initially thought to be harmful to the host, contributing to the untoward consequences of infection and inflammation. In 1898, Metchnikoff first suggested that “the essential and primary element in typical inflammation consists in a reaction of the phagocyte against a harmful agent.” After establishing that phagocytes were helpful in defense against bacteria, Metchnikoff predicted that defects in phagocyte function might predispose the host to increased numbers and severity of infections due to microorganisms. Patients with decreased phagocyte counts or with phagocyte functional defects do, in fact, have recurrent or even fatal infections as well as impaired wound healing. Moreover, evidence has also accumulated demonstrating that aberrant phagocyte activation can contribute to untoward complications of inflammation. Functional defects in phagocytes can lead to recurrent cutaneous abscesses, periodontitis, paronychia, pneumonitis, osteomyelitis, and occasionally life-threatening sepsis. Aberrant phagocyte activation may result in the adult respiratory distress syndrome (ARDS), disseminated intravascular coagulation (DIC), and reperfusion injury. The kinetics of phagocyte production as well as the activation and function of phagocytes has been elucidated for the most part. Upon stimulation by colony-stimulating factors including stem cell factor (SCF), granulocyte-monocyte colony-stimulating factor (GM-CSF), granulocyte colony-stimulating factor (G-CSF), or interleukin-3 (IL-3), phagocyte precursors proliferate and differentiate under the control of certain transcription factors such as purine-rich DNA sequence binding protein (PU.1) and CAAT enhancer binding protein,  $\alpha$  isoform (C/EBP $\alpha$ ), for granulocytic differentiation, as well as PU.1 and mammary cell-activating factor B (c-MafB), for monocytic differentiation in the bone marrow (Tian et al., 1996). Corticosteroids, complement fragments (C3e, C3dg), and adrenergic neurotransmitters (epinephrine, norepinephrine) accelerate the release of mature phagocytes into the

peripheral blood where they circulate and marginate along capillary endothelial surfaces. Adhesive glycoproteins including selectins such as P-selectin, L-selectin, and E-selectin as well as integrins such as fibronectin and complement receptors (CR3 and CR4) promote phagocyte adhesion. Selectins are involved in granulocyte rolling in the blood circulation, while integrins mediate adhesiveness and phagocyte extravasation. In response to chemoattractants such as C5a, IL-8, monocyte chemotactic factor, leukotrienes, and bacterial formylated peptides, phagocytes mobilize and enter tissues and inflammatory sites where they interact with and ingest target organisms, especially if these are coated with immunoglobulin and/or complement. This interaction of phagocytes with microbes is followed by ingestion, degranulation, and respiratory burst activity resulting in extracellular and intracellular killing of the target as well as inflammatory changes in the tissues. Monocytic phagocytes can also differentiate into dendritic cells that present antigens and secrete cytokines to promote optimal T lymphocyte differentiation and activation. Defects or unregulated activation in any aspect of the above phagocytic responses may result in immunodeficiency diseases with associated infections or serious inflammatory disorders. A variety of in vivo, ex vivo, and in vitro studies have resulted in the definition of these disorders and, in some cases, in the development of effective therapeutic regimens. As progress in the characterization of phagocyte activation pathways and function is made, immunopharmacological intervention, bone marrow transplantation, and potential gene therapy may offer hope to many of these patients. Prenatal diagnoses employing restriction fragment length polymorphism, polymerase chain reaction techniques, analysis of X-chromosome inactivation, measurement of gene products, and assessment of granulocyte function in fetal blood make these diseases potentially identifiable and/or treatable in utero or shortly after birth.

**Figure 8.1.** Differentiation of granulocytes and monocytes from myeloid progenitors. Myeloid progenitors derived from  $CD34^+$  stem cells (SC) display  $CD33^+$  under the influence of certain nuclear transcription factors.  $C/EBP\alpha$  (CAAT enhancer binding protein,  $\alpha$  isoform) and PU.1 (purine-rich DNA sequence binding protein) are the key transcription factors for myeloid cell lineage differentiation. Monocyte differentiation is further controlled by macrophage colony-stimulating

factor (M-CSF) and expression of mammary cell-activating factor B (c-MafB), whereas granulocyte differentiation is influenced by  $C/EBP\alpha$  expression and granulocyte colony-stimulating factor (G-CSF) stimulation. In contrast, differentiation of lymphocytes is mainly affected by GATA-2 expression and differentiation of red blood cells (RBC) is mainly affected by GATA-1 expression. MΦ, resident macrophages; NΦ, resident neutrophils; TNFR, tumor necrosis factor receptor.

### Development and Distribution of Phagocytic System

There is evidence that human myelopoiesis occurs early in fetal life, as early as 6–8 weeks of gestational age (Rosenthal et al., 1983). Phagocyte progenitor cells arise from pluripotential hematopoietic stem cells in the bone marrow or in vitro agar culture systems. Bone marrow progenitor cells have been shown to grow into different colonies known as colony-forming units (CFU) granulocyte-monocyte (CFU-GM), granulocyte (CFU-G), and eosinophil (CFU-Eo) (Iscove et al., 1971; Clark and Kamen, 1987). These precursors can give rise to mature phagocytes, including polymorphonuclear granulocytes and mononuclear phagocytes, under the influence of colony stimulation factors (CSFs) such as SCF, GM-CSF, G-CSF, and IL-3. These growth and differentiation factors are derived mostly from the stromal cells in the bone marrow, while some are produced by myeloid cells in the reticuloendothelial system (reviewed by Yang and Hill, 1991, 2001). The differentiation of myeloid progenitors into mature phagocytes probably results in part from the acquisition of specific factor receptors on the cells at different phases of differentiation and maturation. Interaction of lectins on the stromal cells with receptors on phagocyte precursors may be involved in the process of growth and differentiation (Aizawa and Tavassoli, 1987; Nangia-Makker et al., 1993). A number of suppressing mechanisms, by contrast, including endocrine factors such as corticosteroids, erythropoietin levels, and cytokines from lymphoid and myeloid cells, have been shown to provide negative feedback signals. These endocrine factors and paracrine cytokines apparently play a central role in the bone marrow in keeping appropriate homeostasis and cellularity at a myeloid/erythroid (M/E) ratio between 1:3 and 1:4. The molecular mechanism to explain the commitment to different lineages has been recently deciphered. The concept that transcription factors rather than cytokine receptor signals are the early determinants of lineage commitment has been emphasized (Ward et al., 2000). As

shown in Figure 8.1, transcriptional factors PU.1 and  $C/EBP\alpha$  promote G-CSF receptor expression and induce terminal differentiation of granulocytes (Smith et al., 1996; Keeshan et al., 2003), whereas PU.1 and c-MafB promote monocytic differentiation (Hegde et al., 1999; Ward et al., 2000; McIvor et al., 2003). Moreover, the switch of stem cells to a myeloid-committed lineage is also mediated by the interaction between these transcriptional factors. Zhang et al. (1999) showed that GATA-1 repressed PU.1 expression and induced erythroid differentiation, but not myeloid differentiation. Similarly, the interaction of GATA-1 with  $C/EBPs$  specifically regulates eosinophil lineage differentiation (McNagny et al., 1998).

Phagocytes from a 20-week gestational-age fetus were found to have active phagocytic and respiratory burst activity. Phagocytes from full-term newborns, however, do not have complete functional activity. Neonatal granulocytes and monocytes have defects in bone marrow storage pools, cellular activation, and chemotaxis (Christensen et al., 1980, 1986; Marodi et al., 1984; Sacchi and Hill, 1984; Newton et al., 1989; Hill et al., 1991). Studies with adult phagocytes have indicated that a variety of cytokines and glycoproteins can modulate phagocyte functions. These results suggest that intact phagocyte function is due to intrinsic maturation but also modulated by environmental factors that alter the biochemical and physiological status of phagocytes. It is often necessary, therefore, to differentiate developmental defects from abnormalities due to extrinsic environmental factors.

### Distribution of Granulocytes

Granulocytes are produced in the bone marrow and released into the blood and tissues where they act as the first line of defense in host resistance and wound healing. The total granulocyte pool is divided into two compartments: the bone marrow and the circulating pools. The bone marrow provides the environment for the proliferation of myeloblasts, promyelocytes, and myelocytes as well as mat-

uration of metamyelocytes and band form granulocytes. The latter two populations represent the main marrow storage pool of granulocyte precursors containing  $6\text{--}8 \times 10^9$  cells/kg bodyweight. The recycling and the proliferation and maturation phases of granulocytes in bone marrow require 2–3 days and 7–10 days, respectively (Yang and Hill, 1993). In the blood, granulocytes are in the circulating ( $0.3\text{--}0.4 \times 10^9$  cells/kg) and marginating pools ( $0.4 \times 10^9$  cells/kg). Endotoxin, corticosteroids, and complement fragments (C3e, C3d,g) cause accelerated release of mature granulocytes from bone marrow into the blood. Adrenergic neurotransmitters such as epinephrine and norepinephrine can promote blood granulocyte mobilization from the marginating pool into the circulatory pool. Granulocytes in the circulation have a short life span with a half-life of 6–8 hours. In spite of this short half-life, granulocyte numbers in the blood are normally maintained between 3000 and 6000 cells/mm<sup>3</sup>.

### Distribution of Monocytes and Macrophages

Monoblasts are the first recognizable cells of the monocyte series in the bone marrow. There are, however, few monoblasts found in the bone marrow since their storage pool is relatively small. The transit time from a monoblast to a monocyte takes approximately 6 days (Groopman and Golde, 1981). Promonocytes are the prominent cells of the monocyte series in the bone marrow and comprise a major storage pool containing  $6 \times 10^8$  cells/kg (Johnston, 1988). Promonocytes mature into monocytes in the bone marrow and are released into the blood within 2 days. Circulating monocytes in the blood make up 3%–6% of the total leukocytes or about 300–600 cells/mm<sup>3</sup> ( $0.3\text{--}0.6 \times 10^9$  cells/L), while three to four times as many monocytes mobilize in the marginating pool. These monocytes leave the circulation with a half-life of 1–3 days (Groopman and Golde, 1981; Johnston, 1988; Yang and Hill, 1993). Approximately  $10^8$  monocytes are released into the blood and randomly leave for the tissues every day. These monocytes may differentiate into dendritic cells in the blood and tissues in the presence of cytokines such as GM-CSF and IL-4 (Hashimoto et al., 2000). Monocytes can develop into myeloid dendritic cells bearing CD11c and CD14, different from plasmacytoid dendritic cells with a unique marker CD123 (Facchetti and Vermi, 2002; Doni et al., 2003). Myeloid dendritic cells and plasmacytoid dendritic cells not only display different cell surface markers but also produce individual mediators for priming T lymphocyte differentiation (Langenkamp et al., 2003). They can also transform into a variety of tissue macrophages, depending on dif-

ferent conditions in the tissues. The monocyte–macrophage system is widely distributed to a number of organs: microglial cells in the brain, Kupffer cells in the liver, osteoclasts in the bone marrow, Langerhans cells in the skin, mesangial cells in the kidney, and resident macrophages in lungs, spleen, thymus, lymph nodes, pleural and peritoneal cavities, and joint spaces. Macrophages may stay in tissues for a few months or even years. During acute inflammation, the transit time of monocytes from the bone marrow to the inflammatory tissue may be shortened from 2 days to 6–8 hours. In contrast to granulocytes, which do not replicate in the circulation or tissues, both circulating monocytes and tissue macrophages are able to replicate rapidly. In chronic inflammation, especially in a variety of granulomatous disorders, tissue macrophages may transform into giant cells or epithelioid cells in the presence of tumor necrosis factor alpha (TNF- $\alpha$ ) and interferon gamma (IFN- $\gamma$ ) (Groopman and Golde, 1981; Johnston, 1988).

## Activation and Function of Granulocytes

### Granulocyte Activation

Granulocytes respond to a variety of solid and soluble stimuli via nonspecific and specific interactions. Nonspecific interactions including hydrogen bonds, van der Waals, hydrostatic and hydrophobic forces between cells, which along with soluble stimuli, may induce changes in membrane conformation. Specific ligation of ligands to specific receptors on granulocytes can also cause conformational changes in the plasma membrane that consequently mediates signal transduction, resulting in cytoskeleton reorganization, adhesion, respiratory burst activity, degranulation, movement, and phagocytosis. The kinetics of signal transduction is organized as shown in Figure 8.2. Ligation of chemokine or complement receptors (e.g., CXCR, C5aR) or Fc receptors (FcRIII, CD16) on the surface of granulocytes activates a pertussis toxin (PT)-sensitive G protein that directly or indirectly induces cytoskeleton (microfilament and microtubule) reorganization and stimulates phospholipase C (PLC) activation, resulting in hydrolysis of phosphatidylinositol (PI) into inositol 1,4,5-trisphosphate (IP<sub>3</sub>) and 1,3-diacylglycerol (DAG) in a few seconds (Sandborg and Smolen, 1988). IP<sub>3</sub> elicits intracellular calcium mobilization that can promote respiratory burst activity and cell degranulation. DAG activates protein kinase C (PKC) to induce cellular activation through the phosphorylation of enzymes or regulatory proteins, which control cell adhesion and

**Figure 8.2.** Activation and function of granulocytes. Granulocyte cell surface receptors such as chemokine (CXCR), complement (C5aR), and antibody Fc (FcRIII) receptors transduce signals for cell mobilization, phagocytosis, degranulation, and bactericidal activity upon activation. For details, see text. AA, arachidonic acid; DAG, diacylglycerol; Gi, GTP binding protein; IP<sub>3</sub>, inositol triphosphate; MAPK, mitogen-activated protein kinases; PC, phosphatidylcholine; PI, phosphatidylinositol; PI3K, phosphoinositide 3-kinase; PKC, protein kinase C; PLA<sub>2</sub>, phospholipase A<sub>2</sub>; PLC, phospholipase C; Ras, Raf, Rac, Rho, and Cdc42 are small GTP binding proteins.

locomotion. Several lines of evidence, however, indicate that stimulus–response transduction of signal may be mediated by systems other than the PT-sensitive G protein system. For instance, we have found that fibronectin-induced actin organization was also mediated by a PT-sensitive G protein pathway (Yang et al., 1994), whereas Southwick and coworkers (1989a) showed that leukocyte adhesion–induced actin polymerization was mediated by a PT-insensitive pathway. In addition, evidence suggests that hydrolysis of arachidonic acid (AA) and platelet-activating factor (PAF) from membrane phosphatidylcholine (PC) upon granulocyte activation is associated with activation of phospholipase A2 (PLA2), but not PT-sensitive G protein–mediated PLC (Sandborg and Smolen, 1988). Guanine nucleotide–stimulated NADPH oxidase activity is not sensitive to pertussis or cholera toxin (Gabig et al., 1987). A small GTP binding protein, p21 Rac, has been shown to be involved in the NADPH oxidase activation (Wientjes et al., 1996). Similarly, other small G proteins such as Rho and Ras-related Cdc42 GTP binding protein (Cdc42) are also involved in leukocyte adhesion and cytoskeleton organization (Dash et al., 1995; Nobes and Hall, 1995; Hildebrand et al., 1996). These data indicate that there are at least five different G proteins involved in the receptor–response transduction of signal for granulocyte activation and several secondary messengers coupled to these G proteins for signal regulation. Thus, it seems likely that granulocytes are specifically regulated in a variety of inflammatory reactions via different signal transduction pathways. In summary, activation of granulocytes requires several integrated signal pathways. A small G protein, Rac2, is specifically involved in triggering respiratory burst activity (Wientjes et al., 1996). A GTPase, Cdc42, together with Wiskott-Aldrich syndrome protein (WASP) activates actin assembly (Higgs and Pollard, 2000). Another small G protein, Ras, regulates phosphatidylinositol-3-kinase (PI3K) activities for coordination of granulocyte migration (Knall et al., 1997). Moreover, different G proteins can be coupled to different receptors and mediate the degranulation of granulocytes (Cockcroft and Sutchfield, 1989). The differentiation and activation of granulocytes are also regulated by mitogen-activated protein kinases (MAPKs) such as p38 and MEK signaling (Kim and Rikihisa, 2002; Miranda et al., 2002). Further exploration of granulocyte activation will likely contribute to the development of pharmacological intervention in treating certain inflammatory disorders.

### Granulocyte Recognition and Adhesion

Generally, granulocytes function as scavengers in the blood circulation and tissues (reviewed by Yang and Hill, 1993, 2001). Adhesive glycoproteins on granulocytes including selectins, such as L-selectin and P-selectin, as well as integrins, such as fibronectin receptors and complement receptors (CR3 and CR4), direct granulocytes to specific locations and promote granulocyte adhesion and subsequent migration (see Chapter 38). Selectins are involved in granulocyte rolling in the blood circulation, whereas integrins mediate firm adhesion and granulocyte extravasation (Springer, 1990; Long, 1992). Environmental factors can affect the expression of integrin molecules on endothelial cells, promoting adhesion of granulocytes to endothelium, which is a prerequisite for granulocyte diapedesis and emigration into tissues. These factors include GM-CSF, IFN- $\gamma$ , endotoxin, TNF- $\alpha$ , IL-1, IL-8, leukotriene B4 (LTB4), PAF, bacterial formylated peptides, such as formyl Met-Leu-Phe (fMLP) and C5a.

### Granulocyte Migration

Granulocytes are capable of movement in a stimulated, random fashion called *chemokinesis* and in a directional migration pattern called *chemotaxis*. Following exposure to soluble or solid stimuli, the cytoskeleton of granulocytes is reoriented to regulate cell locomotion (Valerius et al., 1981). The cytoskeleton network in granulocytes, which is somewhat similar to that of muscle cells, is composed of actin and myosin as well as the structural protein tubulin, which makes up microtubules (Valerius et al., 1981; Oliver and Berlin, 1983). Assembly and disassembly of the cytoskeleton in granulocytes modulate cell locomotion in an exchangeable dynamic “gel sol” reaction. This gel sol reaction is affected by the interaction of ligands with receptors and regulated by receptor-signaling systems. A series of small G proteins such as Rho, Rac, and Cdc42 are known to mediate changes in the cytoskeleton and cell motility (Nobes and Hall, 1995). The Cdc42 that possesses GTPase activity promotes actin polymerization, whereas WASP is the effector for the Cdc42 GTPase and acts as a link between Cdc42 and the cytoskeleton (see Chapter 31; Kolluri et al., 1996; Symons et al., 1996). Mutation of WASP may impair cytoskeleton structure, resulting in dysfunction of leukocyte migration seen in patients with Wiskott-Aldrich syndrome reviewed by Ochs and Notarangelo 2005; see Chapter 31). In response to chemoattractants such as C5a, IL-8, PAF, leukotrienes, and fMLP, granulocytes reorganize their cytoskeleton and migrate into tissues and inflammatory sites where they interact with target organisms. This is followed by phagocytosis, respiratory burst activity, and degranulation.

### Phagocytosis

The mechanism by which phagocytes ingest microorganisms involves two distinct stages: adhesion (attachment) and internalization. Attachment is mediated by specific ligand–receptor interactions and nonspecific bonds due to hydrophilic and hydrophobic interactions. Internalization results from a zipper process in which circumferential attachment of phagocyte receptors to the target forms an engulfed pouch that is subsequently fused to phagocytic granules. Attachment may be indistinguishable from engulfment when examined by light microscope. Experimental evidence has shown, however, that attachment and ingestion can be separated. When opsonins are not present, attachment may not be followed by ingestion. In addition, different types as well as the status of surface receptors on the phagocytes affect the efficiency of ingestion. Complement receptors (CR1, CR3) and IgG antibody receptors (Fc $\gamma$ R) on granulocytes are the major receptors responsible for phagocytosis. Fc $\gamma$ Rs mediate phagocytosis but different classes of Fc $\gamma$ Rs (Fc $\gamma$ R, I, II, III) may have different efficiencies. Certain Fc $\gamma$ Rs even play an inhibitory function on phagocyte activation and inflammatory regulation (Dietrich et al., 2000). Granulocytes may also take up microbes via nonspecific intercellular interactions (surface phagocytosis) that help humans survive exposure to invasive microorganisms before they develop specific antibodies.

### Respiratory Burst Activity

During membrane perturbation or phagocytosis, granulocytes are activated to induce respiratory burst activity in which reactive oxygen intermediates are formed, resulting in oxygen-dependent bactericidal activities and killing of extracellular and intracellular organisms (see Chapter 37). The respiratory burst is triggered

**Figure 8.3.** Respiratory burst pathways and recycling mechanisms in the phagocyte system. Upon phagocyte activation, cytosolic factors such as p47phox and p67phox are translocated into the plasma membrane in association with the membrane-bound flavocytochrome *b*<sub>558</sub> involving a p91 heavy chain and a p22 light chain to transport electrons from NADPH to O<sub>2</sub>, resulting in O<sub>2</sub><sup>-</sup> production followed by H<sub>2</sub>O<sub>2</sub> and OH<sup>-</sup> formation. (I), (II), and (III) represent major respiratory burst activation pathways in phagocytes, whereas (a), (b), and (c) represent major antioxidative recycling pathways. GSH, reduced glutathione; GSSG, oxidized glutathione; G-6-P, glucose-6-phosphate; G6PD, glucose 6-phosphate dehydrogenase; HMP, hexose monophosphate shunt. (Derived with permission from Yang and Hill, *J Pediatr* 119:343, 1991.)

by activation of an NADPH oxidase coupled to a respiratory chain on the cell surface after translocation of cytosolic factors (Bjerrum and Borregaard, 1989). Respiratory burst activity associated with phagocyte activation is elicited by NADPH oxidase, which is composed of a flavocytochrome *b*<sub>558</sub> associated with a gp91phox heavy chain and a p22phox light chain in the plasma membrane as well as cytosolic proteins, including p40phox, p47phox, p67phox, and a small G protein, p21 Rac (Wientjes et al., 1996). The membrane-bound flavocytochrome *b*<sub>558</sub>, in conjunction with certain cytosolic factors after activation, serves to transport an electron from NADPH to O<sub>2</sub>, resulting in O<sub>2</sub><sup>-</sup> (superoxide) formation (Fig. 8.3). Reactive oxygen intermediates including O<sub>2</sub><sup>-</sup>, H<sub>2</sub>O<sub>2</sub>, and OH are produced, resulting in intracellular microbial killing. These oxygen radicals can also result in auto-oxidation and damage to the granulocyte itself and the surrounding tissues. Granulocytes, however, have several scavenger systems—superoxide dismutase (SOD), catalase, and glutathione reductase—to protect themselves from the oxidative injury. An imbalance between free radicals and endogenous scavengers has been implicated in many harmful processes associated with infections (Baehner et al., 1972; Cooper et al., 1972), endothelial damage (McCord et al., 1994; Bratt and Gyllenhamer, 1995), autoimmune diseases (Lefkowitz et al., 1995), and reperfusion injury (Siminiak et al., 1995). Thus, exogenous scavengers such as β-carotene, *N*-acetylcysteine, and vitamins A, C, and E have been suggested to prevent these disorders (Boxer et al., 1979; Jain et al., 1994; Pejaver and Watson, 1994). In addition to oxygen radicals, nitric oxide (NO) production has also been implicated in the function of granulocytes (Larfars and Gyllenhamer, 1998). However, the biologic role of NO production in human macrophages has been questioned (Harvey, 2000). Mouse macrophages appear to kill intracellular organisms such as *Mycobacterium tuberculosis* with NO. In contrast, human macrophages do not appear to use this mechanism, but use

another unknown mechanism mediated by a toll-like receptor (Thoma-Uszynski et al., 2001).

### Degranulation

In addition to oxygen-dependent bactericidal activity, granulocytes undergo degranulation, which contributes to oxygen-independent bactericidal activity and modulation of tissue inflammation. Release of azurophilic granule contents such as myeloperoxidase, cationic protein, and acid hydrolases can potentiate the digestive and microbicidal activities of phagocytes, called *oxygen-independent cytotoxicity* (Spitznagel and Shafer, 1985). A cationic protein of approximately 55 kDa designated *bacterial/permeability-increasing protein* (BPI) contributes to killing of gram-negative bacteria but also binds to endotoxin, resulting in inhibition of inflammation (Froon et al., 1995). Secretion of secondary granules containing lysozyme (also found in azurophilic granules), collagenase, and lactoferrin also helps to regulate inflammation (Sandborg and Smolen, 1988; Yang and Hill, 1993). In addition, degranulation of tertiary granules is usually concomitantly associated with translocation of fresh receptors (CR1, CR3, fMLP, and laminin receptors), NADPH oxidase, and cytochrome *b*<sub>558</sub> into the plasma membrane (Borregaard and Tauber, 1984; Miller et al., 1987; Sandborg, and Smolen 1988; Bjerrum and Borregaard, 1989). Membrane translocation of these receptors modulates granulocyte adhesion, movement, phagocytosis, and respiratory burst activity. The mechanism by which granulocytes undergo degranulation is closely related to ionic mobilization, microfilament rearrangement (Boyles and Bainton, 1979), and microtubule assembly (Oliver and Berlin, 1983). Factors that can affect membrane perturbation, signal transduction, and metabolic activity regulate the degranulation process. On the other hand, self-protection and prevention of tissue damage from the destructive granular contents may also

result from antiprotease activities in the plasma and from protease inhibitors produced by other leukocytes (Kloczko et al., 1990; van de Winkel et al., 1990; Mohacsi et al., 1992; Allen and Tracy, 1995).

### Granulocyte Apoptosis

Granulocytes tend to have a short half-life in blood circulation. Granulocyte cell death is mediated by the paracrine interaction of the programmed death ligand Fas (FasL) with the death receptor Fas on the cell surface, leading to granulocyte apoptosis (Liles et al., 1996). Soluble FasL or cytokines that bind or regulate Fas expression on the cell surface may also cause granulocytes to either survive or undergo apoptosis (Villunger et al., 2000; see Chapter 24). Briefly, the granulocyte death program starts with ligand–receptor interaction, which is coupled to a signal cascade related to mitochondrial function. This is accompanied by cytochrome-*c* leakage, resulting in caspase-3 activation and irreversible nuclear condensation and DNA fragmentation (Susin et al., 1999). Promotion or inhibition of granulocyte apoptosis might be used as a potential strategy to modulate granulocyteopoiesis and treat infectious or inflammatory diseases in the future.

### Granulocyte Modulation of Inflammatory Reactions

There is also evidence that granulocytes have an important role in inflammatory and degenerative reactions resulting from tissue injury, tumor invasion, viral infection, autoimmune disorders, aging, and atherosclerosis. Enhancement of granulocyte adhesiveness to endothelium may result from thermal injury, hypoxia, bacterial sepsis, and immune complex disorders. Upon traumatic injury, platelets adhere and aggregate on the vascular endothelium and subsequently release chemotactic factors such as LTB<sub>4</sub>, transforming growth factor- $\beta$  (TGF- $\beta$ ), and platelet-derived growth factors. This results in a rapid recruitment of granulocytes and fibroblasts that have a central role in tissue inflammation and wound healing (De Gaetano et al., 1989; Tsjugi et al., 1994). Thermal injury, hypoxia, and bacterial sepsis may cause adult respiratory distress syndrome, which likely results from enhanced and sustained granulocyte adhesiveness and release of toxic granulocyte-derived mediators (Dale, 1975; McCord et al., 1994). Immune complexes, either alone or associated with complement activation, may also promote granulocyte influx, adhesiveness, respiratory burst activity, and degranulation, and contribute to vasculitis and autoimmune inflammatory reactions (Bratt and Gyllenhammer, 1995; Lefkowitz et al., 1995). Cationic proteins released during degranulation are also implicated in bactericidal and cellular cytotoxicity. Furthermore, granulocytes have been shown to have antiviral properties (Roberts et al., 1994) and to mediate antibody-dependent cellular cytotoxicity (ADCC) against tumors (Vaickus et al., 1990; Kushner and Cheung, 1991), especially in the presence of cytokines such as the interferons and GM-CSF. Defects or abnormal activation in any aspect of the above granulocyte responses may result in immunodeficiency diseases or serious inflammatory disorders.

### Activation and Function of Monocytes and Macrophages

Monocytes develop into tissue macrophages, possessing diverse morphology and functions dependent on environment and

immunologic factors. Mononuclear phagocytes, similar to polymorphonuclear granulocytes, can move toward foreign invaders and denatured tissues and destroy them by ingestion, degranulation, and respiratory burst activity. Upon maturation into macrophages, cells of the monocyte series show increases in size, adhesiveness, and functional receptors (e.g., CR1, CR3, FcRI, and FcRII), resulting in enhancement of phagocytosis (Johnston, 1988; Newman et al., 1991). Some evidence indicates that cells of the monocyte series have relatively low microbicidal activity in comparison to granulocytes (Mathy-Hartert et al., 1996). These macrophages lose their myeloperoxidase (MPO), which mediates a potent microbicidal activity by catalyzing halides into halous acid. Loss of MPO may be a differential milestone by which harmless contact between cells of the monocyte series and other immune cells occurs. Lectin-like receptors as well as receptors for lipoproteins are mainly found on macrophages but not monocytes (Nangia-Makker et al., 1993; Watanabe et al., 1994). Defects in the former receptors may impair nonimmunologically mediated reticuloendothelial clearance, while dysregulation of lipoprotein uptake by macrophages may give rise to atherosclerosis.

In addition to the professional function of phagocytosis, cells of the monocyte series have a central role in the modulation of inflammation and tissue repair (De Gaetano et al., 1989; Tsjugi et al., 1994). Upon activation, monocytes ingest particles, produce reactive oxygen molecules, release procoagulant factors, cytokines, and granules, and express adhesive molecules and Ia antigens. One of the most potent macrophage activators is IFN- $\gamma$ . Deficiency of IFN- $\gamma$  receptors or a defect in IFN- $\gamma$  production due to IL-12 or IL-12 receptor deficiency can compromise intracellular mycobacterial killing by macrophages (Altare et al., 1998; Jouanguy et al., 1999; see chapter 28). Procoagulant factors from monocytes or macrophages are involved in coagulation and homeostasis (Carson et al., 1991; Spillert and Lazaro, 1991). Granules from the monocyte series contain lysozymes, proteases, elastase, and collagenase that may augment tissue damage. In contrast, granules containing  $\alpha_1$ -protease inhibitor,  $\beta_2$ -macroglobulin, and IL-1 receptor antagonists from monocytes may provide a mechanism to protect tissues from damage (Kloczko et al., 1990; van de Winkel et al., 1990; Mohacsi et al., 1992; Allen and Tracy, 1995). Cytokines of the monocyte series act in an endocrine (affecting distant cells after bloodstream transportation), paracrine (affecting adjacent cells), and autocrine (affecting themselves) fashion. For instance, IL-1 can act in an endocrine fashion on the regulation of body temperature and sleep patterns in the hypothalamus. Paracrine cytokines of monocyte series include CSFs (GM-CSF, G-CSF, M-CSF, erythropoietin [EPO]), IL-12, TNF- $\alpha$ , and TGF- $\beta$ , which are all known to be involved in immune regulation (Chehimi and Trinchieri, 1994; Matsumoto, 1995). Some of the cytokines also act in an autocrine manner on cells of the monocyte series themselves. For example, ligation of M-CSF to its receptor (a *c-fms* proto-oncogene product) on monocytes induces monocyte differentiation, activation, and proliferation (Horiguchi et al., 1986). Furthermore, cells of the monocyte series are the only cell population in the phagocyte series to express both major histocompatibility complex (MHC) class I and class II antigens (Ia antigens). Antigens are taken up by the monocyte/macrophage series and processed via biochemical and physical reactions. Dendritic cells derived from monocytes or other lineage cells are particularly effective on the antigen presentation to T cells (Facchetti et al., 2002; Doni et al., 2003). They are termed *professional antigen-presenting cells* (Cao et al., 2000). The antigens are presented as

peptides associated with MHC molecules that lymphocyte antigen receptors recognize. Cells of the monocyte series bearing antigen/MHC class I complexes can be recognized and killed by cytotoxic T cells, whereas those bearing antigen/MHC class II molecules interact with helper T cells, resulting in clonal expansion of lymphocytes. Cytokines such as IL-2, IL-4, IL-5, IL-10, and IFN- $\gamma$  produced by lymphocytes may act in an autocrine or paracrine fashion to amplify or suppress proliferation of lymphocyte subpopulations. Eicosanoids such as prostaglandin E<sub>2</sub> (PGE<sub>2</sub>), cytokines (e.g., IL-12, TNF- $\alpha$ , TGF- $\beta$ ), and  $\beta_2$ -macroglobulin from the monocyte series also have immunomodulating functions (van de Winkel et al., 1990; Chu et al., 1991; Hayes et al., 1995; Raab et al., 1995). Dysregulation in the antigen-presenting process may cause immunodeficiency and autoimmune diseases. Abnormal regulation of osteoclast differentiation and activation in the bone marrow by osteoprotegerin (Simonet et al., 1997), TNF-related activation-induced cytokine (TRANCE) (Wang et al., 1999), receptor activator of NF $\kappa$ B ligand (RANKL) (Koga et al., 2004), and osteopodin (Ishijima et al., 2001) have been implicated in osteopetrosis and osteoporosis.

### Integration and Interaction of Phagocytes in Host Defense

There are two major pathways involved in host defense by leukocytes against exogenous microorganisms and endogenous debris or transformed tissues and cells (Fig. 8.4). In response to microbial invasion or tissue damage, granulocytes are attracted into areas by bacterial peptides, complement fragments such as C5a, or platelet-derived chemoattractants such as PAF and LTB<sub>4</sub>. Infiltration of granulocytes may result in clearance of microbes and tissue debris. If granulocytes fail to clear the infection or the tissue debris, activated granulocytes release monocyte chemotactic factors including fibronectin (Kreis et al., 1989) and monocyte

chemoattractant protein1 (MCP-1) (Wuyts et al., 1994), also called CC chemokine ligand-2 (CCL2), to attract monocytes (Doherty et al., 1990). Monocytes recruited into the area are able to release monokines such as IL-1, IL-10, IL-12, TGF- $\beta$  and TNF- $\alpha$  to enhance lymphocyte infiltration and present antigens to lymphocytes for specific lymphocyte transformation (Chehimi and Trinchieri, 1994; Hayes et al., 1995; Matsumoto, 1995). Monocytes and their derived dendritic cells bearing toll-like receptors (TLRs) are responsible for bacterial and viral recognition and signal transduction for a link between innate and adaptive lymphocyte differentiation and activation (Coccia et al., 2004; Kim et al., 2004; Netea et al., 2004). Lymphocyte differentiation and activation may result in a cell-mediated immune reaction (Th1 reaction) and/or T-dependent humoral reactions (Th2 reaction). Th1, Th2, and regulatory T cells (Treg) can regulate one another through a cytokine network in which Th1 cytokines IFN $\gamma$  and TNF $\beta$  promote cell-mediated immunity and suppress humoral immunity, Th2 cytokines IL-4 and IL-13 promote humoral immunity and suppress Th1 reaction, and Treg cytokines IL-10 and TGF $\beta$  regulate and terminate Th1 and Th2 reactions. Chemokines, including CC chemokine ligands (CCLs) and CXC chemokine ligand (CXCLs), from these specific immune reactions regulate phagocyte and lymphocyte functions (Fig. 8.4). The other phagocyte-mediated defense pathway is primarily mediated by resident macrophages in certain organs or in peritoneal and pleural spaces in which macrophages reside and circulate. In response to microbial invasion or endogenous and exogenous insults, resident macrophages release chemotactic factors such as CXCLs and CCLs to attract granulocytes and lymphocytes, respectively. Resident macrophages together with granulocytes act as scavengers to clear microbes or tissue debris; in addition, resident macrophages interact with lymphocytes to mediate specific lymphocyte transformation by which specific cell-mediated and humoral immune reactions are elicited and regulated (Fig. 8.4).

**Figure 8.4.** In the blood and interstitial tissues, neutrophils (N) act as the first line of host defense in clearance of exogenous organisms and endogenous debris through phagocytosis (via Fc receptors [FcR] and complement receptors [CR], etc.) and degranulation (elastase and defensin, etc.), and release monocyte chemotactic factors such as fibronectin (Fn) and CC chemokine ligands (CCLs) through which lymphocytes and antigen-presenting cells (APC) are attracted. The APC present antigen(s) to T cells, resulting in appropriate cellular (Th1), humoral (Th2), and regulatory T (T reg) cell reactions. Th1, Th2, and T reg cells can regulate one another through a cytokine network in which Th1 cytokines IFN $\gamma$  and

TNF $\beta$  can promote cellular immunity and suppress humoral immunity. Th2 cytokines IL-4 and IL-13 can promote humoral immunity and suppress Th1 reaction, and Treg cytokines IL-10 and TGF $\beta$  can regulate and terminate Th1 and Th2 reactions. In tissues or in the pleural and peritoneal spaces, dendritic cells, monocytes, resident macrophages (M $\Phi$ ), and APC play a central role in promotion of immune reaction via recognition of microorganisms and altered tissue antigens via receptors such as toll-like receptors (TLRs), and release chemoattractants such as CXC chemokine ligands (CXCLs) and CCLs to attract granulocytes and lymphocytes for both innate and adaptive immune responses.

## Granulocyte Function Disorders

### Historical Background

Kostmann (1956) first identified an autosomal recessive quantitative phagocyte disorder, congenital granulocytopenia. Patients with Kostmann disease (also called infantile agranulocytosis) usually develop severe, chronic, and eventually fatal bacterial infections early in life (see Chapter 39). Some cases may either be transmitted by an autosomal dominant trait or be sporadic. The first qualitative defect in phagocytes was identified later than Kostmann disease. This disorder, now called chronic granulomatous disease (CGD), frequently caused fatal infections in childhood (Bridges et al., 1959). It most frequently occurred in boys, suggesting an X-linked mode of inheritance (Carson et al., 1965; see Chapter 37). Quie and coworkers (1967) provided the first evidence of an inborn error of qualitative phagocyte function that resulted in CGD. These investigators discovered that granulocytes obtained from patients with CGD were able to ingest bacteria normally but unable to kill the ingested organisms. Of additional interest was the observation that granulocytes from the affected boys' mothers, presumed carriers in an X-linked disorder, were intermediate in their bactericidal capacity. Not only did these

observations establish the first intrinsic defect of phagocyte function, but the intermediate bactericidal defect in maternal granulocytes was consistent with the Lyon hypothesis. These results indicated that phagocyte bactericidal activity could be controlled by a specific gene, which is different from other phagocyte functions such as adhesion, movement, and ingestion. This suggested that other phagocyte defects might also be individually controlled by specific genes, contributing to recurrent infections.

Over the past 30 years, this hypothesis has been proven true. As shown in Table 8.1, an entire spectrum of phagocyte disorders involving adhesion, mobilization, respiratory burst activity, and degranulation defects has been recognized, and most are genetically determined. Serious phagocyte function defects such as the leukocyte adhesion disorders and CGD occur in approximately 2 in 100,000 people and represent one-fifth of the total congenital immunodeficiency patients. Other minor phagocyte defects such as myeloperoxidase (MPO) deficiency have a higher incidence of approximately 1 in 4000 to 1 in 2000 (Lehrer and Cline, 1969). As shown in Table 8.1, prenatal diagnoses, immunopharmacological correction, bone marrow or stem cell transplantation, and gene therapy may be available for certain phagocyte disorders, based on recent progress in the genetics, biochemistry, and physiology of phagocytes.

**Table 8.1.** Pathogenesis and Therapeutic Approaches of Phagocyte Function Disorders

<i>Disease</i>	<i>Inheritance (Chromosome No.)</i>	<i>Defect</i>	<i>Therapy</i>
Congenital granulocytopenia	AR, AD or XL	Differentiation arrest Mutation in G-CSF receptor; neutrophil elastase; WASP	G-CSF, GM-CSF/IL-3. BMT
Cyclic granulocytopenia	AD (19p13.3)	Mutation of neutrophil elastase	G-CSF
Isoimmune granulocytopenia	AR (1q13.4)	Maternal antibody to CD16	IVIg
Leukocyte adhesion defect (LAD1)	AR (21q22.3)	Deficiency of surface adhesion molecule (CD18) with delayed separation of umbilical cord, lack of pus formation	BMT Antibiotics Hygienic precautions
LAD2	AR (11q14.3–isaQ921)	Selecting binding ligands (SLx) defect in fucosylation	BMT Antibiotics Fucose (oral)
X-linked CGD	XL (Xp22.1)	Cytochrome b <sub>558</sub> heavy-chain gp91phox defect	Iconazole IFN- $\gamma$ , BMT Trimethoprim Sulfamethoxazole
Autosomal CGD	AR (1q25; 7q11.23; 16q24)	Cytosolic p67phox, p47phox and membrane p22phox defects	Trimethoprim Sulfamethoxazole IFN- $\gamma$ , Iconazole, BMT
Myeloperoxidase deficiency	AR (17q23.1)	Peroxidase deficiency	Fluconazole for candidiasis
Glutathione synthetase deficiency	AR (20q11.2)	NADPH regeneration defect, hemolysis and infections	Vitamin E
G6PD deficiency	XL (Xq28)	NADPH production defect in affected leukocytes	Symptomatic T <sub>x</sub>
Job syndrome (4q?) Hyper IgE syndrome	Sporadic or AD (4q?)	Staph abscesses, fungal infections, elevated IgE; defective PMN chemotaxis	IFN- $\gamma$ , prophylactic antibiotics, antifungal Vitamin C
Specific granule deficiency	AR	Recurrent infection with defects in chemotaxis and phagocytosis	Symptomatic T <sub>x</sub>
Actin dysfunction	AR	Recurrent infections with defects in chemotaxis and phagocytosis	Symptomatic T <sub>x</sub>
Chediak-Higashi syndrome	AR (1q42–43)	Mutation of <i>LYST</i> , partial albinism, giant granules in phagocytes and neurons	BMT
Griscelli syndrome	AR (15q211 both genes)	Myosin 5A deficiency RAB27A deficiency	BMT (for RAB27 deficiency)
IFN- $\gamma$ receptors, type 1; type 2	AR (6q23–24) AR (21q21–22)	Infections with BCG, atypical TB, salmonellosis	Antibiotics (anti-TB)

AD, autosomal dominant; AR, autosomal recessive; BCG, bacille Calmette-Guérin; BMT, bone marrow transplantation; CGD, chronic granulomatous disease; G6PD, glucose-6-phosphate dehydrogenase; gp 91, glycoprotein 91; IVIG, intravenous immunoglobulin; TB, tuberculosis; WASP, Wiskott-Aldrich syndrome protein; XL, X-chromosome linked.

## Quantitative Phagocyte Defects

A blood granulocyte level of less than 1500/mm<sup>3</sup> is defined as *granulocytopenia*. Granulocytopenia may result from a decrease in bone marrow production or an increase in peripheral destruction of granulocytes by autoantibodies or the reticuloendothelial system. Congenital granulocytopenias are due to a decrease in bone marrow production resulting from defects in growth and differentiation of granulocytes (Weetman and Boxer, 1980). Several kinds of primary quantitative phagocyte deficiencies have been identified. Genetic agranulocytosis (Kostmann syndrome) was first identified as an autosomal recessive disease by Kostmann (1956). A mutation of the G-CSF receptor has been proposed (Deshpande et al., 1999) or, more recently, mutations of neutrophil elastase (Dale et al., 2000; see Chapter 39). Reticular dysgenesis is due to failure of bone marrow production of blood stem cells, resulting in pancytopenia (De Vaal and Seynhaeve, 1959; Church and Schlegel, 1985). Shwachman syndrome is characterized by granulocytopenia, pancreatic insufficiency, and failure to thrive (Shwachman et al., 1964). This syndrome appears to be an autosomal recessive trait; its gene may be located on the long arm of chromosome 6 or 12, as patients with this syndrome may demonstrate t(6; 12) translocations (Masuno et al., 1995). Cyclic granulocytopenia occurs in cycles with periods of normal granulocyte counts of approximately 3 weeks followed by granulocytopenia, secondary to a failure of maturation, which lasts approximately 1 week (Weetman and Boxer, 1980). The disease can be transmitted in an autosomal dominant fashion with mutations of a gene that has been mapped to chromosome 19p13.3 and identified as neutrophil elastase (Dale et al., 2000; see Chapter 39). Other forms of neutropenia in infancy are due to autoantibody (Bux et al., 1998) or maternal isoantibodies directed against CD16 (De Haas et al., 1995). A point mutation within the Cdc42 binding domain of WASP (L270P) that interferes with the self-inhibition of WASP and results in constant activation of Arp2/3 and actin polymerization has recently been shown to cause X-linked congenital neutropenia (Devriendt et al., 2001, see Chapter 31). It appears that a variety of genes that regulate granulocyte growth and differentiation at different levels can affect production of mature granulocytes, although specific gene defects have not always been identified. Patients with congenital granulocytopenia frequently get recurrent infections including omphalitis, septicemia, and abscess formation early in life. Bone marrow transplantation from matched or a T cell-depleted haploidentical donor may be able to rescue these patients if the diagnosis is established early in life. Patients living into childhood with progressive periodontitis and recurrent infections may be given colony growth factors such as GM-CSF, G-CSF, or a

chimeric protein conjugating IL-3 with GM-CSF, which may benefit some patients. Transfusion of irradiated granulocytes may aid patients with overwhelming infections. In addition, early intervention with antibacterial and antifungal treatment and prophylaxis are important because patients with granulocytopenia are more susceptible to extracellular bacteria and fungi. To differentiate congenital granulocytopenia from acquired peripheral granulocyte destruction, bone marrow examination and anti-neutrophil antibody assessment is required (Yang and Hill, 1996).

## Qualitative Phagocyte Defects

Qualitative phagocyte function defects may be divided into defects involving adhesion, movement, respiratory burst-dependent bactericidal activity, and degranulation. Many intrinsic and extrinsic factors contribute to defects in phagocyte function at different stages, resulting in recurrent infections and delayed wound healing.

### Phagocyte adhesion deficiency

Three leukocyte adhesion disorders (LAD1, LAD2, and LAD3) have been identified (see Chapter 38). Most of the affected patients have LAD1 with deficiency of a family of surface glycoproteins, CD11/CD18. The CD11/CD18 family of glycoproteins share an identical  $\beta$  chain (CD18, gp 95 Kda) and separate  $\alpha$  chains—CD11a (gp 180 Kda), CD11b (gp 165 Kda), and CD11c (gp 150 Kda)—which contribute to promotion of leukocyte adhesion, cell migration, phagocytosis, antigen presentation, and ADCC (Crowley et al., 1980; Anderson et al., 1985; Schmalstieg, 1988). Patients with LAD1 frequently show delayed separation of the umbilical cord, perirectal cellulitis, and staphylococcal and gram-negative bacterial infections. Patients surviving infancy often have progressive periodontitis and gingivitis. The gene responsible for LAD1 codes for the synthesis of CD18 and has been mapped to 21q22.3 (Marlin et al., 1986). The clinical manifestations of LAD2 are similar to those seen in LAD1, except that LAD2 patients are severely mentally retarded and deficient in expression of sialyl Lewis X, a carbohydrate ligand for E-selectin on endothelial cells (Etzioni et al., 1993; Phillips et al., 1995). The molecular defect of LAD3 is presently unknown; affected patients have symptoms similar to those observed in LAD1; in addition, they have a bleeding tendency. CD18 is normal but activation of integrins is defective (Kinashi et al., 2004).

### Phagocyte movement (Chemotaxis) defects

Phagocyte mobilization involves an integrated ligand–receptor signal coupling response. Defects at different levels of the response can affect granulocyte locomotion and migration (Table 8.2),

**Table 8.2.** Categories of Granulocyte Chemotaxis Disorders

Category	Disease	Defect (Inheritance)
Ligand deficiencies	C5 dysfunction C5 degradation	Congenital or developmental group A or B streptococcal infections
Adhesion molecule defect	LAD1 LAD2 Localized periodontitis	CD18 deficiency (AR) Selectin binding ligand (AR) Adhesion molecule gp 108 (AD?)
Cytoskeleton assembly deficiency	Actin dysfunction	Retarded actin assembly (AR)
Membrane transportation defects	Chediak-Higashi syndrome Griscelli syndrome Oculocutaneous albinism	CHS protein ( <i>LYST</i> ) defect (AR) Myosin 5A defect (AR) Granule transportation defect
Extrinsic suppressing factors	Hyper-IgE syndrome IgA paraproteins	Defective chemotaxis (AD, sporadic) Myeloma protein

AD, autosomal dominant; AR, autosomal recessive; CHS protein; Chediack-Higashi syndrome protein; LAD; leukocyte adhesion defect.

which explains the extensive heterogeneity existing among these disorders. No single clinical or laboratory finding is consistently abnormal within this group of disorders. Patients with phagocyte chemotactic deficiency can be classified into five different categories based on defects at different levels.

*Defects at the ligand level.* Patients with congenital deficiency of complement components—C1, C4, C2, properdin, C3, and C5—may be unable to produce adequate amounts of C5a, resulting in a defect of chemotaxis (see Chapter 42). C5 functional deficiency has been reported in Leiner disease, which is characterized by seborrheic dermatitis, recurrent gram-negative bacterial infections, intractable diarrhea, and failure to thrive (Leiner, 1908). Patients with this syndrome are reported to have normal C5 levels, but C5 dysfunction associated with a humoral chemotactic and opsonic defect (Miller et al., 1970). The disease was described in two sequential infants in a family, and each died after an illness of several weeks, thus a genetic mechanism was proposed by Miller and Koblenzer (1972). The validity of these observations of C5 functional deficiency in patients with Leiner disease was challenged by the lack of a similar opsonic defect in patients with total absence of C5.

*Defects at the receptor level.* Granulocytes with adhesive-glycoprotein deficiencies as in CD18 (LAD1) or sialyl Lewis X (LAD2) deficiency are unable to adhere to endothelium or interstitial tissue (see Chapter 38) and as a consequence show poor chemotaxis in vivo and in vitro. Juvenile periodontitis usually occurs in adolescents who have impaired chemotaxis and localized periodontitis (Van Dyke et al., 1981; Van Dyke, 1985). Limited evidence suggests that this syndrome is due to a missing cell surface glycoprotein (gp110) (Van Dyke et al., 1987).

*Defects in mechanic organization.* Granulocyte cytoskeleton organization defect has been observed in patients with actin dysfunction syndrome (Boxer et al., 1974). One of the initial cases reported was subsequently diagnosed as leukocyte adhesion deficiency on the basis of intermediate levels of CD11b on neutrophils from surviving family members. Southwick et al. (1988) have shown that actin dysfunction is not usually present in leukocyte adhesion deficiency, but, in rare patients with this disorder, actin polymerization may be abnormal. This may reflect a link between cell surface integrins and the actin cytoskeleton (Southwick et al., 1989a, 1989b).

*Defects in receptor recycling.* Granulocytes with specific granule deficiency have been reported to have a chemotactic receptor recycling defect (Gallin et al., 1982). Granulocytes from patients with the Chediak-Higashi syndrome (see Chapter 40) have a chemotactic defect due to altered microtubular assembly and abnormal signal transduction (Oliver, 1978). This disease is transmitted by autosomal recessive inheritance; the defective gene is likely located on chromosome 1q42–q41 (Fukai et al., 1996). Another granule transport defect called Griscelli syndrome (Chapter 41), which includes albinism and granulocytopenia, is due to a myosin defect, encoded in chromosome 15q21, resulting in an abnormality of granule transport (Pastural et al., 2000).

*Defects due to extrinsic suppressive or lack of enhancing factors.* Many extrinsic suppressive factors such as immune complexes (Hanlon et al., 1980), steroids, and IgA paraproteins (Miller, 1975) can interfere with phagocyte chemotaxis. The hyper-IgE syndrome (Job syndrome, see Chapter 34), which has been asso-

ciated with a granulocyte chemotaxis defect, is characterized by high levels of IgE, altered T cell activity (Geha et al., 1981), or release of allergic mediators (Hill, 1980). Alternatively, the increased concentration of IgE and defective neutrophil chemotaxis may result from abnormal IFN- $\gamma$  production in response to patients' main pathogens, *Staphylococcus aureus* and *Candida albicans* (Borges et al., 2000). This disorder has been shown to be an autosomal dominant trait in certain families with incomplete penetrance (van Scoy et al., 1975; Hill et al., 1997), although most of the patients showed sporadic occurrence (Jacobs and Norman, 1977). In a subgroup of patients with hyper-IgE syndrome, the gene was mapped to chromosome 4q (Grimbacher et al., 1999). The disease has also been reported in association with osteogenesis imperfecta (Brestel et al., 1982; Hill, 1982).

*Treatment of chemotactic disorders.* Patients with chemotactic disorders, like those with other phagocyte defects, frequently suffer recurrent cutaneous abscesses, mucocutaneous candidiasis, pneumonia, and otitis media. These disorders could be assessed with an in vivo Rebuck skin window test (Rebuck and Crowley, 1955) or by in vitro Boyden chamber chemotaxis (Hill, 1980). Although complete correction of granulocyte chemotactic defects is not possible, partial correction for certain patients has been achieved, as shown in Table 8.1. C5 dysfunction may be corrected by replacement with fresh plasma that contains normal C5. Vitamin C has been shown to enhance chemotaxis of granulocytes obtained from patients with Chediak-Higashi syndrome (Boxer et al., 1976). Studies from our laboratory have shown that IFN- $\gamma$  can enhance in vitro chemotaxis of granulocytes obtained from patients with hyper-IgE syndrome (Jeppson et al., 1991; Petrak et al., 1994). For palliative treatment, histamine ( $H_2$ ) antagonists have been reported to reduce the frequency of infection in patients with hyper-IgE syndrome (Thompson, 1988). High doses of vitamin C or E have also been reported to be beneficial in some patients. Prophylactic antimicrobial therapy with trimethoprim sulfamethoxazole or dicloxacillin is also often useful in decreasing the incidence of infections in many of these patients.

#### Disorders of phagocytic uptake

Primary defects in phagocytic uptake are rare; most are secondary to infections, drugs, or systemic disease. Patients with leukocyte adhesion deficiency show defects in particulate-mediated phagocytosis (Anderson et al., 1985). Another disorder resulting in phagocytic uptake deficiency is actin dysfunction syndrome. Granulocytes from a patient with actin dysfunction failed to polymerize actin, resulting in phagocytic defects (Boxer et al., 1974; Southwick et al., 1988). To differentiate an intrinsic phagocytic defect from secondary defects, one should cross over autologous and heterologous serum with the patient's and a control's granulocytes in a phagocytosis assay. Employing fluorescein (FITC)-labeled techniques, phagocytosis can be simply assessed with a flow cytometer (Yang and Hill, 1996). Studies of normal granulocytes demonstrated that several cytokines and glycoproteins enhance motility and phagocytic uptake (Gresham et al., 1986; Yang et al., 1988; Salyer et al., 1990). Such cytokines and glycoproteins may be candidates for the treatment of these phagocytic disorders. Patients with phagocytic defects due to opsonic deficiencies in antibody, complement, or fibronectin may be treated by infusion with the deficient component. For those with transient cytokine (e.g., IFN- $\gamma$ ) deficiency, treatment with a recombinant cytokine may reverse the immune dysfunction (Jeppson et al., 1991; Petrak et al., 1994; Wallis and Ellner, 1994).

### Disorders of granulocyte respiratory burst activity

Granulocytes with defects in respiratory burst activity usually have normal or increased adhesion, chemotaxis, and phagocytic uptake but abnormal intracellular microbicidal activity. These disorders include CGD, glucose-6-phosphate dehydrogenase (G6PD) deficiency, MPO deficiency, and glutathione synthetase deficiency. Defects involving any component of the oxidase system seen in patients with CGD as well as defects associated with the generation of the cofactor for NADPH activation, seen in severe leukocyte G6PD deficiency, or impaired NADPH regeneration, seen in glutathione synthetase deficiency, may result in a deficiency in oxygen-dependent microbicidal activity. Chapter 37 of this text is devoted to chronic granulomatous disease. The gene coding for cytochrome  $b_{558}$  heavy-chain gp91phox (*CYBB*) is located on the short arm of the X chromosome whereas the gene coding for cytochrome  $b_{558}$  light-chain gp22phox (*CYBA*) is located on chromosome 16. Studies indicate that superoxide production requires the participation of both membrane-bound NADPH oxidase and cytosolic factors (Borregaard and Tauber, 1984). The genes coding for the cytosolic factors p47phox (*NCF1*) and p67phox (*NCF2*) are located on chromosomes 7 and 1, respectively (Smith and Curnutte, 1991). Severe forms of G6PD deficiency may present with a CGD-like clinical picture. Cooper et al. (1972) described a 52-year-old Caucasian female with hemolytic anemia, a leukemoid reaction, and fatal *Escherichia coli* sepsis whose leukocytes could not kill *Staphylococcus aureus*, *E. coli*, or *Serratia marcescens* but could kill  $H_2O_2$ -producing *Streptococcus faecalis*. Intraleukocyte reduction of nitroblue tetrazolium (NBT) dye did not occur, nor was  $H_2O_2$  generated and the hexose monophosphate shunt stimulated. There was complete absence of leukocyte G6PD in the patient. Subsequently, Gray and colleagues (1973) reported three male siblings with a syndrome of chronic nonspherocytic hemolytic anemia and neutrophil dysfunction. Each had strikingly elevated reticulocyte counts, less than 1% NBT dye reduction under conditions in which 90% of control neutrophils reduced the dye, and undetectable concentrations of erythrocyte and leukocyte G6PD activity. The oldest boy had 13 episodes of right- or left-sided cervical lymphadenitis associated with mild anemia, slight jaundice, and low-grade fever before 10 years of age. Cultures were either negative or revealed coagulase-positive *S. aureus*. The second male sibling had neonatal jaundice for 6 weeks and several episodes of anemia and jaundice associated with upper respiratory tract infections; he also suffered two episodes of erythema nodosum and one episode of cervical lymphadenitis. The third sibling had neonatal jaundice but had no hemolytic episodes or increased susceptibility to infection. The parents were both healthy, but the mother had persistently elevated reticulocyte counts and 60%–70% of control values for erythrocyte and leukocyte G6PD. Profound deficiency of G6PD leads to a defect in NADPH production, causing impaired respiratory burst activity. The gene coding for G6PD is located on the X chromosome and has a widely variant polymorphism in different populations in the world. Studies in blacks and Caucasians have shown that Caucasians with G6PD deficiency more frequently have affected leukocytes (Ramot et al., 1959; Cooper et al., 1972; Gray et al., 1973; Owusu, 1973). The G6PD enzyme in leukocytes is encoded by the same gene as those in erythrocyte precursors and other tissues. G6PD activity in leukocytes is usually higher than in erythrocytes, so patients with G6PD deficiency-mediated hemolytic anemia usually have normal leukocyte function. Only when leukocytes have less than 5% of

normal G6PD activity does abnormal bactericidal activity appear (Baehner et al., 1972). There may be other unknown factors in leukocytes from different races, which could affect G6PD activities, since patients with G6PD deficiency associated with CGD-like syndrome have been reported in Caucasians but not in blacks or Asians.

Glutathione levels are modulated by NADPH, glutathione reductase, and glutathione synthetase (Fig. 8.3). Granulocytes with glutathione reductase or glutathione synthetase deficiency show normal early respiratory burst activity. However, the continuous production of toxic oxygen products, which are normally handled by glutathione, results in auto-oxidative damage and defective microbicidal activity (Mohler et al., 1970; Jain et al., 1994). Both glutathione reductase and glutathione synthetase deficiencies are transmitted by autosomal recessive inheritance. Patients with glutathione reductase deficiency may have hemolytic crises but have normal phagocyte bactericidal activity, although the granulocyte respiratory burst activity stops abruptly within a few minutes of phagocytosis of bacteria. In contrast, patients with glutathione synthetase deficiency show abnormal bactericidal activity in addition to hemolysis of erythrocytes. Granulocytes with MPO deficiency have normal production of superoxide but defective generation of hypochlorite ion. Patients with this disorder are not uncommon (1 in 2000 to 1 in 4000 of the general population) but are frequently asymptomatic or at most have delayed granulocyte killing activity and recurrent candida infections (Parry et al., 1981). The MPO gene has been cloned and located on chromosome 17 (Weil et al., 1987).

The cellular and molecular bases of disorders related to oxidative microbicidal activity have been extensively explored and pharmacological approaches to treat such patients have been tried for three decades. Most of these therapies have been unsuccessful or controversial (Gonzalez and Hill, 1988). Recent studies have shown, however, that recombinant IFN- $\gamma$  in a low dose (50  $\mu\text{g}/\text{m}^2$ ) given subcutaneously three times a week significantly reduces serious infections in patients with CGD (Ezekowitz et al., 1988; Sechler et al., 1988; International Chronic Granulomatous Disease Cooperative Study Group, 1991; Weening et al., 1995). Bone marrow transplantation in CGD patients has been reported to result in long-term chimeric engraftment with improvement in infectious complication (Kamani et al., 1988; Horwitz et al., 2001; Seger et al., 2002; Del Giudice et al., 2003). Identification of the genes responsible for both X-linked and autosomal recessive forms of CGD (Dinauer et al., 1987; Teahan et al., 1987) makes gene therapy for patients with CGD a future possibility (Zentilin et al., 1996). Indeed, during the 2004 European Society for Immunodeficiencies meeting in Versailles, successful gene therapy of two CGD patients with mutations of gp91phox was reported by a German–Swiss consortium. (Ott, et al., 2004). Glutathione synthetase deficiency can be partially corrected by administration of vitamin E (Boxer et al., 1979). Patients with MPO deficiency are usually asymptomatic; however, for those developing chronic candidiasis, ketoconazole or fluconazole are indicated (Table 8.1). Some very preliminary in vitro and in vivo studies suggest that IFN- $\gamma$  may have some benefit in the treatment of hyper-IgE syndrome (Jeppson et al., 1991; Petrak et al., 1994).

### Disorders of granulocyte degranulation

*Specific granule deficiency.* Oxygen-independent microbicidal defects can arise from absence of granules or from defective degranulation. Several patients lacking specific granules have been described. Studies of granule-deficient granulocytes show

impaired bactericidal activity in addition to impaired chemotaxis (Gallin et al., 1982). The reason for granulocyte dysfunction in these patients is the failure of granule constituents to fuse into the phagosome, resulting in a decrease in oxygen-independent bactericidal activity and a decrease in expression of adhesion molecules and chemotactic receptors on the cell surface. Although it appears that patients with specific granule deficiency have an autosomal recessive inheritance, the gene responsible for the disorder has not yet been identified. Heterozygous siblings or parents are usually healthy and have normal phagocyte function. The diagnosis of granule deficiency is primarily based on the family history and clinical manifestations as well as the granulocyte morphology with an absence of specific granules (Gallin et al., 1982). Furthermore, granulocytes from patients with specific granule deficiency do not release certain constituents from specific granules and show a defect in membrane recycling of adhesion molecules and chemotactic receptors. The constituents inside specific granules such as transferrin and vitamin B12 binding protein can be detected by enzyme-linked immunosorbent assay (ELISA) and radioimmunoassay (RIA), respectively (Yang and Hill, 1996).

*Granule-transporting defect.* Chediak-Higashi syndrome, a granule-releasing deficiency disorder and its murine equivalent, the beige mouse, have in common a defect affecting all granule-containing cells such as melanocytes, neurons, and granulocytes (Blume and Wolff, 1972; Fukai et al., 1996). This syndrome, transmitted by autosomal recessive inheritance, is characterized by partial albinism, granulocytopenia, neurologic deficits, recurrent infections, and neoplastic transformation, especially lymphomas (see Chapter 40). The gene for the Chediak-Higashi syndrome (*LYST* or *CHSI*) has been identified and relevant mutations have been recognized (Barbosa et al., 1996; Nagle et al., 1996; Introne et al., 1999). The diagnosis of Chediak-Higashi is based on the characteristic clinical features and the laboratory findings of altered membrane fusion associated with giant azurophilic granules, defective chemotaxis, degranulation, and bactericidal activity of granulocytes (Boxer et al., 1976). Bactericidal defects in Chediak-Higashi syndrome have been reported to improve after administration of large doses of vitamin C. This may reduce the intracellular cyclic adenosine monophosphate (cAMP) level, resulting in improvement of chemotaxis and bactericidal activity (Boxer et al., 1976). Administration of G-CSF can partially correct Chediak-Higashi syndrome-associated granulocytopenia, chemotaxis, and phagocytosis in an animal model (Colgan et al., 1992). Bone marrow transplantation is the only option for curing patients with this syndrome (Vossen, 1988). Another form of granule transportation defect, Griscelli syndrome, characterized by albinism, granulocytopenia (see Chapter 41), and infections, is due to Myosin 5A or RAB27A deficiency (Pastural et al., 2000; Sanal et al., 2002).

#### Monocyte and macrophage function disorders

Monocytes and macrophages share the same ancestors with granulocytes, so most of the defects present in granulocyte function disorders occur in monocytes and macrophages, including the leukocyte adhesion disorders, phagocyte actin dysfunction, respiratory burst defects such as CGD, degranulation defects such as Chediak-Higashi syndrome, and specific granule deficiency. Primary macrophage function defects are relatively rare, as most of the macrophage function defects are secondary. Monocyte and macrophage function can be compromised by environmental agents, drugs, infections, and metabolic disorders,

resulting in immunodeficiency. For instance, smoke particles, asbestos, silica, hyperbaric oxygen, and air pollution can impair monocyte and macrophage function. In addition, monocytes and macrophages can be seriously impaired in patients with AIDS. Differential induction of cytokine profiles may contribute to resistance or susceptibility of macrophages to infection with intracellular organisms (Wallis and Eliner, 1994). Monokine enhancement of HIV infections and compromise of the antigen presentation by monocytes have been implicated in patients with both AIDS and tuberculosis. Monocytes obtained from patients with chronic mucocutaneous candidiasis may have impaired chemotactic activity (Snyderman et al., 1973), and monocytes obtained from a patient with common variable immunodeficiency were shown to have impaired antigen presentation to T cells (Eibl et al., 1982). Currently, four primary macrophage function defects have been identified: osteopetrosis, toll-like receptor signaling deficiency, IFN- $\gamma$  receptor deficiency, and familial lysosomal storage diseases.

*Osteopetrosis.* This heterogeneous hereditary disorder, due to dysfunction of osteoclasts (specialized macrophages), is the result of enhanced resorption of mineralized cartilage and bony remodeling (Reeves et al., 1979). This syndrome is commonly seen in offspring from consanguineous parents, which suggests an autosomal recessive trait (Sobacchi et al., 2001). Some cases are reported to be mediated by an autosomal dominant trait, especially those found in the adult type of osteopetrosis (Grodum et al., 1995; Felix et al., 1996; Frattini et al., 2003). Some of the genes responsible for osteopetrosis have been identified (Sobacchi et al., 2001; Frattini et al., 2003). Heterozygous carriers have completely normal immune function, so carrier detection is not currently available, except for those with a known gene defect. Abnormal encroachment of sclerotic bone can compromise nerve foramen and bone marrow spaces, resulting in neurologic and hematopoietic defects. Prenatal diagnosis by fetal sonography may be made through recognition of sclerotic, dense, and radiopaque bones (Sen et al., 1995). Patients with osteopetrosis are usually characterized by a generalized increase in bone density, failure to thrive, hypocalcemia with low serum phosphate due to impaired bony resorption, and a variable degree of anemia, thrombocytopenia, and leukopenia. Although monocytes from osteopetrosis patients show normal or minimally impaired phagocyte function, bone marrow transplantation can rapidly reverse abnormal osteosclerotic changes and reconstitute immune function. This finding suggests that a selective macrophage (osteoclast) defect may be present in this disease (Reeves et al., 1979; Taylor et al., 1995; Felix et al., 1996; Sobacchi et al., 2001; Frattini et al., 2003).

*Toll-like receptor signaling deficiency.* There are at least 10 TLRs identified on monocytes and dendritic cells (Hornung et al., 2002; Doni et al., 2003; Coccia et al., 2004). Different TLRs can recognize different microorganisms and mediate signals for innate host defenses and adaptive T cell differentiation (Doni et al., 2003; Coccia et al., 2004; Netea et al., 2004). As a result, patients with defects in different TLRs may be susceptible to certain infections. Recently, a primary defect in TLR signaling has been reported that results in recurrent pneumococcal infections (Currie et al., 2004). Mutations in the interleukin receptor-associated kinase (IRAK-4) have been associated with pyogenic gram-positive bacterial infections and failure to sustain antibody responses (Picard et al., 2003; Day et al., 2004). The infections began early in life but became less frequent and milder with age.

**Interferon gamma receptor deficiency.** Two components of the IFN- $\gamma$  receptor have been identified; they map to C6q23–q24 and C21q21–q22, respectively (Newport et al., 1996; Dorman et al., 1998). IFN- $\gamma$  receptor deficiencies are autosomal recessive diseases that result in a defect in TNF- $\gamma$  production and defective intracellular bactericidal activity. As a consequence, patients suffer disseminated atypical mycobacterial infections and salmonellosis (Jouanguy et al., 1999; Casanova and Abel, 2002). The disorders cannot be differentiated clinically from those with IL-12 or IL-12 receptor deficiencies (Altare et al., 1998), since IL-12 and IFN- $\gamma$  are the major cytokines mediating intracellular bactericidal activity in macrophages (see Chapter 28).

**Lysosomal storage diseases.** Although macrophages may not be the only cell involved, accumulation of lipids or polysaccharides in macrophages may lead to the formation of foam cells and result in defective catabolic function. The fact that several storage diseases such as Gaucher disease, Fabry disease, and Hurler syndrome have been successfully treated by bone marrow transplantation (O'Reilly et al., 1984; Imaizumi, 1995; Krivit et al., 1995) further supports the concept that macrophage catabolic defects play a critical role in the pathogenesis of these diseases. The diagnosis of patients with lysosomal enzyme deficiency–associated lipidoses and mucopolysaccharidoses is usually based on clinical features showing characteristic dysmorphisms including those of the face, chest, and extremities as well as mental retardation and hepatosplenomegaly. The presence of urinary mucopolysaccharides is sometimes characteristic. A definitive diagnosis should be based on specific enzyme assays employing cultured fibroblasts or leukocytes. Heterozygous carriers in some of these storage diseases can be detected by showing one-half the amount of the normal lysosomal enzyme activity in cultured fibroblasts or leukocytes.

Most of the primary macrophage function defects can be effectively treated by bone marrow transplantation, which provides normally functioning macrophages. In some diseases, exogenous replacement with the normal enzyme may be useful. For instance, Hurler syndrome is associated with deficiency of iduronidase and can be partially corrected by replacement with the enzyme. In an animal study, Takahashi et al. (1994) showed that mutant mice with osteopetrosis lacked functional M-CSF activity; exogenous M-CSF could partially correct the defect. The M-CSF gene is mapped to C1p21 in human beings, but is apparently not the disease-causing gene in patients with osteopetrosis (Van Hul et al., 1997). Whether correction of cytokine or stromal cell factor defects in the bone marrow can reverse specific macrophage function defects remains to be determined.

## Prevention and Treatment of Phagocyte Function Disorders

### Primary Prevention

As demonstrated in Table 8.1, most of the phagocyte function disorders exhibit X-linked or autosomal recessive inheritance. Primary prevention for X-linked and autosomal recessive disorders is based on carrier detection (McCabe et al., 1989). Phagocyte disorders for which carrier detection is currently available include CGD (Newburger et al., 1979; Chapter 37), IL-12 receptor  $\beta$ 1 deficiency (Chapter 28), leukocyte adhesion dysfunction (Chapter 38), and Wiskott-Aldrich syndrome (Chapter 31). Heterozygotes that carry a defective lysosomal enzyme gene encoding for macrophage storage disease can be detected by quantitating enzyme activity in cultured fibroblasts and leukocytes.

### Prenatal Diagnosis

Early diagnosis of phagocyte function disorders can be made employing prenatal chromosome analysis, restriction fragment length polymorphism (RFLP), biochemical analysis, gene product determination, and phagocyte function assays. Chorionic villus sampling at 9–10 weeks of gestational age and fetal blood sampling at 16–20 weeks of gestational age (Perignon et al., 1987; Lau and Levinsky, 1988; Villa et al., 2000) can be carried out. Employing the NBT dye reduction test, CGD can be diagnosed prenatally at approximately 16–20 weeks of gestational age (Newburger et al., 1979). The polymerase chain reaction (PCR) may require only a tiny skin sample or amniotic fluid containing 10 to 100 cells and may replace chorion or fetal cord blood sampling for prenatal diagnosis, thereby resulting in lower risk to the pregnancy. Prenatal diagnosis of X-linked CGD by identification of the polymorphism (CA/GT) $_n$  repeats in gp91phox gene can be achieved in hours (Gorlin, 1998). If the mutation in a given CGD family is known, the analysis of fetal DNA can identify the status of the fetus. Patients with Chediak-Higashi syndrome have giant lysosomal granules in phagocytes and skin melanocytes. The characteristic morphology of these granules can be used to detect the syndrome in fetal cord blood samples at 18–20 weeks of gestational age. Similarly, fetal cord blood sampling may provide the diagnosis of disease or carrier detection in the leukocyte adhesion deficiency disorders as well as the IL-12 receptor  $\beta$ 1 deficiency. Cord blood leukocytes or amniotic cells can be cultured to detect metabolic storage diseases by measuring suspected lysosomal enzyme activity. Prenatally detected phagocyte function disorders may be managed by termination of pregnancy or by early bone marrow or stem cell transplantation (see Chapter 47).

### Management of Disease Complications

Patients with phagocyte function disorders should receive psychosocial and rehabilitative support. Appropriate administration of antibiotic prophylaxis, chest physiotherapy, and surgical drainage may decrease sequelae. Regular visits to a dentist familiar with the problems suffered by patients with phagocyte function disorders are essential, especially for leukocyte adhesion deficiency. Patients with phagocyte abnormalities who suffer from recurrent infections starting in infancy usually develop psychologic problems secondary to physical changes (skin scarring, coarse face, hearing loss, dental decay, and/or pulmonary dysfunction), loss of schooling, or the recurring need for hospitalization or intravenous antimicrobial therapy. Progress in bone marrow and stem cell transplantation and gene therapy will have a major impact on the long-term prognosis in these patients by providing techniques to permanently correct these disorders in the future.

## X-Linked Severe Combined Immunodeficiency

JENNIFER M. PUCK

Severe combined immunodeficiency (SCID) comprises a collection of genetic defects that involve both humoral and cellular immunity. A profound lack of immune function leads to infections that are generally fatal in infancy unless the immune system can be reconstituted. X-linked SCID (XSCID, SCIDX1, MIM #300400) is caused by defects in *IL2RG* (MIM \*308380), the gene encoding the interleukin-2 (IL-2) receptor  $\gamma$  chain (Online Mendelian Inheritance in Man [OMIM], 2000), also known as the common  $\gamma$  chain. XSCID is the most frequent genetic form of SCID. Its incidence is unknown, although it has been estimated to occur in at least 1 per 100,000 births. Males, who have a single X chromosome, are affected with XSCID. Female carriers, who have a mutated copy of the gene on one of their two X chromosomes and a normal copy on the other, remain healthy. However, carrier females can pass on the disease to their male offspring and the carrier state to their female offspring. XSCID appears to occur equally in all ethnic groups.

Both a striking male predominance of SCID in all published series and recognition of pedigrees with multiple affected males related through maternal lineages first suggested that XSCID would turn out to be the major form of SCID. When the XSCID genetic locus in Xq13.1 was identified so that mutation diagnosis could be performed, this prediction was directly confirmed (Buckley et al., 1997; Puck et al., 1997b). XSCID accounts for approximately half of all cases of SCID, although there is perhaps a larger proportion in the United States than in European populations (Buckley et al., 1997; Antoine et al., 2003; Buckley, 2004).

### History and Variety of Genetic Forms

The first descriptions of a fatal congenital deficiency of lymphocytes date from the 1950s in Switzerland. Glanzmann and Riniker

(1950) described an idiopathic lymphocyte wasting syndrome with fatal *Candida albicans* infection. Following the discovery of agammaglobulinemia by Bruton (1952), Hitzig and Willi (1961) reported familial alymphocytosis combined with agammaglobulinemia that had a fatal outcome in infancy. No distinction between recessive and X-linked inheritance patterns was made in these early reports. The term “Swiss-type agammaglobulinemia,” originally used to distinguish infants with fungal infections, lymphopenia, and early death, from less severely affected children with agammaglobulinemia alone, has been a source of confusion, in part because the “Swiss-type” label was subsequently applied to patients in kindreds in which SCID was X-linked. With improved immunological tools to characterize immune defects plus the ongoing identification of additional genes associated with specific forms of many immunodeficiencies, disease designations have become more precise.

Failure to recognize immunodeficiency as the underlying cause of recurrent diarrhea, pneumonia, septicemia, fungal infections, or failure to thrive is evident in family histories of many large kindreds in which several generations of male infants have died. Often in the past, these patients were mistakenly diagnosed as having dietary intolerances or cystic fibrosis because of diarrhea, poor weight gain, and pulmonary infections. Some were given diagnoses such as scarlet fever (from the rash of spontaneous graft vs. host disease [GVHD] from maternally derived lymphocytes) or diphtheria (when thrush extending down the throat was thought to represent a diphtheritic membrane). Even today, SCID is frequently not suspected upon presentation to primary physicians or even referral centers. In countries where newborns are routinely vaccinated against tuberculosis with the live attenuated mycobacterial organism bacillus Calmette-Guérin (BCG), infants with SCID may develop fatal, disseminated BCG infection. For these reasons, pediatric immunologists believe that the true

incidence of SCID is greater than the 1 per 100,000 estimate based on diagnosed cases.

Prior to 1968, patients with XSCID almost always died within the first year of life. However, the achievement of immune reconstitution following bone marrow transplantation (BMT) from a human leukocyte antigen (HLA)-identical sibling marked the beginning of successful treatment (Gatti et al., 1968). The unavailability of histocompatible donors for the majority of XSCID patients led to the use of isolation in a germ-free environment for David, the Bubble Boy, a famous Texas patient who came to represent SCID to the general public. Although David succumbed to complications of Epstein-Barr virus (EBV) lymphoproliferation after a BMT at age 12 from a sibling (Shearer et al., 1985), the technique of T cell-depleted haploidentical BMT has now been successfully adopted for treatment of infants with XSCID (see Chapter 47). Early diagnosis, better antibiotics, and intensive supportive care have also contributed to the evolution of XSCID from a fatal to a treatable disease. Currently it is estimated that over 80%–90% of infants with XSCID can be saved by transplantation treatment (Antoine et al., 2003; Buckley, 2004).

Table 9.1 summarizes currently known SCID genotypes and cellular phenotypes and gives a rough breakdown of the relative percentage of cases caused by defects in each gene. Enumeration of T and B lymphocytes and, more recently, natural killer (NK) cells has provided useful correlations of lymphocyte phenotype with genotype. While all patients with SCID have very few T cells, over half have detectable or even increased numbers of B cells that are nonfunctional (T-B<sup>+</sup> SCID) (Stephan et al., 1993; Buckley et al., 1997). Most of these patients are males, but from

the existence of females with T-B<sup>+</sup> SCID it is clear that both autosomal recessive and X-linked gene defects can produce this phenotype. T-B<sup>+</sup> SCID is now associated with defects in any of several genes, including *JAK3*, encoding the signaling kinase that interacts intracellularly with the common  $\gamma$  chain; *IL7R*, encoding the  $\alpha$  chain of the receptor for IL-7 (both discussed in Chapter 10); *CD45*, encoding the cell surface coreceptor CD45 (Chapter 13); the p51 tyrosine kinase *lck* gene (Chapter 14); and *TCRD*, encoding the  $\delta$  chain of the CD3 complex (Chapter 16). In addition, humans with defects in the *FOXN1* transcription factor that is defective in athymic nude mice have autosomal recessive T-B<sup>+</sup> SCID in addition to alopecia totalis (Frank et al., 1999). While most patients with T-B<sup>+</sup> SCID lack NK cells, those with *IL7R* mutations and other defects specifically related to signaling through the T cell receptor generally have intact NK cell development (Table 9.1).

Patients with no T or B cells (T-B<sup>-</sup> SCID) have a more even ratio of males to females, a pattern suggesting autosomal recessive inheritance. Autosomal recessive T-B<sup>-</sup> SCID can be caused by complete deficiency of adenosine deaminase (Chapter 12) and also by defects in the proteins involved in the DNA rearrangement of T cell and B cell receptor genes (Chapter 11). Despite rapid progress in new SCID gene discovery in the past decade, documented in Table 9.1, there are still SCID patients whose molecular diagnosis remains unknown, and many additional SCID gene defects are likely to be found.

The discovery of the XSCID disease gene, *IL2RG* (Noguchi et al., 1993b; Puck et al., 1993b), has led to increased appreciation of the immunologic characteristics of this form of SCID,

**Table 9.1.** Genotypes Associated with Severe Combined Immunodeficiency

Gene Defect	Molecular Pathogenesis	Percent of SCID Cases*	Characteristic Lymphocyte Subpopulations		
			T Cells <sup>†</sup>	B Cells	Natural Killer Cells
<i>IL2RG</i> (X-linked)	Failure of signaling through common $\gamma$ chain receptors for cytokines IL-2, -4, -7, -9, -15, -21 (Chapter 9)	46%	Low/absent	Present	Absent
<i>ADA</i>	Adenosine deaminase deficiency (Chapter 12)	16%	Low/absent	Absent	Absent
<i>IL7R</i>	Failure of signaling through IL-7 receptor (Chapter 10)	9%	Low/absent	Present	Present
<i>JAK3</i>	Failure of Janus kinase 3 activation by common $\gamma$ chain (Chapter 10)	6%	Low/absent	Present	Absent
<i>RAG1</i>	Failure of T and B cell antigen receptor rearrangement (Chapter 11)	<2%	Absent	Absent	Present
<i>RAG2</i>	Failure of T and B cell antigen receptor rearrangement (Chapter 11)	<2%	Absent	Absent	Present
<i>DCLRE1C</i>	Failure of T and B cell antigen receptor rearrangement (Chapter 11)	<5%	Absent	Absent	Present
<i>CD45</i>	Lack of cell surface protein tyrosine phosphatase receptor, PTPRC, required for T and B cell activation by antigen (Chapter 13)	Rare	Low/absent	Present	Low, maybe variable
<i>TCRD</i>	CD3 $\delta$ deficiency with lack of T cell development (Chapter 16)	Very rare	Low/absent	Present	Present
<i>LCK</i>	Lack of lymphocyte tyrosine kinase p56lck, required for T cell development and activation (Chapter 14)	Very rare	Low/absent	Present	Present
<i>FOXN1</i>	Lack of forkhead box N1 transcription factor, required for thymus and hair follicle development (ortholog of nude mouse) (Frank et al., 1999)	Very rare	Low/absent	Present	Present
<i>RMRP</i>	Lack of RNA component of mitochondrial RNA-processing endoribonuclease, causing cartilage-hair hypoplasia (CHH); variable immunodeficiency, in some cases severe (Chapter 36)	Very rare	Low/very low	Present	Maybe low
Complete DiGeorge syndrome	Aplasia of the thymus, most often with chromosome 22q11 deletion (Chapter 33)	Rare	Absent	Variable	Present
Currently unknown	Unknown, including reticular dysgenesis and congenital anomaly syndromes with SCID <sup>‡</sup>	Each one rare	Low/absent	Variable	Variable

\*Based on Buckley (2004), Antoine et al. (2003), and unpublished estimates (J. Puck).

<sup>†</sup>Some patients have substantial numbers of maternally derived T cells at time of diagnosis.

<sup>‡</sup>For example, SCID with multiple intestinal atresia (Gilroy et al., 2004), SCID with musculoskeletal abnormalities (Tangsinmankong et al., 1999).

elucidation of molecular responses of lymphocytes to cytokines, and availability of carrier and prenatal diagnosis by direct detection of mutations. Furthermore, XSCID has become the first disease in humans to be successfully treated by gene therapy (Chapter 48).

### Clinical and Pathologic Manifestations

Male infants with XSCID appear normal at birth. Presenting complaints are highly variable, as summarized in Table 9.2, and are generally not distinguishable from those of patients with autosomal forms of SCID except that female patients are assumed to have autosomal SCID. Although a family history can lead to laboratory confirmation of XSCID before or at the time of birth, over 50% of patients have no maternal male relatives with diagnosed immunodeficiency or early death consistent with XSCID. Whether due to chance and small sibship sizes or to newly arising mutations (see Strategies for Diagnosis of XSCID, below), the most common presentation of XSCID—and also the most common presentation of SCID of any genotype—is a sporadic affected male (Conley et al., 1990; Buckley et al., 1997). As transplacentally transferred maternal IgG wanes, infants with XSCID develop infections that bring them to medical attention generally by 3 to 6 months of age. Thrush or respiratory and gastrointestinal infections may at first seem routine, but they do not respond to the usual medical management. For example, otitis may not resolve despite several courses of oral antibiotics; respiratory syncytial virus (RSV) may be continuously present in pulmonary secretions for several months; and diarrhea leads to failure to gain weight, or even weight loss. Rashes, either erythematous or maculopapular, have been associated with GVHD, either from maternal cells transferred to the infant during birth or from transfusion of nonirradiated blood products prior to recognition of the immunodeficiency.

**Table 9.2.** Clinical Features of X-linked Severe Combined Immunodeficiency (XSCID)

#### Universal Features

Male gender  
Presentation in first year, usually by age 6 months  
Failure to thrive  
Oral thrush, candida diaper rash  
Absent tonsils  
Persistence of infections despite conventional treatment

#### Common Features

Family history of similarly affected maternal male relatives  
Chronic diarrhea  
Respiratory congestion, cough  
Fever  
Pneumonia, especially with *Pneumocystis jiroveci*  
Sepsis, severe bacterial infections  
Viral infections, including cytomegalovirus, adenovirus, Epstein-Barr virus, enteric viruses, varicella, herpes, and respiratory syncytial virus  
Infections with opportunistic pathogens

#### Less Common Features

Erythematous skin rash (often with hepatomegaly and even lymphadenopathy) from spontaneous or transfusion-related graft vs. host disease  
Recurrent bacterial meningitis  
Disseminated infections (salmonella, varicella, Bacillus Calmette-Guérin; rarely, vaccine strain [live] poliovirus)

**Table 9.3.** Pathologic Findings in X-linked Severe Combined Immunodeficiency

#### Primary Absence of T Cell Precursors

Markedly small thymus gland  
Vestigial thymic stroma present  
Absence of lymphocytes in thymus  
No Hassall's corpuscles in thymus  
No corticomedullary distinction

#### Evidence of Infections Secondary to Immunodeficiency

*Candida* pharyngitis, esophagitis  
Pneumonia or pulmonary infiltration with  
    *Candida*, other fungi  
    *Pseudomonas*, other gram-negative bacteria  
    *Pneumocystis carinii*  
    Cytomegalovirus

#### Evidence of Graft vs. Host Disease

Lymphocytic infiltration of skin, liver, other organs

Eventually, a clinical decompensation, diagnosis of an opportunistic pathogen, such as *Pneumocystis jiroveci* (formerly *P. carinii*), or a high index of suspicion leads to consideration of an immune disorder. Decompensating events include bacterial sepsis, meningitis, or deep-seated infections, as well as bacterial, fungal, or viral pneumonias. Three series of SCID patients in France (Stephan et al., 1993) and the United States (Bortin and Rimm, 1977; Buckley et al., 1997) reported a similar large range of infectious agents at presentation, primarily *Candida albicans*; *P. jiroveci*; *Pseudomonas*, *Salmonella*, and other gram-negative bacteria; gram-positive bacteria; respiratory viruses and viruses of the herpes family; and fungi. Infants with SCID who have received BCG vaccination may develop disseminated infection with this organism. Live polio vaccination has uncommonly caused poliomyelitis and carditis, but most infants have protective transplacentally acquired antipoliiovirus antibodies.

The hallmark of XSCID immunopathology (Table 9.3) is an extremely small thymus gland almost devoid of lymphocytes. Thymic stroma is present, but not well differentiated. There are no Hassall's corpuscles and no corticomedullary distinction. Thymic dendritic and epithelial cells are abnormal (Hale et al., 2004). Analysis of T cell receptor  $\beta$  chain rearrangement in thymic tissue from infants with XSCID has shown that the initial D $\beta$ -to-J $\beta$  recombination can occur, but subsequent VDJ rearrangement is blocked (Sleasman et al., 1994). Similarly, in extrathymic lymphoid organs, lymph nodes are small and poorly developed, and T lymphocytes cannot be found. Tonsils are absent. Other pathological findings in infants with XSCID who do not survive include manifestations of their terminal infections and, in some patients, lymphocytic infiltration of skin, liver, and other organs as a result of GVHD.

Unless treated by BMT, infants with XSCID generally succumb to infections before 1 year of age, but in rare cases the diagnosis of XSCID has been made in infants beyond their second birthday. A sheltered home environment may be a factor in late presentation. A mild clinical course has also been associated with particular mutational profiles of *IL2RG*, as discussed below.

### Laboratory Findings

Laboratory values that are useful to diagnose all types of SCID are summarized in Table 9.4. A helpful clue from a simple laboratory test is a low absolute lymphocyte count, compared to values for age-matched normal infants. While not universal, this

**Table 9.4.** Laboratory Abnormalities in Infants with X-linked Severe Combined Immunodeficiency\*

	<i>XSCID Patients</i>	<i>Proportion with Low Numbers</i>	<i>Control Value Range, First Year<sup>*,†</sup></i>
<i>Lymphocyte Counts</i>			
Total lymphocytes/ $\mu$ l	<2000	90%	3400–9000
T cells/ $\mu$ l	200 (0–800)	100%	2500–5600
B cells/ $\mu$ l	1300 (0–3000)	5%	300–3000
NK cells/ $\mu$ l	<100	88%	170–1100
<i>T Cell Receptor Excision Circles (TRECs)</i>			
	Absent	100%	1 per 10 T cells
<i>Antibody Concentrations<sup>†</sup></i>			
IgA, IgM	Extremely low		
IgG	Maternal levels at birth, low by age 3 months		
<i>Lymphocyte Function<sup>†</sup></i>			
Mitogen responses	Very poor		
Mixed lymphocyte response	Very poor		
NK cytotoxicity	Usually very poor; occasionally normal		
Specific antibody	Very poor production		
<i>Other Laboratory Tests</i>			
Absent thymic shadow	Universal on chest radiogram		

\*Adapted from Buckley et al. (1993, 1997); Chan and Puck (2005); Conley et al. (1990); Fischer (1992); Kalman et al. (2004); Schönland et al. (2003); Shearer et al. (2003); Stephan et al. (1993); Stiehm et al. (2004).

<sup>†</sup>Control ranges are approximate and age-dependent, and they may vary between laboratories. One should consult the immunology laboratory performing the test for best interpretation.

indicator should raise the suspicion of a congenital immunodeficiency in an infant with a significant infection. Because of arrested development of T cells, infants with SCID lack T cell receptor excision circles, or TRECs (Chan and Puck, 2005). TRECs are the episomal DNA circles formed by end-joining of genomic DNA segments removed during T cell receptor gene rearrangement; a quantitative polymerase chain reaction (PCR) across the joined ends is used to measure TREC number (Douek et al., 2000; Schönland et al. 2003).

Typically, but not always, the small numbers of lymphocytes found in patients with XSCID are predominantly or entirely B cells, which may be present in normal or even elevated numbers. Thus XSCID is the major disease accounting for T<sup>−</sup>B<sup>+</sup> SCID. Mutation-proven XSCID patients reported by Buckley et al. (1997, 1999) have a lymphocyte profile to similar to that of the T<sup>−</sup>B<sup>+</sup> patients (not all genotyped, but predominantly males) reported by Antoine et al., from Europe (2003).

The B cells found in infants with XSCID are immature and resemble the naive B cell population of normal cord blood in their expression of cell surface markers and in vitro antibody production restricted to immunoglobulin (Ig)M (Small et al., 1989). Sequence analysis of XSCID B cell immunoglobulin heavy chains has demonstrated normal VDJ rearrangement (Minegishi et al., 1994). However, there is overutilization of J<sub>H</sub>3 segments, as seen in fetal and neonatal B cells, and a total lack of somatic hypermutation. In XSCID infants whose maternally acquired IgG antibodies have waned, specific responses to vaccines or infectious agents are severely impaired or absent. Other distinguishing characteristics of XSCID are low numbers of cells that bear NK cell markers and poor NK cell cytotoxicity.

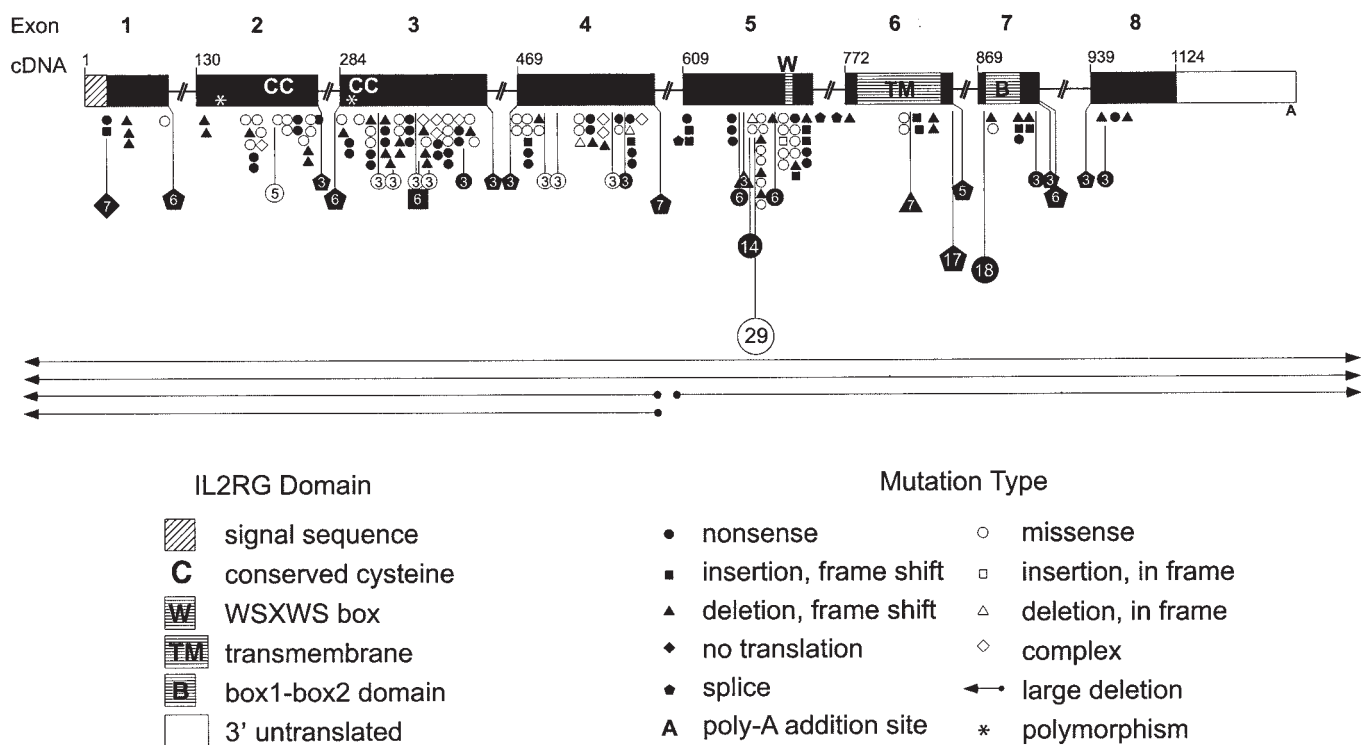

Despite the utility of these generalizations, lymphocyte numbers and function are not uniform in all patients and may be sub-

ject to modification by genetic factors other than *IL2RG* mutation and by environmental factors. For example, patients with *IL2RG* mutations occasionally have low, rather than the typical normal to high, numbers of B cells. Also, patients with proven *IL2RG* defects have been reported who have NK cells and NK cytotoxicity (Pepper et al., 1995).

Spontaneous engraftment of maternal lymphocytes in males with XSCID can be detected by finding XX karyotypes on cytogenetic analysis, by HLA typing, or by using DNA polymorphic markers (Pollack et al., 1982; Conley et al., 1984; Puck et al., 2001). Maternal cells can be found in almost all XSCID patients if sensitive methods are used. Although there may be no discernible consequences of maternal engraftment, the maternal cells may elevate the lymphocyte counts of an infant with XSCID. When sufficient numbers of maternal cells are activated to respond to the infant's paternally derived histocompatibility antigens, an XSCID patient may have eosinophilia and circulating maternal, activated, DR<sup>+</sup> T cells. In patients who have iatrogenic GVHD from transfusion of nonirradiated blood products, these abnormalities can become pronounced, and florid, acute GVHD can occur, including gastroenteritis, hepatitis, and lymphocytic infiltrates in skin, liver, and other organs.

### Molecular Basis: The Disease Gene, *IL2RG*

X-linked SCID was mapped by linkage to the proximal long arm of the X chromosome by De Saint Basile et al. (1987). Gene mapping studies were hampered by the early lethality of XSCID in males and the lack of any clinical or immunologic abnormalities to distinguish carrier females. However, Puck et al. (1987) noted that in contrast to the expected random X chromosome inactivation in female tissues, obligate female carriers of XSCID had only

**Figure 9.1.** Structure of *IL2RG* and mutations found in patients with X-linked SCID, both published and reported to IL2RGbase (<http://www.genome.gov/DIR/GMBB/SCID>; Puck et al., 1996); Genbank accession number L19546. At sites where multiple mutation events have occurred, mutation symbols are enlarged and number of unrelated subjects with mutation indicated.

the nonmutated X chromosome as the active X in their lymphocytes. This nonrandom X inactivation reflected a selective disadvantage in proliferation, differentiation, or survival of lymphocyte progenitors lacking a normal gene product at the SCIDX1 locus. Nonrandom X inactivation is found in T cells, B cells, and NK cells of XSCID carriers. In contrast, random X inactivation patterns are seen in their granulocytes, monocytes, and other tissues (Puck et al., 1987; Conley et al., 1988; Wengler et al., 1993). Thus the SCIDX1 gene product is necessary for the development of lymphoid but not myeloid cells from bone marrow stem cells.

Nonrandom X inactivation in lymphocytes was also used to assign the carrier status of female relatives of XSCID patients, increasing the number of informative individuals for genetic linkage in XSCID pedigrees. Further narrowing of the SCIDX1 region was made possible by the study of males with chorioideremia and deafness, but not immunodeficiency, who had interstitial deletions below Xq13, (Puck et al., 1993a). Until this time, no genes related to the immune system were known to reside in the region defined by mapping studies. However, in 1993, two groups (Noguchi et al., 1993b; Puck et al., 1993b) realized that the  $\gamma$  chain of the receptor for IL-2, cloned the previous year (Takeshita et al., 1992), was located in the region where SCIDX1 had been placed. Deleterious mutations in *IL2RG*, the gene encoding this receptor, were found in XSCID patients, proving that *IL2RG* is the XSCID disease gene.

*IL2RG* encodes the  $\gamma$  chain of the IL-2 receptor; the gene product is now called the common  $\gamma$  chain,  $\gamma_c$ . Two chains of the IL-2 receptor were known to exist before the  $\gamma$  chain was identified. The  $\beta$  chain, constitutively expressed on T cells, has intermediate affinity for IL-2 by itself; and the  $\alpha$  chain, expressed after T cell activation, boosts the affinity for IL-2 of the receptor

complex 100-fold. The existence of a  $\gamma$  chain was postulated when transfection of the  $\alpha$  and  $\beta$  chains of IL-2 receptor into epithelial cell lines failed to produce a receptor that could transmit a signal. A third chain was co-immunoprecipitated with the  $\beta$  chain and subsequently purified by two-dimensional gel electrophoresis (Takeshita et al., 1992). Determination of the amino-terminal sequence led to isolation of full-length cDNA for *IL2RG*. The gene, depicted in Figure 9.1, spans 4.5 kb of genomic DNA in Xq13.1. The coding sequence of 1124 nucleotides is divided into eight exons. *IL2RG*, a type I protein, is a member of the cytokine receptor gene family. It encodes a 5' signal sequence of 22 amino acids, which is cleaved off while targeting the protein for cell surface expression. Four conserved cysteine residues are found at the extracellular amino-terminal end; the juxtamembrane extracellular motif encoded in exon 5, the WSXWS box, is a hallmark of all cytokine receptors; the highly hydrophobic transmembrane domain of 29 amino acids occupies most of exon 6; and the proximal intracellular domain in exon 7 contains a Box1/Box2 signaling sequence homologous to SH2 subdomains of Src-related tyrosine kinases.

The three-dimensional structure of the  $\gamma_c$  protein has been characterized (Wang et al., 2005), and the exact spatial arrangement and interaction between  $\gamma_c$  and its extracellular contacts explains how IL-2 signaling is initiated at the extracellular surface (Stauber et al., 2006). The  $\alpha$  chain binds IL-2 and delivers it to the  $\beta$  chain, following which the  $\gamma$  chain addition to the quaternary complex creates a highly stable signaling structure.

#### Function of $\gamma_c$ , the *IL2RG* Gene Product

The first report of  $\gamma_c$  by Takeshita et al. (1992) established its expression in lymphocytes and cell lines of both T and B cell

**Figure 9.2.** Role of the XSCID gene product  $\gamma_c$  in receptor complexes for multiple cytokines.

lineages. It is not expressed in liver or epithelial cells. Subsequent studies have shown expression in EBV-transformed B cell lines from normal individuals and in mouse hematopoietic progenitor cells, from the earliest stem cell-enriched populations throughout development of myeloid and lymphoid lineages (Orlic et al., 1997). Expression of  $\gamma_c$  on murine thymocytes increases as they mature from CD4<sup>+</sup>/CD8<sup>-</sup> to double-positive to single-positive T cells, and further up-regulation occurs after lymphocyte activation (DiSanto et al., 1994a; Nakarai et al., 1994; Sugamura et al., 1996).

Recognition that  $\gamma_c$  was a component of the IL-2 receptor explained why mitogen responses are poor in infants with XSCID. DiSanto et al. (1994b) showed absence of both binding and internalization of IL-2 in B cell lines from XSCID patients. However, a mouse knockout of the gene for IL-2 did not have a SCID phenotype, but manifested immune dysregulation by developing autoimmune hemolytic anemia and inflammatory bowel disease (Schorle et al., 1991; Schimpl et al., 1994). This apparent paradox could be explained if  $\gamma_c$  were to have additional roles. Indeed, as shown in Figure 9.2, several groups subsequently demonstrated that the XSCID gene product is part of the receptor complexes for multiple cytokines: IL-4 (Kondo et al., 1993; Russell et al., 1993), IL-7 (Noguchi et al., 1993a), IL-9 (Russell et al., 1994), IL-15 (Giri et al., 1994a), and IL-21 (Habib et al., 2002, 2003).

Data from additional mouse knockout experiments and cellular cytokine activation studies suggest that the interaction between IL-7 and the IL-7 receptor complex, which contains  $\gamma_c$ , is an important signal for development of lymphocyte progenitors from undifferentiated hematopoietic stem cells. IL-7 receptor mRNA expression is coordinated with hematopoietic cell commitment to the lymphoid differentiation pathway (Orlic et al., 1997). Mice lacking either IL-7 or the IL-7 receptor  $\alpha$  chain have a SCID phenotype with impaired lymphocyte development (DiSanto et al., 1995a), and IL-7 can induce rearrangement of the T cell receptor  $\beta$  locus in vitro by promoting expression of the recombinase genes *RAG1* and *RAG2* (Muegge et al., 1993).

The importance of IL-4, particularly acting through  $\gamma_c$ , for lymphocyte development and function is less clear. IL-4-deficient mice have T and B cells, although T helper function, particularly in induction of B cell isotype switching to IgE, is defective (Kuhn et al., 1991; Seder and Paul, 1994). Although IL-4 receptor complexes containing  $\gamma_c$  mediate optimal signaling from IL-4,  $\gamma_c$ -defective human XSCID B cell lines exhibit some IL-4 activation through IL-4 receptors without  $\gamma_c$  (Matthews et al., 1995; Taylor et al., 1997). Similarly, the physiologic significance of  $\gamma_c$  within the receptor complex for IL-9 is not yet clear. IL-15 activation of XSCID cell lines does not occur, and IL-15 signals are required for NK cell development (Kumaki et al., 1995; Matthews et al., 1995). IL-21 signaling is important for both innate and adaptive immune responses, not only enhancing NK cell effector functions and interferon-gamma (IFN- $\gamma$ ) production, but also augmenting T and B cell responses to specific antigens (Habib et al., 2003).

After interaction with any one of the above cytokines on the surface of a cell,  $\gamma_c$  transmits an activation signal intracellularly by means of its association with JAK3, a member of the cytoplasmic Janus family of tyrosine kinases (Johnston et al., 1994; Miyazaki et al., 1994; Russell et al., 1994; Ihle, 1995). Specific tyrosine residues of JAK3 become phosphorylated and in turn relay the activation signal to one or more of the signal transducers and activators of transcription, or STAT proteins, which form dimers and migrate into the cell nucleus to alter the cellular transcription program (Fig. 9.2). There is a one-to-one correspondence between cytokine binding to  $\gamma_c$  and phosphorylation of JAK3: only  $\gamma_c$  appears to have the specificity to pass activation signals through JAK3. This fact is demonstrated not only by the lack of JAK3 phosphorylation, noted by several investigators to be a property of XSCID patient B cell lines (Russell et al., 1994; Candotti et al., 1996), but also by the recognition that lack of JAK3 causes SCID that, other than its autosomal recessive inheritance pattern, is indistinguishable from XSCID (Macchi et al., 1995; Russell et al., 1995). For a detailed discussion of JAK3 signaling and SCID, see Chapter 10.

### Mutation Analysis in XSCID

*IL2RG* mutations have been reported in patients with XSCID from every racial group. A database of published and verified mutations, IL2RGbase (Puck et al., 1996), can be accessed on the World Wide Web at <http://www.genome.gov/DIR/GMBB/SCID>. The first 344 unrelated patients had 198 distinct mutations, of which all but 6 were changes in only one or a few nucleotides (Fig. 9.1). The mutations are assigned to the exons and surrounding splice sites in which they are located. XSCID-causing *IL2RG* mutations are not evenly distributed. Exon 5 is the site of 27% of all the mutations, followed by exon 3 with 21%, exon 4 with 14%, and exons 6 and 7 with 10% each. Only three mutations have been found in exon 8.

### Hot spots for mutation in *IL2RG*

Recurrent mutations have been noted at several positions, or “hot spots” in *IL2RG*. In several instances, the new origin of a mutation has been proven by finding only the normal gene sequence in DNA from parents of female carriers or from mothers of affected males. Five hot spots for mutation involve the well-recognized mechanism of cytosine methylation and deamination to thymidine within a CpG dinucleotide (Cooper and Krawczak, 1993). The region of cDNA 666–691 of *IL2RG*, just 5' to the WSEWS motif in exon 5, contains six CpG dinucleotides, the last of which has been the site of 29 independent missense mutations (Pepper et al., 1995). These mutations are both 690C → T, changing arginine 226 to cysteine (R226C), and 691G → A, reflecting a C-to-T mutation on the anticoding strand and changing the same arginine to a histidine (R226H). Just six nucleotides 5' to this hot spot, the mutation 684C → T, causing a nonconservative missense mutation from arginine to tryptophan, R224W, has been reported 14 times in unrelated patients.

Two other hot-spot mutation sites are 879C → T, causing a premature termination, occurring 16 times (Pepper et al., 1995); and 868G → A, producing a R285Q missense mutation in the last nucleotide of exon 6, seen 14 times. A fifth CpG hot spot at cDNA 717, producing premature termination, has been noted six times, and interestingly was only recognized after collection of the mutations of multiple investigators into the database (Puck et al., 1996; see Chapter 45). Unfortunately, from the point of view of ease of molecular diagnostic testing, the above hot-spot mutations combined account for less than one-quarter of the XSCID-causing mutations. Unique mutations continue to be found as more patients are studied.

### Point mutations in *IL2RG*

Single nucleotide changes, found in 57% of all XSCID probands, have produced 35 different termination codons (nonsense mutations, shown as filled circles in Fig. 9.1) and 62 different amino acid substitutions (missense mutations, open circles). It is important to assess the significance of missense mutations. Some are predicted to disrupt known essential elements, such as the first methionine that signals initiation of translation, the four conserved extracellular cysteine residues, the WSEWS motif conserved in all members of the cytokine receptor gene family, or the hydrophobic transmembrane domain. Functional significance is likely for mutations at sites that are conserved not only among mammals, such as human, mouse, rat, and dog, but also between human and more distant species, such as chicken or trout, or between *IL2RG* and other members of the cytokine gene family (Pepper et al., 1995). Amino acid substitutions repeatedly found to be the only change associated with XSCID in unrelated

kindreds are more likely to be pathogenic than to be incidental polymorphisms. Direct proof that a missense mutation is harmful requires testing a cell line from the affected patient for expression of *IL2RG* mRNA and determining whether  $\gamma$ c protein is expressed at the cell surface, whether expressed  $\gamma$ c can bind IL-2, and whether downstream targets such as JAK3 and STAT5 become phosphorylated (Puck et al., 1997b). Rare or private polymorphisms have been found in *IL2RG*, but none that are common in control populations.

### Insertion and deletion mutations and splice mutations

Insertions (square symbols in Fig. 9.1) and deletions (triangles) account for 19% of XSCID mutations. The great majority of them produce frame shifts, predicted to encode variable numbers of missense amino acids before coming to a new termination codon. Similarly, 19% of XSCID mutations alter the conserved splice signals preceding and following each exon (pentagons, Fig. 9.1). One particularly subtle splice mutation, which has been found in six unrelated XSCID families, changes the attacking, or branch, point, adenosine, at position –15 in front of exon 3 (Tassara et al., 1995). The resulting mRNA is unstable because of the inability to form the lariat structure that is a necessary intermediate in mRNA processing. Because exons 2 through 7 of *IL2RG* contain numbers of nucleotides not divisible by 3, all splice mutations that produce exon skipping are predicted to cause frame shifts.

### Expression of mRNA and mutated $\gamma$ c protein

B cells from XSCID patients can be transformed with EBV to make permanent cell lines for functional study. B cell lines from control individuals invariably express *IL2RG* mRNA and  $\gamma$ c protein, detectable with a fluorescent-labeled anti- $\gamma$ c antibody (Ishii et al., 1994; Puck et al., 1993b, 1997b). Absent mRNA, demonstrable for all mutations that produce terminations throughout the first five *IL2RG* exons, is sufficient to prove that a patient with SCID has an *IL2RG* defect. However, studies by Puck et al. (1997b) showed that many *IL2RG* mutations are associated with normal mRNA quantity and size. Because such mutations include the frequently mutated hot-spot sites, as many as two-thirds of all XSCID patients may express some mRNA and abnormal  $\gamma$ c protein. Similarly, many XSCID patients have detectable cell surface  $\gamma$ c protein, specifically those with mutations in the intracellular domains encoded by *IL2RG* exons 7 and 8, with certain extracellular missense mutations or with in-frame insertions or deletions (Puck et al., 1997b). Direct testing of  $\gamma$ c expression and function in peripheral blood from infants with SCID, as suggested by Gilmour et al. (2001), can be combined with sequence-based confirmation of molecular diagnosis but may be inadequate because of small samples available from lymphopenic infants, and inaccurate because of nonmutated maternal lymphocytes that may be present in an affected infant's peripheral blood.

### Genotype–phenotype correlation of XSCID mutations

The expression of functional  $\gamma$ c is severely compromised by all but a handful of the mutations reported; exceptional cases with atypically mild disease, late presentation, or normal numbers of T cells have revealed important aspects of the molecular biology of  $\gamma$ c. In affected males in a family from France, initially normal T cell numbers declined with time and T cell receptor diversity was limited by an *IL2RG* substitution of an A residue for the almost invariant G nucleotide at the end of exon 1 (129G → A). While the missense mutation in  $\gamma$ c encoded by this change, D39N,

appeared not to impair IL-2 binding, the loss of a G-terminal nucleotide in exon 1 caused most of the mRNA to be incorrectly spliced (DiSanto et al., 1994c).

In another mildly affected kindred from Galveston, Texas, many males with recurrent respiratory and viral infections had reduced but not absent T cells; an intracellular *IL2RG* point mutation L293Q within the Box-1/Box-2 intracellular portion of  $\gamma$ c caused decreased interaction with JAK3, helping to prove the importance of JAK3 in the  $\gamma$ c signaling pathway (Russell et al., 1994; Schmalstieg et al., 1995; Goldman et al., 2001).

Another XSCID patient was inexplicably mildly affected despite having inherited an *IL2RG* missense mutation that eliminated the fourth conserved cysteine residue (C115R), required for proper disulfide bond formation and normal configuration of all members of the cytokine receptor family (Stephan et al., 1996; Bousso et al., 2000). Investigations revealed reversion to wild-type sequence, probably at the level of a T lymphocyte progenitor, allowing production of functional T cells with normal  $\gamma$ c. This case illustrated the powerful selective advantage of gene-corrected cells in XSCID, an argument in favor of retroviral gene therapy for this disease (see below).

Two unrelated patients had XSCID with normal numbers of poorly functioning T cells and shared the missense mutation R222C; one of these had a thymus biopsy demonstrating relatively normal histology with preservation of cortical and medullary regions (Scharfe et al., 1997; Mella et al., 2000). However, four other instances of this mutation have been associated with typical SCID (Clark et al., 1995; J. Puck, unpublished report), as have 14 instances of the missense mutation R224W at the same amino position. A patient with missense mutation L162R (Mella et al., 2000) and one with a defect in the poly-A addition site of *IL2RG* mRNA (Hsu et al., 2000) have also been reported. In addition to having more T cells than those of typical XSCID patients, these individuals survived for over a decade without successful allogeneic transplantation, exhibited activated, DR<sup>+</sup> T cells, and suffered from growth delay and chronic pulmonary disease. Taken together, these natural experiments in mutagenesis indicate that low levels of normal  $\gamma$ c or mutated  $\gamma$ c with residual function can allow some T cell development to occur. Additional male patients with combined immunodeficiency less severe than typical SCID may have *IL2RG* mutations.

### Strategies for Diagnosis

Once the clinical suspicion of a combined T and B cell immunodeficiency has been raised, whether by family history, low lymphocyte count, or recurrent or opportunistic infections, the diagnosis of SCID must be made by lymphocyte phenotyping and functional tests. X-linked SCID due to *IL2RG* mutation should then be considered in any male patient, although females with Turner syndrome (45 XO chromosome complement instead of 46 XX) and rare females with constitutionally unbalanced X chromosome inactivation patterns are theoretically also at risk. A clear X-linked family history is sufficient to confirm XSCID with presumed *IL2RG* mutation, but the lack of such a family history does not rule out XSCID. New mutations in *IL2RG* are frequent. Indeed, only 33 of 87 genotype-proven XSCID cases (38%) in a large study had family pedigrees demonstrating X-linked inheritance (Puck et al., 1997b).

Further clues as to the specific XSCID genotype can be gleaned from immunological tests, but atypical values cannot rule out X-linked disease. Males with very few T cells, high proportions of B cells, and absent NK cells are quite likely to have

*IL2RG* defects, although autosomal recessive JAK3 mutations have an identical clinical and immunologic profile. Lymphocyte phenotyping can be misleading in the face of maternal T cell engraftment, transfusion of nonirradiated blood products, and/or infectious agents. The availability of an anti- $\gamma$ c monoclonal antibody makes it possible to evaluate patient peripheral blood lymphocytes for  $\gamma$ c expression (Ishii et al., 1994; Puck et al., 1997b). If  $\gamma$ c is clearly absent from patient cells as compared to controls, XSCID can be diagnosed. However, presence of  $\gamma$ c may indicate that the patient's *IL2RG* gene is encoding an expressed but non-functional protein, or that maternal or other foreign cells in the infant's peripheral blood are positive for anti- $\gamma$ c staining.

Molecular testing for XSCID involves methods discussed in more detail in Chapter 44. Two indirect methods, linkage and maternal lymphocyte X chromosome inactivation, were used before identification of *IL2RG* as the XSCID disease gene. Linkage analysis for diagnosis is a valuable aid, but can only be applied in cases with a clear X-linked family history and available DNA from affected or obligate carrier family members. X chromosome inactivation was originally assayed in mothers of SCID patients by creating a large panel of independent human lymphocyte/hamster fibroblast hybrid cell lines grown in selective medium to ensure retention of the active human X chromosome. DNA from these hybrid clones was then genotyped with a polymorphic marker to identify which of the two X chromosomes was retained in each hybrid cell line (Puck et al., 1992). With the advent of PCR technology, a new assay was developed on the basis of digestion of a polymorphic segment of the androgen receptor gene, *AR*, with methylase-sensitive restriction enzymes. Selective methylation of the inactive *AR* allele, detected as preservation of only a single allele after digestion, suggested skewed X inactivation (Allen et al., 1992). Indirect methods are complex, expensive, time consuming, and not always interpretable, thus they have generally been used only in research laboratories. Although critically important for the gene hunt that identified *IL2RG*, they are now largely replaced by DNA sequence-based analysis.

Definition of the intron-exon boundaries of *IL2RG* and development of primers for PCR amplification of each exon plus flanking regulatory sequences has made mutation screening possible. Single-strand conformation polymorphism (SSCP), carried out by electrophoresis of single exon segments in nondenaturing conditions, was shown to have 83% sensitivity in identifying mutations in *IL2RG* (Puck et al., 1995, 1997a). A modification of this technique, dideoxy fingerprinting (ddF) (Sarkar et al., 1992), had much better sensitivity as a clinical test and detected all of 87 mutations in the series of Puck et al. (1997a, 1997b). Direct sequence analysis of PCR-amplified DNA must be performed to determine the specific mutation observed by a screening technique. A nonpathogenic polymorphism would otherwise not be distinguishable from a deleterious mutation. DNA from females at risk of carrying a mutation known from studying other family members can be analyzed by a proven screening method for that mutation, such as SSCP or ddF, by sequencing, or by digestion with a restriction enzyme that can differentiate wild-type and mutant alleles (Puck et al., 1997a).

### Carrier Detection and Prenatal Diagnosis

Females who carry an *IL2RG* mutation on one of their X chromosomes are immunologically indistinguishable from controls. However, they can be identified by nonrandom X chromosome inactivation, which is seen in their lymphocytes but not in their

granulocytes or nonlymphoid cells (Conley et al., 1988; Puck et al., 1992). This skewed X inactivation is a result of the selective disadvantage of lymphocyte precursors that have inactivated the X chromosome with an intact *IL2RG* gene. When the identity of the mutation in a male proband is known, direct detection of the mutation in the heterozygous state in at-risk female relatives is possible as described above. It is also possible to identify *IL2RG* mutations in potential female carriers when no sample from an affected male is available (Puck et al., 1997a). Females carrying a pathogenic *IL2RG* mutation have a 50% risk of XSCID for each male pregnancy and a 50% risk that each female pregnancy will also carry the mutation. However, as expected with X-linked lethal disorders, new mutations are common and predictions based on testing maternal blood may be inaccurate. Female germ-line mosaicism has been documented in XSCID (Puck et al., 1995), and women have been identified whose blood lymphocytes had no mutation and random X inactivation but who passed an *IL2RG* mutation on to multiple affected offspring (Puck et al., 1995; O'Marcaigh et al., 1997). In 13% of 85 mothers of sons with proven XSCID mutations, the mutations were not present in maternal blood samples (Puck et al., 1997b). Because the mutations in such cases may have existed in only a single maternal oocyte or may represent extensive maternal mosaicism, the recurrence risk for these mothers must be given as between 0 and 50% for a subsequent male pregnancy.

Prenatal diagnosis can be performed by several methods, depending on the amount of information available about the genotype of the family requesting it. If a specific mutation is known, or if the inheritance pattern of SCID is known to be X-linked, analysis of linked polymorphic markers or specific mutation detection can be performed using chorionic villus sample (CVS) or amniocyte DNA prepared directly or obtained from cultured cells (Puck et al., 1990, 1997a). When the genotype of a deceased SCID proband is not known, fetal blood sampling has also been used. Although this procedure must be done later in pregnancy and entails more risk than CVS or amniocentesis, lymphocytopenia, low numbers of T cells, and poor T cell blastogenic responses to mitogens can be definitively demonstrated in affected fetuses by week 17 of gestation (Durandy et al., 1986).

No carrier or prenatal testing should take place without genetic counseling. In considering prenatal diagnosis, the diagnostic options should be weighed against testing at birth for families who would not terminate an affected pregnancy. Regardless of whether prenatal testing is undertaken, education and counseling can clarify the potential benefit of early BMT for affected infants. Many relatives of XSCID patients who did not survive in the past are not aware of the medical advances in transplantation therapy.

Puck et al. (1997a) studied prenatal diagnosis for X-linked SCID in clinical settings. The great majority of families at risk for having an affected pregnancy desired prenatal testing, regardless of whether termination of pregnancy was a consideration. In fact, in only 2 instances out of 13 predicted affected male fetuses did families terminate a pregnancy. To prepare for optimal treatment of an affected newborn, families and their medical providers selected BMT centers, undertook HLA testing of family members, and even began a search for a matched, unrelated bone marrow donor. One family chose an experimental in utero BMT, which was successful (Flake et al., 1996; see below).

### Treatment and Prognosis

XSCID is generally fatal unless an immune system can be reconstituted, either by allogeneic transplantation or correction of

autologous hematopoietic cells by gene therapy. Infants receiving allogeneic BMT soon after birth are less likely to have serious pretransplant infections or failure to thrive. They also appear to have more rapid engraftment, fewer post-transplant infections, less GVHD, and shorter hospitalizations than those whose transplants are delayed (Stephan et al., 1993; Giri et al., 1994b; Meyers et al., 2002; Antoine et al., 2003; Buckley, 2004). Supportive care and management of infections from the time of diagnosis through the transplantation period are essential. Intensive monitoring, parenteral nutrition, immunoglobulin replacement, and antibiotics including antifungal and antiviral agents have dramatically improved the survival of infants with XSCID. Patients should be isolated from exposure to infectious agents in the environment and should not receive live vaccinations. Attempts to maintain a totally aseptic "bubble" environment are not indicated; instead, prompt immune reconstitution should be the goal.

The best current treatment for XSCID is BMT from an HLA-matched, related donor. Unfortunately, most patients lack a matched sibling donor. Haploidentical, T cell-depleted BMT has proven successful (see Chapter 47). Transplantation protocols using matched unrelated bone marrow or cord blood stem cells have also become available. The techniques for eliminating mature T cells from the donor cell population and enriching for stem cells vary between centers and are evolving over time. Similarly, different centers have had different approaches regarding pretransplant chemotherapy for XSCID patients. The potential advantages of controlling GVHD from donor immunocompetent cells and clearing out host bone marrow in the hope of improving B cell engraftment must be weighed against the risks of cytotoxic treatment.

Previously, there were few useful data to compare the regimens used. But now, increased numbers of treated patients and specific mutation diagnosis for most infants with SCID allow these questions to be addressed. Nevertheless, it is not possible to predict which patients may develop GVHD, fail to make adequate antibodies, and require long-term immunoglobulin replacement, or eventually develop T cell dysregulation or decreased T cell function. Some of the oldest surviving individuals with XSCID received HLA-matched related BMT and are now in their 30s and in excellent health. As larger numbers of children are now growing up after transplantation for XSCID, long-term outcome data are becoming available (Antoine et al., 2003; Buckley, 2004). While some subjects remain healthy with full immune reconstitution, others continue to require immunoglobulin replacement, and some eventually experience declines in thymic output, decreased naive T cell numbers, and diminished T cell receptor diversity (Patel et al., 2000; Antoine et al., 2003; Sarzotti et al., 2003; Buckley et al., 2004).

The concept of prenatal treatment for XSCID has been controversial because of the risk of invasive procedures during pregnancy. Advantages of in utero treatment include early reconstitution, a protected intrauterine environment, and the possibility of introducing normal bone marrow stem cells at the gestational age when fetal hematopoiesis is shifting from fetal liver to bone marrow. Early attempts at human in utero BMT were severely compromised by technological limitations, septic complications, and GVHD. In at least two patients with XSCID, these difficulties have been overcome (Flake et al., 1996; Wengler et al., 1996). Fetuses between 17 and 20 weeks of gestation shown by molecular diagnosis to be affected with XSCID were infused intraperitoneally with haploidentical, T cell-depleted, CD34<sup>+</sup> positively selected paternal bone marrow cells. In each of these two cases, infants were born with engrafted, functional T cells from

**Table 9.5.** Advantages and Disadvantages of Gene Therapy for XSCID*Advantages*

Hematopoietic stem cells can be transduced ex vivo and then reinfused. Graft-vs.-host disease is unlikely because gene-corrected cells are autologous. Immune reaction against gene-corrected cells is unlikely in immunodeficiency. The XSCID gene product  $\gamma$ c is normally widely expressed in blood lineages. Overexpression of  $\gamma$ c is apparently not harmful. An in vivo selective advantage for  $\gamma$ c<sup>+</sup> cells favors expansion of corrected lymphocytes. Gene therapy in XSCID animal models has been successful. Human gene therapy trials have provided full reconstitution to XSCID infants.

*Disadvantages*

It is impossible to predict or direct where retroviral genes integrate in host DNA. Retroviral insertion may inappropriately activate or inactivate host genes. Leukemic proliferations of transduced cells have occurred in three of 10 gene therapy recipients in the French trial.

their donors, whereas the XSCID mutation could still be confirmed in the infants' granulocytes. In follow-up both children were reported to have fully reconstituted immunity without requiring immunoglobulin supplementation (Bartolomé et al., 2002; Beggs et al., 2003).

## New Therapies for XSCID

XSCID has recently been successfully treated by gene transfer therapy to hematopoietic stem cells, but serious adverse events have also occurred. Advantages of XSCID as a pilot disease for gene therapy as well as disadvantages that have come to light since initial positive results are summarized in Table 9.5 and discussed in detail in Chapter 48.

Advantages of gene therapy for immunodeficiencies include the safety of ex vivo transduction protocols; avoidance of GVHD often seen in BMT treatment; and the fact that patients lacking normal immunity will be unlikely to generate an immune response against a newly expressed protein. Specific features that favor XSCID as a pilot disease for gene therapy are ubiquitous expression of *IL2RG* mRNA in hematopoietic cells (Orlic et al., 1997); apparent absence of toxicity of high levels of  $\gamma$ c in hematopoietic lineages, suggesting that expression directed by strong retroviral promoters would not be harmful; and, most important, the natural selective advantage for survival and expansion of lymphocytes expressing wild-type  $\gamma$ c, as previously demonstrated by the skewed X chromosome inactivation in lymphocyte lineages of female carriers (Puck et al., 1987, 1992) and somatic reversion to normal of a SCID-causing *IL2RG* mutation (Stephan et al., 1996). Substantial preclinical evidence of effectiveness of *IL2RG* gene therapy was available. Transduction with *IL2RG* retroviruses conferred new expression of normal  $\gamma$ c upon B cell lines from XSCID patients (Fig. 9.3). The same treatment corrected the cytokine signaling defects in these cells, restoring their ability to phosphorylate JAK3 in response to IL-2 and IL-4 (Fig. 9.4) (Candotti et al., 1996; Hacein-Bey et al., 1996; Taylor et al., 1996). Isolated CD34<sup>+</sup> cells from XSCID patients developed into T and B cells in a chimeric sheep model only after transduction with retroviruses encoding *IL2RG* (Tsai et al., 2002).

**Figure 9.3.** Expression of  $\gamma$ c in B cell lines from a healthy control (left) and from an XSCID patient with undetectable *IL2RG* mRNA, before (middle) and after (right) transduction with a retrovirus containing *IL2RG* cDNA under control of the Maloney leukemia virus LTR.

The first clinical trials of human XSCID gene therapy at the Necker Hospital in Paris by Cavazzana-Calvo et al. (2000) enrolled infants with no available HLA-matched donor. Bone marrow from the affected patients was aspirated, enriched for stem cells by positive selection with the cell surface marker CD34, cultured in activating cytokines, exposed to a retrovirus encoding a correct copy of *IL2RG* cDNA, and reinfused into the patients, who received no myelosuppressive treatment (Cavazzana-Calvo et al., 2000; Hacein-Bey-Abina et al., 2002). Of the first five patients treated, four became fully reconstituted with T cells and also developed the ability to make antibody responses (Haciein-Bey-Abina et al., 2002). The remaining infant suffered from disseminated BCG infection and received less than 1 million corrected cells per kg. He later received a successful haploidentical BMT. Further clinical trials in France and England (Thrasher et al., 2005) have proven that gene therapy for XSCID can be successful (see Chapter 48).

An unanticipated adverse event, leukemic proliferations of T cell clones bearing *IL2RG* retroviral insertion near a T cell oncogene, developed in three of 10 treated infants in the French trial, two of whom were the youngest at treatment, 1 and 3 months of age (Haciein-Bey-Abina et al., 2003). Both of these patients had experienced rapid and complete immune reconstitution, but developed leukemia at around 30 months after gene therapy. In each case, the leukemic cells had an insertion of the *IL2RG* retroviral vector near the 5' end of the *LMO2* gene, and one patient died of his leukemia. The second and third leukemia cases have entered continuous remission following treatment, and their immune reconstitution was preserved.

As of this writing at least 18 patients with XSCID have undergone attempts at gene therapy, including infants who have received gene therapy as primary treatment and older children after failure of attempted BMT (Haciein-Bey-Abina et al., 2003; Gaspar et al., 2004; Chinen et al., 2004; and J. Puck, personal communication). Further trials of gene therapy are proceeding with caution in view of new information on risks and benefits (Chinen and Puck, 2004). As part of the informed consent process, potential participants are warned about retroviral insertional mutagenesis, and methods for monitoring retroviral insertion sites have been instituted so that clonal proliferations can be detected at an early stage (see Chapter 48).

## Animal Models

Mice rendered deficient in  $\gamma$ c by gene targeting have been created and studied by several investigators (Cao et al., 1995; DiSanto et al., 1995b; Ohbo et al., 1996). Like humans with

**Figure 9.4.** Phosphorylation of JAK3 induced by IL-2 and IL-4 in B cell lines from a healthy control (lanes 1–3) and from an XSCID patient before (lanes 4–6) and after (lanes 7–9) transduction with an *IL2RG* retrovirus (Candotti et al., 1996). After no stimulation or exposure to IL-2 or IL-4, cell lysates were immunoprecipitated (IP) with anti-JAK3 antiserum ( $\alpha$ JAK3) and immunoblotted (IB) with antiphosphotyrosine ( $\alpha$ PY), top, or  $\alpha$ JAK3, bottom.

XSCID,  $\gamma$ c-deficient mice have low numbers of T cells and NK cells. Unlike humans, however,  $\gamma$ c knockout mice also lack B cells, but develop peripheral T cells with CD4<sup>+</sup> surface phenotype over time. A mouse expressing a truncated, nonfunctional form of  $\gamma$ c also had increased numbers of monocytes and hematopoietic progenitor cells bearing c-kit, Sca-1, and CD34 (Ohbo et al., 1996). Differences between the phenotypes of the different  $\gamma$ c-deficient mice may reflect variation in background genes or environmental conditions, as humans with null mutations vs. truncated  $\gamma$ c protein are not clinically or immunologically distinguishable. In humans IL-2 can bind to  $\gamma$ c complexed with IL-2 receptor  $\beta$  chain, whereas IL-2 binding in the mouse depends on those two chains plus the IL-2 receptor  $\alpha$  chain (Sugamura et al., 1996). The effect on XSCID phenotype of this and other interspecies differences in cytokine pathways involving  $\gamma$ c remains to be clarified.

Another animal model for XSCID is the  $\gamma$ c-deficient dog (Henthorn et al., 1994; Somberg et al., 1994, 1996; Felsburg et al., 2003). Originally diagnosed in a basset hound, the gene defect was bred into a large colony. *IL2RG* null mutations were identified in both this original model and in a second kindred of corgi dogs. The phenotype of these animals is similar to human XSCID in that affected dogs have growth failure, opportunistic and invasive infections, hypogammaglobulinemia, elevated numbers of B cells, and absent T cell mitogen responses. Failure of canine XSCID T cells to respond to IL-2 was noted even before the identification of *IL2RG* as the disease gene. Most affected dogs develop low numbers of peripheral blood T cells after several weeks of age, but these cells are poorly functional. Successful BMT has been performed in XSCID dogs, and gene transfer studies are under way. This large animal model may assist the development of new therapeutic approaches for human XSCID patients, such as cytokine administration to accelerate immune reconstitution after BMT.

### Concluding Remarks

The dramatic turnaround in outlook for patients with XSCID and their families over the past generation is one of the most striking in modern medicine. A previously uniformly fatal disease is now treatable, the cause and pathogenesis of the disease are known, specific gene defects can be identified and traced in patients and

at-risk family members, and prenatal diagnosis opens up potential new avenues for effective treatment options. XSCID has become the first human disease to be treated successfully by gene therapy, although the tragic complication of leukemia in three gene therapy recipients must be further studied and understood. Defining which SCID-affected patients have *IL2RG* defects makes possible further studies of genotype-specific management, both in the process of immune reconstitution and in the late post-transplant follow-up period. Families with SCID are communicating with each other on the World Wide Web (for example, a SCID homepage at <http://scid.net>) and becoming advocates for newborn screening. Parents, physicians, and researchers have thus formed alliances to educate physicians and the public and to learn how to diagnose and manage XSCID even more effectively in the future.

In-utero transplantation of parental CD34 haematopoietic progenitor cells in a patient with X-linked severe combined immunodeficiency (SCIDX1). *Lancet* 348(9040):1484–1487, 1996.

# Autosomal Recessive Severe Combined Immunodeficiency Due to Defects in Cytokine Signaling Pathways

FABIO CANDOTTI and LUIGI NOTARANGELO

Immunophenotypic and functional analysis of circulating lymphoid cells allows classification of severe combined immunodeficiency (SCID) into distinct subgroups (Fischer, 2001): (1) reticular dysgenesis; (2) adenosine deaminase deficiency; (3) SCID with a low number of circulating T and B cells and presence of natural killer (NK) cells ( $T^{-}B^{-}NK^{+}$  SCID); (4) SCID with a low number of circulating T lymphocytes and NK cells, but normal to increased number of B cells ( $T^{-}B^{+}NK^{-}$  SCID); (5) SCID with a low number of circulating T lymphocytes, but normal to increased number of B lymphocytes and presence of NK cells ( $T^{-}B^{+}NK^{+}$  SCID); and (6) SCID characterized by severe functional defects. The subgroups of SCID with B lymphocytes ( $B^{+}$  SCID) account for at least 50% of all cases of SCID (Fischer et al., 1990; Stephan et al., 1993; Haddad et al., 1998; Bertrand et al., 1999; Buckley, 2000b, 2004; Antoine et al., 2003). Many are due to known molecular defects that interfere with signaling of a series of critical hematopoietic cytokines. Most patients with  $B^{+}$  SCID are males, a pattern reflecting the occurrence of X-linked SCID (see Chapter 9). This disorder is due to mutations at the *IL2RG* locus (Noguchi et al., 1993; Puck et al., 1993), which encodes the common  $\gamma$  chain ( $\gamma_c$ ) shared by cytokine receptors for interleukin-2 (IL-2), IL-4, IL-7, IL-9, IL-15, and IL-21 (Leonard, 1996; Sugamura et al., 1996; Asao et al., 2001). The existence of autosomal recessive (AR)  $B^{+}$  SCID is indicated by the demonstration that  $B^{+}$  SCID may also occur in females, and in infants born to consanguineous parents (Stephan et al., 1993). Neither immunological nor clinical features can be used to distinguish between X-linked and AR  $B^{+}$  SCID (Stephan et al., 1993).

The finding that cytokine receptors that use the  $\gamma_c$  always associate with the intracellular Janus-associated tyrosine kinase (JAK) designated JAK3 (Fig. 10.1) and the discovery that the major cytokine receptor transducing subunit binds to another

JAK kinase, JAK1 (Miyazaki et al., 1994; Russell et al., 1994), provided clues to the molecular basis of AR  $B^{+}$  SCID. A mild form of X-linked SCID in humans was shown to result from a point mutation in the cytoplasmic tail of  $\gamma_c$ , diminishing but not completely abolishing its interaction with JAK3 (Russell et al., 1994). On the basis of this information, it was hypothesized that AR  $B^{+}$  SCID in humans could be caused by defects in JAK3. This hypothesis was proved correct by two groups of investigators who reported markedly reduced expression of JAK3 protein due to mutations in the *JAK3* gene in unrelated infants with  $B^{+}$  SCID (MIM \*600173, #600802) (Macchi et al., 1995; Russell et al., 1995; Candotti et al., 1997; Online Mendelian Inheritance in Man, 2000).

The critical role of JAK3 for lymphoid development and function has been further illustrated by the generation of Jak3-deficient mice, using homologous recombination and gene disruption (Nosaka et al., 1995; Park et al., 1995; Thomis et al., 1995). The immunologic phenotype of Jak3 knockout mice is very similar to that of  $\gamma_c$  knockout mice (Cao et al., 1995; DiSanto et al., 1995; Ohbo et al., 1996), thus substantiating the notion that the  $\gamma_c$  and Jak3 proteins act together in the same signaling pathway.

Mice with targeted genetic disruption of the genes encoding IL-7 or the IL-7 receptor  $\alpha$  chain (IL-7R $\alpha$ ) also have profound defects in T cell development that are similar to those of  $\gamma_c$  and Jak3 knockout animals (Peschon et al., 1994; von Freeden-Jeffrey et al., 1995). This observation led to the additional hypothesis that mutations specifically affecting IL-7 signaling could result in SCID in humans. The search for such patients ultimately demonstrated that *IL7R* mutations can cause AR  $B^{+}$  SCID and that such patients have residual development of NK cells (Puel et al., 1998). Thus, AR  $B^{+}$  SCID patients provide additional evidence of the integral importance of cytokine signaling in the development of the immune system.

**Figure 10.1.** Schematic representation of the IL-2-mediated JAK-STAT signaling pathway and its negative regulation.

### Biology of the JAK-STAT Signaling Pathway

The biological effects of cytokines are mediated through interaction with specific receptors; this leads to phosphorylation of intracellular proteins. Members of the cytokine receptor superfamily do not have intrinsic kinase activity, but recruit intracellular protein kinases following interaction with their ligands (Ihle, 1995; Taniguchi, 1995; Leonard and O'Shea, 1998). The tyrosine kinases that couple extracellular cytokine binding to intracellular phosphorylation of protein substrates, and eventually to cell growth and differentiation, are members of the Janus-associated kinase (JAK) family. The JAK kinases were originally cloned while searching for novel protein tyrosine kinases through a polymerase chain reaction (PCR)-based approach (Wilks, 1989), and their functional role was first demonstrated in response to interferons (Muller et al., 1993; Watling et al., 1993). Thus far, four distinct members of the JAK family are known in humans: JAK1, JAK2, JAK3, and Tyk2.

The JAK family members share a similar structure (Ihle, 1995; Taniguchi, 1995; Leonard and O'Shea, 1998), with a C-terminal kinase domain (termed JAK homology 1, JH1), a more proximal kinase-like domain (JH2) whose function is not completely defined, and five other N-terminal regions of homology (JH3-JH7). The JH2 domain lacks highly conserved critical residues found in other typical kinase domains; when expressed in a recombinant form, JH2 is in fact devoid of kinase activity, but instead has important regulatory functions perhaps through binding to the kinase domain and sequestering substrates until the kinase domain is activated by extracellular signals (Gurniak and Berg, 1996). The N-terminus of the JAKs has homology to another conserved domain defined in a superfamily of proteins called the FERM proteins (named for band 4.1, ezrin, radixin, and moesin). FERM domains were originally implicated in cross-linking of the cytoplasmic tails of transmembrane proteins to underlying structural and regulatory elements, but they may

also mediate interactions with transmembrane receptor chains independent of cytoskeletal binding (Zhou et al., 2001).

The *JAK3* and *TYK2* genes are located near each other on human chromosome 19p13.1. The *JAK3* cDNA is composed of 4,064 nucleotides and contains an open reading frame that encodes 1,124 amino acids (Kawamura et al., 1994). Immunoprecipitation studies, using specific antisera, suggest a molecular weight of approximately 125 kDa (Kawamura et al., 1994). While JAK1, JAK2, and TYK2 are broadly expressed, JAK3 is largely restricted to the hematopoietic system (Kawamura et al., 1994). The cDNA of JAK3 (originally designated L-JAK) was identified in NK cells and NK-like cell lines, but not in resting T lymphocytes, although expression could be induced following in vitro T cell activation (Johnston et al., 1994; Kawamura et al., 1994). In B cells, JAK3 expression is increased following in vitro activation and is high in B cell malignancies (Tortolani et al., 1995). A splice variant, devoid of kinase activity, has also been identified in epithelial cells (Lai et al., 1995). Studies of murine Jak3 have revealed high levels of expression in fetal and adult thymus and somewhat lower levels in fetal liver, adult bone marrow, lymph nodes, spleen, and CD4<sup>+</sup>CD8<sup>+</sup> thymocytes (Gurniak and Berg, 1996). These data imply a crucial functional role of the Jak3 protein in lymphoid differentiation.

The intracellular signaling mediated by JAKs has been extensively investigated. Members of the IL-2R superfamily (i.e., IL-2R, IL-4R, IL-7R, IL-9R, IL-15R, IL-21R) physically associate with JAK1 and JAK3 (Miyazaki et al., 1994; Russell et al., 1994; Foxwell et al., 1995; Johnston et al., 1995b; Malabarba et al., 1995; Pernis et al., 1995; Yin et al., 1995b). The observation that distinct cytokines signal through the same set of kinases indicates that JAKs are not directly involved in controlling the specificity of the signal. In the IL-2R, JAK1 interacts with the serine region of IL-2R $\beta$ , whereas the 48 C-terminal residues of the  $\gamma_c$  chain are required to bind JAK3 (Miyazaki et al., 1994). Both regions of the IL-2R chains are critical for JAK activation and

signal transduction (Johnston et al., 1994; Miyazaki et al., 1994; Witthuhn et al., 1994). Following cytokine–cytokine receptor interaction and dimerization of the cytoplasmic tails of the cytokine receptor chains, the JAKs are brought into close proximity and may cross-phosphorylate each other. Activation of JAK3 in response to IL-2, IL-4, and IL-7 is more pronounced than that of JAK1 (Witthuhn et al., 1994; Foxwell et al., 1995; Johnston et al., 1995b; Malabarba et al., 1995; Sharfe et al., 1995). In addition, JAKs phosphorylate the intracellular portions of cytokine receptor chains, thus generating docking sites for SH2-containing proteins (Ihle et al., 1994; Ivashkiv, 1995; Taniguchi, 1995).

Several signaling pathways are elicited by JAK1/JAK3 activation in members of the IL-2R cytokine receptors superfamily (Fig. 10.1). First, the phosphorylated cytokine receptor may associate with the adaptor SHC (Egan et al., 1993; Karnitz and Abraham, 1995), which is itself phosphorylated and binds to Grb2. Grb2 may thus anchor to Sos, the Ras guanine nucleotide exchanging factor (Li et al., 1993; Holsinger et al., 1995; Karnitz and Abraham, 1995). Membrane translocation of the Grb2/Sos complex catalyzes the conversion of inactive, GDP-bound Ras to the active, GTP-bound state. This results in the activation of raf-1, mitogen-activated protein kinase (MAPK), and eventually in the induction of immediate-early genes (*c-fos*, *c-jun*) (Blumer and Johnson, 1994). This signaling pathway, however, is apparently not used by all  $\gamma$ c receptor complexes, and in particular is not triggered by IL-4 (Welham et al., 1994).

Second, JAKs may bind and phosphorylate insulin receptor substrates (IRSs) (Johnston et al., 1995b; Keegan et al., 1995; Sharfe et al., 1995; Yin et al., 1995a). JAK activation by IL-2, IL-4, IL-7, IL-9, and IL-15 results in phosphorylation of IRS-1, whereas evidence of JAK-dependent tyrosine phosphorylation of IRS-2/4PS (which is strictly homologous to IRS-1) has so far been obtained only for IL-2, IL-4, and IL-15 (Johnston et al., 1995b; Keegan et al., 1995). The ability to phosphorylate IRS substrates is restricted to proliferating cells, as IL-4-dependent proliferative responses are not obtained with IL-4R mutants that are unable to recruit IRS-1 (Keegan et al., 1994). Once activated, IRS may bind the SH2 domain of the p85 subunit of phosphatidylinositol-3-kinase (PI3K) (Myers et al., 1992; Sun et al., 1995), and the catalytic activity of the p110 subunit of PI3K is eventually elicited. In addition to promoting PI3K activation, tyrosine phosphorylated IRS may recruit Grb2 and thus amplify the Ras/raf-1 signaling pathway (White and Kahn, 1994).

A third essential component of the JAK signaling pathway is phosphorylation of the class of transcription factors known as signal transducers and activators of transcription (STATs) (Taniguchi, 1995; Ihle, 1996; Leonard and O'Shea, 1998). The STATs contain a tyrosine residue that may undergo JAK-mediated phosphorylation, and they also contain SH2 and SH3 domains. Following cytokine interaction with receptor and triggering of the JAK-mediated signaling pathway, STATs may interact with the cytokine receptor complex by binding via their SH2 domain to the phosphotyrosine of the cytokine receptor chain. In addition, following STAT phosphorylation, STAT–STAT homo- or heterodimerization occurs, with the SH2 domain of one STAT molecule binding to the phosphotyrosine of the second STAT. Six different classes of STATs have been reported; furthermore, two different forms of STAT5 (STAT5a and STAT5b) have been characterized at the molecular level (Lin et al., 1996). The specificity of the response to cytokines is largely dependent on the particular combination of STATs recruited by the different signal-transducing chains of the cytokine receptor (Fenghao et al., 1995; Foxwell et al., 1995; Gilmour et al., 1995; Hou et al.,

1995; Johnston et al., 1995a; Taniguchi, 1995; Ihle, 1996). The differences in the STAT binding residues of the various cytokine receptors result in recruitment of specific STATs. However, three crucial lymphocyte growth factors, IL-2, IL-7, and IL-15, all activate STAT3 and STAT5 (Fenghao et al., 1995; Foxwell et al., 1995; Gilmour et al., 1995; Hou et al., 1995). STAT5 is the predominant protein induced by IL-2 in phytohemagglutinin (PHA)-stimulated lymphocytes (Hou et al., 1995).

Following dimerization, STATs translocate to the nucleus, where they bind to consensus sequences in the enhancer elements of the promoter regions of target genes and favor gene transcription (Ihle, 1996). Gene accessibility to STAT binding is another mechanism through which specific responses to distinct cytokines are obtained. It has been suggested that JAK-dependent STAT activation is more crucial to cell differentiation than to proliferation. In fact, deletion of the C-terminal H domain of IL-2R $\beta$  abolishes IL-2-induced STAT5 activation but not JAK1 and JAK3 activation; nor does it affect cell proliferation (Fujii et al., 1995). However, IL-4-induced thymocyte proliferation is somewhat diminished in STAT6 knockout mice, which suggests that STAT activation contributes to cytokine-induced growth-promoting activity (Kaplan et al., 1996; Shimoda et al., 1996; Takeda et al., 1996).

Additional possibly JAK-independent signaling pathways elicited following cytokine–cytokine receptor interaction include activation of src-related kinases (e.g., of lck, lyn, and fyn in response to IL-2) (Taniguchi and Minami, 1993), through their association with the acidic domain of IL-2R $\beta$ . Deletion of this domain abolishes IL-2-induced lck activation yet does not affect IL-2-regulated cell growth, implying that activation of src-related kinases may not be crucial for cell proliferation. Finally, induction of Syk, c-myc and bcl-2 requires the S region of IL-2R $\beta$  (Minami and Taniguchi, 1995). JAK3 mutants devoid of the JH1 kinase domain cause markedly diminished induction of c-myc, but intact induction of bcl-2. This finding indicates that these are independent signaling pathways and that JAK3 may be involved in c-myc transcription (Kawahara et al., 1995).

The need for JAK3 in IL-2-induced cell proliferation has been illustrated by the observation that in the NIH3T3 $\alpha\beta\gamma$  cell line (which expresses the  $\alpha$ ,  $\beta$ , and  $\gamma$  chains of the IL-2 receptor, as well as JAK1 and JAK2, but not JAK3), IL-2 does not promote cell proliferation; however, proliferative response to IL-2 is restored after JAK3 is transfected into and expressed by these cells (Miyazaki et al., 1994). Furthermore, the requirement for integrity of the structure of JAKs in regulating cell growth and differentiation has been indicated by the fact that JAK3 mutants that lack the JH3–JH7 domains, but not the JH1 protein tyrosine kinase domain, are unable to interact with  $\gamma$ c (Taniguchi, 1995), whereas mutants that lack the JH1 kinase domain may bind to  $\gamma$ c, but are unable to transduce activation signals (cell growth, induction of *c-fos* and *c-myc*) in response to IL-2 (Taniguchi, 1995). Finally, overexpression of JAK3 mutants that lack the JH1 kinase domain may inhibit the IL-2-induced phosphorylation of JAK1 and JAK3 (Kawahara et al., 1995). Similar experiments with JAK2 mutants suggest that multiple JH domains are required for functional interaction with the cytokine receptor and target cytoplasmic substrates (Tanner et al., 1995).

A number of mechanisms serve to terminate the activity initiated by cytokine signals (Fig. 10.1). SH2 domain-containing protein tyrosine phosphatases SHP-1 and SHP-2 are important inhibitors of signaling events and are thought to dephosphorylate receptor chains and JAK molecules through SH2–phosphotyrosine interaction (Migone et al., 1998; You et al., 1999). Other mechanisms for attenuation of cytokine signaling involve the members

of the suppressor of cytokine signaling (SOCS) family of proteins. These proteins are induced by cytokine stimulation following a classic feedback mechanism. Eight members of this family are known (CIS, SOCS1–7) (Yoshimura et al., 1995; Endo et al., 1997; Naka et al., 1997; Starr et al., 1997; Hilton et al., 1998). Although their function is incompletely understood, SOCS proteins appear to inhibit cytokine signaling through a variety of mechanisms, including competition with STATs for the phosphorylated docking sites on receptor chains and inhibition of kinase activities.

### Severe Combined Immunodeficiency Due to Mutations of JAK3

#### Clinical Features

Mutations in the *IL2RG* gene encoding  $\gamma_c$  (see Chapter 9) are responsible for X-linked SCID in humans, who typically present with T<sup>+</sup>B<sup>+</sup>NK<sup>−</sup> SCID. The recognition of the crucial role of JAK3 in signaling through  $\gamma_c$ -containing receptors led to the hypothesis that *JAK3* defects might account for autosomal forms of SCID in humans (Russell et al., 1994). In the original reports, three SCID patients with *JAK3* mutations were described (Macchi et al., 1995; Russell et al., 1995), and many other similar patients have subsequently been observed (Candotti et al., 1997; Bozzi et al., 1998; Buckley et al., 1999; Schumacher et al., 2000; Frucht et al., 2001; Mella et al., 2001; Roberts et al., 2004).

The clinical features of the first series JAK3-deficient patients who have been described in some detail are summarized in Table 10.1 and are indistinguishable from the features commonly observed in infants with X-linked SCID. In two cases, the diagnosis of SCID was established immediately after birth, either because of family history of SCID or because of fortuitous recognition of markedly reduced circulating T cells. Most patients, however, were diagnosed following development of upper and lower respiratory tract infections, variably associated with chronic diarrhea, central nervous system involvement, and failure to thrive during the first few months of life. In all cases, peripheral lymph nodes were undetectable. Although splice variants of *JAK3* mRNA have been identified in nonhematopoietic human tissues (Lai et al., 1995), no unique manifestations of primary organ dysfunction unrelated to immune deficiency have been detected in JAK3-deficient infants. Parental consanguinity was documented for 10 infants, 2 of whom were siblings.

#### Laboratory Findings

The immunologic phenotype of JAK3-deficient patients is very consistent (Table 10.1) and similar to that observed in infants with X-linked SCID. In the first series of 27 JAK3-deficient SCID patients, the proportion of CD3 lymphocytes was most often markedly reduced (0.2%–2%), while that of CD19 B cells was increased (74%–96%). Occasionally, as for patient 1 in Table 10.1, the proportion of circulating T cells may appear normal or near normal, due to the presence of maternally derived T lymphocytes. The augmented number of B lymphocytes often results in normal absolute lymphocyte counts (Table 10.1) and almost always in a less profound lymphopenia than that in patients with B<sup>−</sup> SCID. An interesting feature of JAK3 deficiency, also typically shared by X-linked SCID, is the severely reduced number of NK cells; NK cytolytic activity is consequently absent or severely depressed (Macchi et al., 1995; Russell et al., 1995; Bozzi et al., 1998; Candotti et al., 1997; Buckley et al., 1999; Schumacher et al., 2000; Frucht et al., 2001; Mella et al., 2001).

Because JAK3 is constitutively expressed in NK cells (Kawamura et al., 1994) and carrier females of X-linked SCID have nonrandom inactivation of the mutated X chromosome in not only T and B cells but also in NK cells (Wengler et al., 1993), it appears that integrity of the  $\gamma_c$ /JAK3 signaling pathway is essential to development of NK cells.

In addition to being severely reduced in number, T cells from JAK3-deficient infants are also functionally impaired. The proliferative responses to mitogens, antigens, and alloantigens are abolished or severely reduced. Despite the increased proportion of circulating B cells, immunoglobulin serum levels are markedly decreased (with the possible exceptions of IgG that is maternally derived during the early months of life and IgM), and no antibody responses are elicited following antigen stimulation. Failure to generate antibody responses is partly due to lack of effective helper T cell activity, but it also reflects an intrinsic B cell defect. In fact, defective induction of STAT activation has been reported following cytokine stimulation in Epstein-Barr virus (EBV)-transformed B cells from these patients (Russell et al., 1995; Candotti et al., 1996; Oakes et al., 1996; Frucht et al., 2001).

The recent report of the immunological phenotype of a series of seven JAK3-deficient patients described by Roberts et al. (2004) has confirmed earlier findings in these patients. Interestingly, however, the typical immunologic phenotype, lack of circulating T cells, and increased proportion of B cells may change during the course of the disease. We observed a rapid appearance of T cells (up to 41% of total circulating lymphocytes) in the peripheral blood of patient 7, who had a typical T<sup>+</sup>B<sup>+</sup>NK<sup>−</sup> phenotype during the first month of life (Table 10.1). The late-developing T cells were phenotypically and functionally abnormal. They were all CD4<sup>+</sup> and coexpressed the activation markers CD45R0 and DR; in addition, they were found to be oligoclonal (Brugnoni et al., 1998), and they failed to respond to PHA and to CD3 stimulation alone, but showed some response to the combination of anti-CD3 and IL-2. At the same time that these T cells were found, the patient developed markedly elevated levels of serum IgE (1000 IU/ml, with normal levels being <100 IU/ml). Interestingly, this phenotype of partial preservation of the responsiveness to IL-2 by activated T cells correlated with *JAK3* gene mutations (A1537G and deletion exons 10–12) that permitted residual protein expression and function (Candotti et al., 1997). The contributory role of residual functional activity of JAK3 is less clear, however, if one considers that Jak3 knockout mice develop activated CD4 T cells (see below). It is therefore possible that the T cell differentiation defect imposed by JAK3 deficiency allows changes of the immunologic phenotype with time or that some degree of T cell development is possible independent from JAK3. Our recent observation of patients 22a and 22b (Table 10.1) add complexity to these considerations. One child of this kindred died of *Pneumocystis* pneumonia before any laboratory analysis could be performed; a second child (patient 22a) developed severe lymphoproliferative disease and an additional sibling (patient 22b) was clinically nearly normal, but had lymphopenia with oligoclonal T cell expansion and increased numbers of activated and memory T cells. These cells also had poor expression of the pro-apoptotic molecule, Fas ligand, which is typically up-regulated by IL-2; thus these cells were reminiscent of the T cells that develop in mice that are deficient in either  $\gamma_c$  or Jak3 (Frucht et al., 2001). These findings suggest that all patients with immunodeficiency and residual T cell function should probably be evaluated for possible JAK3 (and, if male,  $\gamma_c$ ) mutations.

**Figure 10.2.** Schematic representation of organization of the human JAK3 protein and *JAK3* gene organization. In the upper panel, the boxes represent the JAK homology domains (JH1–JH7). Location and predicted protein effect of known *JAK3* mutations is indicated although not all mutant alleles give rise to stable mRNA or protein. The lower panel shows exons and introns of the *JAK3* gene (in scale) with the number of mutations found in each exon (solid boxes) and intron (connecting lines).

It is also well recognized that JAK3 is expressed in myelomonocytic cells, including human monocytes (Witthuhn et al., 1994; Musso et al., 1995), in vitro stimulation with lipopolysaccharide (LPS) and interferon increases JAK3 expression in monocytes (Musso et al., 1995). Furthermore, IL-2 and IL-4 (i.e., two cytokines that signal through  $\gamma$ c-bearing receptors) have profound effects on cells of the monocyte–macrophage lineage (Fenton et al., 1992; Vannier et al., 1992; de Waal Malefyt et al., 1993) and induce tyrosine phosphorylation and activation of JAK3 in these cells (Witthuhn et al., 1994; Musso et al., 1995). The possibility that mutations of the *JAK3* gene might affect the differentiation and/or function of the myelomonocytic lineage has been considered. However, monocyte numbers are normal in JAK3-deficient SCID infants (Villa et al., 1996; L. Notarangelo, unpublished results) and monocytes from one JAK3-deficient patient showed normal responses to IL-2 (measured as release of tumor necrosis factor and IL-8) and to IL-4 (release of IL-1R antagonist) (Villa et al., 1996), indicating that JAK3 is dispensable for monocyte differentiation and responsiveness to cytokines that interact with  $\gamma$ c receptors.

### Molecular Basis of JAK3 Deficiency

JAK3 mutations identified in the published series of patients are reported in Figure 10.2. A total of 34 unique mutations affecting all seven structural JH domains have been identified. Many mutations are clustered in the JH2 and JH3 domains.

While there are no obvious mutational hot spots, five mutations (D169E, R445X, C565X, R651W, and V722I) have been described in two unrelated families each. The types of the 34 unique mutations identified in unrelated families (Fig. 10.2), include 14 missense, 9 nonsense, 5 splice site (2 of which resulted in deletion and frameshift at the mRNA level), 4 genomic deletion, and 2 insertion.

### Functional Aspects

Most *JAK3* mutations drastically reduce the expression of the protein; however, a number of missense or small in-frame deletions have been identified that permit near-normal levels of protein

expression (Notarangelo et al., 2001; Roberts et al., 2004). The analysis of the effect of these mutations has provided important insights into the function of the different JAK3 domains.

Not unexpectedly, mutations of the kinase domain (JH1) can affect phosphorylation of JAK3 and its substrates IL-2R $\beta$  and STAT5, as demonstrated in patients with nonsense and frameshift mutations (Notarangelo and Candotti, 2000; Schumacher et al., 2000). More interesting have been the consequences of the frequent mutations in the pseudokinase domain (JH2). Constitutive phosphorylation of JAK3 was detectable in a patient with a C759R missense mutation in the JH2 domain, yet IL-2 stimulation did not result in up-regulation of JAK3 phosphorylation, nor did it induce STAT5 phosphorylation. In other patients with missense or deletion mutations in the JH2 domain, no JAK3 or STAT5 phosphorylation occurred in response to IL-2 (Candotti et al., 1997). The functional effects of these mutations have also been evaluated with heterologous systems. Mutant JAK3s were normally expressed after cDNA transfection, but their kinase activity was undetectable in vitro (Chen et al., 2000). Moreover, JAK3 mutants were unresponsive to IL-2 stimulation, even though they could normally bind to  $\gamma$ c. Surprisingly, however, the mutated JAK3 appeared in some cases to be hypertyrosine phosphorylated compared with wild-type JAK3. This finding suggests that the physiological role of the JH2 pseudokinase domain is to regulate kinase activity and therefore substrate phosphorylation by directly interacting with the JH1 kinase domain. To confirm this relationship, it was shown that, in contrast to the wild-type JAK3 pseudokinase domain, which modestly inhibits the JAK3-mediated signaling pathway, JAK3 with the mutated JH2 pseudokinase domains from the two patients studied had an increased capacity to inhibit kinase activity. Thus kinase dysregulation in these patients appeared to have contributed to their disease pathogenesis (Chen et al., 2000). Also in the JH2 domain, the R582W substitution was found to result in two different products: one had normal length but was not phosphorylated, and the other, with a 71 amino acid deletion in the downstream JH2 domain, was also expressed and could be phosphorylated, but was insufficient for signal transduction (Bozzi et al., 1998).

Mutations in the JH3 domain are also compatible with JAK3 expression, as was the case of a patient who carried one missense

mutation (E481G) and one deletion (K482-S596del) in this domain. These are predicted to result in both a normal-sized and a low-molecular weight mutant JAK3 product. In EBV B cells from this patient, IL-2 induced some residual phosphorylation of the normal-sized mutant JAK3 product. Furthermore, STAT5 phosphorylation was also detected (although at reduced levels), indicating that the glutamic acid-to-glycine substitution at codon 481 in the JH3 domain does not completely abrogate JAK3 function. Interestingly, the immunological phenotype of this patient was atypical; he developed a substantial number of autologous T cells (although with abnormal phenotype and function) and NK lymphocytes (Candotti et al., 1997; Brugnani et al., 1998).

Mutations in the N terminus of JAK3 have indicated the important role that this portion of the protein plays for receptor interaction. Cells from patients with single amino acid substitution or deletion in the JH7 domain express JAK3 protein with severely decreased interaction with  $\gamma_c$  (Cacalano et al., 1999) and with abrogated in vitro catalytic activity (Zhou et al., 2001). Similar results can be observed in the presence of missense mutations affecting the JH2 domain (Roberts et al., 2004). A detailed molecular analysis with constructs carrying the SCID-associated FERM mutation has shown that the JAK3 FERM and kinase domains associate and reciprocally influence each other's function and structure (Zhou et al., 2001). Thus, in SCID patients with FERM mutations, two mechanisms contribute to the disease pathogenesis: impaired  $\gamma_c$ /JAK3 association and inactivation of catalytic activity.

#### Strategies for Diagnosis: From Disease Confirmation to Prenatal Diagnosis

From the published literature, JAK3 deficiency appears to account for ~6% of all cases of SCID in the United States, thus occupying a less prominent role than X-linked SCID and adenosine deaminase (ADA) deficiency (Roberts et al., 2004). Until more SCID patients are analyzed for JAK3 mutations, the prevalence of this defect within the heterogeneous group of SCID disorders cannot be firmly established.

In the single-center experience of the Department of Pediatrics, University of Brescia, 14 cases of JAK3 deficiency were identified in a cohort of 96 consecutive patients with SCID, giving an overall figure of 14.3%. However, because JAK3 deficiency is usually characterized by a consistent B<sup>+</sup> phenotype, the proportion of JAK3 deficiency among infants with B<sup>+</sup> SCID is higher (37.8% in the Brescia series). It is possible that this rather elevated figure reflects the high frequency of consanguineous marriages in some parts of Italy. In any case, it appears that after mutations at the *IL2RG* locus, mutations of the *JAK3* gene are the second-most frequently reported molecular cause of B<sup>+</sup> SCID in the Mediterranean region.

To date, the diagnostic identification of a JAK3 defect is through Western blotting and functional assays, once  $\gamma_c$  defects have been ruled out; in fact, all patients identified thus far had undetectable or severely reduced levels of JAK3 protein. Furthermore, EBV-transformed cell lines from these patients show striking defects in JAK3 and STAT5 phosphorylation upon stimulation with IL-2. The advent of fluorescence-activated cell sorter (FACS) analysis of STAT phosphorylation provides the opportunity for early functional analysis after EBV immortalization (Roberts et al., 2004). However, functional assays are presently highly specialized research tests and require availability of appropriate cell lines. Because of the low levels of expression

of the JAK3 protein in circulating B cells, generation of lymphoblastoid cell lines has been necessary for reproducible Western blot analysis, although protein assays on peripheral blood mononuclear cells (PBMCs) have also been successfully performed (Gilmour et al., 2001a). Regardless, molecular testing, based on identification of *JAK3* mutations at the genomic level, remains the most reliable assay for the diagnosis of JAK3 deficiency. Analysis of *JAK3* mutations has been facilitated by elucidation of the genomic structure (Riedy et al., 1996; Villa et al., 1996; Schumacher et al., 2000). From these data it is now known that the human *JAK3* gene is organized into 23 exons and 22 introns. The complete definition of the intron-exon boundaries has allowed development of screening assays based on single-strand conformation polymorphisms (SSCP) techniques. This is particularly important for the evaluation of historical deceased cases of SCID when only DNA is available, as well as for patients fully reconstituted following bone marrow transplantation, in whom *JAK3* mutations can be determined only by analyzing DNA from nonhematopoietic tissues. The characterization of the *JAK3* genomic structure, for example, has allowed demonstration of splice-site mutations (Villa et al., 1996) and made possible the first prenatal diagnosis through SSCP-analysis on chorionic villi DNA (Schumacher et al., 1999). Because the *JAK3* gene is not expressed in chorionic villi, prenatal diagnosis was based on genomic analysis.

#### Treatment and Prognosis

The prognosis for JAK3-deficient SCID patients is the same as for all cases of B<sup>+</sup> SCID; unless treated by successful bone marrow transplantation, SCID due to JAK3 deficiency is a lethal disorder. Optimal results (up to 95% survival rate) have been obtained with bone marrow transplantation (BMT) from human leukocyte antigen (HLA)-matched siblings, whereas the survival rate is lower (~70%) when HLA-mismatched related donors are used. Furthermore, particularly when no conditioning regimen is given, engraftment of donor-derived T cells is associated with persistence of autologous B cells (Buckley, 2000a; Antoine et al., 2003), making post-transplantation treatment with infusion of immunoglobulins necessary on a chronic basis. Use of pretransplant conditioning has been claimed to favor the engraftment of donor-derived B cells (Wijnaendts et al., 1989; Dror et al., 1993; van Leeuwen et al., 1994; Haddad et al., 1998). However, it will be important to validate this assumption through prospective analysis of the outcome of bone marrow transplant in mutation-proven JAK3-deficient infants. In the Brescia series, of 13 Jak3-deficient patients who were treated with BMT, 9 received T-depleted marrow from haploidentical parents, 3 received T-depleted marrow from a matched unrelated donor (MUD), and only 1 had an HLA-identical sibling donor. In 12 of the 13 patients, engraftment of donor-derived T cells was achieved, whereas engraftment of donor-derived B cells was observed following HLA-matched and MUD transplantation, but less so following haploidentical transplantation. One patient who underwent haploidentical BMT died from infectious complications early after transplant, and one additional patient has severe neurological impairment due to pretransplant encephalitis. All of the four patients who received HLA-matched transplantation (three from a matched unrelated donor, and one from an HLA-identical sibling) are alive and well with full engraftment of both T and B lymphocytes of donor origin.

In a series of 10 JAK3-deficient patients who underwent BMT at Duke University Medical Center in North Carolina, 2 received

HLA-identical sibling marrow and 8 received maternal haploidentical transplantation without pretransplant cytoreductive chemotherapy. Among the latter patients, one died and a subsequent transplantation of cord blood (preceded by chemoablation) was necessary in one patient (Roberts et al., 2004). The nine surviving patients showed development of normal T cell immunity. Donor B cells, however, were detected only in the patient who received chemoablation, and six patients continued to require intravenous immunoglobulin (IVIG) therapy. Natural killer cell activity was not reconstituted in seven of the nine survivors (Roberts et al., 2004).

Because of the phenotypic and biological similarities between JAK3 deficiency and  $\gamma$ c deficiency, and in light of the early success of gene therapy in the latter condition (Cavazzana-Calvo et al., 2000; Hacein-Bey-Abina et al., 2002), genetic correction of JAK3 deficiency may also result in clinical benefit. Preclinical experiments in vitro (Candotti et al., 1996; Oakes et al., 1996) and in vivo in a murine model (Bunting et al., 1998, 1999, 2000) have illustrated the potential benefit of gene therapy for JAK3 deficiency. Retroviral-mediated JAK3 gene transfer was able to correct the biological abnormalities of JAK3-deficient human B cell lines, leading to reconstitution of IL-2 signaling as assessed by IL-2-induced phosphorylation of IL-2R $\beta$ , JAK1, JAK3, and STAT5, as well as IL-2-mediated cell proliferation (Candotti et al., 1996; Oakes et al., 1996).

A compelling series of in vivo mouse experiments has also shown that ex vivo retroviral-mediated JAK3 gene transfer into hematopoietic progenitors from JAK3 knockout mice was able to restore specific T and B cell functions in Jak3 knockout mice transplanted with gene-corrected cells. Treated mice developed T lymphocytes able to respond to mitogens and make specific cytotoxic responses. In addition, good reconstitution of humoral immunity was achieved following the procedure; experimental animals developed increased numbers of B lymphocytes and antibody production. More important, the same mice generated specific antibody responses upon immunization, and survived exposure to influenza virus (Bunting et al., 1998, 1999). Another crucial finding of these experiments was that myeloablation was not necessary to achieve these significant improvements (Bunting et al., 2000). The strong selective advantage of JAK3-corrected lymphoid cells over unmodified autologous counterparts, illustrated by these results, seems to indicate that preparative conditioning may not be needed for JAK3 gene therapy in humans.

One potential concern of using current "gene addition" approaches is that the expression of the transferred gene is liberated from the physiologic cellular mechanisms of regulation, being constitutively expressed under the influence of strong viral promoters. Because of the important role of JAK3 in cell proliferation (Miyazaki et al., 1994; Oakes et al., 1996), deregulated JAK3 expression could potentially result in uncontrolled cell division and cause malignancy.

In the animal experiments above, however, adverse events were not observed, supporting development of a clinical trial that recently enrolled a single JAK3-deficient patient who had failed BMT treatment. The results of this human trial have not been published. However, the occurrence of leukemia in two children treated with gene therapy for X-linked SCID has caused this trial to be placed on clinical hold and prevented the accrual of additional patients. Analysis of the monoclonal leukemic cell populations in the X-linked SCID trial has shown that the retroviral vector was integrated in or near the *LMO2* gene locus, resulting in aberrant expression of this transcript (Hacein-Bey-Abina et al., 2003) (see Chapters 9 and 48).

Activation of LMO2 by translocation is found in some forms of childhood acute T lymphoblastic leukemias. The proliferation advantage given by the expression of  $\gamma$ c to the cells containing the LMO2 integrants seems to explain the development of leukemia and it is reasonable to assume that expression of JAK3 could have similar consequences. For these reasons, in February 2005, the FDA Biological Response Modifiers Advisory Committee made the recommendation that, until more information is acquired, gene therapy for X-linked SCID and JAK3-SCID in the United States should be performed only in patients for whom alternative therapies are not available or have already failed.

### Murine Models of JAK3 Deficiency

The crucial role of JAK3 in lymphoid differentiation and function has been assessed through animal models. In 1995, three groups reported studies of mice with targeted disruptions of *Jak3* (Nosaka et al., 1995; Park et al., 1995; Thomis et al., 1995). Viable homozygous *Jak3* knockout mice of normal growth and size were generated in the expected proportion indicating that *Jak3* is not crucial to fetal development and survival.

Pathologic examination of the thymus in *Jak3* knockout mice revealed markedly reduced cellularity with a very low number of early lymphoid precursors (lin<sup>-</sup>/c-kit<sup>+</sup>), indicating abnormal seeding of lymphoid precursors into the thymus (Park et al., 1995). However, thymocyte differentiation stages were discernible, and CD4<sup>+</sup> and CD8<sup>+</sup> single-positive thymocyte subsets were identified. An excess of CD4<sup>+</sup> over CD8<sup>+</sup> single-positive cells developed with time, suggesting that cytokine signaling through  $\gamma$ c/Jak3 is more crucial for the maturation and/or survival of the murine CD8 lineage than of CD4 thymocytes. The proliferative response of thymocytes to various combinations of mitogens was severely reduced and was not increased by addition of exogenous IL-2. Interestingly, intermediate responses to phorbol myristate acetate (PMA) or concanavalin A (Con A) and cytokines have been recorded with thymocytes from heterozygous mice (Park et al., 1995).

Although the spleen in *Jak3*-deficient mice was generally smaller than that in controls, its cellularity was less severely affected than that of the thymus. However, a sharp reduction of mature B220<sup>+</sup>sIgM<sup>+</sup> B cells (around 1% of normal) was observed, associated with a profound defect of B cell differentiation in the bone marrow, where a reduced transition from pro-B (B220<sup>+</sup>CD43<sup>+</sup>) to pre-B (B220<sup>+</sup>CD43<sup>+</sup>) cells was documented (Park et al., 1995; Thomis et al., 1995). In the T cell compartment of the spleen, a progressive appearance of CD4<sup>+</sup> T cells was observed; furthermore, these cells expressed activation antigens CD44 and CD69, but showed greatly diminished in vitro proliferation and little IL-2 production in response to mitogen stimulation (Thomis et al., 1995; Thomis and Berg, 1997). These abnormalities, also observed in  $\gamma$ c knockout mice, may reflect anergy of splenic T cells, possibly as a result of prior stimulation through the T cell antigen receptor in the absence of *Jak3*. This would be consistent with the observation that activation of *Jak3* is associated with prevention of anergy (Boussiotis et al., 1994). Indeed, peripheral expression of *Jak3* is required to maintain T lymphocyte function. In transgenic mice that express *Jak3* in the thymus but not in the periphery, T cell development in the thymus is restored, but progressive accumulation of activated and anergic T cells is observed in the spleen (Thomis and Berg, 1997).

In *Jak3* knockout mice, self-reactive T cells are not deleted in the thymus and periphery; furthermore, the activated, anergic T cells that accumulate in the spleen contain self-reactive lymphocytes (Saijo et al., 1997). These data indicate that *Jak3* expression

is essential to the process of negative selection. Peripheral lymph nodes are nearly undetectable in Jak3 knockout mice. These mice also lack NK cells, T lymphocytes, dendritic epidermal T cells, and intestinal intraepithelial lymphocytes (Park et al., 1995).

The proportion of early hematopoietic precursors ( $\text{lin}^{-}/\text{c-kit}^{+}/\text{Sca-1}^{+}$ ) in the bone marrow is normal, as are the numbers of monocytes, macrophages, and myeloid and erythroid lineage cells. However, myeloid lineages in these mice are also affected by the loss of Jak3. Splenomegaly is common in these mice by 4 months of age and increased numbers of neutrophils and cells of the monocytic lineage are present in the peripheral blood. If Jak3 knockout mice are crossed with a transgenic mouse expressing Jak3 in the T and NK cell compartments, the splenomegaly and myeloid expansion are accentuated, while no splenomegaly or myeloid expansion is apparent when Jak3 knockout mice are crossed with Rag1-deficient animals that lack T lymphocytes. These findings suggest that the absence of Jak3 in the T cell compartment is responsible for the dysregulated myelopoiesis in Jak3 knockout mice (Grossman et al., 1999). As mentioned above, no overt anomalies of the myeloid compartment are detectable in JAK3-deficient humans.

On the whole, the immunological abnormalities in Jak3 knockout mice are similar to those of  $\gamma\text{c}$  knockout mice (Cao et al., 1995; DiSanto et al., 1995; Ohbo et al., 1996). Both knockouts share a profound defect in B cell differentiation but allow some T cell maturation (particularly of  $\text{CD4}^{+}$  T cells). Furthermore, a similar phenotype (with disturbed differentiation of T and B lymphocytes) has been observed in IL-7R knockout (Peschon et al., 1994) and IL-7 knockout (von Freeden-Jeffry et al., 1995) mice, consistent with the notion that IL-7/IL-7R interaction and signaling through the  $\gamma\text{c}$ /Jak3 axis is a nonredundant function in lymphoid development.

In contrast to what has been observed in mice, JAK3 and  $\gamma\text{c}$  deficiencies in humans are not characterized by severe defects in B cell differentiation. This finding suggests that IL-7 is an essential pre-B cell growth factor in mice but not in humans.

### Severe Combined Immunodeficiency Due to Mutations of IL-7 Receptor $\alpha$ Chain

#### Clinical Features

Patients with IL-7R $\alpha$  deficiency present with classical signs and symptoms of SCID. The original report (Puel et al., 1998) described two patients with T $^{-}$ B $^{+}$ NK $^{+}$  SCID characterized by failure to thrive, recurrent otitis, viral infections, candidiasis, diarrhea, and fever. A subsequent report described an additional family with extensive consanguinity and three subjects affected with T $^{-}$ B $^{+}$ NK $^{+}$  SCID having persistent oral thrush and failure to thrive. Absence of palpable lymph nodes and thymus shadow on chest radiograph were also described. Three infants from the same family had died from failure to thrive, diarrhea, and fungal and bacterial infections (Roifman et al., 2000). In a series of 169 SCID cases diagnosed at Duke University Medical Center, 16 patients (9.5%) were found to have IL-7R $\alpha$  deficiency, thus making this disorder the third-most common case of SCID in that series, after X-linked SCID and ADA deficiency (Buckley, 2004).

#### Laboratory Findings

Lymphopenia with elevated numbers of B cells, greatly diminished  $\text{CD3}^{+}$  T lymphocytes, and normal or elevated numbers of  $\text{CD16}^{+}$  NK cells have been described as characteristic signs of

IL-7R $\alpha$  deficiency. Proliferation to mitogens and allogeneic cells is defective, but NK cell killing of K562 target cells is normal. Patients have defective production of immunoglobulins and fail to respond to vaccinations (Puel et al., 1998; Roifman et al., 2000).

#### Molecular Basis of IL-7R $\alpha$ Deficiency

IL-7R $\alpha$  (CD127) is a type 1 cytokine receptor chain devoid of intrinsic tyrosine kinase activity. This 460 amino acid-long chain can bind IL-7 with consequent dimerization with  $\gamma\text{c}$ , which in turn results in JAK3-mediated phosphorylation of IL-7R $\alpha$  and recruitment of JAK2 and STAT5 transcription factors. The *IL7R* gene, located on chromosome 5p13 in humans, is organized into eight exons and seven introns, with exons 1–5 encoding the extracellular portion of the receptor, and exon 6 and exons 7–8 encoding the transmembrane region and the intracellular tail, respectively (MIM \*146661, #608971) (Online Mendelian Inheritance in Man, 2000). The *IL7R* cDNA is 1,380 nucleotides long and encodes a protein of the estimated molecular weight of ~90 kDa. The expression of *IL7R* mRNA can be detected in the earliest stages of lymphocyte differentiation ( $\text{CD4}^{-}\text{CD8}^{-}$  double-negative thymocytes and  $\text{c-kit}^{+}\text{B220}^{+}$  B cell progenitors) (Sudo et al., 1993; Orlic et al., 1997).

Although the cases reported in the literature are still limited, mutations of *IL7R* seem heterogeneous; missense, nonsense, and splice mutations have all been found. These mutations resulted in compound heterozygosity for two missense mutations (Thr66Ile in exon 2 and Ile138Val in exon 4) or for a nonsense (Trp217stop in exon 5) and a splice mutation at the acceptor site of intron 4, respectively, in the first two patients described (Puel et al., 1998), and in homozygosity for a missense mutation (Pro132Ser in exon 4) in a consanguineous family (Roifman et al., 2000).

#### Functional Aspects

The mechanism leading to SCID for the Thr66Ile and Ile138Val missense mutations remains unclear. When expressed in heterologous systems, these mutants are able to bind IL-7 and induce STAT5 activation (Puel et al., 1998). However, these alleles were not expressed by the heterozygous parents of the proband, a finding suggesting that decreased mRNA expression or stability could account for the SCID phenotype in this patient. The Trp217stop and the  $-1\text{ G}\rightarrow\text{A}$  mutations at the acceptor site of intron 4 are predicted to prevent expression of functional IL-7R $\alpha$  (Puel et al., 1998). Interestingly, the Pro132Ser missense mutation interfered with IL-7 binding and signal transduction and thus caused disease in one family (Roifman et al., 2000).

#### Strategies for Diagnosis

It has been proposed that the T $^{-}$ B $^{+}$ NK $^{+}$  SCID immunophenotype is characteristic of IL-7R $\alpha$  deficiency, although patients affected with other forms of B $^{+}$  SCID can also have considerable numbers of NK cells (Candotti et al., 1997; Brugnani et al., 1998). Studies of IL-7R $\alpha$  mRNA and/or protein expression (Western blot, flow cytometry) can be informative and be performed on fresh PBMCs (IL-7R $\alpha$  is expressed on immature B and T cells, mature T and NK cells, and macrophages) or EBV-transformed lymphoblastoid B cells. The definitive diagnosis is provided by detection of pathogenic mutations in affected subjects and their parents. The available information about intron–exon boundaries of the IL-7R $\alpha$  gene facilitates genomic DNA analysis for this disease.

## Treatment and Prognosis

Allogeneic BMT can provide full immune reconstitution for IL-7R $\alpha$  deficiency (Buckley et al., 1999; Roifman et al., 2000) and is the treatment of choice. Similar to other forms of B<sup>+</sup> SCID, early diagnosis and prevention of infections are associated with better outcome of the transplantation procedure and ultimate prognosis for affected patients. Because it affects the same signaling pathway as that in XSCID and JAK3 deficiency, IL-7R $\alpha$  deficiency may be a good candidate for gene therapy, with similar prospects of risks and success.

## Murine Models of IL-7R $\alpha$ Deficiency

IL-7R $\alpha$  participates with both the IL-7 and thymic stromal lymphopoietin (TSLP) cellular receptors, in association with  $\gamma$ c and TSLPR, respectively, a receptor chain with 24% homology to  $\gamma$ c (Pandey et al., 2000; Park et al., 2000). IL-7R $\alpha$  knockout mice, therefore, lack both IL-7 and TSLP signaling. These mice are viable and fertile and retain normal proportions of all major thymocyte populations during fetal life (Crompton et al., 1998). Adult IL-7R $\alpha$ -deficient mice, however, present with ~20-fold reduction of thymic precursors and decreased peripheral lymphocyte numbers (Peschon et al., 1994). Thymocyte development is arrested at the CD4<sup>+</sup>CD8<sup>+</sup> double-negative stage, before the occurrence of T cell receptor (TCR) gene rearrangement (Maki et al., 1996a; Candeias et al., 1997; Crompton et al., 1997; Perumal et al., 1997). The reduced numbers of T cells that populate the periphery are dysfunctional and characterized by impaired survival and reduced proliferation to mitogens and alloantigens (Maraskovsky et al., 1996). Development of  $\gamma$  $\delta$  T cells is also blocked in IL-7R $\alpha$ -deficient mice, whereas NK cells develop normally (He and Malek, 1996; Maki et al., 1996b; Kang et al., 1999). Interestingly, thymocyte development can be restored by introduction of a transgenic TCR, which suggests that IL-7R $\alpha$  is needed to initiate TCR gene rearrangement (Crompton et al., 1997). T lymphopoiesis is also restored in IL-7R $\alpha$ -deficient mice by the transgenic expression of the anti-apoptotic molecule bcl-2 and ameliorated by the concomitant absence of the pro-apoptotic protein Bax. These data indicate that the critical consequence of engagement of IL-7R $\alpha$  in T cell development may be the integration of cell survival signals (Akashi et al., 1997; Maraskovsky et al., 1997; Khaled et al., 2002).

IL-7R $\alpha$ -deficient mice also show an incomplete block of B cell development at the transition from the pro-B to pre-B cell stage, which results in a 10-fold reduction in precursor B cells and severely decreased numbers of mature, peripheral B lymphocytes expressing surface immunoglobulin (Peschon et al., 1994). This defect is not corrected by transgenic expression of Bcl-2 (Maraskovsky et al., 1998) and is characterized by normal D-J segment joining but impaired recombination of antibody heavy-chain V segments (Corcoran et al., 1998). The reduction of B lymphocyte numbers in IL-7R $\alpha$ -deficient mice does not parallel the human phenotype, perhaps because the essential role of TSLP in maturation of pre-B cells in mice (Friend et al., 1994; Levin et al., 1999) is not conserved in humans (Reche et al., 2001; Soumelis et al., 2002).

## IL-2 Receptor $\beta$ and IL-15 Receptor $\beta$ Chain Deficiency

IL-2 and IL-15 signal through cellular receptors that share both  $\gamma$ c (CD132) and IL-2R $\beta$ /IL-15R $\beta$  chain (CD122), the latter encoded

by the *IL2R $\beta$*  gene (MIM\*146710) on chromosome 22q11.2-q13 in humans (Online Mendelian Inheritance in Man, 2000). Their receptors are distinguished by their ligand-specific subunits, IL-2R $\alpha$  (CD25) and IL-15R $\alpha$ , respectively. IL-2 is predominantly produced by activated T cells and plays an essential role in control of peripheral self-tolerance (Nelson, 2002) through activation-induced cell death (Frucht et al., 2001), thymic selection (Bassiri and Carding, 2001), and maintenance of regulatory T cells (Shevach, 2000; McHugh et al., 2001; Shevach et al., 2001). After binding to its receptor, IL-2 activates JAK1, JAK3, and STAT5.

Despite shared receptor usage with IL-2, IL-15 has a quite distinct function. This cytokine is essential for the maintenance of CD8<sup>+</sup> memory T cells that gradually decline after viral infections in the absence of IL-15 (Becker et al., 2002; Goldrath et al., 2002; Schluns et al., 2002). IL-15 is also important for the development of NK cells, as illustrated by the lack of NK cells in IL-15 knockout and IL-15R $\alpha$  knockout mice (Mohamadzadeh et al., 2001; Becker et al., 2002; Goldrath et al., 2002). Thus, the NK cell deficiency observed in X-linked SCID and JAK3-deficient patients is thought to be due to lack of IL-15 signaling.

One recently described patient with T<sup>low</sup>B<sup>+</sup>NK<sup>−</sup> SCID presented with undetectable expression of the  $\beta$  chain of the cellular receptor used by both IL-2 and IL-15 (Gilmour et al., 2001b). The infant, born to nonconsanguineous parents, had a history of severe infections including respiratory syncytial virus bronchiolitis, *Candida* enteritis, and meningoencephalitis. He had failure to thrive, hepatomegaly, and moderate lymphopenia. Immunophenotype analysis showed markedly reduced T cell numbers and absent NK cells, with B lymphocytes within normal range values. Serum immunoglobulin levels were normal, although the patient failed to produce specific antibodies following immunization with tetanus toxoid and *Hemophilus influenzae* vaccines. The patient underwent allogeneic BMT from an unrelated donor and had good immune reconstitution and resolution of clinical symptoms.

Flow cytometry and Western blot analyses showed significant decrease of IL-2R $\beta$ /IL-15R $\beta$  chain expression in the patient's PBMCs. Similarly, Northern blot analysis showed a marked reduction of *IL15R* mRNA expression in the proband's cells. No abnormalities of *IL15R* were demonstrated; whether this clinical presentation was due to undetected mutations of *IL15R* or a defect that prevented transcription of *IL15R* remains unclear.

It is interesting to note that mice lacking IL-2R $\beta$ /IL-15R $\beta$  show defective NK cell development, a phenotype observed in this patient. In contrast, T cells of IL-2R $\beta$ /IL-15R $\beta$ -deficient mice are abnormally activated, resulting in dysregulated differentiation of B cells into plasma cells and consequent high levels of serum immunoglobulins. Autoantibodies are also produced that cause hemolytic anemia (Suzuki et al., 1995).

## Lck Deficiency

Lck (p56lck) is an intracellular protein tyrosine kinase that is critically involved in TCR-mediated signaling. Its N-terminal region associates with the cytoplasmic tail of the CD4 and CD8 coreceptors (Chow and Veillette, 1995), thus bringing Lck into close proximity with the TCR. Lck is known to contribute to tyrosine phosphorylation of the immunoreceptor tyrosine-based activation motifs (ITAMs) of the TCR complex (Iwashima et al., 1994; van Oers et al., 1996). In keeping with the role played by Lck in early steps of TCR-mediated signaling, targeting of the

Lck gene (Molina et al., 1992) or expression of a dominant negative Lck transgene (Levin et al., 1993) results in a severe T cell developmental defect, with profound thymic atrophy, a dramatic reduction in the number of double-positive thymocytes, and only few circulating mature T cells.

One infant with a putative Lck defect has been reported to date (Goldman et al., 1998). The patient presented with chronic diarrhea and failure to thrive at 1 month of age, and developed *Enterobacter cloacae* sepsis, cytomegalovirus infection, and persistent oral candidiasis. Laboratory investigation disclosed pan-hypogammaglobulinemia, lymphopenia with a low proportion (9%–22%) of CD4<sup>+</sup> T cells, and a progressive decline in T cell proliferation to mitogens and anti-CD3 monoclonal antibody. CD8<sup>+</sup> T cells, if activated with anti-CD3, failed to express the activation marker CD69, whereas activation with phorbol esters and ionomycin resulted in normal CD69 expression, indicating a TCR signaling defect proximal to protein kinase C activation. A marked reduction in the level of Lck protein and an improperly spliced mRNA transcript of the *LCK* gene on chromosome 1p35-34.3 (MIM \*153390) lacking the exon 7 coding domain were demonstrated (Online Mendelian Inheritance in Man, 2000). The molecular basis for this abnormal finding remains unclear. The milder immunologic phenotype observed in the patient compared with gene-targeted *Lck* knockout mice could be explained by residual, although low, expression of Lck or species differences in redundancy of related signaling kinases. The clinical course of the infant was typical for SCID; he ultimately required BMT, which was reportedly curative.

### Short Stature and Immunodeficiency Due to Mutations of STAT5b

#### Clinical Features

A single patient has recently been reported who had STAT5b deficiency resulting in postnatal growth failure, facial dysmorphism, and immunodeficiency (Kofoed et al., 2003; Rosenfeld et al., 2004). This daughter of consanguineous healthy parents of normal stature had severe growth failure with growth hormone insensitivity. By the age of 16.5 years she was the height of an average 6.5-year-old. She also suffered from chronic diarrhea, generalized eczema, and respiratory ailments, periodically requiring oxygen supplementation. A lung biopsy indicated lymphoid interstitial pneumonia for which the patient was treated with oral steroids. At age 8 she developed severe hemorrhagic varicella, followed by multiple episodes of herpes zoster. At age 10, progressive worsening of her pulmonary function occasioned a repeat lung biopsy in which *Pneumocystis jiroveci* and *Rodococcus equi* were isolated. Institution of appropriate treatment and chronic management of combined immunodeficiency have resulted in an improved quality of life.

#### Laboratory Findings

High levels of endogenous growth hormone, low insulin-like growth factor, normal growth hormone binding protein, and normal growth hormone receptor (GHR) coding sequence pointed to an intracellular defect distal to the GHR, a member of the cytokine receptor gene superfamily that acts through phosphorylation of STAT5b. Indeed, expression of STAT5b was only poorly detectable in patient fibroblasts, which failed to show phosphorylation of the protein in response to GH. STAT5a expression and phosphorylation were normal. Details about the patient's

lymphocyte profile and immune functional studies have not been published in detail.

### Molecular Basis of STAT5b Deficiency

This patient was found to be homozygous for the missense mutation in the *STAT5B* (MIM \*604260) gene, which is located adjacent to STAT3 and STAT5A on human chromosome 17q11.2 (Online Mendelian Inheritance in Man, 2000). The mutation is due to the substitution of C for the G nucleotide at cDNA 2057 in the alanine 630 codon, changing alanine to proline (A630P). The mutation lies in the highly conserved SH2 domain of STAT5b. Although protein is produced (but poorly recognized by some monoclonal antibodies), it is unable to be phosphorylated, preventing dimerization, translation to the nucleus, and activation of transcription.

### Functional Aspects and Animal Model of STAT5b Deficiency

STAT5a and STAT5b are transcription factors that are 96% homologous to each other and are located adjacent to one another in head-to-head orientation in both human and mouse, suggesting that these genes arose by gene duplication. The precise role of each of the two *STAT5* genes is not completely worked out in humans or in mice. Murine knockouts of STAT5a show impaired prolactin-dependent mammary gland development (Liu et al., 1997), while STAT5b knockout mice have a phenotype similar to that observed in GHR-deficient mice (Udy et al., 1997). Deletion of both STAT5a and STAT5b results in a phenotype closely resembling that observed in prolactin receptor-deficient mice, including decreased body size in males, anemia, and impaired mammary gland development in females. These features reflect the role of STAT5 proteins as intracellular transducers of signals from growth hormone, erythropoietin, and prolactin receptors. In addition, STAT5a and STAT5b double-knockout mice show a profound T cell proliferation defect similar to that observed in IL-2R $\beta$ -deficient mice (Teglund et al., 1998). Partial T cell defects can be observed in both STAT5a and STAT5b single-knockout mice (Nakajima et al., 1997; Imada et al., 1998), indicating that the two STAT5 proteins play critical, redundant roles in mouse peripheral T cell activation and proliferation.

### Diagnosis, Treatment, and Prognosis

The coexistence of extreme short stature and combined immunodeficiency may suggest STAT5b deficiency, particularly in a consanguineous family. Because only a single patient has been described to date, the clinical spectrum of disease severity is not known. The multiple roles of STAT5b in many tissues indicate that bone marrow transplantation would not be expected to correct the entire phenotype.

### Concluding Remarks

The recent identification of patients with JAK3 deficiency and IL-7R $\alpha$  deficiency has greatly contributed to our understanding of biological and clinical aspects of B<sup>+</sup> SCID. In a series of 96 children with SCID in Europe, JAK3 deficiency was found to be responsible for ~40% of the B<sup>+</sup> SCID patients, making JAK3 SCID nearly as common as X-linked SCID. This finding is in contrast to recent reports from the United States, where fewer than 10% of B<sup>+</sup> SCID patients with known genetic cause have

defects in JAK3 (Buckley, 2000b). This discrepancy may reflect a real variability in the incidence of the disease in different gene pools, but it may also be due in part to an ascertainment bias. Autosomal recessive SCID is less likely to have a positive family history than X-linked SCID, and infants presenting with serious infections may die before referral to immunology centers for diagnosis. In addition, we have shown that several patients with JAK3 defects express substantial amounts of JAK3 protein, indicating that specialized functional assays and DNA sequence determination are the only reliable tools for unequivocal identification of patients with SCID due to JAK3 mutations. On the other hand, the development of molecular and biochemical assays to identify JAK3 (and  $\gamma$ c) defects demonstrated that not all T-B<sup>+</sup> SCID patients have abnormal JAK3 or  $\gamma$ c and opened the way to the identification of *IL7R* and *IL2R $\beta$*  defects (Puel et al., 1998; Gilmour et al., 2001b).

Longitudinal observation of patients with mutations in genes responsible for B<sup>+</sup> SCID has clearly established the gradual appearance of circulating T lymphocytes with abnormal activation markers and low proliferative responses to mitogens (South et al., 1977; Morelon et al., 1996; Mella et al., 2000; Frucht et al., 2001). There is no clear explanation for these findings at present; however, in light of the progressive appearance and accumulation of activated and anergic T cells described in *Jak3* knockout mice, it is tempting to speculate that the occurrence of circulating T lymphocytes in these patients may reflect the natural history of JAK3 deficiency as well as other immunodeficiencies caused by disorders of cytokine signaling. If this hypothesis proves to be correct, the clinical and immunological spectrum of these forms of combined immunodeficiencies may be broader than currently appreciated. Patients now classified as having combined immunodeficiency with residual T cell function could, in fact, carry mutations in genes of cytokine signaling molecules.

## V(D)J Recombination Defects

JEAN-PIERRE DE VILLARTAY, KLAUS SCHWARZ, and ANNA VILLA

The vertebrate cognate immune system recognizes and responds to a virtually infinite number of foreign antigens via antigen-specific immunoglobulin (Ig) or T cell receptor (TCR) molecules expressed on the cell surface of B and T lymphocytes, respectively. While the Ig receptor of B cells binds to soluble antigens, the TCR receptor recognizes peptide antigens presented by human leukocyte antigen (HLA) molecules. In general, allelic exclusion prevents expression by a single lymphocyte of two different receptors encoded by homologous alleles. The expression of each distinct receptor is maintained in the clonal progeny of a lymphocyte.

### V(D)J Recombination

Immunoglobulin and TCR chains consist of two structural domains: the constant regions mediate effector functions, while the variable part of the receptor chains forms the antigen-binding pocket. A site-specific recombination event (VDJ recombination) leads to generation of the variable domains of mature antigen receptor genes from a set of subgenic segments classified as variable (V), diversity (D), and joining (J) elements (for review see Schlissel and Stanhope-Baker, 1997; Nemazee 2000). In principle, each of the V elements can join to any of the D and J modules, thus a finite number of subgenes can establish the enormous antigen receptor diversity.

Seven gene loci encoding the Ig heavy (IgH) and light chains as well as the TCR  $\alpha$ ,  $\beta$ ,  $\gamma$ , and  $\delta$  chains can potentially undergo somatic DNA recombination during lymphocyte development. The loci share a similar conserved overall organization (Color Plate 11.IA); however, the precise number of subgenic segments and their organization vary between different loci and species (Litman et al., 1993).

The principle of V(D)J recombination is a simple cut-and-paste mechanism, fusing in each step two subgenic DNA segments

(Color Plate 11.IB) (Lewis, 1994). This reaction is based on a universal tag for all V, (D), and J modules. These gene segments are flanked by recombination signal sequences (RSS) (Color Plate 11.IA), which consist of a conserved heptamer and an AT-rich nonamer nucleotide motif, separated by a  $12 \pm 1$  bp or  $23 \pm 1$  bp spacer (Ramsden et al., 1994). Spacer length, therefore, defines two types of RSSs, termed 12-RSS and 23-RSS, and efficient recombination occurs only between a 12-RSS and a 23-RSS, a restriction called the *12/23 rule*. Additional regulatory effects of RSS sequence on recombination have been recently described (Bassing et al., 2000).

The V(D)J recombination reaction can be divided into two main steps involving several different subreactions (Table 11.1). The first part of the recombination process is lymphocyte-specific and results through an endonucleolytic cut in DNA double-strand breaks (DSB) at the border between the RSS heptamer and the flanking coding segment. In vivo, in a single V(D)J recombination reaction, four DNA ends are generated simultaneously through the synchronous cut at two distinct gene segments: two blunt, phosphorylated signal ends and two hairpin-sealed coding ends. The second part of the V(D)J rearrangement involves the processing of the signal and coding ends, in which, ultimately, factors of a ubiquitous DNA double-strand repair pathway are recruited to link the signal and coding ends.

The standard products of V(D)J recombination result from ligation of the two coding elements (coding joints) and of the two heptamers of the RSS (signal joints). Depending on the orientation of the two RSSs to each other, the rearrangement process leads to a DNA deletion or inversion (Color Plate 11.IC). Most rearrangement events stem from a deletion of the DNA connecting the recombined V(D)J elements and produce an extrachromosomal DNA circle with a signal joint (Fujimoto and Yamagishi, 1987; Okazaki et al., 1987). At the TCR $\beta$ , TCR $\delta$ , and

RSS, recombination signal sequence; TdT, terminal deoxynucleotidyl transferase.

\*Alternative models suggest that steps 2 and 3 are interchangeable and that step 7 may precede steps 5 and 6.

Ig $\alpha$  loci, inversions have been noticed (Feddersen and van Ness, 1985; Malissen et al., 1986; Korman et al., 1989), with a slight preference of deletions over inversions (Hesse et al., 1987).

V(D)J recombination can result in alternative products such as “hybrid” or “open-and-shut” junctions (Plate 11.IC). *Hybrid joints* arise through the ligation of one coding end to the signal end of the other. In an *open-and-shut joint*, which is less common, the signal and coding ends created by site-specific cleavage are modified prior to their religation (Lewis, 1994). These alternative products are rare events, but they obey the rules of V(D)J recombination and are indicative of the notion that four open DNA ends are intermediates in the rearrangement process.

The signal ends are usually ligated without modification of the DNA (Lieber et al., 1988). In contrast, joining of coding ends is generally imprecise, with base losses and/or additions (N and P nucleotides) of approximately 10 to 15 nucleotides. This process helps to diversify the receptor repertoire but includes the risk of creating nonfunctional genes because of out-of-frame joining and/or introduction of premature stop codons. The enzyme terminal deoxynucleotidyl transferase (TdT) adds random, GC-enriched nucleotides (N nucleotides) to coding ends by a template-independent polymerization. P nucleotides represent short, palindromic repeats of coding end DNA. They are thought to be generated when the “hairpin,” a coding end intermediate of the V(D)J recombination reaction (Color Plate 11.II), is resolved through an endonucleolytic attack, not at the tip of the covalently closed termini but within the coding element. Other mechanisms contributing to junctional diversity are erosion of a small and variable number of bases at coding ends by exo- or endonucleases, and homology joining through short-sequence homologies at free DNA ends (for review see Fugmann et al., 2000).

The “recombinase” machinery, a multiprotein complex, is responsible for the V(D)J recombination. At present, it is unclear if all of the recombinase constituents interact physically at a single time point or if single functions of the machinery follow each other in an ordered fashion. Nine proteins have been identified thus far as participating in the various phases of the V(D)J recombination reaction (Table 11.1). The recombination activating genes 1 and 2 (*RAG1* and *RAG2*) are necessary and sufficient to initiate V(D)J recombination on an accessible antigen receptor gene locus (McBlane et al., 1996). The second phase of this reaction requires Artemis in addition to *RAG1/RAG2* for the process

**Table 11.2.** Constituents of the Recombinase Machinery

	Human Gene Locus	Human Disease	Animal Model	Cell Lines
RAG1	11p13	SCID	KO mouse	AMuLV-transformed pre-B cells

AMuLV, Abelson murine leukemia virus; DNA-PKcs, DNA-protein kinase–dependent catalytic subunit; KO, knockout.

of the coding end intermediates. The template-independent DNA polymerase TdT adds N nucleotides and contributes substantially to receptor diversity. The DNA-dependent protein kinase (DNA-PK), with its DNA binding constituents KU70 and KU80 and its catalytic subunit DNA-PKcs, recognizes open DNA ends. *XRCC4* (the gene responsible for the defect present in cells of group 4 of X-ray cross-complementing cell lines) seems to interact with ligase IV in the ligation step of DNA DSB repair. Despite the recent cloning of Artemis, many different factors of the recombinase machinery (*trans*-acting factors for locus accessibility and exo- and endonucleases) are still unknown. Of the identified factors, only the *RAG1*, *RAG2*, ligase IV, and Artemis genes have been implicated in an inborn immunodeficiency (Table 11.2) (Schwarz et al., 1996; Villa et al., 1998; Corneo et al., 2000; Moshous et al., 2001; O’Driscoll et al., 2001). Lastly, a human severe combined immunodeficiency (SCID) condition with V(D)J recombination deficiency caused by an undescribed gene has recently been reported (Dai et al., 2003).

### Complete *RAG1* and *RAG2* Deficiency (B-T<sup>−</sup> SCID)

#### History

Siblings with diarrhea, candidiasis, lymphopenia, and diminished lymphoid tissue were first described by Glanzman and Riniker (1950). Thymic dysplasia and hypogammaglobulinemia were subsequently analyzed in new cases (Cottier, 1958; Hitzig et al., 1958). Knowledge of the antigen receptor gene structures and their processing allowed the definition of recombinase defective patients (Schwarz et al., 1991; Abe et al., 1994). A subgroup of patients with defective V(D)J recombination exhibited *RAG1/2* mutations (Schwarz et al., 1996).

#### Definition

The functional failure of one of the constituents of the V(D)J recombinase machinery, such as *RAG1* or *RAG2*, results in

a SCID without B and T cells (B<sup>-</sup>T<sup>-</sup> SCID), MIM (Mendelian Inheritance in Man) numbers 179615 and 179616, respectively.

### Clinical Manifestation

Severe combined immunodeficiency has an estimated incidence of approximately 1 per 100,000 live births (Stephan et al., 1993). In the original report, six patients of 30 SCID cases analyzed exhibited a RAG1/2 defect, thus the RAG deficiency may account for a substantial proportion of human SCID cases (Schwarz et al., 1996). In a recent large series about 20% of SCID cases were RAG-dependent (Villa et al., 2001).

The clinical presentation is relatively uniform. As a rule, no symptoms are detected during pregnancy or birth or within the first few weeks of life. In most cases, the symptoms start within the second or third month after birth. Infectious complications are the hallmark of the disease, with a high preponderance of opportunistic infections (e.g., *Pneumocystis carinii* infection). The clinical signs are characterized by chronic, persistent disease of the airways, recurrent acute pneumonia, therapy-resistant mucocutaneous candidiasis, eczematous dermatitis, and local as well as systemic bacterial infections (otitis, mastoiditis, purulent rhinitis and conjunctivitis, septic disease, meningitis, arthritis, and local abscesses). The recurrent infections in addition to chronic enteritis lead to therapy-resistant growth failure. Furthermore, intracellular parasites (*Listeria*, *Legionella*) as well as viruses (Epstein-Barr virus [EBV] and cytomegalovirus [CMV]) may cause lethal complications.

Noninfectious clinical manifestations may result from graft-vs.-host disease (GVHD). Because of the immunodeficiency, patients cannot reject allogeneic cells. Allogeneic cells are introduced into patients either through maternofetal transfusion or as supportive, nonirradiated blood products. While GVHD due to maternal lymphocytes is usually relatively mild with erythrodermia, eosinophilia, enteritis, and hepatitis, GVHD following transfusion is frequently lethal. Vaccination with living organisms such as application of the bacillus Calmette-Guerin (BCG) strain may cause fatal consequences. All SCID children die within a few months if they are not provided with hematopoietic stem cells.

Physical examination of completely RAG-deficient patients reveals unusual infections and a characteristic absence of lymphatic organs. In most cases cervical lymph nodes and tonsils are undetectable.

### Laboratory Findings

Patients exhibit no B and T cells of their own in the peripheral blood (B<sup>-</sup>T<sup>-</sup> SCID) (Table 11.3). Maternal T lymphocytes have been detectable in more than 50 cases and functional natural killer (NK) cells are present. After loss of the initially present maternally transfused immunoglobulins, no antibodies circulate in the peripheral blood of RAG-deficient patients. In vivo and in vitro functional lymphocyte tests are not informative because of the lack of the respective cells.

The RAG1 and RAG2 deficiency is an autosomal recessive disease. Both genes are located on chromosome 11p13 (Oettinger et al., 1992; Schwarz et al., 1994). Carriers of the mutant genes are healthy without any immunologic disturbances and are therefore only detected through molecular identification of the mutation in question. A B<sup>-</sup>T<sup>-</sup> SCID immunophenotype in umbilical cord blood may suggest, among others, a RAG defect that must be confirmed by molecular analysis.

**Table 11.3.** Laboratory Findings in Peripheral Blood of Recombination-Deficient Patients

	<i>RAG-SCID</i>	<i>Omenn Syndrome</i>	<i>Artemis RS-SCID</i>

NA, not applicable; NK, natural killer.

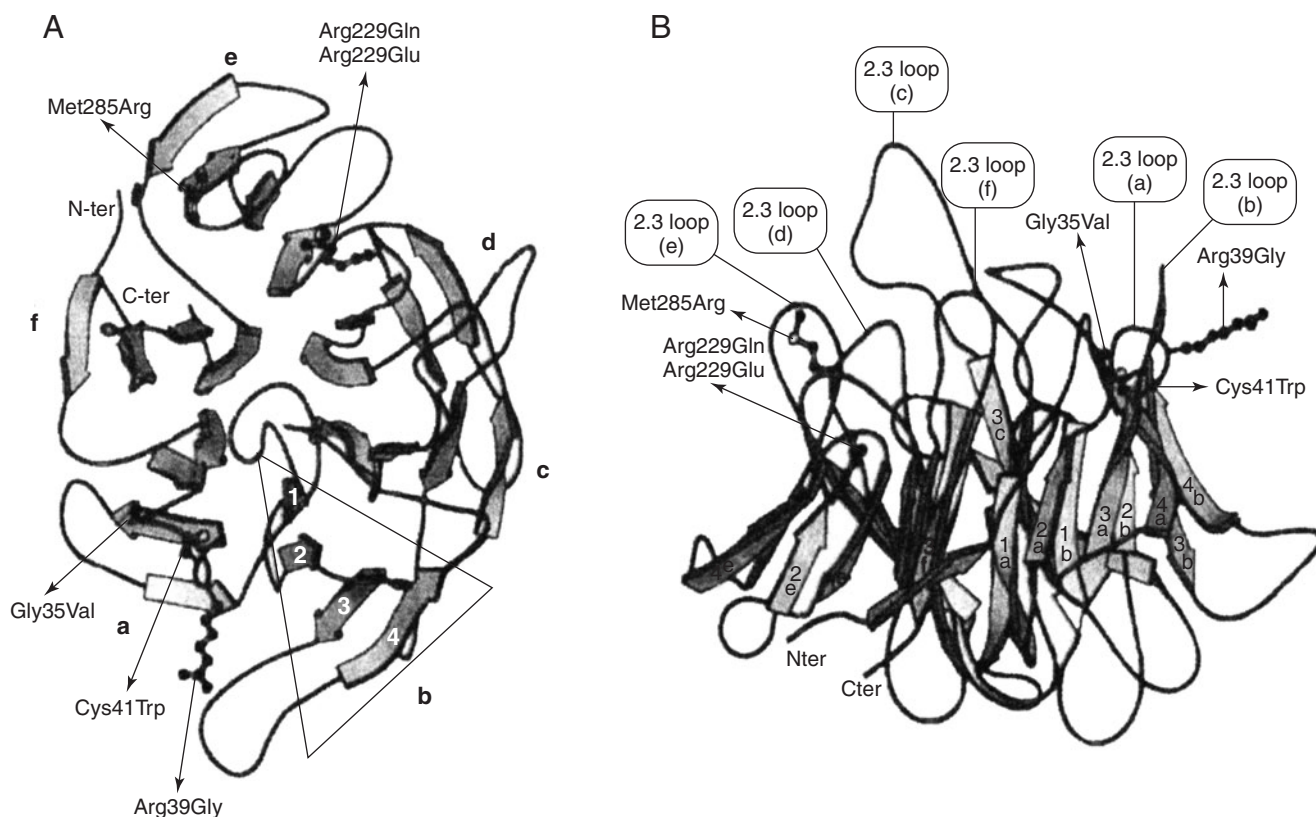

\*After exclusion of maternally transfused T cells, which can be detected in more than 50% of the cases.

### RAG Gene Structure and Function

The murine *Rag1* and *Rag2* genes were initially identified and cloned on the basis of their ability to rearrange an integrated artificial recombination substrate in a cell line (Schatz et al., 1989; Oettinger et al., 1990). The two complementing genes show a unique organization. Their 3' ends face each other and are separated in human DNA by 15–18 kb. The coding sequences and the 3' untranslated region (UTR) of both genes are located on one exon (Ichihara et al., 1992). *RAG1* possesses one extra 5' UTR exon, whereas in the *RAG2* locus at least two 5' UTR exons have been identified (Lauring and Schlissel, 1985). The amino acid sequence and the overall genomic organization are highly conserved throughout evolution from zebrafish to humans (Bernstein et al., 1994; Wienholds et al., 2002). No homologues have been found in lower organisms. The human *RAG1* gene codes for 1403 amino acids; the *RAG2* gene, for 527 amino acids.

RAG1 and RAG2 protein sequences are not related to each other. A sequence comparison of RAG1 with other proteins shows that RAG1 possesses five basic regions that are necessary for nuclear localization (binding sites for nuclear protein SRP1 and RCH1), a region with homology to bacterial invertases and homeodomain proteins, zinc finger domains, and a zinc binding dimerization motif (Color Plate 11.III) (Silver et al., 1993; Difilippantonio et al., 1996; Rodgers et al., 1996; Spanopoulou et al., 1996). More recently, extensive mutagenesis of acidic amino acids in RAG1 identified three catalytic residues (D600, D708, and E962, DDE motif) critical for both nicking and hairpin formation (Landree et al., 1999); two of these (D600 and D708) coordinate catalytic divalent metal ions (Kim et al., 1999; Landree et al., 1999; Fugmann et al., 2000b). These residues are located in a region that displays marked conservation in predicted secondary structure with the catalytic cores of other transposases (Fugmann et al., 2000b). Further insight into RAG1 activities has been derived from mutants blocking the hairpin formation, which are all in the vicinity of D600 (Kale et al., 2001). Recent studies have demonstrated that two regions of RAG1, the nonamer binding domain and the carboxy-terminal domain, contact DNA containing the coding flank at the cleavage site (Mo et al., 2001).

The molecular roles of RAG2 in V(D)J recombination are less known. The presence of RAG2 is required for all catalytic steps and helps to form the RAGRSS complex. Secondary structure prediction and mutagenesis studies have suggested that

**Figure 11.1.** (A) Beta-propeller structure of RAG2. Each blade of the propeller consists of a four-stranded beta sheet. (B) Beta-propeller structure viewed along the perpendicular axis. Mutated amino acids are indicated.

RAG2 adopts a six-bladed  $\beta$ -propeller fold (Fig. 11.1) (Callebaut and Morion, 1998; Corneo et al., 2000; Gomez et al., 2000), a structural motif found in many proteins of diverse function (Adams et al., 2000). Biochemical analysis of the recombinant RAG2 proteins has allowed the identification of a number of basic residues mutants defective in catalysis in vitro and V(D)J recombination in vivo, supporting the direct involvement of RAG2 in DNA binding during all steps of the cleavage reaction. According to these experiments, Schatz proposed a model for the interaction of RAG2 with DNA in which two amino acids (K119 and K283) directly contact DNA (Fugmann and Schatz, 2001). The C-terminal region of RAG2 (from aa 417 to 484) shows homology with the plant homeodomain (PHD), a motif that has been identified in chromatin remodeling proteins. In line with a potential role in chromatin remodeling, this region has been implicated in facilitating the ordered rearrangement of IgH chains (Kirch et al., 1998) and in binding to the core histone proteins (West et al., 2005).

Another role of RAG genes is the ability to catalyze in vitro transpositional insertion which suggests that this process could be a source of genomic instability in vivo (Agrawal et al., 1998; Hiom et al., 1998). Recent work has shown that RAG transposase forms productive complexes with target DNA both before and after RSS cleavage and, these show a preference for transposition into nearby targets, such as Ig and TCR loci. This could bias transposition toward relatively safe regions in the genome (Neiditch et al., 2001). In addition, the transposition events are stimulated and targeted by the presence of distorted DNA structures such as hairpins (Lee et al., 2002). Because there are no evidence that RAG-mediated transposition occurs in vivo, it is

likely that regulatory mechanisms could limit the frequency of transposition events in lymphocytes. During lymphocyte development in adults, the RAG genes are convergently transcribed in thymic and bone marrow cells with a capability for V(D)J recombination (Schatz et al., 1989; Oettinger et al., 1990; Turka et al., 1991). Mature RAG proteins are localized to the nucleus (Silver et al., 1993; Leu and Schatz, 1995). In developing thymocytes, RAG expression is first detected in committed T cell precursors that are double negative (DN), whereas the first B cells expressing RAG1 and RAG2 are AA.4.1<sup>+</sup>HSA<sup>+</sup>B220<sup>+</sup>CD4<sup>+</sup>CD43<sup>+</sup> even at very low levels. The RAG expression increases as B cells mature. Following the proliferative expansion of pre-B and pre-T cells, a second wave of RAG expression is initiated in CD25<sup>+</sup> pre-BII cells and CD4<sup>+</sup> and CD8<sup>+</sup> (DP)T cells. This second expression has been shown to be regulated by elements at the 5' end of RAG2 promoter (Yu et al., 1999). RAGs are not expressed in mature T cells. Immunohistochemical analysis detected RAG expression in germinal centers in the mouse (Han et al., 1996; Hikida et al., 1996); however, transgenic indicator and gene-targeted indicator lines have shown that the small number of cells expressing RAG are immature B cells (reviewed in Nagaoka et al., 2000).

The minimal promoter of RAG1 has been mapped (nucleotides 111 to 97 relative to the position of the major transcriptional start site) (Brown et al., 1997; Zarrin et al., 1997). The promoter exhibits neither the presence of an initiator motif nor a functional TATA box. Several potential recognition sites for the E2A-, Ikaros-, and ETS-family transcription factors are present within the RAG1 promoter. In addition, consensus PEPB2/CBF and Y-box/CCAAT sequence motifs are detectable.

Nuclear factor-Y (NF-Y) binds to the RAG1 Y-box motif. A mutation of the Y-box motif abolishes the binding of NF-Y transcription factor and significantly reduces RAG1 promoter activity (Brown et al., 1997). Through in vivo investigation with bacterial artificial chromosome transgenes containing a fluorescent indicator, the coordinate expression of RAG1 and RAG2 in B and T cells was found to be regulated by distinct genetic elements mapping on the 5' side of the *RAG2* gene (Yu et al., 1999). Recently a new element, named Erag, which seems to have a role in RAG transcription in B cells, has been identified (Hsu et al., 2003).

### Mutation Analysis

Mutagenesis experiments have defined core regions for RAG1 and RAG2 that are necessary and sufficient to recombine extrachromosomal V(D)J recombination substrates. The RAG1 core spans from amino acids 392 to 1011, whereas the RAG2 core extends from amino acids 1 to 382 (Sadofsky et al., 1993, 1994; Silver et al., 1993; Cuomo and Oettinger, 1994). Mutation analysis through single-strand conformation polymorphism (SSCP) assays in 14 T-B<sup>-</sup> SCID patients detected six SCID cases with RAG defects (Table 11.4) (Schwarz et al., 1996). After sequencing the respective *RAG* genes, five missense and three nonsense mutations and one deletion mutation were detected (Table 11.4). All of the mutations were inherited. All human RAG1 substitutional mutations map to phylogenetically conserved residues within the RAG1 core region, whereas the Cys (478)-to-Tyr mutation of RAG2 is located outside the RAG2 core region. No functionally relevant RAG mutation was detected in healthy subjects or B SCID patients. After the first description of T-B<sup>-</sup> SCID cases, many other mutations have been detected in RAG1 and RAG2 (Corneo et al., 2000, 2001; Gomez et al., 2000; Villa et al., 2001). Mutation analysis of RAG1 and RAG2 (<http://bioinf.uta.fi/RAG1base> and <http://bioinf.uta.fi/RAG2base>) indicates that most of them are null mutations (nonsense or frameshift). In addition, although some patients with classical

T-B<sup>-</sup> SCID bear missense mutations, biochemical studies have shown that these amino acid changes completely abrogate recombination ability and therefore represent null alleles (Schwarz et al., 1996; Corneo et al., 2000; Gomez et al., 2000). In transient transfection assays with artificial extrachromosomal rearrangement substrates, the mutants derived from completely RAG-deficient SCID patients show only residual recombination values that are typically 0.1–1 of wild type for both coding and signal joint formation. Although the mutant RAGs result in a marked decrease in recombination efficiency, rare signal and coding joints occur that are qualitatively indistinguishable from wild type, indicating that the enzymatic machinery following the initial DNA DSB induced by the RAG protein is unaffected by these mutations.

Pre-B and pre-T cells do not survive during lymphocyte development if they do not obtain a survival signal from their respective pre-B and pre-T cell receptors. The heavy chain of the IgM molecule and the TCR chain are necessary constituents of the respective receptors. In case of a complete RAG deficiency, V(D)J recombination cannot be initiated; thus IgM and TCR chains are not synthesized and are not available for a pre-B or pre-T cell receptor. The precursor lymphocytes receive no survival signal and die, hence the alymphocytosis in patients with complete RAG1 and RAG2 deficiency.

### Diagnosis

At present, no simple functional test exists to reveal a V(D)J recombinase defect in general or a specific RAG defect. Protein analysis is not a practical alternative because the relevant recombining cells are a minority within the bone marrow cell population or are amenable to analysis only after thymic biopsy. Thus, only a direct or indirect genetic analysis of the *RAG* genes on genomic DNA can be carried out in B-T<sup>-</sup> SCID cases.

### Treatment

Treatment of RAG-defective children consists of a combination of supportive measures (see Chapter 46) and curative therapy of bone marrow or peripheral stem cell transplantation (see Chapter 47). An HLA-identical donor is no longer a prerequisite for reconstitutive hematopoietic stem cell transplantation, since depletion of T cells from a nonidentical graft omits or greatly reduces the risk of GVHD. When indicated, patients may be transplanted without a prior conditioning regimen because their immunodeficiency renders a reduced frequency of graft rejection. Survival after transplantation procedures in the small RAG-deficient group is 65%. In utero bone marrow transplantation (BMT) has also been performed in selected patients (F. Porta, personal communication).

An alternative therapeutic approach is gene therapy (Cavazano-Calvo et al., 2000; Fisher et al., 2002). Although there have been no studies of RAG gene therapy in humans, experiments of retrovirally mediated *Rag2* gene transfer in hematopoietic stem cells of *Rag2* knockout mice showed good results, opening the door to clinical application (Yates et al., 2002).

### Animal Models of RAG1/2 Deficiency

Mice with homozygous deletions of either *Rag1* or *Rag2* have been created by gene targeting (Mombaerts et al., 1992; Shinkai et al., 1992). Both mouse strains exhibit an identical phenotype to that of each other or that of human RAG-deficient patients. The

animals cannot initiate V(D)J recombination, thus lacking B and T cells and their immunological functions. During lymphocyte development, RAG1- and RAG2-deficient thymocytes accumulate as quiescent cells with a heat-stable antigen (HSA)-positive, CD25, CD4, c-kit-low phenotype resembling normal cells just prior to functional TCR chain expression. B cell development is halted at the pre-B cell stage (Mombaerts et al., 1992; Shinkai et al., 1992; Diamond et al., 1997). Functional defects other than the immunological ones are not known in Rag-deficient mice. There is only one report in the literature showing that Rag1 knockout mice exhibiting increased locomotor activity and reduced levels of fearfulness (Cushman et al., 2003).

Recently, Rag2 mice were generated replacing the endogenous Rag2 locus with core Rag2, thus generating mice lacking the “dispensable” C-terminal domain. These mice display a reduction in the total number of B and T cells, reflecting impaired lymphocyte development at the progenitor stage associated with reduced chromosomal V(D)J recombination (Liang et al., 2002; Akamatsu et al., 2003). This finding demonstrates that the C-terminal domain, which is dispensable for V(D)J recombination in vitro, has relevant functions in vivo. This is also true for the “dispensable” Rag1 N-terminal domain (see below).

### Partial RAG1 and RAG2 Deficiency (Omenn Syndrome)

Omenn syndrome (OS) is a rare disorder that has been an enigma for pediatricians and immunologists for a long time. First defined in 1965 (Omenn, 1965), OS is a rare autosomal recessive disease characterized by symptoms of SCID associated with other findings including erythrodermia, eosinophilia, hepatosplenomegaly, lymphadenopathy, and elevated serum IgE levels, suggesting a defect in the activation and/or regulation of T cell proliferation (MIM 267700). The identification of specific mutations of RAG genes in OS patients has now made it clear that the underlying defect of this particular syndrome affects the maturation of both T and B lymphocytes and that the activation of the T cell subset is secondary to a partially defective V(D)J recombination process (Villa et al., 1998). However, the occurrence of the same mutation responsible for partial V(D)J activity in patients with T-B<sup>-</sup> SCID and those with OS raises the possibility that additional factors such as epigenetic factors are required for the development of the Omenn phenotype (Corneo et al., 2001; Villa et al., 2001).

#### Clinical and Pathological Manifestations

Patients with OS present with early-onset generalized erythrodermia (Color Plate 11.IV), lymphadenopathy, hepatosplenomegaly, fever, protracted diarrhea, and failure to thrive. Protein loss due to diarrhea and exudative erythrodermia often leads to generalized edema. The presence of a massive inflammatory infiltrate gives the skin a unique appearance and consistency (pachydermia). Alopecia is a frequent finding (Aleman et al., 2001).

Despite the presence of reactive lymph nodes and variable, often elevated, numbers of circulating T lymphocytes, OS patients are severely immunodeficient and thus highly susceptible to bacterial, viral, and fungal infections. Unless treated by BMT the disease is invariably fatal. Infections and severe malnutrition are the main causes of death (Gomez et al., 1995). Septicemia, often arising from skin infections, is common.

The clinical hallmarks of the disease (summarized in Table 11.5) are reminiscent of GVHD. Indeed, in some cases the

**Table 11.5.** Diagnosis of Omenn Syndrome: Clinical and Laboratory Hallmarks

#### Clinical Features

Early onset, generalized erythrodermia  
Failure to thrive  
Protracted diarrhea  
Edema  
Lymphadenopathy  
Hepatosplenomegaly  
Severe infections (pneumonia, sepsis)

#### Laboratory Features

Hypoproteinemia  
Frequent anemia, thrombocytopenia  
Remarkable eosinophilia (usually >1000/ $\mu$ l)  
Very low IgG, IgA, and IgM, but usually increased IgE  
Very low or absent circulating B cells  
Variable (often elevated) number of activated (CD45RO<sup>+</sup>, DR<sup>+</sup>) circulating T cells  
Very low in vitro proliferative responses to antigens, variable response to PHA  
Low, IgM-restricted, antibody responses

occurrence of maternal T cell engraftment in infants with SCID may result in clinically overt GVHD and mimic OS (Pollack et al., 1982; Le Deist et al., 1987). Furthermore, transfusion of unirradiated blood products into SCID babies also results in severe GVHD that resembles OS (Anderson and Weinstein, 1990). Because of the similarities in clinical presentation, these cases are also referred to as Omenn-like syndrome. For a diagnosis of OS, it is therefore essential that, in addition to typical clinical and laboratory findings, maternal T cell engraftment and transfusion-associated GVHD be excluded. The similarity of OS to GVHD is further reinforced by the pathologic features of OS. Skin biopsies reveal lymphocytic infiltrates in the upper dermis, with occasional histiocytes and eosinophils (Dyke et al., 1991). Immunohistochemical analysis shows that the lymphocytic infiltrate is composed of activated (CD45RO, DR) T cells, many of which coexpress CD30, a surface molecule predominantly expressed by lymphocytes producing Th2-type cytokines (Chilosi et al., 1996b). The differential diagnosis of OS includes severe atopic dermatitis, GVHD, and histiocytosis X, known as Letterer Siwe syndrome (Aleman et al., 2001).

Lymph node enlargement, typically observed in OS, is in contrast to the paucity of peripheral lymphoid tissue usually detected in patients with combined immune deficiencies. However, the lymph node architecture is severely altered in OS, as shown by a lack of follicles, depletion of the normal lymphocytic population, and increased proportion of interdigitating reticulum cells and eosinophils (Omenn, 1965; Barth et al., 1972; Dyke et al., 1991; Martin et al., 1995). On the basis of these findings, the disease was originally also named *familial reticuloendotheliosis with eosinophilia* (Omenn, 1965), or *combined immunodeficiency and reticuloendotheliosis with eosinophilia* (Ochs et al., 1974). Immunohistochemistry indicates that the lymphocytic component in the lymph nodes is due to activated T cells (CD3, CD45RO, DR) that often coexpress CD30 and/or CD25 (Chilosi et al., 1996a, 1996b; Brugnani et al., 1997). In contrast, staining for B cells is typically negative. The splenic white pulp, Peyer's patches, and lamina propria of the gut are also markedly depleted of lymphocytes. Severe abnormalities have also been reported in the thymus, which is profoundly hypoplastic, with

a noticeable depletion of the lymphoid components and often lack of Hassal's bodies (Barth et al., 1972; Businco et al., 1987).

### Laboratory Findings

As summarized in Table 11.5, the main laboratory findings in OS consist of eosinophilia, hypogammaglobulinemia with increased serum IgE, presence of activated circulating T lymphocytes, in contrast to the usual lack of peripheral blood B cells, and a poor in vitro proliferative response of T lymphocytes to specific antigens (with variable responses to mitogens). Additional laboratory findings include the frequent occurrence of anemia (and sometimes of thrombocytopenia) and of severe hypoproteinemia due to protein loss through the stools and the skin.

In contrast to most forms of combined immunodeficiency, the total number of circulating T cells is variable but often elevated (Table 11.3). Distribution of the main T cell subsets (i.e., CD4 vs. CD8) is frequently imbalanced (Karol et al., 1983; Le Deist et al., 1985; Businco et al., 1987; Brugnoni et al., 1997). In a few cases, circulating T cells that express the form of the T cell antigen receptor (TCR) predominate over TCR T cells (Brugnoni et al., 1997). An extreme example of the variability in T cell number in OS (which has offered a crucial clue to the definition of the molecular basis of the disease) is represented by a pedigree in which one patient had typical OS with an increased number of circulating T cells, whereas one of his younger brothers died with B-T<sup>+</sup> SCID (de Saint Basile et al., 1991).

Many of the immunological hallmarks of the disease reflect the presence of activated T cells that are skewed to a Th2 phenotype. Similar to what has been observed in the skin and lymph nodes, circulating T cells coexpress activation markers (CD45R0, DR, CD25, CD95, CD30). These activated T cells secrete predominantly Th2-type cytokines (IL-4, IL-5) upon in vitro activation. Accordingly, serum levels of IL-4 and IL-5 are increased. In contrast, the in vitro production of IL-2 and IFN- $\gamma$  is reduced, as are their serum levels (Schandene et al., 1993; Chilosi et al., 1996a; Brugnoni et al., 1997). The abnormal production of IL-4 and IL-5 is supposed to be responsible for the increased production of IgE and eosinophilia, respectively.

The serum levels of IgG, IgA, and IgM are markedly reduced, yet in vivo antibody production is severely but not completely impaired (Le Deist et al., 1985), as indicated by a measurable although low and IgM-restricted antibody response to immunization with bacteriophage x174 (Ochs et al., 1974). Hypogammaglobulinemia is partially due to protein loss but also reflects defective B cell differentiation, with a very low or absent number of circulating B cells. Because B lymphocytes are usually undetectable in the lymph nodes and the gut, it remains unknown where the IgE secretion occurs.

Although T lymphocytes are consistently present and show an activated phenotype, they are functionally defective, with reduced proliferative responses to antigens and occasionally to mitogens as well (Le Deist et al., 1985; Businco et al., 1987; Brugnoni et al., 1997; Harville et al., 1997). Contributing to this T cell defect is increased cell death through two distinct mechanisms. Reduced expression of antiapoptotic molecules (e.g., bcl-2) and poor production of IL-2 (a growth-promoting cytokine) have been observed (Schandene et al., 1993; Brugnoni et al., 1997), both contributing to increased programmed cell death. Furthermore, it has been shown that T lymphocytes from OS patients are highly susceptible to activation-induced cell death (AICD), particularly through CD95 signaling (Brugnoni

et al., 1997). This susceptibility to CD95-dependent AICD likely reflects chronic antigenic stimulation in vivo. The observation that occasionally patients with OS have an expansion of TCR, double-negative (CD4<sup>+</sup>CD8<sup>+</sup>) T cells (Wirt et al., 1989) could reflect an attempt to overcome chronic in vivo activation, similar to what has been reported in patients with autoimmune lymphoproliferative disease (CD95 deficiency). Oligoclonality of circulating T cells has been consistently described in OS (Wirt et al., 1989; de Saint Basile et al., 1991; Harville et al., 1997; Rieux-Laucat et al., 1998; Villa et al., 1998). Although the use of distinct variable (V) gene segments is not particularly biased, few clones are expanded within each population of T cells that express specific V genes, as demonstrated by sequence analysis showing sets of identical V(D)J sequences (Harville et al., 1997; Villa et al., 1998). It has been hypothesized that restriction of the TCR repertoire could arise in the periphery or in the thymus, leading to the inability to properly accomplish all the steps required for intrathymic maturation. By analyzing T cells from both thymus and peripheral blood from a deceased patient, it has been demonstrated that the TCR $\beta$  repertoire is already restricted in the thymus, although further selection occurs in the periphery (Signorini et al., 1999; Pirovano et al., 2003).

### Mutation Analysis in Patients with Omenn Syndrome

Because of the rarity of the disorder, analysis of OS by positional cloning has not been possible; for a long time the search for the responsible gene has been elusive. For this reason, most investigators have relied on the candidate gene approach to try to identify the molecular defect of OS. This strategy is particularly useful in genetic diseases affecting the immune system, as much information has been gathered over the past years on the various steps in the differentiation of lymphoid cells and on the genes involved in this maturation process.

As mentioned above, the clinical picture of OS is atypical and there were few reasons to suspect that RAG mutations could be responsible for this disease. However, one hint came from descriptions of the occurrence of OS and SCID within members of the same family (de Saint Basile et al., 1991). The issue was also complicated by the similarities between OS and SCID with maternal engraftment. Nevertheless, the analysis of RAG genes showed mutations in typical OS patients (Villa et al., 1998; Corneo et al., 2001). To explain why a defect in the same genes can give rise to such different phenotypes, factors such as genetic background, modifier genes, and epigenetic events are often called into question. However, it is now clear that mutations in different domains of RAG genes can affect the protein structure to various extents, leading either to null alleles in which the gene is completely inactivated or to hypomorphic alleles retaining variable degrees of function. This phenomenon is not unprecedented: among immunodeficiency diseases, one of the best examples is the Wiskott-Aldrich syndrome (WAS), X-linked thrombocytopenia (XLT), and X-linked neutropenia. Once thought to be separate entities, these disorders are now known to have abnormalities in the same gene, the WASP gene (Derry et al., 1994; Villa et al., 1995; Devriendt et al., 2001).

Careful analysis of the OS mutations support the hypothesis that while SCID represents "null" RAG alleles, the OS phenotype is caused by hypomorphic RAG alleles that retain a partial V(D)J recombination activity. According to this view, OS is a "leaky" SCID, allowing some degree of maturation along the

T cell lineage to occur. In contrast to the mutations noted in T-B<sup>-</sup> SCID patients, Omenn patients show predominantly missense mutations, with at least one missense mutation being present in every patient. This finding, together with the presence of oligoclonal cells in the periphery, led us to suggest that limited V(D)J recombination events occur in these patients. Biochemical assays analyzing the capacity to mediate full V(D)J recombination events, SCC formation, and the introduction of double-strand breaks reveal that the proteins containing missense mutations have a reduced but still detectable activity. Hence, in general, SCID patients have two entirely defective alleles, whereas OS patients have at least one allele that is partially functional and capable of establishing the restricted receptor repertoire seen in OS. The view of the Omenn and SCID phenotypes as being dependent on the severity of the genotypic lesion in *RAG* genes is supported by analysis of the 56 OS patients described thus far in the literature (Villa et al., 1998; Wada et al., 2000; Corneo et al., 2001; Kumaki et al., 2001; Villa et al., 2001; Noordzij et al., 2002). Particularly interesting is the description of Omenn cases with alleles carrying nucleotide deletions in the N-terminal domain (Noordzij, 2000; Santagata et al., 2000; see also below).

The biochemical analysis of both null and hypomorphic mutations in *RAG1* and *RAG2* have provided valuable insights into the biology of the RAG1/RAG2 recombinase. The importance of the NBD has been reinforced by the finding that over 30% of *RAG1* mutations identified in Omenn patients result in amino acid substitutions in the NBD, a region spanning only 4% of the molecule. Furthermore, three different substitutions have been identified in the GGRPR motif of RAG1 at position R396 (to C, H, and L) in multiple Omenn patients. This "hot-spot residue" corresponds to R393 of mouse Rag1, located in a region that had previously been identified by homology to the Hin homeodomain and that, if mutated to R393L, retains 30% of wild-type activity. In addition, the capacity of Rag1 to form broad contacts outside of the nonamer is indirectly supported by the preponderance of substitutions in positively charged arginines throughout the molecule. This finding suggests that Rag1 uses a broad, positive-charged surface for interacting with the DNA.

The structural model of Rag2 as a six-bladed  $\beta$ -propeller molecule with a C-terminal PHD finger has been supported by functional data from a number of identified Omenn and SCID mutations. Amino acid substitutions in three SCID patients were localized to the second  $\beta$  strand of the first, second and fourth kelch repeats of RAG2 and were shown to abrogate the V(D)J recombination activity of the altered proteins (Corneo et al., 2000; Gomez et al., 2000). These  $\beta$  strands are highly conserved between and within kelch repeat-containing proteins, where they appear to form the hydrophobic structural core of the molecule. Site-directed mutagenesis targeting many residues in the second  $\beta$  strand revealed that nearly all of the mutant proteins were devoid of recombination activity, further confirming the importance of these conserved regions (Gomez et al., 2000). Moreover, many of the null and hypomorphic RAG2-active core mutations have a spatial clustering on one face of the predicted  $\beta$  propeller, thereby defining a potentially critical surface for interaction with RAG1 (Corneo et al., 2000). Indeed, two of the mutations, C41W and M285R, have been shown to reduce the interaction between RAG2 and RAG1 in coprecipitation assays (Villa et al., 1998). Further support of the structural model of RAG2 has been provided by the identification of four mutations leading to amino acid substitutions in the C-terminal PHD finger (C423Y, W453R, N474S, and C478Y). The W453R substitution was identified in an Omenn patient and has residual levels of recombination

activity (Gomez et al., 2000), while the other three substitutions were found in T-B<sup>-</sup> SCID patients and are likely inactive for recombination. Two of the altered amino acids, C423 and C478 (Schwarz et al., 1996, A. Villa et al., unpublished results), are predicted to coordinate zinc ion and are therefore entirely conserved in all known PHD fingers.

The in vivo importance of the RAG1 N terminus is supported by a novel class of frameshift mutations identified in a group of Omenn patients (Santagata et al., 2000). We have described seven Omenn patients with either one (A887) or two (AA368-9) nucleotides deleted in the 5' coding region of RAG1, resulting in a frameshift and the predicted production of severely truncated and inactive forms of RAG1. In two cases the patients are homozygous for the allele harboring the frameshift deletion and in the remaining five cases the frameshift deletion alleles are coupled with alleles generating proteins that are fully inactive for recombination. Hence, the recombination activity responsible for generating the partial immune repertoire in these patients must be provided by the frameshift alleles. In fact, an N-terminus-truncated active RAG1 protein is generated from these alleles by reinitiation from internal in-frame methionine residues downstream of the deletion. Using a cell culture-based recombination assay, we observed a deficiency in both inversional and deletional recombination capacity of these mutants. While multiple in vitro assays of RAG function can be efficiently performed in the absence of the RAG1 N terminus, the immunodeficiency observed in these patients, coupled with work demonstrating the importance of the N terminus for recombination of endogenous immunoglobulin loci, provides compelling in vivo evidence for a critical role of the N terminus of RAG1 in the recombination reaction. Noordzij and colleagues have reported a similar T<sup>+</sup>/B<sup>-</sup> Omenn patient homozygous for an allele with a single nucleotide deletion (T631) that also demonstrates partial recombination capacity and appears to result in the formation of a partially restricted receptor repertoire (Noordzij et al., 2000).

To gain further insight into the cellular defect resulting from loss of the initial amino acids of the N-terminal domain of RAG1, we analyzed the fluorescence localization in transfected cells of both wild-type and deleted forms of RAG1 fused in-frame to GFP protein. Interestingly, fluorescence was observed in cells transfected with both fusion constructs. Wild-type RAG1/GFP localized to the nucleus as expected, whereas the GFP fusion to  $\Delta$ 368A/369A-RAG1 had an aberrant pattern of localization with most of the fluorescence located in the cytoplasm. These data implicate a defective ability to properly migrate into the nucleus as a component of the pathogenesis associated with  $\Delta$ 368A/369A. This interpretation is strengthened by the identification, in another OS patient, of a frameshift mutation at nt 887, in which translation occurred at an internal methionine, showing similar aberrant cellular localization.

### Mutation Analysis in Atypical SCID Patients

The analysis of a large series of immunodeficient patients with RAG defects has enabled the identification of a new group of patients with some, but not all, of the clinical and immunologic features of OS, a condition we call "atypical SCID/OS." In terms of the molecular basis this category seems to be more like OS than classic SCID because all of these patients carry at least one missense mutation, some of which are shared with those of OS patients. This finding supports the idea that in these patients, partial RAG activity is responsible for the development of a low number of T and possibly B lymphocytes. A third phenotype for mutations

in recombination activating gene 1 (*RAG1*), in addition to the already known phenotypes of SCID and Omenn syndrome has been described (de Villartay et al., 2005; Ehl et al., 2005). The presence of partial RAG activity may be a prerequisite for OS but other epigenetic factors are needed to understand the disease (Corneo et al., 2001; Villa et al., 2001). Alternatively, it is possible that individual differences such as early or delayed medical treatment could contribute to clinical and immunological heterogeneity, particularly because some patients undergo to BMT very early in the course of the disease and this treatment could prevent the development of typical OS symptoms.

### Treatment

Unless treated by BMT, OS is invariably fatal because of infections and/or malnutrition. The clinical presentation is usually so severe that supportive treatment is warranted, even before a diagnosis of OS is formally established (see Chapter 46).

Despite this broad supportive treatment, the clinical status of OS patients waiting for BMT often remains critical, mainly because of cutaneous and intestinal problems directly related to deranged T cell activation. As an attempt to overcome the activation of Th2 cells and to achieve better control of disease activity, different strategies have been used. The daily use of IFN- $\gamma$  (the rationale being to restore the balance between Th1- and Th2-type cytokines) succeeded in the amelioration of clinical conditions in one infant, concurrently with a decrease in eosinophil count and increase in lymphocyte proliferation to mitogens (Schandene et al., 1993). Other groups have tried to block T cell activation using immunosuppressive drugs. Steroids have proven ineffective or only partially effective (Omenn, 1965; Barth et al., 1972; Ochs et al., 1974; Le Deist et al., 1985). Somewhat better results have been obtained with cyclosporine A (Wirt et al., 1989; Brugnani et al., 1997). However, the potential beneficial effect of immunosuppressive drugs and IFN- $\gamma$  is of limited duration, and ultimate treatment is still based on BMT. Because of the specific features of OS, the overall results of BMT in these children are less satisfactory than in other forms of combined immunodeficiencies. The first attempts reported in the literature were disappointing, as only 7 of 26 patients who received BMT were cured (Barth et al., 1972; Junker et al., 1988; Fischer et al., 1990, 1994; Bruckmann et al., 1991; Heyderman et al., 1991; Schofer et al., 1991; Loechele et al., 1995). A high frequency of graft failure was observed, reflecting the presence of activated T cells that prevent engraftment of donor-derived hematopoietic stem cells. Aggressive conditioning with myeloablative and immunosuppressive drugs is needed to circumvent this problem. More recently, the use of appropriate supportive treatment and prophylaxis of infection, together with tailored conditioning regimens, has resulted in a better outcome for BMT. Taking advantage of these advances, Gomez et al. (1995) reported the cure of OS by BMT in six of nine patients; similarly, another group achieved successful treatment in four of five OS patients (Chilosi et al., 1996a; Brugnani et al., 1997). The successful engraftment of donor-derived hematopoietic stem cells is associated with the development of normal numbers and functions of both T and B lymphocytes, with full clinical and immunological recovery.

### Questions for Future Research

In light of these results, the pathogenesis of OS lies in a defect of the V(D)J recombination system that allows the occurrence of some rearrangements. For this reason, some T cells with bona fide

TCR rearrangements can exit the thymus, expand either in the thymus itself or in the periphery, and produce Th2-type cytokines, which in turn are responsible for some features of the characteristic phenotype of OS patients, such as hypereosinophilia and hyper-IgE.

Although the identification of a defect in V(D)J recombination has given an elegant unifying explanation for OS, several aspects have not yet been clarified. First, the reasons for the apparent expansion of the Th2 subset are not clear. Selective expansion of certain TCR clones may be a consequence of either intrathymic selection of specific rearrangements or peripheral expansion in response to infections or perhaps autoantigens. It has been suggested that given the extreme disorganization of the thymic microenvironment in OS, negative selection of autoreactive clones may be inoperative, and a few residual T cell clones may expand in the periphery because of their autoreactive character (Fischer and Malissen, 1998).

Another unexplained phenomenon is the fact that RAG proteins direct recombination in both B and T cells, yet B cells are absent in peripheral blood of OS patients. In view of the constant presence of elevated IgE levels in OS patients, it is clear that somewhere, perhaps in the gastrointestinal tract, B cells, which perform Ig loci rearrangements and switch to IgE production, do exist. It is noteworthy that V(D)J recombination deficiencies that lead to low-to-normal numbers of T cells in the absence of mature B cells is a recurring theme. When the differentiation defect in Rag-deficient or *scid* mice is rescued by DNA-damaging agents or by genetic manipulation such as by p53 or poly(ADP-ribose) polymerase (PARP) inactivation, the T cell, but not the B cell compartment, is restored (Danska et al., 1994; Guidos et al., 1995, 1996; Nacht et al., 1996; Livak et al., 1996; Bogue et al., 1997; Morrison et al., 1997). The mechanisms underlying these differences between B and T cell development remain to be defined.

Another point that must be clarified is the role of environmental factors in the pathogenesis of the Th2 expansion and the resulting clinical features. As observed in other cases, immune-deficient individuals have by definition a more intense antigen exposure and a defect in antigen clearance that results in persistent high antigen load. If, as in OS, the genetic defect is permissive and allows the development of limited clones of mature T cells, the antigen overload favors prolonged T cell activation that has been associated with increased IL-4 secretion and polarization toward a Th2 phenotype (Hsieh et al., 1993; Hosken et al., 1995). Re-creation of missense mutations in mice via homologous recombination could solve this problem by comparing mutant mice kept in germ-free facilities to those kept in a normal environment.

### The Link between V(D)J Recombination and DNA Double-Strand Break Repair

V(D)J recombination is initiated by lymphoid-specific RAG1 and RAG2 proteins, which introduce DSBs precisely between Ig and TCR coding gene segments and flanking. RAG-mediated cleavage generates four broken-end intermediates: two blunt signal ends and two covalently closed (hairpin) coding ends. The subsequent resolution of V(D)J ends into coding and signal joints requires ubiquitously expressed factors playing a role in the DNA repair. The nonlymphoid-restricted components identified thus far are the DNA-PK-dependent catalytic subunit (DNA-PKcs), Ku70, Ku80, XRCC4, ligase IV, and, very recently, Artemis; all of these proteins play a role in DNA DSB repair as

well as in V(D)J recombination. At least two other nonlymphoid-specific components are involved in the VDJ process, HMG1 and HMG2, although their role is not clear (reviewed in Bassing et al., 2002; Gellert, 2002). After the RSS cleavage, performed by RAG proteins, the RAG complex remains bound with the resulting 5' phosphorylated blunt signal end and hairpin coding end (postcleavage complex). At this stage, the generation of junctional diversity is initiated by the opening of hairpin coding ends. The molecule responsible for hairpin opening is not known with certainty, although both RAG complex and MRE11 can mediate the hydrolysis of hairpin in vitro (Besmer et al., 1998; Shockett and Schatz, 1999; Fugmann et al., 2000). Recently it has been proposed that Artemis, after phosphorylation by DNA-PKcs, can play a key role in hairpin cleavage (Ma et al., 2002).

While the RAG proteins are specifically expressed in lymphoid cells, the rejoining steps require other actors of the DNA nonhomologous end-joining (NHEJ) machinery. NHEJ requires the heterodimeric Ku protein (Ku70 and Ku80) and a large protein DNA-PKcs, which associates with Ku to form the DNA-PK complex. DNA ligase IV and Xrcc4 are successively required for the rejoining steps. All the animal models carrying a defective gene of either one of the known V(D)J recombination/DNA repair factors, either natural (murine and equine *scid*) or engineered through homologous recombination, exhibit a profound defect in the lymphoid developmental program owing to an arrest of the B and T cell maturation at early stages (Nussenzweig et al., 1996; Zhu et al., 1996; Jhappan et al., 1997; Shin et al., 1997; Barnes et al., 1998; Frank et al., 1998; Gao et al., 1998a, 1998b; Taccioli et al., 1998). Mutants lacking Ku or Xrcc4/DNA ligase IV complex show pronounced defects in the rejoining of both blunt signal and hairpin coding ends, whereas mutants lacking DNA-PKcs show a marked impairment in coding join formation.

### Radiosensitive B-T<sup>-</sup> SCID

#### Definition

Some B-T<sup>-</sup> SCID patients do not have a mutation in either the *RAG1* or *RAG2* genes, despite having the very same clinical presentation as that with typical RAG defects (Table 11.3). The alymphocytosis in these patients is accompanied by an increased cellular sensitivity to ionizing radiation (RS-SCID, MIM 602450 and 605988), a situation highly reminiscent of the murine *scid* condition, leading to the hypothesis that a general defect in the DNA repair machinery is responsible for this deficit. The RS-SCID phenotype is also found with high incidence among Athabascan-speaking Native American Indians (1 in 2000 live births among Navajo Indians) (Hu et al., 1988).

#### Laboratory Findings

Patients with RS-SCID are characterized by an increase sensitivity to ionizing radiation of bone marrow cells (CFU-GM) and primary skin fibroblasts (Cavazzana-Calvo et al., 1993), as well as a defect in V(D)J recombination in vitro, in fibroblasts (Nicolas et al., 1998). Although this condition suggests that RS-SCID could have a general DNA repair defect reminiscent of the murine *scid* condition, DNA-PK activity is normal in these patients and the implication of the DNA-PKcs gene has been unequivocally ruled out by genetic means in several consanguineous families (Nicolas et al., 1996). A role for all the other known genes involved in V(D)J recombination and DNA repair was equally excluded (Nicolas et al., 1996, 1998). V(D)J recombination analysis

in fibroblasts from Athabascan SCID patients suggested a common molecular defect (Moshous et al., 2000) and, therefore, the existence of a gene coding for a new factor of the V(D)J recombination. The disease-related locus in both situations was assigned to the short arm of human chromosome 10 (Li et al., 1998; Moshous et al., 2000).

#### The Artemis Factor

Given the location of the RS-SCID gene on human chromosome 10, an in silico strategy was adopted for its identification. Genomic DNA sequences released by the Sanger Center, which covered this chromosomal region, were systematically analyzed using two computer programs, FGENESH and GENESCAN, aimed at identifying putative genes in large genomic sequences. On the basis of a putative peptide proposed by these programs, a full-length cDNA coding for a new factor called *Artemis* was isolated (Moshous et al., 2001). Functional complementation studies and mutation analyses certified that Artemis was indeed the gene defective in RS-SCID (see below). As expected, because of the ubiquitous increase of cellular radiosensitivity in RS-SCIDs, the expression of Artemis was detected in every tissue tested. Although Artemis does not have any global homologues in the databases, BLAST search analyses revealed some interesting features of this new protein. Significant similarities to several proteins, including the yeast PSO2 and murine SNM1 proteins, were found over the first 360 amino acids of Artemis. Subsequent iterations with the PSI-BLAST program highlighted significant similarities of the first 150 amino acids to well-established members of the metallo- $\beta$ -lactamase superfamily. The metallo- $\beta$ -lactamase fold, first described for the *Bacillus cereus*  $\beta$ -lactamase (Carfi et al., 1995), is adopted by various metallo-enzymes with a widespread distribution and substrate specificity (Aravind, 1997). It consists of a four-layered  $\beta$  sandwich with two mixed  $\beta$  sheets flanked by  $\alpha$  helices, with the metal-binding sites located at one edge of the  $\beta$  sandwich (Color Plate 11.V). Sequence analysis and secondary structure prediction for Artemis clearly indicated the conservation of motifs typical of the metallo- $\beta$ -lactamase fold, participating in the metal-binding pocket and representing the catalytic site of the metallo- $\beta$ -lactamases. Altogether, this analysis indicated that Artemis not only probably adopted the  $\beta$ -lactamase fold, but may also have conserved an associated catalytic activity, in contrast to several other proteins having lost many of the catalytic residues (Aravind, 1997).

#### Mutation Analysis

The first indication that Artemis was indeed the gene involved in the RS-SCID came from the identification of mutations in several patients (Color Plate 11.VI); 8 different alterations of the gene were found in 11 families. Although some of the mutations were recurrent, it was not possible to draw any clear correlation with the geographical origins of the patients. Several interesting features arose from the analysis of these mutations. First, three of the identified modifications involved genomic deletions spanning several exons, leading to frameshift and appearance of premature terminations in two cases and in-frame deletion of 216 amino acids in one case. This finding indicates that the Artemis gene may represent a hot spot for gene deletion. Second, none of the mutations consisted of simple nucleotide substitutions generating amino acid changes, and only one, the C279T modification, created a nonsense mutation. The other nucleotide changes affected splice donor sequences leading to either frameshifts in

three cases or to in-frame deletion of part of the protein in one case. Another interesting feature is that in three patients the genomic deletion comprised exons 1 to 4, which resulted in a complete absence of Artemis, encoded cDNA. This deletion, which can be considered as resulting in a null allele, demonstrated that Artemis is not an essential protein for viability, in contrast to XRCC4 and DNA-ligase-IV, for example (Barnes et al., 1998; Frank et al., 1998; Gao et al., 1998a), or that it is partly redundant. Finally, the implication of Artemis in the RS-SCID condition was unequivocally established by complementation of the V(D)J recombination defect in patients' fibroblasts upon transfection of a wt Artemis cDNA. Other mutations of the Artemis gene, including amino acid substitutions, were subsequently described (Li et al., 2002; Kobayashi et al., 2003; Noordzij et al., 2003). Hypomorphic Artemis mutations have been described in a patient affected by Omenn syndrome. The clinical presentation as well as the immunophenotype of this OS is indistinguishable from that caused by hypomorphic mutations found in Rag1 and Rag2 mutations. (Ege et al., 2005). Artemis knockout mice are viable and recapitulate the phenotype seen in human RS-SCID patients, with one noticeable and interesting difference (Rooney et al., 2002). Significant numbers of bona fide mature T lymphocytes, mostly CD4<sup>+</sup>, are detected in the periphery of certain mice. Artemis deficiency in mice results in chromosomal fragments, fusion, and detached centromeres in both embryonic stem cells and murine embryonic fibroblasts (Rooney et al., 2002, 2003). These findings strongly suggest that Artemis has an important role in genome stability and may be considered a genomic caretaker similar to other factors of the V(D)J recombination/DNA repair machinery. Indeed, hypomorphic mutations of Artemis in humans that allow the emergence of a few B and T lymphocytes are accompanied by the development of EBV-associated B-cell lymphomas in a general context of genomic instability (Moshous et al., 2003). This result is reminiscent of the pro-B cell lymphomas that emerge in NHEJ-deficient mice when crossed onto a cell-cycle checkpoint defect such as p53<sup>-/-</sup> (Ferguson et al., 2001).

### Structure and Function

The repeated search for a global ortholog of both human and murine Artemis in other species in protein databases has failed to provide a strong candidate, and we are left with the similarity of Artemis to the various members of the metallo- $\beta$ -lactamase family, including both murine SNM1 and yeast PSO2. However, Artemis is clearly not the human ortholog of either of these two proteins, for several reasons. First, despite their SNM1 similarity regions, the three proteins differ in their associated domains. In particular, the 331 amino acids composing the C-terminal region of Artemis are not present in SNM1/PSO2 and do not share any obvious similarities with any other known protein. Second, while murine and yeast SNM1/PSO2 mutants demonstrate a strong defect in the repair of DNA damages caused by DNA interstrand cross-linking agents (Henriques and Moustacchi, 1980; Dronkert et al., 2000), they do not display elevated sensitivity to ionizing radiations, indicating that these two proteins are probably not directly involved in the repair of DNA DSB. This is in sharp contrast to the phenotype of RS-SCID patients, whose primary molecular defect is indeed the absence of DNA DSB repair, illustrated by the lack of coding joint formation in the course of V(D)J recombination and the increased sensitivity of bone marrow and fibroblast cells to  $\gamma$  rays (Cavazzana-Calvo et al., 1993; Nicolas et al., 1998). Interestingly, Artemis, murine SNM1, and

yeast PSO2 share a domain adopting a metallo- $\beta$ -lactamase fold (Aravind, 1997) and possibly its associated enzymatic activity, given the presence of nearly all the critical catalytic residues. However, there is no obvious consensus on the nature of the various metallo- $\beta$ -lactamase substrates, outside of a general negatively charged composition. Sequence analysis revealed the existence of a conserved region that accompanies the metallo- $\beta$ -lactamase domain in members of the Artemis/SNM1/PSO2 subfamily, including various other sequences related to nucleic acid metabolism such as two subunits of the cleavage and polyadenylation specificity factor (CPSF). We named this domain  $\beta$ CASP, for metallo- $\beta$ -lactamase-associated CPSF Artemis SNM1/PSO2 domain (Callebaut et al., 2002). This domain harbors several conserved residues, which could play a role in the reaction catalyzed by members of this subfamily. It is tempting to speculate that this domain could contribute to substrate binding, in a way similar to the  $\alpha$ -helical domain of glyoxalase, another member of the  $\beta$ -lactamase family (Cameron et al., 1999).

DNA DSB can be repaired either by homologous recombination (HR) or by the NHEJ (reviewed in Haber, 2000). Whereas HR is the predominant repair pathway in yeast, NHEJ is mostly used in higher eukaryotes and represents the DNA repair pathway followed during V(D)J recombination. At least two protein complexes are thought to act in concert or sequentially at the site of the RAG1/2-derived DSB. The Ku70-80 complex is probably recruited first at the site of the lesion, followed by the addition of the DNA-PKcs subunit. This initial complex is considered the primary DNA damage sensor that will activate the DNA repair machinery. The XRCC4/DNA-ligase IV complex represents the best candidate to actually repair the gap. Careful analysis of the various phenotypes among the different V(D)J recombination deficient models, including RS-SCID, has provided some hypotheses regarding the possible role of Artemis during V(D)J recombination. Two major differences exist between the RS-SCID condition and that of XRCC4 and DNA-ligase IV knockout mice. First, a complete null allele of Artemis does not lead to embryonic lethality in humans. This observation, therefore, does not support an implication of Artemis in this phase of NHEJ. Second, the rejoining of linearized DNA constructs introduced in RS-SCID fibroblasts is not altered (J.P. de Villartay, unpublished observations), whereas this assay, when defective, is highly diagnostic of abnormal NHEJ in yeast (Teo and Jackson, 1997; Wilson et al., 1997). Perhaps the most evident link between Artemis and NHEJ is found in regard to the Ku/DNA-PK complex. Indeed, human RS-SCID patients and *scid* mice, which harbor a mutation in the DNA-PKcs encoding gene, are the only two known conditions in which a V(D)J recombination-associated DNA repair defect affects uniquely the formation of the coding joints, leaving signal joint formation unaltered. This is in striking contrast to all the other known V(D)J recombination/DNA repair deficiency settings. Hairpin-sealed coding ends represent the unprocessed V(D)J recombination intermediates that accumulate in murine *scid* lymphoid cells. Although recent data have indicated that RAG1 and RAG2 are capable of opening these hairpin structures in vitro, the situation of the murine *scid* strongly suggests that DNA repair factors such as DNA-PK may be required for this process in vivo. This observation suggests that Artemis, through its putative hydrolase activity, may participate in opening the hairpin at the coding ends in vivo. Artemis does indeed possess an intrinsic exonuclease activity in vitro that can be redirected to an endonuclease activity capable of resolving Rag1/2-generated hairpins in vitro when Artemis is complexed to and phosphorylated by DNA-PKcs (Ma et al., 2002). The catalytic

core of Artemis is carried by the metallo- $\beta$ -lactamase/ $\beta$ CASP domain (J.P. de Villartay, unpublished observations). The accumulation of hairpin-sealed coding ends in thymocytes from Artemis knockout mice and scid/DNA-PKcs KO mice strongly support this function (Rooney et al., 2002).

### DNA-Ligase IV Defects

As previously described, DNA ligase IV forms a complex with XRCC4, which is essential for NHEJ and for the V(D)J recombination process (Critchlow et al., 1997; Grawunder et al., 1997). The inactivation of both alleles of DNA ligase IV in a human pre-B cell line confers high radiosensitivity and abrogates the V(D)J recombination activity (Grawunder et al., 1998a). Riballo and coworkers (1999) identified a patient with a defect in NHEJ bearing a missense mutation in the gene encoding DNA ligase IV. This patient did not show any immunodeficiency; however, he developed leukemia at age 14 and overresponded to radiotherapy (Riballo et al., 2001). More recently, the finding of LIG4 mutations in four patients diagnosed as having Nijmegen breakage syndrome (NBS) at clinical presentation but who were normal for NBS1 led to the identification of a new syndrome, designated *LIG4 syndrome*. This disorder is characterized by developmental delay, chromosomal instability, and immunodeficiency (O'Driscoll et al., 2001).

The clinical features of these patients resemble those of NBS but the cellular phenotype is distinct. Although cells from both syndromes show radiosensitivity, LIG4 cell lines have normal checkpoint function and are defective in DSB repair. The analysis of chromosome breakage in peripheral blood lymphocytes obtained from LIG4 patients did not show any translocations or inversions involving chromosomes 7 and 14, which are typical of ataxia-telangiectasia and NBS.

Many of the features of patients with LIG4 syndrome resemble a particular form of dwarfism named *Seckel syndrome*, recently found to be due to AT and Rad3-related protein defects (O'Driscoll et al., 2003). Patients had microcephaly and one of them had a typical bird-like face. Pancytopenia is a common feature in these patients, but they do not develop a SCID phenotype, consistent with the hypothesis that the mutations impair but not abolish the VDJ activity. Another clinical feature is the occurrence of skin alteration (plantar warts, psoriasis, and photosensitivity). None of these patients developed cancer, although two of four patients showed hypothyroidism and hypogonadism.

### Mutations

The first patient described by Riballo and coworkers (1999) who developed leukemia had a missense R278H mutation mapping to the ligase IV active site. The same mutation was also present in one of four patients, even though the clinical features were completely different. This discrepancy suggests that epigenetic factors may influence the onset of the disease. Two of the mutations identified in the other patients were stop mutations (R580X–R814X) leading to protein truncation in the BRCT region, which is supposed to interact with XRCC4 (Grawunder et al., 1998b). The fourth mutation, G469E, was an amino acid change located on a surface loop important for DNA binding. It is noteworthy that LIG4-null mutations in mice result in embryonic lethality. This finding suggests the hypothesis that the mutations found in these patients could be hypomorphic, thus explaining the mild phenotype of the immunodeficiency. However, the R580X stop mutation is not easily reconciled with this hypothesis.

### Acknowledgments

We thank A. Jacobs for excellent secretarial assistance, S. Fugmann for helping in design of the figures, and L. Doostar, F. Radecke, and H.D. Ochs for review of the manuscript. This work was supported by a grant from Sonderforschungsbereich 322 of the Deutsche Forschungsgemeinschaft (K.S.), by BMBF grant IZKF.C05 (K.S.), by National Institutes of Health (NIH) grants A140181 (E.S.), and by grants from AFM/Telethon GAT0203 (A.V.). In addition, this work was supported by the Genoma 2000/IBTA project, funded by CARIPLO, Italy, and grant RBNE019J9W from MIUR-FIRB to A.V. This work was also supported by institutional grants from INSERM (J.P.V.) and grants from ARC (J.P.V.) and CEA (J.P.V.).

## Immunodeficiency Due to Defects of Purine Metabolism

ROCHELLE HIRSCHHORN and FABIO CANDOTTI

Genetic deficiency of the purine salvage enzyme adenosine deaminase (ADA) provides the molecular basis for approximately 40% of autosomal recessive cases of severe combined immunodeficiency (SCID) and therefore approximately 20% of all cases of SCID (Hirschhorn, 1979b; Bertrand et al., 1999; Buckley, 2000). The identification, over two decades ago, of deficiency of ADA as the basis for immunodeficiency (MIM #102700) was serendipitous and unexpected (Giblett et al., 1972). By contrast, immunodeficiency due to genetic deficiency of purine nucleoside phosphorylase (PNP), the next enzyme in the purine salvage pathway, was identified by specific screening for deficiency of enzymes in this pathway in immunodeficient patients (Giblett et al., 1975). PNP immunodeficiency (MIM #164050) is even rarer than ADA deficiency, having been reported in fewer than 30 unrelated families (Markert, 1991; Carpenter et al., 1996; Markert et al., 1997; Sasaki et al., 1998; Dalal et al., 2001; Baguette et al., 2002; Moallem et al., 2002; Tsuda et al., 2002; Tabarki et al., 2003; Grunebaum et al., 2004). Study of patients with these two disorders has shed light on the significance of the purine salvage pathway for lymphoid cells as well as on the potential for development of new antileukemic agents (Hirschhorn, 1993; Markert, 1994; Suetsugu et al., 1999; Herschfield and Mitchell, 2001; Dillman, 2004).

Both ADA and PNP are ubiquitous, “housekeeping” enzymes whose deficiency essentially results in “metabolic poisoning,” with the most deleterious effects manifested in lymphoid cells. As a result, both are diseases characterized by increasing attrition in immune function over time and by blocks at specific steps of differentiation of lymphoid cells. Because the toxic metabolites that accumulate on account of the enzyme defect derive primarily from dying cells, it is not surprising that clinical histories, particularly of later-onset patients, are consistent with the hypothesis that each infection results in additional attrition of immune cells and function.

Since the first edition of this book, several important advances concerning ADA and PNP deficiency have been made that include both clinical and basic science of these disorders. ADA deficiency continues to be diagnosed in ~20% of patients with SCID and therefore in ~40% of autosomal recessive patients. Interestingly, however, only two novel mutations have been reported in recent years (Ariga et al., 2001a), suggesting that this disease may be inherited from a restricted number of ancestors or founders in the populations studied or that only specific locations of the ADA gene are susceptible to the effects of genetic mutations. Additional cases of reversion of inherited ADA mutations have been described (Hirschhorn et al., 1996; Ariga et al., 2001b), reflecting the recent observations of somatic mosaicism, due to *in vivo* reversion to normal, of inherited mutations in several different immunologic and nonimmunologic disorders (reviewed in Hirschhorn, 2003). On the clinical side, renewed interest has been devoted to the pathophysiology of previously described neurologic findings (Hirschhorn et al., 1980a) and of more recently described sensorial and cognitive function of ADA-deficient patients who do not seem to respond to hematopoietic cell transplantation (Tanaka et al., 1996; Rogers et al., 2001; Albuquerque and Gaspar, 2004). The report of severe mental retardation without immunodeficiency resulting from genetic deficiency of S-adenosylhomocysteine (SAH) hydrolase (Baric et al., 2004) raises the possible role of the secondary decrease of SAH hydrolase found in ADA deficiency in bringing about neurologic abnormalities. Finally, from a therapeutic perspective, results of a recent European survey indicate that haploidentical transplantation off allogeneic bone marrow has a poor prognosis in ADA deficiency (~25% survival at 3 years after the procedure) (Antoine et al., 2003). These findings coincide with reports of the first true successes of gene therapy for ADA deficiency (Aiuti et al., 2002a).

In the PNP field, the high-resolution crystal structure of PNP has been recently determined, allowing a more precise analysis of the active site of the enzyme and generating a more reliable model for substrate binding and for the design of PNP inhibitors (de Azevedo et al., 2003). Another development is the generation of a PNP “null” mouse model that has provided a new hypothesis as to the possible biochemical mechanisms leading to immunodeficiency (Arpaia et al., 2000). Finally, recent clinical observations have reinforced the notion that PNP-deficient patients often present with marked neurodevelopmental delay that clearly precedes the onset of immunodeficiency (Baguette et al., 2002; Tsuda et al., 2002), thus suggesting particular vulnerability of the nervous to PNP deficiency.

## Clinical and Pathologic Manifestations

### ADA Deficiency—Clinical Spectrum of Immunodeficiency

#### Early-onset disease

The early descriptions of clinical and pathologic manifestations in ADA-deficient SCID patients were based on retrospective studies of children diagnosed as having classical SCID with marked developmental delay and failure to thrive (Meuwissen et al., 1975; Hirschhorn, 1979a). Because of the original means of identifying patients to be tested for ADA deficiency, over 95% of the initial cases were clinically and immunologically virtually indistinguishable from patients with other forms of classical SCID. These ADA-deficient patients had neonatal-onset disease with lymphopenia, absence of both cellular and humoral immune function, failure to thrive, and a rapidly fatal course due to infections with fungal, viral, and opportunistic agents (Meuwissen et al., 1975; Hirschhorn, 1979a). Many of these early-onset cases lacked B cells as well as T cells and would now be classified as T-B<sup>-</sup> SCID. However, in addition to immunological defects, a distinguishing feature in approximately 50% of this group of patients was a skeletal abnormality of the costochondral junctions, best visualized by X-ray on a lateral exposure of the chest as cupping and flaring, and having a unique histological appearance (Cederbaum et al., 1976). A small percentage of cases, including the first two cases described, exhibited a somewhat delayed onset of disease, with diagnosis as late as the second year of life. In such patients there was transient retention of the capability to produce autologous immunoglobulins, although both patients produced essentially no specific antibodies (Table 12.1).

#### Delayed and late-onset disease

It is now apparent that the clinical spectrum resulting from ADA deficiency is much broader than that of classical SCID. Testing for ADA deficiency in a range of individuals with abnormal immune function has already broadened the spectrum considerably, not only in age of onset but also in immunologic abnormality. Initially patients with somewhat delayed onset were recognized in the first 2 years of life to have retention of immunoglobulins, similar to the first two described patients. An increasing number of patients are now being described with late-onset ADA deficiency, diagnosed from 3 to 15 years of age and even in adulthood, rather than only during infancy (see Table 12.1) (Geffner et al., 1986; Morgan et al., 1987; Levy et al., 1988; Hirschhorn et al., 1993b, 1996; Shovlin et al., 1993; Ozsahin et al., 1997; Herschfield, 1998; Antony et al., 2002). These late-onset patients will have significant immunodeficiency, but variable clinical

**Table 12.1.** Clinical Phenotypes in ADA Deficiency

1. Neonatal/infantile onset—severe combined immunodeficiency	Clinically indistinguishable from other forms of SCID, except for bony abnormality in 50% of patients. Progressive attrition of immunity.
2. Delayed or late onset—combined immunodeficiency	May present with recurrent bacterial sinopulmonary infections; lymphopenia, hyper-IgE, eosinophilia, autoimmunity. May be diagnosed in adulthood because of persistent viral warts, herpes zoster, immune-mediated thrombocytopenic purpura, lymphopenia.
3. ADA deficiency without immunodeficiency (“partial”)	Identification by population screening or analysis of relatives of affected individuals. No confirmed immunodeficiency to date
4. Somatic mosaicism (“de novo” or “revertant” mutations)	May show improvement over time without therapy, lower than expected metabolite levels and residual ADA enzyme activity

manifestations, including an initial clinical history of recurrent sinopulmonary bacterial infections, primarily pneumonia frequently due to *Streptococcus pneumoniae*, and septicemia. After infection or immunization these children typically fail to produce antibody to some antigens such as *S. pneumoniae* polysaccharides. They may lack IgG2, but have markedly elevated IgE and/or eosinophilia. Immune dysregulation may be manifested by autoimmunity including autoimmune hypothyroidism, diabetes mellitus, hemolytic anemia, and idiopathic thrombocytopenia. All patients have had lymphopenia.

Similar to the late-onset patients, the small number of adult patients who have been diagnosed with ADA deficiency have had variety of infections and autoimmune clinical presentations, including recurrent sinopulmonary bacterial infections, pneumonia and septicemia. Persistent viral warts, recurrent herpes zoster infections, asthma, autoimmune hypothyroidism, hemolytic anemia, and idiopathic thrombocytopenia have been described. Initial immunologic investigations have revealed absence of IgG2, failure to produce antibody to pneumococcal antigens, elevated IgE, eosinophilia, and autoantibodies. Diagnosis of ADA-deficient immunodeficiency states in adulthood can be complicated by effects of administration of immunosuppressive medications for autoimmune disorders. The autoimmune phenomena probably reflect abnormal regulation of immune responses, as described for other forms of immunodeficiency. In all three cases described, lymphopenia was present prior to diagnosis of immunodeficiency (Shovlin et al., 1993; Ozsahin et al., 1997).

The first described cases of ADA deficiency with immunodeficiency diagnosed in adulthood were in two siblings, who in retrospect had the onset of immunologic abnormalities during late adolescence (Shovlin et al., 1993; Antony et al., 2002) and had recalcitrant warts as a major manifestation. One the sibs died with severe lung disease in her late 30s, despite enzyme replacement therapy (PEG-ADA, see Treatment and Prognosis). The surviving sib improved substantially with PEG-ADA but then developed an antibody response to the enzyme sufficient to preclude continued therapy for control of the severe dermatologic manifestations. One additional patient was diagnosed at the age

of 39 after a long history of multiple infections and leukopenia in childhood. In adult life she was well until septicemia followed a caesarian section. She also exhibited hepatic granulomas of unknown etiology and pulmonary tuberculosis as well as asthma and elevated IgE (Ozsahin et al., 1997).

It is likely that these adult patients with ADA defects constitute one subset of patients currently classified as common variable immunodeficiency (CVID, see Chapter 23), although a screening of 44 unselected CVID patients failed to identify any individuals with ADA or PNP deficiency (Fleischman et al., 1998), suggesting that ADA deficient do not comprise a large subset of CVID. Perhaps selection for such markers as early lymphopenia, hyper-IgE, eosinophilia, asthma, and persistent warts might be informative.

#### ADA deficiency with normal clinical phenotype ("Partial" ADA deficiency)

An additional group of individuals with absence of ADA activity in erythrocytes has been identified by screening of normal populations or among healthy relatives of affected patients. Most of these individuals were identified as newborns through a screening program directed at early detection of ADA-deficient SCID patients. These patients were initially termed "partially deficient" because while they showed absent ADA activity in red blood cells (RBCs), they retained 5%–80% of normal ADA enzyme activity in nonerythroid cells (Hirschhorn et al., 1979a, 1983, 1989, 1990, 1997; Borkowsky et al., 1980; Hirschhorn and Ellenbogen, 1986). These children had dATP levels only marginally elevated and insignificant relative to values observed in immunodeficient patients. Although these children were healthy in early childhood, and one subject (homozygous for Ala215Thr mutations) as late as 18 years of age, their eventual outcomes are unknown. One of these children, lost to follow-up, carried a partial mutation heterozygous with a "null" similar to that of adult-onset patients (Shovlin et al., 1993).

A number of healthy relatives in families with a proband with SCID were found to carry additional ADA mutations and to exhibit very low levels of ADA activity in blood cells (Ozsahin et al., 1997; Ariga et al., 2001a).

#### ADA Deficiency—Nonimmunologic Abnormalities

Several abnormalities have been described in only a few patients and therefore could reflect effects of infectious agents rather than primary defects due to ADA deficiency. These include renal and adrenal abnormalities, neurologic abnormalities similar to those seen in PNP deficiency (see below), pyloric stenosis, and hepatic disease (Hirschhorn, 1979a; Ratech et al., 1985, 1989; Bollinger et al., 1996; Hershfield and Mitchell, 2001; R. Hirschhorn, unpublished results). Abnormal platelet aggregation has also been described (Schwartz et al., 1978). Although it is difficult to prove that neurological abnormalities are not secondary to viral encephalitis, we have suggested that these abnormalities might reflect interaction of high concentrations of adenosine with known adenosine A1 receptors in nervous tissue. This hypothesis was based on our finding of amelioration of neurologic manifestations concomitant with therapeutic measures that resulted in a lowering of metabolites that otherwise accumulate in ADA deficiency (Hirschhorn et al., 1980a). Lymphoma, often associated with cells bearing Epstein-Barr virus (EBV) genomes, has occurred in several patients (see Pathology section, below).

Recent observations have demonstrated that ADA deficiency can frequently be accompanied by cognitive and behavioral abnormalities, as well as neurosensory deafness, that appear not to be shared by patients affected with other forms of SCID (Tanaka et al., 1996; Rogers et al., 2001; Albuquerque and Gaspar, 2004).

#### PNP Deficiency—Clinical Spectrum of Immunodeficiency

Purine nucleoside phosphorylase deficiency is a rare combined immunodeficiency disorder with autosomal recessive inheritance. Although the most characteristic immune abnormality is a profound T cell defect, abnormal B cell function, including defective antibody production, is common and in part due to abnormal T cell help (Giblett et al., 1975; Markert, 1991; Hershfield and Mitchell, 2001). In some patients clinical findings are compatible with the diagnosis of SCID and most patients present with failure to thrive; lymph nodes are small, the thymus is absent, and splenomegaly may be present in those patients with autoimmune disease. Additional patients have been described who did not present with clinically apparent immunodeficiency until later in childhood (Fox et al., 1977). It has been estimated that approximately 4% of patients with symptoms of SCID have PNP deficiency (Markert, 1991).

To date, patients with PNP deficiency from approximately 30 families have been identified and reported (Markert, 1991; Andrews and Markert, 1992; Aust et al., 1992; Tam and Leshner, 1995; Broome et al., 1996; Carpenter et al., 1996; Pannicke et al., 1996; Banzhoff et al., 1997; Markert et al., 1997; Sasaki et al., 1998; Yamamoto et al., 1999; Classen et al., 2001; Dalal et al., 2001; Baguette et al., 2002; Moallem et al., 2002; Tsuda et al., 2002; Dror et al., 2004; Grunebaum et al., 2004). The most common presenting complaint to clinical immunologists and/or infectious disease specialists is recurrent infections of the upper and lower respiratory tract due to common bacterial pathogens, viruses, or opportunistic infections such as *Candida albicans* and *Pneumocystis jiroveci*. These infections usually begin during the first year of life; however, the onset of symptoms may vary, with patients reported to be asymptomatic, in rare instances, until several years of age. Infections most commonly observed include pneumonia, otitis media, sinusitis, and urinary tract infections, usually caused by common bacterial pathogens. However, because of the profound T cell abnormality, disseminated vaccinia as a result of small pox vaccination, disseminated varicella, and persistent herpes simplex infection have been severe or even fatal. One patient developed chronic meningoencephalitis due to echovirus infection (Markert, 1991), a complication more often seen in patients with X-linked agammaglobulinemia. One single case of fatal pneumonia due to *Pneumocystis jiroveci* and *Legionella* infection has been observed (McGinniss et al., 1985). In contrast, PNP-deficient patients receiving *Bacillus Calmette-Guérin* (BCG) immunization have not developed disseminated disease (Markert, 1991).

#### PNP Deficiency—Nonimmunologic Abnormalities

Neurologic abnormalities develop in more than one-half of PNP-deficient children, a complication rarely observed in other types of SCID. These neurologic problems include spastic diplegia or tetraparesis, ataxia, tremor, retarded motor development, hyper- or hypotonia, behavioral difficulties, and varying degrees of

mental retardation (Markert, 1991). Neurologic deficits have been observed in some patients prior to the onset of infection. The association of SCID and nervous system manifestations strongly suggests the diagnosis of PNP deficiency. Autoimmunity is another common finding in PNP deficiency. Thirteen of 34 patients had one or more autoimmune disorders, including autoimmune hemolytic anemia, idiopathic thrombocytopenia, autoimmune neutropenia, lupus, and central nervous vasculitis (Markert, 1991; Carpenter et al., 1996). Four of those patients had developed lymphoma or lymphosarcoma and one had a pharyngeal tumor.

### Pathology

Examination of tissues at autopsy has been reported only in ADA-deficient patients with early-onset "classical" SCID. Abnormalities in spleen, lymph nodes, gut, and thymus reflect primarily an absence of cells of the lymphoid system (Hirschhorn, 1979b; Ratch et al., 1985, 1989). Thymic pathology, examined by biopsy as well as autopsy, demonstrates an absent or small dysplastic organ with absent or sparse lymphocytes, as seen in most SCID and not specific for ADA deficiency. Although florid pathology in this group of patients is predominantly limited to the immune system, some nonlymphoid organs also show unusual features (Simmonds et al., 1978; Hirschhorn et al., 1982; Mills et al., 1982). Thus, approximately 50% of early-onset ADA-deficient SCID patients exhibit a radiologically detectable bony lesion accompanied by a histologic appearance unique to ADA deficiency (Cederbaum et al., 1976). While the lesion may be pathognomonic histologically, we have shown that the radiologic abnormality is not specific for ADA-deficient SCID and can be seen in other disorders as well (Hirschhorn et al., 1979b). Nonetheless, the correct diagnosis of ADA-deficient SCID has not infrequently been suggested by the characteristic appearance of flared costochondral junctions on routine chest X-ray, best appreciated on a lateral view, as well as by the physical finding of a "rachitic rosary." Abnormalities of renal function have been noted in some patients, and we have described an unusual mesangial sclerosis in autopsy material from six of eight patients (Ratch et al., 1985). Renal abnormalities have also been described in the murine model for ADA deficiency, suggesting that this abnormality is due to the disease itself. Additionally, we have described in these same patients an unusual form of adrenal cortical fibrosis. However, in view of the overwhelming and multiple infections in these children, the significance of the renal and adrenal lesions remains to be evaluated by comparison with autopsy material from SCID patients who were not ADA deficient. In a single patient with neonatal onset of disease, hepatic pathology, with early giant-cell transformation, enlarged foamy hepatocytes, and portal and lobular eosinophilic infiltrates, has been reported (Bollinger et al., 1996). Again, despite the exclusion of known pathogens, it is difficult to consider this abnormality a primary result of ADA deficiency since these striking abnormalities were not appreciated in autopsies of the above eight patients with similar disease onset.

Both histologic and clinical evidence for graft-vs.-host disease (GVHD) have been commonly reported at the time of diagnosis because of maternal T cell engraftment or the administration of unirradiated blood products containing human leukocyte antigen (HLA)-incompatible lymphocytes that attacked the patient's tissues. Graft-vs.-host reactions are fortunately now a rare complication of transfusions, but they can still be observed after transplantation therapy.

The characteristic finding at autopsy of PNP-deficient patients is the marked depletion of lymphoid tissues (Markert, 1991). The thymus is absent or small and contains poorly formed Hassall's corpuscles. Tonsils are atrophic and germinal centers cannot be identified. Lymph nodes lack paracortical regions. The spleen shows lymphocytic depletion in the perivascular sheaths. In contrast, plasma cells can be identified in spleen, lymph nodes, and in the lamina propria of the intestines. Anatomic abnormalities associated with the neurologic deficits have not been investigated.

## Laboratory Findings

### Immunological Findings

#### Immunodeficient individuals with ADA deficiency

Lymphopenia and attrition of immune function over time are the two findings common to all presentations of immunodeficiency due to ADA deficiency (Table 12.2). Lymphopenia as well as elevation of toxic metabolites, such as deoxy-ATP (dATP) in RBCs, is already present prenatally and at birth, as has been demonstrated in affected pregnancies of families with prior children with early-onset ADA deficiency (Hirschhorn et al., 1980b; Linch et al., 1984). In early-onset patients, there is essentially a complete absence of lymphocytes and of both cellular and humoral immune function. Isoagglutinins are generally absent; immunoglobulins, particularly IgA and IgM, are low to absent, although absence of IgG, and occasionally other isotypes, is not easily evaluated because of maternally derived IgG and variable amounts of immunoglobulins transiently produced in infants. Antibody responses to T-dependent antigens are severely depressed. In ADA-deficient patients with delayed presentation, B cells and antibodies may be found, but eventually all functional antibodies are lost, and an oligoclonal distribution of immunoglobulin may be detected. Abnormal laboratory results seen in autoimmune states are another feature of late-onset patients.

#### Immunodeficiency in individuals with PNP deficiency

Deficiency in PNP has a profound effect on T cell function. Most patients are severely lymphopenic ( $<500$  lymphocytes/mm<sup>3</sup>) with a markedly depressed T lymphocytes (1%–3% of lymphocytes). Mitogen-induced lymphocyte proliferation is also severely impaired, and lymphocytes from most patients respond poorly in mixed lymphocyte reaction. However, several patients with normal responses to mitogens during infancy have subsequently progressed to nonresponsiveness. Although early reports suggested that B cell function in PNP deficiency may be normal, more recent studies clearly demonstrated abnormal B cell function. In some patients, a decline in antibody production was observed over time. Isohemagglutinins may be present or absent. Two patients with PNP deficiency were immunized with the T cell-dependent antigen, bacteriophage  $\Phi$ X174, and responded with markedly depressed antibody titers, poor amplification, and complete inability to switch from IgM to IgG, a response that is almost identical to that of patients with ADA deficiency. These abnormal responses, characteristic for defective T and B cell interaction, are very similar to those observed in patients with X-linked hyper-IgM syndrome, whose defect is due to a primary T cell abnormality (Nonoyama et al., 1993). A possible explanation for a predominant T cell defect in PNP deficiency is discussed below. However, an intrinsic defect in B cell function has not been excluded.

**Table 12.2.** Commonly Found Abnormalities in Laboratory Tests of ADA-Deficient Individuals with Immunodeficiency

Test	Clinical Presentation Subtype		
	Infantile Onset	Late Onset	Adult Onset
<i>ADA Enzyme Activity</i>			
In erythrocytes	<1%	<1%	≤1%
In lymphocytes	0.5%	0.5%–3%	3%–?%
SAH hydrolase, erythrocytes	10%	10%	?
<i>Metabolites*</i>			
Erythrocyte dATP <sup>†</sup>	327–2248	174–247	100–150
Lymphocyte dATP <sup>‡</sup>	1150	?	?
Urinary dAdo**	442–1500	54–270	
Urinary Ado**			
Plasma dAdo (μM)	0.6–2		
Plasma Ado (μM)	1–6		
<i>Immunologic Tests</i>			
Lymphopenia	++++	++	++
CD3 lymphocytes	Absent to trace	Markedly diminished	Markedly diminished
CD4/CD8 ratio	Too few cells to test	Often reversed	Reversed
Eosinophilia	Rare	Frequent	Frequent
Proliferation to PHA	Absent to markedly reduced	Absent to markedly reduced	Absent to markedly reduced
MLR	Reduced		
Antigen response	Absent to trace	Trace	Trace
Immunoglobulins	Maternal IgG	Low to absent (IgG2)	Normal; (low IgG2)
Specific antibody responses	Absent	Absent to very low	?
High IgE	Not reported	Frequent	Frequent
Infections	Predominantly viral, fungal, and opportunistic; also bacterial sepsis	Increasing proportion of bacterial sinopulmonary	Bacterial sinopulmonary; herpes zoster, herpes simplex; candida
Other clinical abnormalities	50% costochondral junction abnormality	Autoimmunity; possibly increased asthma incidence	Autoimmunity; possibly increased asthma incidence

Ado, adenosine; dAdo, deoxyadenosine; dATP, deoxyadenosine triphosphate; MLR, mixed lymphocyte reaction; PHA, phytohemagglutinin.

## Biochemical Findings

### Protein expression and enzymatic activity

Adenosine deaminase enzyme activity in cells from patients with classic ADA-deficient SCID is essentially undetectable (Table 12.2). The reported activity must take into account the minor activity of a nonrelevant isozyme that exhibits ADA activity but is encoded by another genetic locus not affected in ADA-deficient SCID (Hirschhorn and Ratech, 1980; see Biochemistry of ADA, below). Late-onset patients may retain 2%–5% of normal activity, with the highest residual activity reported in subjects with adult-onset disease (Shovlin et al., 1993). In most patients, ADA protein, assessed with anti-ADA antibodies, has been undetectable, a finding suggesting that most ADA gene mutations result in no protein production or unstable proteins (Wiginton and Hutton, 1982; Arredondo-Vega et al., 2001; Otsu et al., 2002). However, it is possible that the antibodies used did not recognize some mutant proteins.

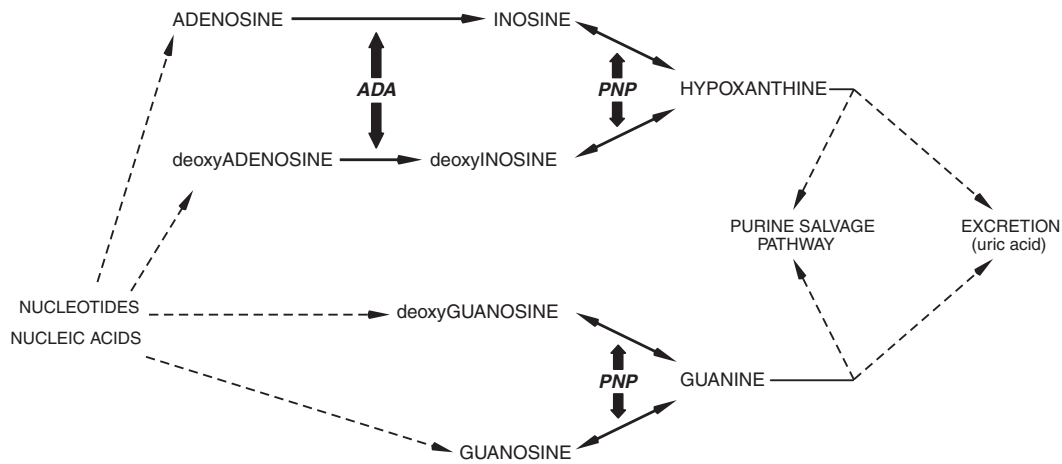

Our own unpublished experiments using quantitative immunoprecipitation with a polyclonal antibody and a series of mutants did detect protein in quantities proportional to the relative enzyme activity. One patient originally reported to have normal protein

for the amount of enzyme activity seen was demonstrated to be a somatic mosaic, with some cells expressing normal ADA (Hirschhorn, 1994b; see Molecular Biology of ADA, below).

As mentioned above, partially ADA-deficient individuals lack ADA activity in erythrocytes but express 5%–80% normal activity in nonerythroid cells, such as cultured EBV-transformed lymphoid cells. These individuals were ascertained as a result of population screening undertaken in both normal adults and newborns (Hirschhorn, 1979b, 1990). They have been designated partial ADA deficient and have not presented with immunodeficiency. However, one of the same mutations that expresses approximately 5% of normal activity has recently been identified in patients with adult-onset immunodeficiency. This finding suggests that some of the mutations present in partially ADA deficient may not be benign when heteroallelic with a mutation that totally abolishes activity (see Genotype–Phenotype Correlations, below).

Enzymatic activity of PNP in RBC lysates of affected patients is universally absent. Immunoreactive protein, measured by Western blot analysis, may be present or absent. In one family, the mutant protein could not be demonstrated in the patient's cells but was present in both consanguineous parents; thus the mutated protein may be unstable (Osborne et al., 1977; Gudas et al., 1978).

**Figure 12.1.** Schematic representation of adenosine deaminase (ADA) and purine nucleoside phosphorylase (PNP) metabolic pathways.

### Metabolic consequences of ADA and PNP deficiency

Adenosine deaminase is an enzyme of the purine salvage pathway that catalyzes the deamination of adenosine and 2-deoxyadenosine, as well as several naturally occurring methylated adenosine compounds (Hirschhorn and Ratech, 1980; Ratech et al., 1981, 1982). The deamination of adenosine and deoxyadenosine gives rise to inosine and to deoxyinosine, respectively (Fig. 12.1). These compounds can be further converted into hypoxanthine and then either enter a nonreversible pathway to uric acid in humans or, by the initial action of hypoxanthine phosphoribosyl transferase (HPRT), are salvaged back from hypoxanthine into other purines. The absence of ADA would be expected to result in diminution of the products of the reaction, inosine and 2-deoxyinosine. However, the presence of alternative “bypass” pathways apparently results in normal concentrations of these two products of the enzyme reaction in patients with ADA deficiency and, in contrast to PNP deficiency, in normal concentrations of uric acid, the final product of the pathway. Conversely, the absence of the enzyme would be expected to result in accumulation of the substrates adenosine and 2-deoxyadenosine. Not only are these substrates found in increased amounts in plasma and urine, but they also “spill over” into additional pathways that are normally only minimally used (Cohen et al., 1978; Coleman

et al., 1978; Kuttisch et al., 1978; Simmonds et al., 1978, 1982; Hirschhorn et al., 1981, 1982; Mills et al., 1982; Morgan et al., 1987; Fairbanks et al., 1994).

Deoxyadenosine is a component of DNA and primarily derives from the breakdown of DNA (Fig. 12.1 and 12.2). Therefore, deoxyadenosine would be expected to be in highest concentrations at sites of cell death, such as the thymus, where lymphocytes undergo apoptotic death during the course of differentiation and selection. Adenosine is a component of adenine nucleotides including ATP and RNA, and can be made both from the normal intracellular breakdown of ATP and from degradation of RNA following cell death. Both adenosine and deoxyadenosine are normally present in plasma with normal concentrations of approximately  $1 \mu\text{M}$  for adenosine and  $0.5 \mu\text{M}$  for deoxyadenosine.

In patients with ADA-deficient SCID, there are elevated concentrations of adenosine and deoxyadenosine in plasma ( $1\text{--}6 \mu\text{M}$  for adenosine and  $1 \mu\text{M}$  for deoxyadenosine). The actual concentrations in plasma are difficult to determine by ordinary procedures, as both compounds are almost instantaneously taken up by erythrocytes during drawing of a blood sample and are trapped intracellularly by phosphorylation. The most striking alteration in ADA deficiency is the accumulation of massive amounts of dATP in erythrocytes and lymphocytes (Hirschhorn et al., 1992). This results from uptake of the increased deoxyadenosine present in

**Figure 12.2.** Adenosine deaminase deficiency: cellular and metabolic interactions. RBCs, red blood cells.

surrounding body fluids with subsequent intracellular phosphorylation and trapping. In cases with the most marked accumulation of dATP, ATP concentrations fall. The accumulation of dATP in a particular cell type or tissue is dependent on the rate of phosphorylation vs. the rate of dephosphorylation. There has been only one published study of dATP in additional tissues (in a patient dying with lymphoma and previously treated with partial exchange transfusions). This study of heart, brain, liver, and spleen reported only modest elevations in dATP (recalculated as 2–20 vs. the 500–2000 found in RBCs; Coleman et al., 1985). Surprisingly, among several nonlymphoid tissues examined, massive accumulation of phosphorylated deoxyadenosine was found only in the kidney (R. Hirschhorn, unpublished studies).

Patients with ADA deficiency additionally show a massive increase in excretion of deoxyadenosine in urine, where it is normally undetectable. By comparison, excretion of adenosine is only minimally elevated over that found in normal individuals. Several naturally occurring methylated adenosine compounds that are substrates for ADA are also excreted in urine in increased amounts in ADA-deficient individuals (Hirschhorn et al., 1982).

The increased concentrations of deoxyadenosine also inactivate SAH hydrolase, resulting in a secondary deficiency of that enzyme activity in erythrocytes (Hershfield et al., 1979; Hershfield and Mitchell, 2001). Normalization of SAH hydrolase activity appears to be the most sensitive indicator of normalization of metabolite concentrations (see Treatment and Prognosis, below). Although several other alterations in metabolites have been proposed, on the basis of *in vitro* investigations of proposed pathophysiologic mechanisms, none of these additional alterations has been demonstrated *in vivo*.

In general, adenosine metabolite concentrations correlate with severity of disease. In partially ADA-deficient individuals who are healthy, metabolite concentrations are on average greater than normal but markedly lower than those found in immunodeficient patients. Red blood cell dATP in partially deficient subjects ranges from 5 to 40 nmol/ml, compared to 25-fold increased in adult-onset patients and over 1000 fold-increased concentrations in infantile-onset patients (Table 12.2) (Hirschhorn et al., 1982, 1997). Deoxyadenosine excretion parallels concentrations of dATP, whereas adenosine concentration in urine is a poor discriminator between different types of individuals (R. Hirschhorn, unpublished results).

Different therapeutic maneuvers lower the concentrations of metabolites to differing degrees. Following bone marrow transplantation, metabolites in red cells, plasma, and urine are dramatically decreased. However, sensitive measurements indicate that metabolites are still elevated compared to normal, and in particular that plasma adenosine remains very high. Whether this is influenced by the bone marrow donor being a carrier or homozygous normal for the disorder is unknown. Metabolite concentrations following polyethylene glycol (PEG)-ADA therapy (see Treatment and Prognosis) are lower with respect to dATP in red cells than seen following bone marrow transplantation or vigorous partial-exchange transfusion (Hirschhorn et al., 1980a, 1981). It is not surprising that adenosine concentrations are less diminished since the affinity of ADA is greater for deoxyadenosine than for adenosine.

Purine nucleoside phosphorylase catalyzes the reversible phosphorylation of inosine, deoxyinosine, guanosine, and deoxyguanosine to their respective bases plus deoxyribose-1-phosphate (Fig. 12.1). The purine bases hypoxanthine and guanine may then be recycled by the action of HPRT to inosine monophosphate (IMP) and guanosine monophosphate (GMP), respectively, or excreted

as uric acid by the action of xanthine oxidase. The reverse reaction is not likely to occur *in vivo* because of the low levels of deoxyribose-1-phosphate and the rapid metabolism of the bases hypoxanthine and guanine by HPRT. PNP deficiency results in accumulation of its substrates with high serum levels of inosine and guanosine, and high urinary excretion of inosine, deoxyinosine, guanosine, and deoxyguanosine (Hershfield and Mitchell, 2001). These findings are accompanied by low serum and urinary levels of uric acid.

## Biochemical and Pathophysiology Basis

### Biochemistry of ADA

Adenosine deaminase (EC 3.5.4.4) is an enzyme of the purine salvage pathway that catalyzes the irreversible deamination of adenosine and, perhaps more significantly, deoxyadenosine, to inosine and deoxyinosine, respectively. The enzyme is an ubiquitous “housekeeping” enzyme that exists as a 40 kDa monomer predominantly in the cytoplasm (Daddona and Kelley, 1977; Schrader and Stacy, 1977). A small proportion of the enzyme is present on the surface of fibroblasts, T lymphocytes, and probably most cells, as a dimer complexed to two molecules of a combining protein, now identified as CD26 in T lymphocytes (Nishihara et al., 1973; Hirschhorn, 1975; Kameoka et al., 1993). It is hypothesized that ADA on the cell surface serves to regulate local concentrations of adenosine and thus engagement of the various cellular stimulatory and inhibitory adenosine receptors. ADA is also genetically polymorphic, with two common biochemical variants, or allozymes, segregating in the normal population (Spencer et al., 1968).

Although ADA is present in all cell types, enzyme activity differs considerably in different tissues. The highest amounts in humans are found in lymphoid tissues, particularly intrathymic immature T cells, as well as the brain and gastrointestinal tract, whereas the lowest activity is seen in erythrocytes (Hirschhorn et al., 1978). In lymphoid cells, enzyme activity declines with maturation of T cells but is higher in peripheral blood T cells than in B cells (Tung et al., 1976). In addition to the ADA encoded on chromosome 20 and deficient in ADA deficiency, there is an additional isozyme of ADA that accounts for 1–2% of total ADA activity but that deaminates adenosine only at higher than physiologic concentrations and is not inhibited by EHNA, an inhibitor of the major ADA isozyme (Daddona, 1981).

Murine ADA has been crystallized, and areas of evolutionary conservation from *E. coli* to humans have been identified (Chang et al., 1991; Wilson et al., 1991; Sharff et al., 1992; Wilson and Quijcho, 1993). The enzyme is composed of a motif of eight  $\beta$ -pleated sheets alternating with eight  $\alpha$  helices. There are also five clearly defined additional  $\alpha$  helices, three following the first  $\beta$  sheet, and the fourth and fifth following the last  $\beta$  sheet. The  $\beta$  sheets form a barrel shape surrounding the catalytic site which lies at the carboxyl end of the barrel. There is a zinc ion coordinately bound at the bottom of the  $\beta$  barrel, under the substrate-binding site. The unexpected presence of zinc within the catalytic pocket of ADA and other enzymes of the purine and pyrimidine salvage pathways could potentially illuminate the immunodeficiency associated with zinc deficiency. Several amino acids have been identified that are significant for binding of zinc and for catalysis. The precise mechanism of catalysis is under investigation by analysis of effect of mutations as measured by various parameters, including crystallography (Bhaumik et al., 1993; Ibrahim et al., 1995; Mohamedali et al., 1996; Sideraki et al., 1996).

**Figure 12.3.** Metabolic consequences of enzyme deficiency found in adenosine deaminase-deficient patients.

Proposed Mechanisms for ADA Deficiency

Although much is known about the biochemistry of ADA, the mechanism(s) whereby deficiency of a ubiquitous enzyme results in predominantly lymphospecific pathology remains an area of investigation (reviewed in Hirschhorn, 1993; Benveniste and Cohen, 1995; Sekhsaria et al., 1996; Hershfield and Mitchell, 2001). On the basis of metabolic consequences of ADA deficiency (Fig. 12.3), several pathophysiologic mechanisms have been proposed and supported by in vivo or in vitro findings (Table 12.3). Deoxy ATP is known to be a feedback inhibitor of ribonucleotide reductase, an enzyme required for normal DNA synthesis. The observed marked elevation of dATP could explain the lack of lymphocyte proliferation required for further differentiation to mature cells. The lymphospecific toxicity has been explained by in vitro studies showing that in lymphocytes, and particularly immature T cells, the pathway for phosphorylation of deoxyadenosine is more active than the reverse pathway leading to dephosphorylation; this results in intracellular trapping of the phosphorylated compound. However, while this simplistic explanation is easily remembered and therefore attractive, more recent observations suggest that preferential trapping of dATP is more closely correlated with maturity of lymphoid cells than subtype, which is further supported by the greater sensitivity of chronic lymphocytic leukemia cells and hairy cell leukemia cells

(both usually derived from B cells) to ADA inhibitors or toxic adenosine analogues (Dillman, 2004).

An additional mechanism is suggested by the finding of marked diminution of SAH hydrolase activity. Deoxyadenosine irreversibly inactivates SAH hydrolase; markedly reduced activity of this enzyme is found in untreated ADA-deficient children. In vitro, this has been shown to result in accumulation of the substrate *S*-adenosylhomocysteine. Elevated concentrations of SAH result in feedback inhibition of the conversion of *S*-adenosylmethionine to *S*-adenosylhomocysteine and therefore prevent the transfer of methyl groups required for virtually all essential methylation reactions. The role of SAH hydrolase inactivation in the pathogenesis of the clinical findings in ADA deficiency remains to be determined. Interestingly, genetic deficiency of SAH hydrolase is not associated with any immune abnormalities, but with profound psychomotor delay, hypotonia, and defects of myelination (Baric et al., 2004).

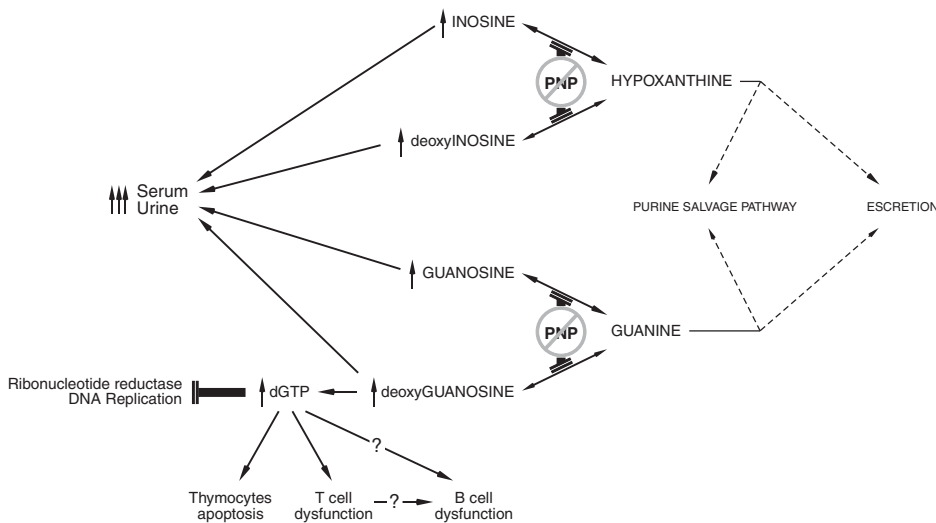

Elevation of SAH has not been demonstrated in vivo in ADA-deficient patients, and inhibition of SAH hydrolase is still found in bone marrow-transplanted children who have normal immune function. However, administration of deoxycoformycin, a known inhibitor of ADA, to patients with leukemia was accompanied by elevations of SAH in vivo. The significance of this observation for patients with ADA deficiency is difficult to evaluate for several reasons. Deoxycoformycin also inhibits at least one other relevant enzyme, AMP deaminase, and the elevations of deoxyadenosine resulting from death of malignant cells in the presence of ADA inhibition (and of uric acid) far exceeded that observed in any SCID patients. No explanation for this mechanism leading to lymphospecific toxicity has been advanced.

Elevation of cyclic AMP, known to inhibit lymphocyte function, has also been demonstrated in lymphocytes in vitro but not in vivo. A proposed mechanism, inhibition of pyrimidine biosynthesis by elevation of ATP, can no longer be supported because, in fact, decreased rather than increased ATP is found in SCID patients with the most marked elevations of dATP (the original report of elevated ATP used an assay that measured dATP as well as ATP). Additional pathophysiological mechanisms have been proposed on the basis of in vitro observations (e.g., activation of ATP catabolism by deoxyadenosine and interference with terminal transferease by dATP), which, however, have not yet found confirmation in vivo. In summary, while the bulk of data support dATP as an important toxic metabolite, several in vitro observations

**Table 12.3.** Proposed Pathophysiologic Mechanisms

Elevated deoxy ATP	Inhibition of ribonucleotide reductase (required for DNA synthesis) and block of DNA replication
Elevated deoxyadenosine	Inhibition of DNA repair, leading to chromosome breakage. Induction of apoptosis
Elevated adenosine	Interaction with adenosine receptors. Induction of apoptosis
Inhibition of SAH hydrolase	Inhibition of methylation reactions (may play a role in neurologic changes and not in immunodeficiency, based on phenotype of SAH hydrolase-deficient humans)

SAH, *S*-adenosylhomocysteine.

**Figure 12.4.** Metabolic and proposed cellular consequences of purine nucleoside phosphorylase (PNP) deficiency.

remain unexplained. It is likely that additional mechanisms are operative. However, all pathophysiologic mechanisms in ADA deficiency result from the presence of increased concentrations of substrates of ADA. These concentrations are particularly high in tissues, within which lymphoid cells normally undergo division and apoptosis, such as the thymus and infected or inflamed tissues. Deoxyadenosine has been reported to result in chromosome breakage and to induce apoptosis in immature thymic lymphocytes by a pathway found after DNA breakage, requiring expression of p53 and reversible by overexpression of Bcl-1. These studies correlate with the relatively high expression of p53 and low expression of Bcl-1 in immature intrathymic lymphocytes and suggest that the major block in lymphocyte differentiation resulting from ADA deficiency is intrathymic (Benveniste and Cohen, 1995). However granulocyte-macrophage colony stimulating factor (G-CSF)-stimulated recovery of CD34<sup>+</sup> hematopoietic progenitors is lower in ADA-deficient patients than in normal individuals, a finding suggesting that there is also a block at an earlier stage (Sekhsaria et al., 1996).

### Biochemistry of PNP

Human PNP is a trimer with a molecular weight of about 90 kDa (Osborne, 1980; Markert, 1991). The three-dimensional structure of human red cell PNP was resolved at 3.2 Å (Ealick et al., 1990) and confirmed a trimeric structure for the native enzyme. A motivation for determining the crystallographic structure of PNP was to provide a tool for computer-assisted design inhibitors of PNP (Ealick et al., 1991, 1993) for the selective abrogation of T cell function in vivo. Several groups have synthesized high-affinity inhibitors of PNP (Sircar et al., 1987; Ealick et al., 1993). By simulating the enzyme deficiency, PNP inhibitors may selectively depress T cell function to prevent allograft rejection or treat leukemia. Inhibition of PNP in rats correlated with increased levels of deoxyguanosine triphosphate (dGTP) selectively in proliferating thymocytes (Osborne and Barton, 1986). In dogs, inhibition of PNP prevented rejection of allogeneic platelets and appeared to induce tolerance (Osborne et al., 1986). The recent determination of high-resolution crystal structure (2.3 Å) provides a more reliable model for substrate binding and thus for designing PNP inhibitor molecules (de Azevedo et al., 2003).

PNP activity of RBC lysates can be estimated radiochemically or spectrophotometrically at 292 nm with coupled conversion of inosine to uric acid in the presence of xanthine oxidase (Osborne, 1980; Chu et al., 1989; Hershfield and Mitchell, 2001). Through this assay, the mean normal erythrocyte PNP activity has been determined to be 18.6 U/ml packed red cells. An estimation of the quantity of PNP protein can be obtained by Western blotting. Other readily available cell types for enzyme analysis include peripheral blood lymphocytes, EBV-induced B lymphoblastoid cell lines, and fibroblasts.

### Proposed Mechanisms for PNP Deficiency

In inherited PNP deficiency, PNP substrates, which are normally low or undetectable, accumulate in the plasma and are excreted in the urine (Rich et al., 1980). DeoxyGTP has been found in patients' RBCs, in contrast to normal cells, where it is not measurable (Cohen et al., 1978).

Pathogenic mechanisms proposed in PNP deficiency (Fig. 12.4) have focused on the nucleoside substrates that accumulate, implicating either the nucleosides themselves or their metabolic products (Hershfield and Mitchell, 2001). Of the four PNP substrates that accumulate in PNP deficiency, deoxyguanosine and, to a lesser extent, guanosine, are toxic to cultured lymphoid cells (Chen et al., 1979; Henderson et al., 1980; Hershfield and Mitchell, 2001). Human lymphoblastoid cell lines with T cell characteristics are particularly sensitive to deoxyguanosine. At low micromolar concentrations of deoxyguanosine (e.g., 1 μM), <sup>3</sup>H-thymidine and <sup>3</sup>H-leucine incorporation into T-cell lines is markedly decreased, and at concentrations of 10 μM, no cell growth occurs and 50% of the cells are killed. Growth and incorporation of <sup>3</sup>H-thymidine and <sup>3</sup>H-leucine are decreased at higher deoxyguanosine concentrations in human B cell lines. Patients with PNP deficiency accumulate deoxyguanosine at levels that adversely affect dividing T lymphocytes. The extreme sensitivity of the T lymphoblasts and relative resistance of B lymphoblasts to the toxicity of deoxyguanosine may explain the selective loss of T cell function over time and the relatively mild effect on B cell function in patients with PNP deficiency (Ochs et al., 1979).

In support of this mechanism, virtually all cell types, including lymphocytes, exhibit facilitated nucleoside transport with a broad specificity (Plagemann et al., 1988). Inside the cell, deoxynucleosides are subject to enzymes with kinase activity to

produce monophosphate metabolites. Once phosphorylated to deoxynucleoside monophosphate (dNMP), the nucleotide is effectively trapped in the cell, if the pathway to dNDP and dNTP formation is more active than the catabolic pathway mediated by nucleotidase to reform nucleosides. Because lymphocytes possess high deoxynucleoside kinase activity toward purine and pyrimidine deoxynucleosides (Barton and Osborne, 1986; Osborne, 1986), nucleotide formation is favored. Furthermore, deoxyguanosine kinase activity is higher in T cells than in B cells, consistent with the predominant T lymphocyte defect in PNP deficiency (Osborne, 1986; Osborne and Scott, 1983). This can result in accumulation of dGTP, which in turn will inhibit ribonucleotide reductase, the enzyme responsible for the production of a balanced supply of DNA precursors (Thelander and Reichard, 1979). There may be other mechanisms contributing to the lymphopenia in PNP deficiency, and the focus on ribonucleotide reductase inactivation may be overly simplistic (Hershfield and Mitchell, 2001).

## Molecular Biology

### Molecular Organization of the ADA Gene

The human *ADA* gene (MIM\*608958) is localized on the long arm of chromosome 20 at 20q12–q13.1. Both the cDNA and the genomic DNA have been isolated and analyzed (Daddona et al., 1984; Wiginton et al., 1984, 1986; Valerio et al., 1984, 1985; Aronow et al., 1995). The cDNA for human *ADA* contains a coding region of 1089 nucleotides, including the initiation methionine codon ATG, and predicting a polypeptide of 363 amino acids with a calculated molecular weight of 40,638 Daltons. The *ADA* cDNA is contained in 12 exons within 32,040 nucleotides of genomic DNA, from the major cap site at position 95 from the ATG to the polyadenylation site. The first 230 bp upstream of the coding region are sufficient to promote expression of the *ADA* cDNA, as tested by DNA-mediated gene transfer of a minigene construct. The promoter is of the GC-rich type with binding sites for Sp1, now recognized in many housekeeping genes, and lacks obvious CAAT or TATA boxes. Additional regulatory sequences are present in the large (15 kb) first intron, including an enhancer responsible for high expression in T cells. Studies with transgenic mice indicate that sequences controlling differences in tissue expression are contained in the first intron, with enhancer elements and elements directing high expression in T lymphocytes as well as an element responsive to the transcription activator cMyb (Aronow et al., 1995). The seventh intron is very small and appears to be unspliced in a small, but detectable, portion of *ADA* mRNA in normals. The gene is very rich in repetitive sequences of the Alu type; 23 copies of Alu account for 1890 of the total genomic sequence. Seventeen Alu re-

peats are in the first two introns, with three additional Alu repeats in the 5' upstream region. Alu repeats throughout the genome are known to be sites for gene deletions and duplications resulting from misalignment when homologous chromosomes pair during meiosis followed by unequal recombination. Alu repeats have been shown to be involved in causing deletions in the *ADA* gene (see below).

### Mutation Analysis of ADA

The types and variety of mutations are not the same in all genetic diseases (see Chapter 2). The predominant mutations seen can vary at different genetic loci or with differing phenotypes at the same locus. Moreover, at different genetic loci there can be many different mutations or a few major mutations causing the majority of the disease cases. Finally, even when there are multiple different mutations, a particular population or ethnic group may demonstrate only a few of them.

#### Mutations in immunodeficient patients

In *ADA* deficiency there are multiple different mutations, but some are more common than others and have been found in unrelated individuals (Fig. 12.5). Several of the more common mutations share ancestral origins, whereas others represent independent recurrences of mutation at “hot spots” within the *ADA* gene. In the initial cases reported, there was a predominance of single base-pair changes resulting in amino acid substitutions, or missense mutations, at mutational hot spots. In late-onset patients, there appears to be an increased incidence of splice-site mutations. There is also an increasing number of recognized small deletions and insertions, as the methods of *ADA* patient diagnosis have turned to examination of genomic DNA sequence. Some ethnic concentrations of particular mutations appear to be emerging.

Over 50 deleterious mutations have been identified in *ADA*-deficient immunodeficient patients. An additional 11 “partial” mutations have been identified. Table 12.4 lists published mutations, and Table 12.5 indicates mutations found in multiple unrelated patients by the Hirschhorn laboratory. Additional mutations have been identified, but are not yet published from this laboratory, and not all reported mutations have been seen in this laboratory. Approximately two-thirds of the deleterious mutations have been reported by the Hershfield group (Duke University Medical Center). With respect to type of mutation, most of the clearly deleterious mutations (31) are missense mutations, followed by 10 splice-site mutations, 9 deletions or insertions, and 4 nonsense mutations. The missense mutations appear to be concentrated in exons 4, 5, and 7, regions known to encode amino acids involved in substrate binding or catalysis. Despite the multiplicity of mutations, 12 mutations account for almost two-thirds of

\*Mutation originally found in ADA-deficient child without immunodeficiency, heteroallelic with null missense mutation. Also found in ADA-deficient patient diagnosed in adulthood, heteroallelic with promoter-exon1 deletion. Probably the lowest activity of mutant enzymes is found in immunodeficient patients.

Unpublished data are from R. Hirschhorn, D. Yang, and C. Jiang.

mutant chromosomes in 47 patients studied in the Hirschhorn laboratory (Table 12.5). The majority of patients carried 1 of these 12 mutations on at least one chromosome. Additionally, the leucine-to-proline mutation at amino acid 107 (Leu107Pro) and neighboring proline to leucine at position 104 (Pro104Leu) have also been found in more than one patient, as has the Gln3stop mutation (two Somali patients). As more patients from different areas are studied, this distribution is likely to change. Over two-thirds of patients are compound heterozygotes with two different mutations, the remainder being homozygous for a single mutation. Homozygosity is typical of rare autosomal recessive diseases, for

which consanguinity is an important risk factor. In the case of ADA deficiency, many patients with homozygous mutations are from populations with a history of reproductive isolation, including the American Amish community in Pennsylvania (Gly216Arg), Swiss and French Canadians (deletion of five nucleotides of exon10), inhabitants of Newfoundland (Gly20Arg), African Americans (Ala329Val), Canadian Mennonites (Arg142Stop), and Somalis (Gln3Stop).

The presence of the same mutation in unrelated individuals can result from descent from an unidentified common ancestor or from independent recurrence, usually at a site that is a hot spot for mutation. Descent from a common ancestor can be suspected if there is a common ethnic background or if both patients are also identical for other uncommon DNA polymorphic markers within the *ADA* gene, suggesting an ancestral haplotype (Chapter 2). Conversely, independent recurrence is indicated by differences in alleles at closely associated polymorphic DNA markers. Hot spots for independent recurrence of mutations include CpG dinucleotides (representing 30 of all human disease-related mutations), highly repetitive sequences (such as Alu sequences), and small repeat sequences that have been identified empirically. Over half of the missense mutations described to date in ADA-deficient patients are at CpG dinucleotides, a frequency much greater than that reported for many other diseases and setting the stage for independent recurrence. As an example, the Ala329Val mutation, the single-most commonly occurring *ADA* mutation, is at a CpG hot spot, in which the C residue of the GCG codon for alanine is changed to T. The mutation is found on two different haplotypes, one in African Americans and the second in Caucasians, consistent

with independent recurrence in each of these groups at some time in the past.

One of the two reported large deletions, including the gene promoter region and exon 1, is relatively common and also appears to have arisen independently in different patients (Table 12.4) (Shovlin et al., 1994; Jiang et al., 1997). This deletion occurs through homologous recombination between two Alu repeats surrounding the promoter and first exon. Such a deletion has been reported in three patients, but with different sequences at the junctions of the deletion, indicating independent recurrence. Presence of this deletion can be easily missed unless tested for specifically such as single-strand conformation polymorphism (SSCP) or analysis of cDNA or of polymerase chain reaction (PCR)-amplified genomic DNA. In a study of 29 patients we found this mutation in 4 patients in whom we had been initially unable to identify a mutation on the second allele (R. Hirschhorn, unpublished data). By contrast with the independent recurrence of the promoter/exon 1 deletion, a 5 bp deletion in exon 10 has been identified in at least four unrelated patients but appears to have derived from a common ancestor in these apparently unrelated individuals. In all four patients, the deletion is found on an extremely rare chromosomal background defined by the presence of two rare nondeleterious missense mutations (normal variants) and, in the three patients studied more fully, a rare combination of restriction fragment length polymorphisms (RFLPs) (haplotype V) (Tzall et al., 1989). Nonetheless, the deletion occurs at a site empirically identified with increased frequency of small deletions and has homology with a site for topoisomerase; the deletion of five bases would fit with loss of a half turn of the helix due to breaks associated with topoisomerase. It is therefore possible for this mutation to recur independently.

Splice-site mutations have been reported particularly in individuals with later onset of disease. It can be expected that more nonsense mutations, small deletions, small insertions, and splice-site mutations (all of which can result in unstable mRNA) will be found as the predominant method of analysis changes from examination of cDNA to direct sequencing of genomic DNA.

Identification of the specific ADA mutation(s) present in a newly diagnosed patient may be aided by considering the frequency of different mutations in the relevant ancestral background.

#### Mutations in partially deficient individuals

In addition to mutations found in immunodeficient patients, 11 different missense mutations retaining differing amounts of easily detectable enzyme activity in nonerythroid cells have been identified in the course of screening erythrocytes from clinically

normal individuals. These individuals were categorized as having partial ADA deficiency, based on absence of RBC ADA but presence of residual (5%–80% of normal) ADA in nonerythroid cell types, and identification either by screening of normal individuals or as an incidental finding in apparently healthy relatives of ADA deficient. Several of their ADA mutations have been found in multiple individuals, many of whom derive from the same geographic area in the Caribbean or share African descent (Hirschhorn et al., 1990). One of these partial mutations, Arg211Cys, is listed with mutations in immunodeficient patients (Table 12.4). Originally identified through population screening of newborns, heteroallelic with a null-mutant allele, this mutation has now been identified in siblings with adult-onset immunodeficiency whose mutation on their opposite ADA allele is the del promoter-exon 1 (Table 12.4) (Daddona et al., 1983; Hirschhorn et al., 1990, 1997; Shovlin et al., 1993). It is possible that the original unaffected child identified through screening with the Arg211Cys mutation will develop immunodeficiency. The remaining two missense mutations were identified in healthy relatives of ADA-deficient patients (Gly239Ser and Met310Thr), as was a second instance of the Ala215Thr mutation. It is also possible that additional partial mutations that express very low, but easily detectable, ADA activity (Leu152Met), when heteroallelic with null mutations, will be found in patients with late-onset immunodeficiency. It is noteworthy that the majority of patients are of African descent (including a Kung tribesman), and a selective advantage for malaria is possible.

#### Effect of Different Mutations on Residual ADA Activity

As is most readily apparent from study of mutations found in partially ADA-deficient immunocompetent individuals, ADA mutations may not totally abolish enzyme activity (Table 12.6). This is also true for mutations found in immunodeficient individuals. In published and unpublished studies, we have compared the ability of over 20 different missense mutations to code for ADA proteins with residual activity in vitro. The mutations fall into four different groups:

1. Approximately half of the mutations found in immunodeficient patients do not express enzyme activity detectable by the methods used.
2. The remainder of the missense mutations found in immunodeficient patients express detectable residual ADA activity ranging from 0.5% to 2% of normal. (An exception is the mutation Arg211Cys, found in adult-onset immunodeficiency, which expresses somewhat more than 2% of normal activity.)
3. A borderline group of mutations encoding ADA expressing 3%–6% of normal activity; this group contains the above mutation Arg211Cys,

**Table 12.6.** Relative Ability of Mutant Enzymes to Express Residual ADA Activity

<i>Enzyme Activity*</i>			
<i>Not Detectable</i>	<i>0.5%–2%</i>	<i>2.5%–6%</i>	<i>10%–80%</i>
Gly20Arg	Arg156His	Arg211Cys	Arg149Gln

Ser291Leu	Arg211His		Ala215Thr
Arg101Trp	Leu107Pro		
	Leu304Arg		

\*Mutations listed in order of decreasing activity.

originally found in heterozygosity in a child ascertained by newborn screening, but more recently found heteroallelic with a large deletion in adult-onset immunodeficiency in siblings. Also in this category is the Leu152Met mutation present in homozygosity in a child ascertained by newborn screening who is currently healthy at 12 years of age, but had a prior sibling who died in infancy with an infectious disease (Hirschhorn et al., 1997).

4. Mutations expressing 10%–80% of normal, all found by screening of normal individuals. The effect of mutations on residual enzyme activity may be due to instability of the mutant enzyme, a direct effect on the binding of substrate, disruption of the zinc-interacting residues, or changing residues central to the catalytic mechanism. Although some of these effects can be hypothesized on the basis of crystal structure of the murine ADA molecule, definitive conclusions must await direct examination of mutant enzymes.

Analysis of activity of different mutant protein, has also been measured by expression in *E. coli* that are genetically devoid of endogenous ADA activity (Arredondo-Vega et al., 1998; Hershfield and Mitchell, 2001). On the basis of activity expressed in *E. coli*, various mutations were divided into four different groups that appear to correlate well with clinical and biochemical phenotype. Fourteen of the 29 mutations tested in *E. coli* had also been tested for expression in mammalian cells (Table 12.6, R. Hirschhorn and D. Yang, unpublished results). Mutations with the highest activity (class IV and class III) were seen in patients with partial deficiency. In general, the results of expression in mammalian cells correlated well with the results from the *E. coli* experiments.

### Genotype–Phenotype Correlations

Correlations of phenotype with genotype are being examined for many inherited disorders with the increased definition of mutations at multiple different disease loci. However, other genetic and nongenetic factors can greatly modify the disease phenotype of patients with identical mutations. Phenotypic differences between siblings carrying the same mutation(s) could be due to modifying genes unlinked to the primary disease locus. Differences between unrelated individuals carrying the same mutation have been attributed to differences in chromosomal background within the gene. Environmental factors can also modify genetic disease phenotypes to a greater or lesser extent, depending on the particular disease. Lastly, a milder phenotype than predicted by the specific mutation can result from somatic mosaicism.

In an autosomal recessive disorder due to defects in a monomeric enzyme, such as ADA, presence of a null allele with a mutant allele expressing residual ADA activity is expected to result in a mild phenotype. Homozygosity for two such mutant alleles could theoretically result in an even milder phenotype. The expression of residual ADA could result from a missense mutation that doesn't totally abolish enzyme activity or of a mutation at a splice site that demonstrates "leakiness"—that is, allows some degree of normal splicing. Critical evaluation of phenotype vs. genotype would be best carried out by comparing patients with identical homozygous mutations to siblings carrying the same mutations. However, for a disorder as rare as ADA deficiency in which there exist multiple different mutations, definitive correlations may not be possible. Moreover, in ADA deficiency, environment, particularly exposure infections, could play a major modifying role. Additionally, as discussed more fully below, somatic mosaicism, due to *de novo* mutations during embryogenesis or to reversion of one of the inherited mutations to normal, can dramatically modify the phenotype.

Despite these caveats, correlations on a less stringent basis between specific mutations, metabolite concentrations, residual ADA activity, age of onset, and severity of disease appear to be present in ADA deficiency. Several mutations in homozygosity or quasi-homozygosity have been recognized in neonatal-onset patients that are consistent with the phenotype. These include a Gly20Arg, Glu217Lys, and Gly216Arg (heteroallelic with a large deletion including the promoter through exon 5), all of these missense mutations being at critical areas of the molecule. The deletion of five nucleotides in exon 10 and possibly the Arg142Stop mutations may also be associated with neonatal-onset SCID. As noted above, several splice-site mutations and the Arg211Cys mutation expressing some activity appear to be associated with later onset and milder perturbations of immune function and metabolites. While relative concordance between siblings (modified by early institution of supportive therapy) has been noted, marked discordance between one set of siblings has also been reported, suggesting the existence of modifying genes or other factors (Arredondo-Vega et al., 1994). The discordant siblings were heterozygous for two different splice mutations. One allele had in intron 2, at the invariant position IVS2(+1), a guanine changed to an adenosine nucleotide. The other allele bore a complex 17-bp rearrangement in intron 8 of the 3' splice site of IVS8; this mutation involved insertion of the purine-rich antisense strand of the poly-pyrimidine tract between the conserved CAG and the normal pyrimidine tract of the 3' splice-site junction (Arredondo-Vega et al., 1994). Presence of mRNA with normal splicing indicated that one or both mutations were somewhat leaky, and the difference in phenotype between the siblings was attributed to genetic variation in splicing efficiency. Although it would not be surprising to find that there are modifying genes, in this family the more severely affected sibling was retrospectively diagnosed, having a hepatoblastoma at the time of diagnosis of immunodeficiency. Interestingly, this tumor manifested trisomy of chromosome 20, characteristic of hepatoblastomas, and this is the chromosome on which the ADA gene resides. The presence of the tumor could well have contributed to the earlier development of immunological manifestations (Umetsu et al., 1994).

Somatic mosaicism: *de novo* and by reversion to normal of inherited mutations

Somatic mosaicism has clearly been identified as a modifier of phenotype, most commonly in autosomal dominant genetic disorders. In such cases, somatic mosaicism is caused by occurrence of a *de novo* mutation at some point during embryogenesis, resulting in a proportion of cells that carry a mutation and a proportion that are normal. Individuals with somatic mutation in general have a milder phenotype, but if the mutation is present in their germ cells, their offspring, to whom they transmit the mutation, carry the mutation in all cells and have a more severe phenotype. Somatic mosaicism is more difficult to identify for autosomal recessive disorders, but has been found in relatively common disorders such as cystic fibrosis and thalassemia. We have identified somatic mosaicism in two patients with ADA deficiency (Hirschhorn et al., 1994b, 1996); in one of them it occurred by reversion to normal of an inherited mutation. In both patients, mosaicism was uncovered during investigations directed at understanding why there had been improvement of the clinical phenotype, rather than deterioration, over time despite absence of any form of therapy. In the first patient, somatic mosaicism was demonstrated by isolation of B cell lines that expressed ADA and lacked one of the two mutations (IVS1(+1)c) carried by this

child (but retained the Arg101Gln mutation), as well as by demonstration of absence of the splice-site mutation in a proportion of peripheral blood DNA. DNA was not available from the parents; we therefore could not prove or disprove that mosaicism had resulted from the usual mechanism of a de novo mutation during embryogenesis (Hirschhorn et al., 1994b).

In the second child, we determined that somatic mosaicism had occurred because of the unexpected reversion to normal of an inherited point mutation (Hirschhorn et al., 1996). A prior sibling had died of an immunodeficiency disorder that would now be categorized as SCID but was designated Nezeloff syndrome by his physicians at the time. Each parent carried a different point mutation at the *ADA* locus, each of which had been identified in other *ADA*-deficient patients with SCID (maternal = Arg156His; paternal = IVS5(+1)a). However, the child's concentrations of abnormal metabolites were relatively low, and residual *ADA* activity in peripheral blood cells was relatively high. Moreover, instead of deteriorating clinically without therapy, which had been refused for religious reasons, the child progressively improved. We identified multiple B cell lines that expressed *ADA* and determined that these carried only the paternal mutation. However, the maternal chromosome that originally bore the maternal mutation (Arg156His) was still present in these B cell lines, as evidenced by presence of a unique maternally derived RFLP linked to the mutation. Approximately 15 clones isolated from peripheral blood also contained the maternal marker but did not carry a mutation, confirming that reversion had occurred *in vivo*. The detectability of this reversion to normal probably required a selective advantage for survival of revertant cells. Whether there was an additional specific mechanism increasing the frequency of reversion at specific sites remains to be investigated.

Reversion to normal in additional cases of *ADA* deficiency has now been reported (Ariga et al., 2001b). In one case, probable reversion of the paternal Gln119stop mutation was demonstrated in a polyclonal population of herpesvirus saimiri-immortalized T cells that expressed half the normal level of *ADA*. Revertant cells were not recovered from the peripheral blood of the patient and therefore could represent an *in vitro* event. The observation of the revertant was made before the patient had started PEG-*ADA* treatment. Evidence supporting the occurrence of the reversion event *in vivo* included markedly lower dAXP levels in the patient's RBC at diagnosis than those expected in *ADA*-deficient patients carrying the same mutation. In addition, *ADA* activity was detectable at diagnosis at ~8 nmol/min/10<sup>8</sup> cells and decreased to ~3 nmol/min/10<sup>8</sup> cells after PEG-*ADA*, which could be explained by the reduction in numbers of the revertant, *ADA*-expressing cells that lost their selective advantage over the deficient cells after the initiation of enzyme replacement treatment. In the second case, reversion of an Arg235Gln maternal mutation was detected; however, because the sample studied was a monoclonal T cell line, the possibility could not be excluded that the reversion had occurred *in vitro* (Ariga et al., 2001b).

More recently, somatic mosaicism was demonstrated in a 16-year-old patient from a family in which *ADA* deficiency was due to homozygosity for an intronic mutation in the last splice acceptor site of the *ADA* gene (IVS11(-15)a). Aberrant splicing due to the original mutation resulted in change of the last four *ADA* residues and added a stretch of 43 amino acids that rendered the protein unstable. The genotypic characteristics of the mosaic patient were investigated because he had greater residual immune function and less elevated erythrocyte deoxyadenosine nucleotides than his 4-year-old affected sister. Studies revealed that the patient's T cells and EBV B cell line had 75% of normal *ADA* activ-

ity and *ADA* protein of normal size by Western blot. In addition, DNA from peripheral blood mononuclear cells showed two mutant *ADA* alleles, both carrying the IVS11(-15)a splice site mutation, but one with an acquired deletion of the 11 adjacent nucleotides (del IVS11(-4 to -14)), which suppressed aberrant splicing and restored protein expression and function. Interestingly, enzyme replacement therapy with PEG-*ADA* in this case was also followed by a reduction of *ADA* activity in T cells, as well as a marked decrease of the peripheral blood lymphocytes carrying the "second-site" revertant allele (Arredondo-Vega et al., 2001).

Reversion to normal of inherited mutations has now been reported in several different disorders, including dermatologic and metabolic disorders and various immunologic disorders additional to *ADA* deficiency. These disorders include X-linked SCID, Wiskott Aldrich syndrome, Fanconi syndrome, Bloom syndrome, tyrosinemia, and epidermolysis bullosa (reviewed in Hirschhorn, 2003). Mosaicism with or without reversion should be suspected in patients with atypical or mild presentation of immunodeficiency. Reversion is probably a more frequent occurrence in other disorders, in addition to those reported, but is most easily ascertained in disorders such as those involving hematopoietic cells and skin, where phenotypic reversion can most easily be detected. The mechanisms that could be involved include intragenic recombination, mitotic gene conversion (both requiring heterozygosity), second-site compensating mutations, DNA slippage, and site-specific reversion of a mutated nucleotide to normal by undefined mechanisms (probably involving DNA breakage and repair). True reversions or involvement of second-site mutations may be a more common event than currently appreciated and could explain both published and anecdotal reports of T cell lines that, even though derived from immunodeficient patients, unexpectedly express *ADA*. In addition, somatic mosaicism has been described in other primary immunodeficiencies.

### Molecular Organization of the PNP Gene

The disease gene for PNP, designated *NP* (MIM + 164050), is encoded by a single structural gene on human chromosome 14q13 (Ricciuti and Ruddle, 1973; George and Francke, 1976; Aitken and Ferguson-Smith, 1978). The human *NP* gene is about 7.5 kb in length and contains six exons (Williams et al., 1984). A cDNA of 1.7 kb has been cloned that contains a 289-codon open reading frame, encoding a 32 kDa protein (Goddard et al., 1983). The human *NP* promoter has been defined in 2 kb of the 5' flanking region, containing a TATA box, an inverted CCAAT sequence, and two GC-rich regions within a 216bp segment. Interestingly, although PNP is ubiquitously expressed in human tissues, the *NP* promoter does not conform to a normal GC-rich, constitutively expressed housekeeping promoter. The PNP protein is a homotrimer, therefore it is possible that dominant negative effects will be seen.

### Mutational Analysis of PNP

Similar to *ADA* deficiency, mutation analysis of PNP has to examine both alleles. In some patients' cells, neither PNP protein nor PNP biochemical activity can be detected; in others, protein detectable by antibody assay but without enzymatic activity is found. In one family, the mutant protein could not be demonstrated in the patient's cells but was present in both consanguineous parents, a finding suggesting that mutated protein was unstable or may not have formed stable trimers (Osborne et al., 1977; Gudas et al., 1978). Results of mutation analysis, carried out so far

□ MISSENSE

**Figure 12.6.** Mutations at the purine nucleoside phosphorylase (PNP) locus.

in 15 patients, are summarized in Figure 12.6 and Table 12.7. A homozygous mutation affecting codon 89 (Glu89Lys) was the first PNP mutation recognized (Williams et al., 1987). The affected patient from a second family was found to have a deletion of 170 bp in the *NP* mRNA due to a G-to-T transversion at the terminal nucleotide of exon 2 in the maternal allele, which caused skipping of exon 2 during mRNA processing. The paternal allele of this patient was found to carry a point mutation (Arg234Pro) in exon 6 (Andrews and Markert, 1992; Markert et al., 1997). The affected patient from a third family was found to be a compound heterozyte for an Asp-to-Gly substitution at codon 128 and an Arg-to-Pro substitution at codon 234; these mutations resulted in absence of immunoreactive protein with complete loss of functional activity (Aust et al., 1992; Buckley et al., 1997). Compound heterozygosity for a missense mutation (Tyr192Cys) and a 1 nucleotide deletion in exon 6 were later demonstrated in a patient with PNP deficiency and severe immunodeficiency (Pannicke et al., 1996). The mutations of four additional unrelated patients were also reported (Markert et al., 1997). These included two novel missense mutations (Ala174Pro

and Gly190Val) and a single amino acid deletion in exon 4 (del Ile129). One patient of this series had a point mutation in intron 3 (–18 g to a) resulting in an alternative splice site, frameshift, and premature stop codon, producing an unstable truncated protein; however, a small amount of normally spliced product could be detected, explaining the patient's late onset and mild course. Finally, two additional Arg234Pro mutations were also found, suggesting that codon 234 may be a mutational hot spot or, alternatively, that the affected individuals have a common ancestor (Markert et al., 1997). Nonsense mutations (Arg24Stop, Arg57Stop) have also been found in two unrelated patients in the homozygous state (Sasaki et al., 1998) and in heterozygosity with a splicing defect of the donor site of intron 3 (Dalal et al., 2001). Two additional reports on mutation analysis of PNP-deficient patients described the presence of novel homozygous missense mutations (Tyr166Cys and Gly156Ala). A recent report identified His257Asp and Arg234Stop mutations (Grunebaum et al., 2004). Of the 30 mutated alleles studied, 19 had missense mutations, 19 had nonsense mutations, 6 had splice-site mutations resulting in frameshift, and 2 had nucleotide deletions.

Because of the low numbers of PNP-deficient patients described to date, no clear genotype–phenotype correlations can be established for this disease. No PNP patients with somatic mosaicism have been described.

### Strategies for Diagnosis

Given the emerging phenotype of late- and adult-onset immunodeficiency disease due to ADA deficiency, any individual with lymphopenia of unexplained etiology and frequent infections of any type, with or without autoimmunity, should be tested for ADA deficiency. In this setting an initial abnormal screening result obtained on erythrocytes should be followed by assay of ADA in nonerythroid cells.

Diagnosis of ADA deficiency in immunodeficient patients can be made by enzyme assay of several easily available cell types, including erythrocytes, lymphocytes, EBV-transformed B cells, and fibroblasts. If the patient has received a transfusion, erythrocytes are unreliable, and assay of a transformed B cell line or of fibroblasts should be used. If the diagnosis is suggested by abnormal assay of RBC, assay of lymphocytes and/or fibroblasts should also be performed to rule out the (unlikely) possibility of partial ADA deficiency, which would not be expected to give rise to immunodeficiency. Alternatively, analysis of DNA and identification of previously reported deleterious mutations can be performed. While there may not be sufficient lymphocytes for assay in the initial blood sample, there is usually sufficient DNA in the buffy coat that is removed prior to assay of RBCs. This DNA should be saved and can be used to sequence all exons and flanking regions. Determination of dATP and of deoxyadenosine in urine can also aid in diagnosis.

A variety of assays can measure the hydrolytic deamination of adenosine (Zielke and Suelte, 1971). We have not found assays measuring release of ammonia to be reliable. For initial screening, we routinely use a linked spectrophotometric assay in which uric acid is the final end product (Edwards et al., 1971; Hirschhorn, 1979b). This assay is relatively sensitive, rapid, and easily performed. A second spectrophotometric method measuring the conversion of adenosine to inosine by loss of absorbance at the peak for adenosine is also simple and widely used, but it is much less sensitive because of the limitation in the concentration of substrate and in the amount of cell lysate that can be included in the assay. The most sensitive and specific assays are those that use radiolabeled adenosine as substrate in the presence and absence of the inhibitor EHNA and separate the products from the substrate by methods such as thin-layer chromatography (Hirschhorn, 1979b). The amount of enzyme activity inhibited by EHNA measures the activity resulting from the ADA locus affected in ADA-deficient immunodeficiency. The alternate isozyme of ADA is encoded by a distinct locus not affected in ADA-deficient immunodeficiency. Although this locus accounts for only 1%–2% of ADA activity in normal cells, its presence can confuse detailed characterization of residual ADA in diagnosis of ADA deficiency. We have also used a high-performance liquid chromatography (HPLC) assay using unlabeled adenosine and standard methods of separation (Hirschhorn et al., 1982), but this requires expensive machinery not commonly available. However, this assay could be easily automated with current available technology; it does not require radioactivity, and it is sensitive. Other methods amenable to automation have also been described (Carlucci et al., 2003).

Patients presenting with recurrent bacterial, viral, and fungal infections, neurologic deficits, lymphopenia due predominantly to

the absence of T lymphocytes, abnormal T cell function, and defective antibody responses should be investigated for PNP deficiency. Absence of PNP enzymatic activity in RBC lysates, determined by radiochemical or spectrophotometric assays, will confirm the diagnosis. The linked spectrophotometric assay described above also measures PNP activity. Indeed, all patients must be tested for both deficiencies if the linked assay is used. The linked ADA assay depends on endogenous PNP, and therefore absence of PNP can resemble ADA deficiency. Immunoreactive protein, measured by Western blot analysis, may be present or absent. The diagnosis of PNP deficiency is strongly supported by low uric acid in serum (<2 mg/dl, and usually <1 mg/dl) and urine. High serum levels of inosine and guanosine and high urinary excretion of inosine, deoxyinosine, guanosine, and deoxyguanosine are characteristic for PNP deficiency (Cohen et al., 1978; Hershfield and Mitchell, 2001). An increase of dGTP has been reported in red cells of PNP-deficient patients (Cohen et al., 1978).

### Prenatal Diagnosis and Carrier Detection

#### Prenatal diagnosis

Prenatal diagnosis of ADA deficiency has been made by enzyme assay on chorionic villous samples, amniotic cells, and fetal blood (Hirschhorn et al., 1975, 1992; Hirschhorn, 1979b, 1979c; Durandy et al., 1982; Simmonds et al., 1983; Linch et al., 1984; R. Hirschhorn, unpublished results). We have performed prenatal diagnosis in over 20 cases by enzyme assay of amniotic cells and correctly diagnosed the expected 25% to be affected. Predictions were confirmed either by postnatal ADA assay of erythrocytes and/or identification of mutations on both chromosomes in amniotic cells; infants predicted to be unaffected had ADA activity by assay of erythrocytes after birth. There was a clear separation between affected fetuses and fetuses at risk, but not affected. However, homozygous normals vs. carriers could not be definitively identified by enzyme assay in cases where we could identify carriers by heterozygosity for a mutation.

DNA-based diagnosis can definitively diagnose carriers, affected subjects, and normals in a setting where both ADA mutant alleles are known; this is feasible if the mutations have been studied in a previously affected child in the family or can be rapidly determined in the parents or samples preserved from a deceased affected child. Although RFLPs, when informative, could in theory also be used for diagnosis, we suggest that the AluVpA polymorphism described upstream of the first exon not be used for diagnosis, as we have identified a crossover in this region (Hirschhorn et al., 1994b). Direct detection of the specific pathologic mutations or enzyme assay is preferable, and identification of the mutations present can be performed given the availability of PCR and rapid sequence analysis.

Prenatal diagnosis can be valuable not only if parents wish to terminate an affected pregnancy but also for facilitating therapy of an affected infant after birth. A number of families have chosen to carry the pregnancy of an affected child to term (Jiang et al., 1997). HLA typing has then allowed rapid bone marrow transplantation (both histocompatible and T-depleted haploidentical) before onset of infections (Pollack et al., 1983). Prenatal diagnosis has also made possible harvest of cord blood for gene therapy (Kohn et al., 1995, 1998).

Similar to ADA deficiency, both amniotic cell culture and chorionic villus sampling have been used successfully to identify PNP deficient fetuses by assessing PNP activity (Carapella De Luca et al., 1986; Perignon et al., 1987; Kleijer et al., 1989).

Obviously, if the mutations of the *NP* gene are known in an affected family member, direct sequence analysis of fetal DNA will identify the PNP status of the fetus.

#### Carrier detection

Determination of heterozygotes can be attempted by assay of ADA in erythrocytes and demonstration of anomalous inheritance within the family of the normal ADA polymorphism (Chen et al., 1974; Scott et al., 1974; Hirschhorn et al., 1975; Hirschhorn, 1992). There is a large range of normal ADA activity; values follow a normal distribution only after log conversion. Most obligate carriers demonstrate, as expected, approximately half-normal ADA activity. However, approximately 10%–20% of carriers fall within the normal range, and 1% of normals have activity in the carrier range. Most troubling are those individuals at risk for being carriers who are at the borderline of normal. A definitive means for identification of carriers is demonstration of anomalous inheritance of the normal ADA polymorphism in a family at risk. However, the frequency of this normal polymorphism is low, therefore the number of families in which this approach is useful is also low.

We no longer attempt carrier identification as a definitive diagnostic measure, for several reasons. First, the problem of overlap does not allow the test to be definitive except in cases where both parents have markedly reduced activity (25% of absolute values; 50% of log conversion). Second, if heterozygote testing is being performed for relatives of a patient with known ADA deficiency, mutation detection now offers a definitive test. Third, in the case of a pregnancy at risk for SCID of unknown etiology, the prenatal diagnosis of SCID can be made by examination of lymphocytes in fetal blood, at which time ADA deficiency can be diagnosed with the erythrocytes obtained. Alternatively, and preferably, if amniocentesis has been performed for other reasons, ADA can be assayed in cultured amniocytes. Clearly a consensus is needed on the most efficient, sensitive, and specific strategies to be used for prenatal diagnosis of SCID that would avoid the danger of fetal blood sampling.

Carriers for PNP deficiency frequently have decreased PNP activity in red cell and white cell lysates. The distribution of PNP activity is much narrower than for ADA. If the mutations of the affected offspring are known, mutation analysis will definitively determine carrier status.

### Treatment and Prognosis

Several management options are available for ADA deficiency. These are listed in Table 12.8 and include both prevention (e.g., prenatal diagnosis with selective pregnancy termination) and therapeutic approaches based on hematopoietic bone marrow/stem cell transplantation (HSCT), enzyme replacement, and gene therapy. For PNP deficiency, prevention and bone marrow transplantation are currently the only available alternatives.

#### Hematopoietic Bone Marrow/Stem Cell Transplantation

Allogeneic HSCT from a histocompatible sibling or other close relative in inbred communities is the therapy of choice for ADA deficiency (Parkman et al., 1975; Chen et al., 1978; Zegers and Stoop, 1983; Friedrich et al., 1985; Buckley et al., 1986, 1993, 1999; Fischer et al., 1986, 1990; Markert et al., 1987; Silber et al., 1987; Boulieu et al., 1988; Wijnaendts et al., 1989; Gaines

**Table 12.8.** Therapeutic Options for ADA Deficiency

1. Preventive
  - a. Prenatal diagnosis with selective pregnancy termination
  - b. Prenatal diagnosis to assist postnatal therapy: HLA typing, germ-free delivery
  - c. Preimplantation diagnosis with selective implantation of nonmutant embryos
2. Hematopoietic stem cell transplantation
  - a. Potential donors
    - i. Histocompatible-related donor (usually sibling)\*
    - ii. Haploidentical-related donor (usually parent)
    - iii. Matched unrelated donor
  - b. Potential sources of hematopoietic stem cells
    - i. Bone marrow
    - ii. Mobilized peripheral blood
    - iii. Cord blood
3. Enzyme replacement
  - a. Partial-exchange transfusion (no longer used)
  - b. PEG-conjugated calf intestinal ADA (ADAGEN)
4. Gene therapy
  - a. Into cultured expanded T cells
  - b. Into CD34<sup>+</sup> stem cells
    - i. Cord blood
    - ii. Bone marrow

\*Therapy of choice if available.

et al., 1991; Parkman, 1991; Fischer, 1992; Haddad et al., 1998; Bertrand et al., 1999; Amrolia et al., 2000; Rubocki et al., 2001; Antoine et al., 2003). This therapeutic maneuver has the greatest efficacy, does not necessarily require prior marrow ablation or permanent ongoing therapy, and has a relatively low morbidity and mortality. After successful HSCT, deoxyadenosine-based metabolites are dramatically lower than in untreated patients, but are still detectably higher than normal (Hirschhorn et al., 1981). The diminution of adenosine concentrations is not as dramatic, and this observation is to be expected because the ADA enzyme has a greater affinity (lower  $K_m$ ) for deoxyadenosine than for adenosine. Surprisingly, adenosine in plasma can remain very high without apparent adverse effects, although in ADA-deficient mice, elevated adenosine has significant effects (see Animal Models, below). Additionally, SAH hydrolase activity remains low, reflecting retention of increased amounts of metabolites (Hirschhorn et al., 1981). The incomplete metabolic correction may explain the persistence of nonimmunologic manifestations in transplanted patients, such as sensorineural deafness and cognitive and behavioral abnormalities (Tanaka et al., 1996; Rogers et al., 2001; Albuquerque and Gaspar, 2004), despite the fact that the bony abnormalities disappear rapidly. Genetic deficiency of SAH hydrolase is now known to result in mental deterioration, hypotonicity, and myopathy as well as multiple biochemical aberrations including hypermethionemia, but without signs of immunodeficiency (Baric et al., 2004). The ability of dietary manipulation to reverse the metabolic abnormalities and apparently the mental deterioration in SAH-deficient patients (Baric et al., 2004) raises the need to assess the correction of SAH pathway in ADA deficient after HSCT and offers a possible role for dietary manipulation in ADA- but also PNP-deficient patients at risk for cognitive defects. Finally, it is also not known if transplantation from an ADA-heterozygous carrier donor is less efficacious than from a donor who is homozygous normal. Metabolites have not been reported in patients transplanted following marrow ablation sufficient to result in replacement of all hematopoietic elements with donor-derived precursors.

Unfortunately, in an outbred population with small family size, as typically exists in the United States, fewer than 25% of patients have an HLA-matched related donor. Haploidentical transplantation from a related donor has higher morbidity and mortality in all forms of SCID than HLA-matched transplantation. It usually requires pre-treatment myeloablation, but it is performed in the absence of preparative chemotherapy in some centers (Buckley et al., 1999) and can result in permanent engraftment (see Chapter 47). The European Bone Marrow Transplantation (EMBT) working party has recently published the analysis of 30 years of cumulative experience with haploidentical transplantation for ADA deficiency, which showed a 3-year survival of only ~25% compared to 81% after HLA-identical HSCT (Antoine et al., 2003). Currently, therefore, it appears that ADA-deficient patients are poorer candidates for haploidentical transplantation than those with other forms of SCID, in which the average survival is >54% (Antoine et al., 2003). HSCT from matched unrelated donors has been successfully used in a few cases of ADA deficiency (Amrolia et al., 2000; Kane et al., 2001); however, the limited experience thus far does not allow us to draw definitive conclusions on safety and efficacy of this procedure, compared to use of related donors. Similar considerations also apply to use of cord blood from unrelated donors; despite initial encouraging results, more extensive investigation is still needed.

Bone marrow transplantation is the treatment of choice for PNP deficiency (see Chapter 47). There is, however, only limited clinical experience because of the rarity of the disease. Only about half of the transplanted PNP-deficient cases reported in the literature showed full engraftment and cure of their immunodeficiency (Markert, 1991; Broome et al., 1996; Carpenter et al., 1996; Hallett et al., 1999; Classen et al., 2001; Baguette et al., 2002). The procedure appears most successful if carried out at an early age and if the patient is conditioned prior to transplantation (Rich et al., 1980; Staal et al., 1980; Carpenter et al., 1996). Low-toxicity conditioning should probably be considered, as it can result in successful engraftment while avoiding the risk of further neurological deterioration (Classen et al., 2001). Unfortunately, however, even in successfully transplanted patients, the neurologic deficits have not improved (Markert, 1991; Carpenter et al., 1996; Hallett et al., 1999; Baguette et al., 2002). In view of these disappointing results,

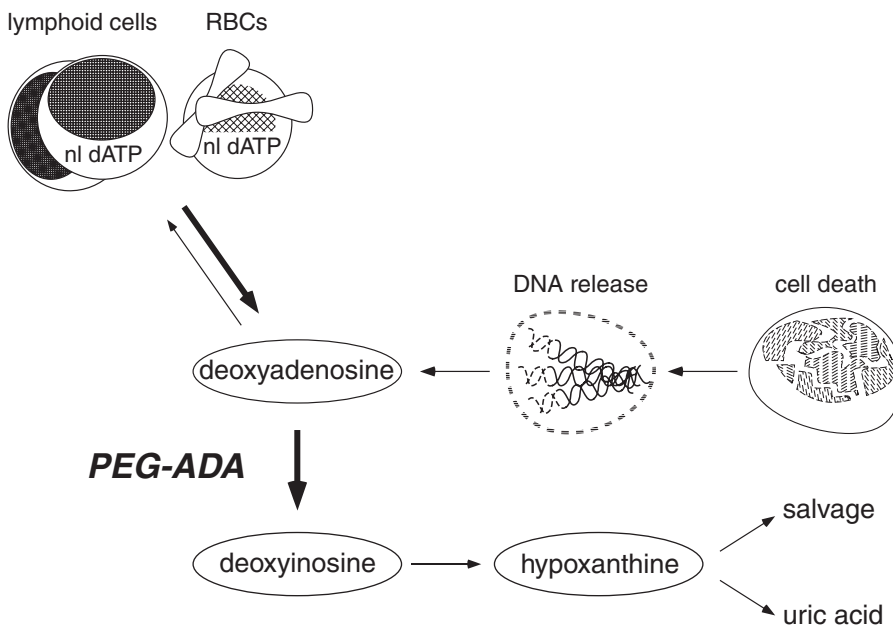

whether PNP-deficient patients with severe neurological deficits should be considered candidates for HSCT is unclear. Attempts at treating PNP deficiency with fetal thymus transplants have also generated discouraging results (Markert, 1991).

Overall, the long-term prognosis of PNP deficiency remains poor. Thirty-one of 39 patients in published reports have died (Markert, 1991; Carpenter et al., 1996; Banzhoff et al., 1997; Hallett et al., 1999; Classen et al., 2001; Baguette et al., 2002; Tsuda et al., 2002). Seventeen deaths were due to infections, including four that were caused by varicella. Six were due to tumors (five lymphoma/lymphosarcoma) and three patients died of GVHD following bone marrow transplantation. Because of the abnormal antibody responses, clinical management of PNP-deficient patients should include regular treatment with intravenous immunoglobulin (IVIG). Prophylaxis against *Pneumocystis jiroveci* infection is also indicated.

### Enzyme Replacement Therapy

Enzyme replacement therapy for ADA-deficient SCID does not require uptake of the enzyme into cells. Therapy is based first on the fact that metabolites are present in plasma and body fluids, where they can be degraded by administered enzyme present in the plasma. Second, additional toxic metabolites such as dATP are in equilibrium with the precursors in plasma (Polmar et al., 1976; Hirschhorn et al., 1980a; Hopp et al., 1985; Hershfield et al., 1987, 1993; Ochs et al., 1992; Weinberg et al., 1993; Hershfield, 1995a, 1995b, 2000).

Therefore, lowering of substrate concentrations in plasma results in lowering of intracellular concentrations of metabolites as well (Fig. 12.7). The first attempts at enzyme therapy used partial-exchange transfusion with normal, irradiated erythrocytes, because erythrocytes have transport sites for both adenosine and deoxyadenosine and contain ADA. Partial-exchange transfusion lowered metabolite concentrations dramatically, restored normal growth and development, and prolonged survival in at least six patients. However, this treatment did not alter immunologic responsiveness in most patients and, moreover, any improvement in immunologic parameters was often short-lived (Ochs et al., 1992). Additionally, transfusion carried the risk of transmission of infec-

**Figure 12.7.** Adenosine deaminase deficiency: effects of enzyme replacement therapy. PEG-ADA, polyethylene glycol-adenosine deaminase; RBCs, red blood cells.

tious agents and resulted in iron overload. Three patients first treated with transfusion therapy survived until over 10 years of age and were then placed on PEG-ADA therapy. Two of these patients were siblings and were still alive at approximately 20 years of age.

The development of PEG-ADA enzyme replacement therapy (polyethylene-glycol-modified calf intestinal ADA; ADAGEN®) has replaced the original enzyme replacement treatments. The modification, involving addition of PEG to lysine residues, is designed to mask the enzyme from endogenous antibody-mediated destruction so that its half-life is markedly prolonged. While dosages recommended are from 15 to 30 U/kg of body weight weekly, regimens may be individualized, based on monitoring of plasma ADA activity. In practice, early-onset SCID patients are treated with twice-weekly intramuscular injections of 30–60 U/kg, based on ideal body weight, for the first several months of therapy. There may be a diminished half-life of the enzyme in very ill infants and/or poorer responses to usual doses. Monitoring of dATP, total deoxyadenosine nucleotides, and SAH hydrolase activity is recommended since increases in deoxynucleotides and decreases in SAH hydrolase activity have been associated with a reduction in lymphocyte counts and function (Chun et al., 1993). Periodic testing for development of anti-ADA antibodies is also advisable.

PEG-ADA therapy has completely replaced partial-exchange transfusion because it is safer; it can deliver greater amounts of enzyme and therefore more completely lower metabolites. In addition to restoration of normal growth and development and prolongation of life, it results in the development of protective, although not normal, T cell immunity in ~80% of treated patients. To date, more than 120 patients have been treated with PEG-ADA worldwide, with a survival rate of approximately 80%. Virtually all patients on PEG-ADA develop antibody against the bovine ADA protein. In ~10% of cases neutralizing antibodies impair the function of the injected enzyme and require an increase in the dosage or discontinuation of PEG-ADA in an attempt of achieving desensitization (Chaffee et al., 1992; Chun et al., 1993; Hershfield, 2004). Other complications in patients on PEG-ADA treatment include autoimmune hemolytic anemia and EBV-positive lymphoproliferative syndrome, which require therapeutic attempts with HSCT. In one case, a patient responsive to transfusion treatment died of uncontrollable autoimmune hemolytic anemia following a viral infection (Ratech et al., 1985). A second patient died at 6 years of age of overwhelming varicella when exposure was not recognized in time to administer appropriate antiviral therapy. Of note, elective HSCT after PEG-ADA treatment has resulted in survival of ~50% of cases. This finding suggests the use of PEG-ADA to stabilize the metabolic status of patients after diagnosis so that transplantation can have the best chance of benefit.

Overall, clinical response of children on PEG-ADA has been good, as measured by normal growth and development, ability to attend school, absence of opportunistic infections, and normal recovery from varicella and other viral infections. Early mortality appears to be limited to early-onset cases with severe infectious complications. Immune reconstitution, as measured by lymphocyte counts and *in vitro* function, has been less complete, and approximately 20% of patients, predominantly with infantile-onset disease, show slower and lesser improvement. An increase in B cells usually precedes the increase in T cells and appearance of mitogen responses. Although mitogen responses improve from the initial 0%–10% of normal, they then fluctuate between 25% and 90% of normal. After the first year, most patients remain lym-

phopenic. Specific antibody responses have been detected in half of the patients, and half no longer receive regular IVIG replacement (Hershfield, 2004). Elegant studies of two patients with ADA-deficient SCID of early onset during their first year of enzyme therapy have provided evidence that the therapy results in apparent rescue of immature lymphocyte progenitors. It was shown that mature immunocompetent lymphocytes were recruited from progenitors, recapitulating ontogeny, rather than merely expanding a small pool of relatively mature cells (Weinberg et al., 1993). Thus PEG-ADA therapy, adjusted as needed to normalize SAH hydrolase activity, resulted in the sequential appearance of CD3<sup>dim</sup> cells, followed by transient appearance of cells expressing both CD4 and CD8, and finally the mature phenotype of CD3<sup>bright</sup> cells expressing either CD4 or CD8. These changes were observed between 3 and 5 months following the start of therapy. The appearance of mature T cells was then followed by IL-2-dependent mitogen responses and then rapidly by IL-2-independent responses and antigen-specific responses, also initially transiently IL-2 dependent. Other studies have demonstrated normalization of the antibody response, as indicated by appearance of reactivity to the bacteriophage  $\Phi \times 174$  (Ochs et al., 1992).

Enzyme replacement therapy results in dramatic lowering of metabolites, most notably in returning SAH hydrolase activity to normal or almost normal. Activity of SAH hydrolase appears to be the most sensitive indicator of total body concentration of toxic metabolites. The major questions remaining about PEG-ADA therapy are whether immune function will remain improved over the years and whether the efficacy will be limited by the underlying phenotype or by prior history of infections that have presumably destroyed a significant portion of the pool of “rescueable” lymphocyte precursors. Follow-up studies in nine ADA-deficient patients treated with PEG-ADA for ~10 years have been recently published and showed that despite initial improvements, a gradual decline of lymphocyte counts and mitogenic proliferative responses occurred after a few years of treatment. ADA-deficient patients on PEG-ADA therefore should be followed closely to detect declining immune function with aging (Chan et al., 2005).

The major disadvantages of PEG-ADA therapy are its high cost, the necessity for weekly, lifelong therapy (requiring ongoing monitoring of metabolites for adjustment of dose), and the possibility of developing clinically significant anti-enzyme antibody. The cost and need for ongoing therapy are important although not insurmountable. A recombinant human form of the enzyme could solve or reduce the problems of anti-ADA antibody. The major question is that of long-term efficacy; until that is defined, further investigation of alternative or adjunctive therapies appears justified.

In contrast to ADA deficiency, enzyme replacement therapy for PNP by means of irradiated RBC transfusions (Zegers et al., 1978; Rich et al., 1980; Staal et al., 1980) has not been definitively proven beneficial for PNP deficiency. A purified form of the enzyme conjugated to polyethylene glycol (PEG-PNP) could potentially find a role in the clinical management of this disease (Hershfield et al., 1991). Alternative approaches with administration of deoxycytidine and tetrahydrouridine, oral uridine or guanine, or thymosin fraction 5 have been unsuccessful (Markert, 1991).

### Gene Therapy

Adenosine deaminase-deficient SCID has been the pioneer disorder for development of human gene therapy (Blaese et al.,

1995; Bordignon et al., 1995; Kohn et al., 1995; Hoogerbrugge et al., 1996; Onodera et al., 1998; Aiuti et al., 2002a). This deficiency appeared to be an excellent candidate for gene therapy, based on the knowledge that the disease could be corrected by HSCT manipulation of bone marrow cells *ex vivo* prior to transplantation is routine and could be easily adapted to allow for introduction of the ADA cDNA into cells, and regulated expression did not appear to be required. Additionally, experiments in mice and humans suggested a selective survival advantage for cells carrying a functional ADA allele. Experiments in mice indicated that lymphoid cells containing the ADA gene have a marked advantage over ADA-deficient cells in an ADA-sufficient environment, a surrogate model for enzyme therapy (Ferrari et al., 1991). In humans, results of bone marrow transplantation were also consistent with the hypothesis that endogenous ADA is more effective than exogenous ADA. HSCT, while lowering metabolite concentrations, results in selective engraftment of donor T cells, rather than both rescue of host cells and engraftment of donor cells. Host B cells are often “rescued” without engraftment of donor B cells. These data superficially are also consistent with the finding of a lack of host T cell precursors to be rescued but a relative sufficiency of host B cells. This would imply that multipotential lymphoid stem cells are not engrafted or that T cell precursors have a stronger selective advantage than their B lineage counterparts.

These observations provided a rationale for attempts at gene therapy for ADA deficiency despite the availability of alternative modes of therapy (e.g., bone marrow transplantation, PEG-ADA). Gene therapy has important theoretical advantages, such as avoidance of the threat of GVHD and a potential reduction in therapeutic maneuvers required. To be successful, efficient and stable gene transfer into patients' cells is a prerequisite and, ideally, genetic correction of hematopoietic stem cells should be achieved. Achieving efficient transduction into stem cells and maintaining multipotentiality of this elusive cell type throughout the required manipulations are areas under active investigation (see Chapter 48).

Gene therapy for treatment of ADA deficiency by introduction into hematopoietic cells of a normal ADA cDNA contained in a retroviral vector has been pursued in the United States, the Netherlands, Italy, and Japan. As of 2004, approximately 25 patients had enrolled in these trials, although published data are available for only about half of the cases. All patients were treated with a retroviral vector containing the normal ADA cDNA and with *ex vivo* gene transfer. In all but one of the most recent trials reported to date, PEG-ADA was concurrently administered. The greatest amount of published information is available for the U.S. and Italian trials. The U.S. trials initially used T cells expanded *in vitro* as the recipient cells in two patients (Blaese et al., 1995; Mullen et al., 1996) and subsequently CD34<sup>+</sup> cells isolated from the patients' cord blood in three newborns diagnosed prenatally (Kohn et al., 1995, 1998). Patients treated with T cell gene therapy showed improvement of immunologic parameters (Blaese et al., 1995), although the concomitant PEG-ADA treatment made it difficult to attribute these results to gene therapy alone. Nevertheless, this trial demonstrated that retroviral-mediated ADA gene transfer into T cells can achieve long-term (12+ years) presence and expression of the exogenous gene (Muul et al., 2003).

In the Italian trial, multiple injections were given over several months in two patients to simultaneously introduce peripheral blood cells containing the ADA cDNA, and T cell–depleted bone marrow cells containing the same construct marked with a different restriction site to obtain information about safety and possible efficacy. Both of these patients were 2 years of age before initiation

of PEG-ADA therapy, having been previously supported with irradiated red cell transfusions. They were considered to have failed PEG-ADA therapy, despite marked clinical and immunological improvement, because of failure to maintain lymphocyte counts and antigen-specific and nonspecific proliferative responses. One of these patients had delayed-onset disease (Notarangelo et al., 1992). The results indicated that short-term reconstitution was achieved from cells derived from peripheral blood, whereas reconstitution after 1 year was from bone marrow–derived cells. Reconstitution ranged from 0.8% to 30% of normal, depending on the assay used (Bordignon et al., 1995). In the face of continued enzyme replacement therapy, it is difficult to assess the contribution of gene-corrected cells to any improvement in immunologic function. However, on the basis of preliminary data indicating a selective advantage for gene-corrected cells, PEG-ADA was withdrawn in one of the treated patients. There was a consequent progressive increase in the proportion of gene-corrected T lymphocytes that ultimately replaced the ADA-negative cells and led to improvement of T cell functions (Aiuti et al., 2002b).

More recently, multilineage engraftment of gene-corrected cells, metabolic correction, and improvement of immune function were achieved in two ADA-deficient patients who were not treated with PEG-ADA and received genetically modified CD34<sup>+</sup> cells after preparative nonmyeloablative chemotherapy (Aiuti et al., 2002a). These results suggest that gene therapy may soon become a real alternative treatment option for ADA deficiency. However, the occurrence of two cases of T cell leukemia in patients with X-linked SCID treated with gene therapy (Hacein-Bey-Abina et al., 2003) has provided an important word of caution on the possible secondary risks of retroviral gene addition.

Because PNP and ADA deficiency are caused by similar biochemical aberrations, it seems likely that gene therapy could also be beneficial for PNP-deficient patients. In preclinical studies using retroviral-mediated gene transfer, “*in vitro*” reconstitution of PNP activity in T lymphocytes derived from PNP-deficient subjects has been described (Nelson et al., 1995). These results suggest that T cells could potentially be used as vehicles for therapeutic *NP* gene expression. A clinical protocol testing this hypothesis was proposed in the mid-1990s, although technical difficulties have prevented it from entering the clinical stage. Because most PNP-deficient patients are profoundly lymphopenic and, in contrast to ADA deficient, this disease cannot be improved with enzyme replacement treatment, one expected problem in T lymphocyte–directed gene therapy for PNP deficiency is that patients will not have a sufficiently developed peripheral T cell repertoire before treatment to achieve meaningful immune reconstitution after gene correction. Moreover, the major neurologic abnormalities are not affected by either enzyme replacement in the form of exchange transfusions nor by HSCT.

## Animal Models

### ADA Knockout Mice

Although there are no known naturally occurring models of ADA deficiency, at least two groups have succeeded in generating ADA knockout mice (Blackburn et al., 1995; Migchielsen et al., 1995, 1996; Wakamiya et al., 1995). However, absence of ADA in mice leads to perinatal lethality. This finding is in contrast to the situation in humans; individuals homozygous for deletion of the promoter and exon 1 have been born alive and presented with a disease indistinguishable from that in other

patients with ADA-deficient SCID. Pathologically, newborn knockout mice exhibit marked hepatocellular degeneration, atelectasis, and intestinal abnormalities. In contrast to humans with ADA-deficient SCID, in whom marked lymphopenia is evident by 18–20 weeks of gestation, there were only minor reductions in CD4<sup>+</sup>/CD8<sup>+</sup> lymphoid cells in livers of ADA knockout mice.

The mice were rescued from perinatal lethality by two different approaches. Expression of a human ADA transgene containing human regulatory elements made them viable (Migchielsen et al., 1996), demonstrating that the lethality was not due to disruption of a gene within the ADA gene. More significantly, however, mice were rescued by expression of a transgene containing a promoter element restricting expression to the placenta and gastrointestinal tract organs with very high ADA activity in mice (Blackburn et al., 1995). Several of the metabolic abnormalities seen in humans were reproduced in these mice, including increased deoxyadenosine and dAMP in thymus and reduced SAH hydrolase in thymus, spleen, and liver. The mice showed moderate reductions in size of the thymus and spleen and in absolute numbers of lymphocytes in these organs. In summary, evidence for a mild immunodeficiency was found. It is possible that the postnatal expression of intestinal ADA provided partial immunologic rescue, suggesting that oral therapy might be ameliorative in human ADA deficiency. As an alternative explanation for the absence of profound immunodeficiency in the partially corrected mice, compensating pathways may exist in the mouse that alter the pathophysiology of ADA deficiency. It is well recognized that the final common pathway for purine metabolism, ending in uric acid, is quite different in mice from that in humans. Not infrequently, immunologic knockouts give phenotypes that differ between humans and mice.

More recently, a mouse deficient for ADA that does manifest combined immunodeficiency has been created by a two-stage genetic engineering strategy (Blackburn et al., 1998). These mice appear to reproduce not only the biochemical but also the immunologic abnormalities of the human disease. This model may therefore help clarify the role of enzyme deficiency in production of various human phenotypic features. ADA-deficient splenic B lymphocytes show defects in proliferation and activation with high propensity to undergo B cell receptor-mediated apoptosis. As a result, profound loss of germinal center architecture is noted, which may be responsible for impaired B cell development (Aldrich et al., 2003). In addition, the finding of renal pathology in these animals suggests that the renal abnormalities previously reported in humans with ADA deficiency are a manifestation of ADA deficiency (Ratech et al., 1985). Treatment of these mice with PEG-ADA showed that, while low doses could prevent the pulmonary insufficiency, the immunodeficiency could only be ameliorated by high doses, thus demonstrating a different impact of the therapy in different tissues (Blackburn et al., 2000). Further, these mice provided evidence that the respiratory failure was attributable to IL-13-mediated accumulation of activated alveolar macrophages and eosinophils and mast cell degranulation with airway hyperresponsiveness (Blackburn et al., 2000, 2003; Chunn et al., 2001). This finding offers insights into the mechanisms potentially responsible for asthmatic conditions and pulmonary insufficiency observed in some ADA-deficient humans.

### PNP Knockout Mice

There are no known naturally occurring models for PNP deficiency. Attempts to develop PNP-deficient mice by mutagenizing drugs resulted in the identification of three missense mutations

leading to severely reduced (1%–4.6%) but not absent PNP activity in erythrocytes (Mably et al., 1989; Snyder et al., 1997). Progressive thymic hypocellularity due to a reduction in CD4<sup>+</sup>/CD8<sup>+</sup> double-positive cells was observed in these mice, which also showed a marked reduction in peripheral T lymphocyte numbers and function. Although these mice were similar to humans with PNP deficiency, the delayed onset of the immune deficiency and the residual PNP activity were considered reasons to pursue total knockout models by gene targeting. PNP knockout animals were recently generated and show impaired thymic differentiation due to apoptotic signals originating in the mitochondria and decreased numbers of mature, dysfunctional T lymphocytes (Arpaia et al., 2000). As in humans with PNP deficiency, the B cell compartment in these mice is less affected with an increase in immature splenic pre-B cells. However, frequency of mature B lymphocytes is normal (Arpaia et al., 2000). These mice should prove useful for the testing of potential therapies such as PEG-PNP (Hershfield et al., 1991) and gene therapy.

Mouse models undoubtedly provide valuable insights into the pathogenesis of immunodeficiency due to defects of purine nucleotide metabolism. However, important differences may exist between mice and humans regarding both critical metabolic networks and alternative biochemical pathways. Conclusions on the significance of the findings observed in ADA and PNP knockout animals will have to be supported by confirmatory results obtained from studies in human patients.

### Future Directions and Challenges

Even though ADA and PNP deficiency have been known to be the molecular basis of immunodeficiency and have been extensively investigated, major challenges remain from diagnostics to therapy to insights into the basic biology.

The discovery of the molecular basis of the various immunodeficiency disorders discussed in this volume makes it important to develop an overall strategy for diagnosing immune disorders. Currently, in a severely ill child, the first step is to determine the presence or absence of ADA deficiency, as enzyme replacement can provide a life-saving intervention. With development of other diagnostic and therapeutic options for additional disorders, this commonly used strategy may become outdated. With respect to diagnostics, ADA deficiency as an inherited disorder involves a family. The importance of experienced genetic counselors in helping family members deal with issues of identification as a carrier cannot be overemphasized. We are often contacted by family members to determine if they are carriers of the mutation(s) in their families. Currently, these investigations are “cottage industry” in approach. The development of “chip” technology for rapid scanning for mutations, now being applied on a research basis, could revolutionize diagnosis. However, given the rarity of the disease, automated mutation detection is unlikely to be developed by industry. Should there be an “orphan drug” equivalent for diagnostics to facilitate relatively noninvasive prenatal diagnosis not only for prevention but also for early institution of therapy when available? These concerns apply to virtually all primary immunodeficiency disorders.

With respect to basic biology, the role of ADA and adenosine is increasingly being investigated. Adenosine interacts with multiple receptors that have opposing actions in different cell types. ADA bound to CD26 at the cell surface plays a role in regulating local concentrations of adenosine. The potential role of adenosine in the clinical aspects of ADA deficiency has been ignored

for some time. Because of the observation that children were immunocompetent after bone marrow transplantation, despite persistently elevated plasma adenosine concentrations, we have assumed there is no major role for adenosine in the pathophysiology of immunodeficiency. However, adenosine appears to be important in the pathogenesis of asthma, which may be more common in ADA-deficient patients than in the general population. Adenosine also has important roles in the cardiovascular and nervous systems. ADA shows localization to the nervous system, and recent experiments indicate a role for adenosine in regulating intracellular signaling pathways. An additional line of evidence of the importance of adenosine at the central nervous system (CNS) level comes from the clinical observation that methotrexate-induced coma is caused by elevated levels of adenosine and can be resolved by administration of an adenosine receptor antagonist (i.e., aminophylline). One of the most widespread clinical observations made by physicians treating ADA-deficient children for immunodeficiency has been that alertness improves when enzyme replacement therapy is instituted. Insufficient data are available, however, on long-term survivors of ADA-deficient SCID after HSCT to know whether these patients may have an intellectual or attention deficit.

With respect to therapy, the challenges are obvious. Roles for PEG-ADA and gene therapy exist for ADA-deficient patients lacking suitable donors for HSCT, but the risks of gene transfer into the hematopoietic stem cells for this disease must be defined.

Progress in clinical management of PNP deficiency is acutely needed to modify what is currently a poor prognosis. Even if successful HSCT can correct the immunodeficiency, the procedure most likely cannot reverse the CNS injury. An alternative therapy that needs to be explored is enzyme replacement with PEG-PNP, analogous to the use of PEG-ADA in ADA deficiency. In PNP knockout animals, PEG-PNP has been reported to raise the whole-blood PNP activity to 20% of wild-type levels and improve the metabolic abnormalities. PNP may also be a disease for hematopoietic stem cell gene therapy. With availability of PNP knockout mice, preclinical safety studies are now likely to begin.

## Severe Combined Immunodeficiency Due to Mutations in the CD45 Gene

TALAL A. CHATILA and MARKKU HEIKINHEIMO

The protein tyrosine phosphatase CD45, also known as protein-tyrosine phosphatase, receptor type, C (PTPRC), and leukocyte common antigen (LCA), is a high-molecular weight type I transmembrane protein that is exclusively expressed on all nucleated hematopoietic cells (Tonks et al., 1988; Thomas, 1989; Trowbridge and Thomas, 1994). It is an abundant protein estimated to comprise up to 10% of the cell surface areas of B and T lymphocytes. Despite its abundance and potentially high catalytic capacity, CD45 activity is directed at a limited number of physiologically relevant substrates that include Src and Janus kinases (Jak). CD45 plays a pivotal role in promoting signaling via lymphocyte antigen receptors by regulating the activity of receptor-associated Src-type tyrosine kinases (Ashwell and D'Oro, 1999; Thomas, 1999; Thomas and Brown, 1999; Alexander, 2000; Penninger et al., 2001; Hermiston et al., 2002). Its absence is associated with a profound block in signaling via antigen receptors (Pingel and Thomas, 1989; Koretzky et al., 1990; Desai et al., 1994). CD45 also serves to negatively regulate the function of integrin-mediated adhesion and cytokine receptor signaling by dephosphorylating integrin-associated Src kinases (Roach et al., 1997) and cytokine receptor-associated Jak kinases, respectively (Irie-Sasaki et al., 2001).

CD45 deficiency in humans (MIM 151460) results from rare deleterious point mutations and deletions that are inherited in an autosomal recessive manner. Two patients have been described to date, both of whom presented in infancy with severe combined immunodeficiency (SCID) associated with T cell depletion and failure of the residual T cells in the periphery to respond to mitogenic stimuli (Cale et al., 1997; Kung et al., 2000; Tchilian et al., 2001). The B cells, whose development was spared, failed to develop germinal centers or to sustain normal immunoglobulin production. The immunological abnormalities suffered by these patients mirrored those noted in genetically engineered

animal models of CD45 deficiency (Kishihara et al., 1993; Byth et al., 1996; Mee et al., 1999), and reflect an obligate requirement for CD45 in antigen receptor signaling during T cell development and upon T and B cell activation in the periphery.

### Regulatory Functions of CD45

The CD45 gene is located on chromosome 1q31–32 and contains 34 exons (Hall et al., 1988). The extracellular portion of CD45 is long (up to 51 nm) and heavily *O*-glycosylated. It can be divided into an amino-terminal region containing the *O*-linked glycosylation sites and cysteine rich region containing fibronectin type III sequence motifs. Cell type-specific alternative splicing of exons 4/A, 5/B, and 6/C, encoding sequences at the NH<sub>2</sub>-terminal region of the protein, results in the generation of up to eight CD45 isoforms. These isoforms vary in size of the extracellular region (ranging from 391 to 552 amino acids) and the extent of *O*-glycosylation (Rogers et al., 1992), and may differentially interact with other proteins either in *cis* or in *trans*. This interaction may in turn influence cell migration patterns and alter biochemical signaling events regulated by CD45.

In T cells, different CD45 isoforms are expressed in a developmental stage- and activation state-specific manner (reviewed in Trowbridge and Thomas, 1994). Immature thymocytes express low-molecular weight CD45 isoforms. Naive T cells express high-molecular weight, CD45RA-containing isoforms. Following activation, T cells switch to express a lower-molecular weight isoform lacking all three alternatively spliced exons (CD45RO). The CD45RO phenotype, frequently used to denote memory T cells, is reversible in that CD45RO T cells can reexpress the high-molecular weight isoforms. B cells express the largest CD45 isoform of 220 kD molecular weight (also known as B220) containing all three exonic sequences (CD45RABC).

The CD45 cytoplasmic region contains two prototypic phosphatase domains in tandem. The membrane-proximal domain is catalytically active whereas the membrane-distal domain is inactive (pseudophosphatase domain) but promotes recruitment of substrate proteins (Kashio et al., 1998). Reconstitution of the cytoplasmic domain of CD45 as part of chimeric molecules restores signaling via the T cell antigen receptor in CD45-deficient cell lines, indicating that the lack of CD45 phosphatase activity is the fundamental abnormality underlying the failure of antigen receptor signaling in CD45 deficiency (Desai et al., 1994).

The role of CD45 in lymphocyte antigen receptor signaling centers on regulating the activity of antigen receptor-associated Src family kinases: p56Lck and p59Fyn in T cells, and Lyn in B cells (Thomas and Brown, 1999). A major function of CD45 is to maintain these kinases in a quiescent state yet poised for activation upon engagement of antigen receptors. The activity of Src kinases is regulated by the phosphorylation status of two tyrosine residues: one at the carboxyl terminus, which serves a negative regulatory function, and the other within the kinase domain, which serves a positive regulatory function. In CD45-deficient cells, the C-terminal regulatory tyrosine residue is consistently found hyperphosphorylated, indicating that CD45 functions to maintain this site in a dephosphorylated form. Phosphorylation of the C-terminal regulatory tyrosine residue results in its intramolecular association with the SH2 domain of the same Src kinase, which locks the kinase in a closed conformation that renders it inactive. The deleterious impact of hyperphosphorylation Src kinase C-terminal inhibitory tyrosine in CD45 deficiency is highlighted by the observation that a constitutively active Lck mutant, in which the C-terminal tyrosine residue is changed into a phenylalanine, rescues the profound block in T cell development in CD45-deficient mice (Pingel et al., 1999; Seavitt et al., 1999; see below).

The positive regulatory tyrosine residue in the catalytic domain of Src kinases also serves as a substrate for CD45. This role is particularly important in regulating the function of Lck activity in thymocyte development and in down-regulating the activity of the Src kinases Hck and Lyn during integrin-mediated adhesion in macrophages.

Given that the net effect of CD45 is to maintain Src kinases in a dephosphorylated, yet primed state, how are the positive effects of CD45 on antigen receptor signaling mediated? One answer to this question was provided by the finding that CD45 is excluded from the immunological synapse, the supramolecular structure formed at the interface of T cells with antigen-presenting cells that includes the T cell receptor (TCR), CD4 and CD8 coreceptors, antigen-presenting major histocompatibility complex (MHC) molecules, and a variety of signaling molecules (Johnson et al., 2000). Lipid rafts containing the TCR, Lck, and the adapter protein LAT but excluding CD45 cluster at the immunological synapse, allowing effective src kinase activation.

A second mechanism by which CD45 activity is regulated involves receptor dimerization. On the basis of crystal structure of a related phosphatase, RPTP $\alpha$ , it was predicted that the juxtamembrane and proximal catalytic domain of CD45 form dimers in which the catalytic site of one catalytic domain is blocked by a wedge formed by the juxta-membrane region of its partner. Consistent with this model, mice carrying a mutation in which a highly conserved glutamic amino acid residue predicted to lie at the tip of the CD45 wedge domain is changed into arginine develop a lymphoproliferative disease and severe autoimmune nephritis. This phenotype is associated with hyperactive src kinases in lymphocytes (Majeti et al., 2000). While molecular

interactions governing CD45 dimer formation and dissolution remain unclear, it has been hypothesized that different CD45 isoforms may vary in their capacity to form dimers (Hermiston et al., 2002). According to this hypothesis, the extensive *O*-linked glycosylation and sialylation found on the alternatively spliced exons 4–6 render the large CD45RA isoforms expressed on naive T cells more resistant to dimerization because of electrostatic repulsion. In contrast, the absence of this electrostatic barrier in the CD45RO isoform found on memory T cells promotes dimerization. This may explain the more effective signaling in memory T cells.

While CD45 promotes signaling via antigen receptors, it can dampen signaling by other receptor complexes. For example, CD45 negatively regulates integrin-mediated adhesion, an effect related to its ability to dephosphorylate Src kinases at integrin focal adhesion sites (Roach et al., 1997). Consistent with this function is the observation that CD45-deficient T cells and macrophages are abnormally adherent, a phenotype that is reversed by reconstitution of CD45 expression. As in the case of lymphocyte antigen receptor, a topological explanation underlies the regulatory function of CD45 in integrin-mediated adhesion (Thomas and Brown, 1999). Unlike the case of signaling via antigen receptors, where CD45 is excluded from the immunological synapse, CD45 colocalizes with integrin-centered focal adhesion sites. This serves to maintain Src kinases clustered at these sites under negative dephosphorylation pressure.

Another system in which CD45 exerts negative regulatory pressure is signaling via cytokine receptors, where CD45 acts to dephosphorylate receptor-associated Jak kinases (Irie-Sasaki et al., 2001; Penninger et al., 2001). Consistent with this finding, CD45-deficient mice exhibit increased cytokine-dependent myelopoiesis and erythropoiesis and are resistant to otherwise fatal cardiomyopathy associated with Coxsackie virus B3 infection. Given that other molecules such as SOCS (suppressor of cytokine signaling) and nonreceptor phosphotyrosine phosphatases SHP1 and SHP2 also contribute to negative regulation of Jak kinase activation, the precise role of CD45 in negative regulation of Jak kinase activation remains to be fully mapped.

## Clinical and Pathological Manifestations

The clinical and pathological features are summarized in Table 13.1. Of the two reported cases of CD45 deficiency, one was a boy born to unrelated Finnish parents (Kung et al., 2000), and the other was a girl born to consanguineous Kurdish parents (Cale et al., 1997; Tchilian et al., 2001). Both children exhibited clinical features typical of SCID. The Finnish child suffered from recurrent infections starting at 6 weeks of age, including candidal skin and oral infections, recurrent otitis media, bronchitis, conjunctivitis, impetigo, gluteal abscess, and chronic rotavirus diarrhea. At around that time, he was noted to have severe anemia requiring transfusions in the face of marrow erythropoiesis. He was also noted to have leukopenia and lymphopenia. Reticulocytes appeared in the blood at the age of 3 months and his hemoglobin levels normalized thereafter, but his lymphopenia persisted. He was vaccinated with *Bacillus Calmette-Guerin* (BCG) at birth. Generalized BCG infection was noted at age 4 months and isoniazide treatment was instituted. Despite supportive therapy, he suffered from severe malnutrition and failure to thrive. He had unrelenting chronic diarrhea associated with persistent *Clostridium difficile* and rotavirus infection. Respiratory syncytial virus antigen test was repeatedly positive in his

**Table 13.1.** Clinical Findings in CD45-Deficient Patients

Factor	Finnish Patient	Kurdish Patient
Age at presentation	6 weeks	2 months
Failure to thrive	Yes	Yes
Recurrent bacterial or viral infections	Yes	NR
Chronic rotaviral diarrhea	Yes	NR
Opportunistic infections	BCG, oral candidiasis	CMV
Bone marrow transplant	No	Yes
Terminal event	B cell lymphoma	Reactivated CMV infection

Data on the Finnish and Kurdish patients are from the reports of Kung et al. (2000), and Cale et al. (1997) and Tchilian et al. (2001), respectively. BCG, *Bacillus Calmette-Guerin*; CMV, cytomegalovirus; NR, not reported.

nasopharyngeal aspirate. He was evaluated for bone marrow transplantation at the age 1 year and 5 months. His weight at that time was only 5.5 kg, and the height was 66.5 cm (−3 SD). He died soon thereafter from an aggressive B cell lymphoma.

The Kurdish child presented at the age of 2 months with disseminated, postnatally acquired cytomegalovirus infection associated with fever, rash, pneumonitis, lymphadenopathy, hepatosplenomegaly, and pancytopenia. On the basis of her clinical phenotype and laboratory investigation, she was determined to have SCID and underwent bone marrow transplantation at the age of 8 months. Despite T cell engraftment, her cytomegalovirus infection was reactivated and she died 55 days after the bone marrow transplant.

### Laboratory Findings

The laboratory findings of children with CD45 deficiency were in good concordance with the results obtained in the genetically engineered animal models of this disease (Table 13.2). Both children exhibited absolute lymphopenia resulting from depletion of the T cell population (8.9% in the Finnish infant, 15% in the Kurdish infant). The CD4 population was particularly affected (0.9% and 4%, respectively). The B cell population was normal in number. The natural killer (NK) cell population was decreased in the Finnish infant (3%) but undetermined in the Kurdish infant. CD45 expression as determined by flow cytometry was

**Table 13.2.** Lymphocyte Subpopulations in Human and Murine CD45 Deficiency

		Cell Count (% of Peripheral Lymphocytes)	
	CD45 knockout mice	Finnish Patient	Kurdish Patient
CD3	Depleted	Depleted (8.9%)	Depleted (14.9%)
CD3/4	Depleted	Depleted (0.9%)	Depleted (4%)
CD3/8	Depleted	Depleted (4.9%)	Decreased (20%)*
TCRαβ	Depleted	Depleted (2.2%)	NR
TCRγδ	Preserved	Normal (6.7%)	NR
NK	Preserved	Decreased (3%)	NR
B cells	Preserved	Normal (84.5%)	Normal (68.9%)

Murine data are derived from studies in mice deficient in exons 6, 9, and 12 (Byth et al., 1996; Kishihara et al., 1993; Mee et al., 1999). Data on the Finnish and Kurdish patients are from the reports of Kung et al. (2000), and Cale et al. (1997) and Tchilian et al. (2001), respectively. NR, not reported. \*Percentage refers to total CD8<sup>+</sup> cells in the periphery.

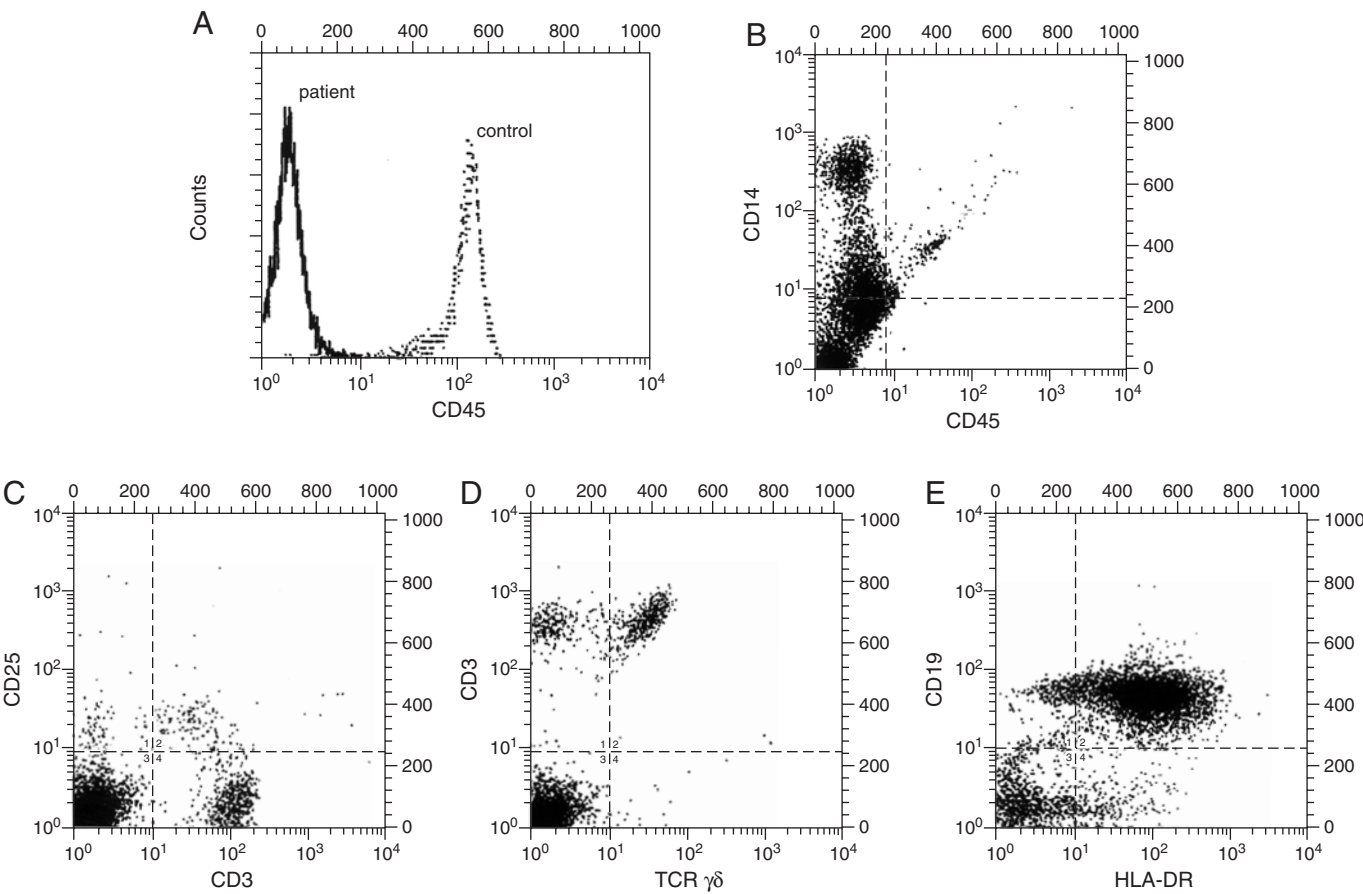

either totally absent (Finnish infant) or minimally present (Kurdish infant) (Fig. 13.1). Parents of both children exhibited normal levels of CD45 expression. Proliferative responses to mitogenic lectins were totally absent. Hypogammaglobulinemia was noted in both infants.

### Molecular Basis

Both children suffered from autosomal recessive defects in the CD45 gene (Fig. 13.2). In the Finnish infant, the allele inherited from the mother carried a large deletion localized to the 3' region of the gene, while the other allele had a G-to-A transition at position +1 of the donor splice site of intron 13 (Kung et al., 2000). Sequencing of reverse transcribed and polymerase chain reaction (RT-PCR)-amplified CD45 transcripts derived from a patient with Epstein-Barr virus-transformed B lymphoblastic cell line demonstrated that the splice junction mutation interfered with splicing at the donor splice site of intron 13. Whereas aberrantly spliced CD45 transcripts resulting from the intron 13 donor splice junction mutation were detected by RT-PCR, no CD45 mRNA transcripts were detected by Northern blot analysis, indicating that truncated and/or aberrant CD45 mRNA are rapidly degraded. In the Kurdish infant with SCID, a 6 bp deletion was identified at nucleotide 1168 in exon 11 of the CD45 gene. This results in the deletion of two amino acids (glutamic acid 339 and tyrosine 340) in the first fibronectin type III module of the CD45 extracellular domain (Tchilian et al., 2001). Both parents were heterozygous for the deletion. Expression analysis studies in which a mutant CD45 cDNA carrying the 6 bp deletion was transfected into Chinese Hamster Ovary (CHO) and mouse EL-4 thymoma cells revealed that the mutant protein failed to express at the cell surface, although it was detected at reduced levels intracellularly. This finding indicated that the deleted amino acids may contribute to the proper folding, stability, and/or correct localization of the mutant protein.

### Strategies for Diagnosis

Both cases of CD45 deficiency presented with a characteristic picture of SCID with profound but not total T cell depletion, absent proliferative responses to T cell mitogens, and normal B cell numbers. In both cases, definitive diagnosis of CD45 deficiency was made by flow cytometry, which revealed little or no expression of CD45 on the surface of peripheral blood mononuclear cells. Because CD45 staining is routinely included as part of flow cytometric screening of patients suspected of immunodeficiency, identification of patients with absent CD45 expression would be easy to make. However, two caveats should be noted. The first involves cases suffering from loss-of-function CD45 mutations associated with only partial loss of CD45 expression. These may be easily missed unless careful attention is paid to the mean fluorescence intensity of CD45 staining. The second involves even more challenging cases, those associated with loss-of-function mutations in CD45 cytoplasmic tail, including the active phosphatase domain. These cases may present with normal CD45 expression levels despite absent or near-absent phosphatase function. In this situation, the clinical picture may overlap with atypical forms of X-linked SCID (in boys) or Jak3 kinase deficiency. It will be useful to place CD45 deficiency in the differential diagnosis of such cases. Such cryptic CD45 abnormalities can be excluded by evidence of normal signaling events triggered via TCR/CD3, including calcium mobilization and tyrosine phosphorylation.

**Figure 13.1.** Flow cytometry analysis of peripheral lymphocytes of CD45-deficient Finnish infant. (A) Single-color analysis of CD45 expression in the index patient and a control subject. (B–E) Two-color analysis of patient lymphocytes: (B) CD14 and CD45, (C) CD25 and CD3, (D) CD3 and TCRγδ, (E) CD19 and HLA-DR.

**Treatment and Prognosis**

Definitive therapy for CD45 deficiency is similar to that for other SCID disease—namely, bone marrow transplantation. The fatal outcome in the two patients reported to date, including one who died with cytomegalovirus infection after bone marrow transplant, point to the lethal nature of this immunodeficiency and the urgent need for timely immune reconstitution. As in other cases

of SCID, the ideal transplant would be with bone marrow from a human leukocyte antigen (HLA)-matched sibling, followed by bone marrow from matched unrelated donors or HLA-mismatched family members. Problems relating to T cell deficiency dominated the clinical presentation of the two patients, and it remains possible that partial immune reconstitution may be achieved upon infusion of donor marrow in the absence of a conditioning regimen. However, because CD45 is expressed on

**Figure 13.2.** Genomic organization of CD45 gene organization. The mutations found in the respectively affected infant are indicated. The Finnish infant suffered from a large deletion in the 3' region of the gene, and a

G → A substitution in the splice donor junction of intervening sequence (IVS) 13. The Kurdish infant suffered from a homozygous 6 bp deletion in exon 11, corresponding to nucleotides 1168–1173 of CD45 cDNA.

nucleated cells of all hematopoietic lineages, it can be predicted that effective immune reconstitution will require a conditioning regimen to enable replacement of all recipient lineages with those of donor origin.

### Animal Models

Studies on three different CD45 knockout mice, targeting exons 6, 9, and 12, respectively, have revealed a critical function for CD45 in thymocyte development (Byth et al., 1996; Kishihara et al., 1993; Mee et al., 1999). The most pronounced defect in the development in CD45-deficient thymocytes involves positive selection at the CD4<sup>+</sup>CD8<sup>+</sup> stage. This results in the exit into the periphery of only 5%–10% of the expected number of mature T cells. Negative selection is also impaired, though less severely. Both defects reflect reduced, though not totally absent, T cell receptor signaling in CD45-deficient thymocytes, leading to a raised selection threshold. As noted above, a constitutive active p56Lck mutant rescues thymocyte development in CD45-deficient animals, consistent with impaired activation of Lck as the principal underlying mechanism involved in ineffective selection of CD45-deficient thymocytes (Pingel et al., 1999; Seavitt et al., 1999). In the periphery, T cell activation via the TCR is completely abrogated. Both T cell proliferation and cytokine secretion in response to TCR ligation are abolished.

B cell development is spared in CD45-deficient mice. However, the B cell receptor (BCR) signaling threshold is increased, leading to impaired proliferation of B cells in response to cross-linking of surface IgM (Benatar et al., 1996). Heightened signaling threshold also leads to defects in positive and negative selection of maturing B cells (Cyster et al., 1996). The transition for IgM<sup>hi</sup> IgD<sup>lo</sup> B cells to IgD<sup>hi</sup> cells during the final maturation stage, which reflects positive selection by constitutive BCR signaling, is impaired. Negative selection at this stage is also impaired, also a reflection of attenuated BCR signaling. T cell-independent responses continue to proceed, but T cell-dependent responses are compromised.

### Conclusions and Future Directions

CD45 deficiency is the first protein-tyrosine phosphatase deficiency identified in humans and may be the prototype of a novel class of human immunodeficiencies due to defects in protein phosphatases. The SCID phenotype associated with CD45 deficiency reflects the critical role played by this phosphatase in promoting antigen receptor signaling and in regulating the function of other signaling complexes including cytokine receptors and integrins. CD45 deficiency expands the spectrum of immunodeficiency diseases associated with phosphotyrosine signaling pathways, including ZAP-70 and IL-7 receptor/common gamma chain/Jak3 kinase deficiency syndromes in T cells and Btk deficiency in B cells. It is plausible that CD45 deficiency represents the extreme end of a spectrum of CD45-related diseases associated with immunodeficiency, autoimmunity, and/or inflammation. Such disorders may result from selective defects in the expression of individual CD45 isoforms or abnormalities in CD45 function related to one or more receptor complexes. In mice, enhanced expression of particular CD45 isoforms in T cell subsets has been associated with a number of autoimmune diseases (Penninger et al., 2001). In humans, a C → G polymorphism at nucleotide 77 in exon 4/A of CD45 that results in defective alternative splicing of exon 4/A has been associated with multiple sclerosis, although this association was not reproduced by other

studies (Jacobsen et al., 2000; Barcellos et al., 2001; Vorechovsky et al., 2001). Future studies will further clarify mechanisms by which CD45 deficiency leads to SCID and the role of CD45 in other immunological diseases.

### Acknowledgments

We dedicate this publication to the memory of Dr. Matthew L. Thomas (1953–1999). We would like to thank our collaborators at Washington University School of Medicine, St. Louis, MO, USA; University of Helsinki, Finland; and University of Oulu, Finland. This work was supported by grants from the National Institutes of Health (HD35694) to T.A.C. and from Sigrid Juselius Foundation to M.H.

# Severe Combined Immunodeficiency Due to Defects in T Cell Receptor–Associated Protein Tyrosine Kinases

MELISSA E. ELDER

ZAP-70 is a  $\zeta$  chain–associated protein of 70,000 kDa, (MIM+176947). Deficiency of ZAP-70 leads to a rare autosomal recessive form of severe combined immunodeficiency (SCID) characterized by the selective absence of CD8<sup>+</sup> T cells and by abundant CD4<sup>+</sup> T cells in the peripheral blood that are unresponsive to T cell receptor (TCR)–mediated stimuli in vitro. Peripheral T lymphocytes from most affected patients demonstrate defective signaling following TCR engagement by antigen because of inherited mutations within the kinase domain of the cytoplasmic protein tyrosine kinase (PTK) ZAP-70. ZAP-70 deficiency provided the first evidence that PTKs, and ZAP-70 in particular, are required for normal human T cell development and function. More recently, deficiency of another critical PTK, Lck, has been associated with a SCID phenotype in isolated patients as well.

## T Cell Signal Transduction

The processes involved in CD4 vs. CD8 selection during T cell ontogeny are not fully understood, but are known to require intact signal transduction through the TCR of the differentiating thymocyte (Pfeffer and Mak, 1994; Robey and Fowlkes, 1994). The signal transduction events mediated by the TCR on thymocytes are thought to be similar to those responsible for the activation of mature T cells. Propagation of antigen-binding signals from the TCR to the nucleus is dependent on the activation of the PTKs Lck and ZAP-70 (reviewed in Chan et al., 1994a; Weiss and Littman, 1994; Cantrell, 1996; Wange and Samelson, 1996; Kane et al., 2000). PTK activation is a rapid and critical event that results in phosphorylation of numerous downstream molecules, including phospholipase C $\gamma$ 1 (PLC $\gamma$ 1), linker for activation of T cells (LAT), Src homology 2 (SH2) domain–containing 76 kDa leukocyte protein (SLP-76), and the Vav guanine nucleotide exchange

factor (reviewed in Wange and Samelson, 1996; Qian and Weiss, 1997; Rudd, 1999; van Leeuwen and Samelson, 1999; van Oers, 1999; Kane et al., 2000). These tyrosine phosphorylation events are required for mobilization of intracellular free calcium ( $[Ca^{2+}]_i$ ) and activation of the Ras/mitogen-activated protein kinase (MAPK) and phosphatidylinositol-3 (PI3) kinase pathways. These downstream reactions culminate in activation of T cells and initiation of T cell–specific responses, described in more detail in Chapter 6.

## T Cell Receptor–Associated Protein Tyrosine Kinases

Stimulation of either the TCR or the B cell receptor (BCR) results in the activation of certain nonreceptor cytoplasmic PTKs whose functions are critical for lymphocyte responses to antigens (see Chapter 6). The importance of these PTKs to T cell development and function has been established by findings of immunodeficiency in both humans and PTK-deficient mice. Of the PTKs that have been described in T cells, the function of Lck is best understood. Lck is a 56 kDa Src family PTK that is expressed at high levels in peripheral T cells and in thymocytes at all stages of maturation (Perlmutter et al., 1988). Numerous in vivo and in vitro studies have confirmed the importance of Lck to normal T cell signal transduction. Recruitment of ZAP-70 to the TCR is dependent on the phosphorylation of consensus immunoreceptor tyrosine-based activation motifs (ITAMs) in the  $\epsilon$  and  $\zeta$  chains of CD3 by Lck (Gauen et al., 1994; Iwashima et al., 1994; Weiss and Littman, 1994; van Oers and Weiss, 1995; Weil et al., 1995). The ITAMs are found either singly or multiply in the CD3 $\epsilon$  and  $\zeta$  chains and mediate TCR interactions with PTKs involved in signal transduction and with ZAP-70 in particular (Irving et al., 1993; Gauen et al., 1994; Weiss and Littman,

1994; van Oers and Weiss, 1995). Lck is also primarily responsible for mediating ZAP-70 phosphorylation, thereby triggering critical downstream signaling events required for T cell activation (Watts et al., 1994; Chan et al., 1995).

Studies in genetically altered mice demonstrate that Lck is also required for differentiation events in the transition of double-negative (pre-TCR<sup>+</sup>CD4<sup>-</sup>CD8<sup>-</sup>) thymocytes to double-positive (TCR<sup>+</sup>CD4<sup>+</sup>CD8<sup>+</sup>) thymocytes (Molina et al., 1992; Levin et al., 1993). Disruption of Lck results in SCID in mice characterized by markedly decreased numbers of double-positive thymocytes and few single-positive (CD4<sup>+</sup> or CD8<sup>+</sup>) thymocytes or peripheral T cells (Molina et al., 1992). This block in T cell development is related to a requirement for Lck in signaling through the pre-TCR CD3 complex (Mombaerts et al., 1994; Anderson and Perlmutter, 1995; Levelt et al., 1995). Lck is activated upon successful TCR  $\beta$  chain rearrangement; once activated, Lck functions to initiate TCR  $\alpha$  chain rearrangement and prevent further TCR  $\beta$  chain rearrangement events.

Fyn, a 59 kDa Src family PTK expressed predominantly in neuronal cells and T lymphocytes, also participates in TCR signaling (Cooke et al., 1991). However, mice deficient in Fyn have relatively normal T cell development, although mature single-positive thymocytes exhibit some defects in signal transduction (Appleby et al., 1992; Stein et al., 1992). Even though Fyn does not appear to be essential for peripheral T cell function and its absence is not associated with a SCID phenotype in animals, mice lacking both Lck and Fyn have no thymocytes more mature than those at the double-negative stage. This finding suggests that Fyn can partially compensate for loss of Lck, and Fyn alone is sufficient to allow some T cell development (van Oers et al., 1996).

Another PTK involved in TCR signaling is Syk, a 72 kDa PTK with structural homology to ZAP-70. Syk is expressed predominantly in B cells, myeloid cells, and thymocytes, and is expressed only at very low levels in peripheral T cells (Chan et al., 1994c). Syk is critical to BCR signaling and may function in B cells in a role similar to that of ZAP-70 in T cells (Reth, 1995; DeFranco, 1997). Syk-deficient mice die shortly after birth from severe bleeding and demonstrate arrested B cell development at the pro-B cell stage (Cheng et al., 1995; Turner et al., 1995). Although ZAP-70 is not physiologically expressed in B lymphocytes, it can reconstitute BCR function in Syk-deficient mice (Kong et al., 1995). Similarly, there appears to be a role for Syk in TCR signaling. Syk has been shown to bind phosphorylated  $\zeta$  and to be activated in response to TCR stimulation in thymocytes (Chan et al., 1994c; Gelfand et al., 1995; van Oers and Weiss, 1995), but absence of Syk does not affect T cell development in mice other than the maturation of V $\gamma$ 3<sup>+</sup> thymocytes and  $\gamma\delta$  T cells in epithelial tissues (Mallick-Wood et al., 1996). Studies in mice have demonstrated that Syk expression is highest in thymocytes in which the pre-TCR is first expressed and is down-regulated when pre-TCR signals induce transition from the double-negative to the double-positive thymocyte stage (Chu et al., 1999). In contrast to ZAP-70-deficient mice, which are blocked at the double-positive stage of thymocyte development, mice made doubly deficient in ZAP-70 and Syk demonstrate complete arrest of thymic development at this pre-TCR checkpoint (Cheng et al., 1997), a finding suggesting that Syk does play a role in pre-TCR signaling and early  $\alpha\beta$  T cell differentiation.

ZAP-70 is a 70 kDa Syk family PTK expressed exclusively in T cells and in natural killer (NK) cells (Chan et al., 1992). ZAP-70 is expressed in all thymocyte subpopulations and is constitutively

associated with phosphorylated CD3 $\zeta$  in thymocytes and T cells in vivo (Chan et al., 1994c; van Oers et al., 1994, 1996). This association is in contrast to findings in vitro, in which ZAP-70 is not constitutively localized with the TCR, but rapidly binds phosphorylated  $\zeta$  and CD3 $\epsilon$  following TCR stimulation (Chan et al., 1991). Recruitment of ZAP-70 to the TCR is essential for its subsequent activation and for induction of downstream signaling events critical for induction of T cell-specific responses (Wange et al., 1995b; Weil et al., 1995; Weiss and Littman, 1994). As described above, Lck mediates the phosphorylation of both tyrosine residues within each ITAM of CD3 $\zeta$  and CD3 $\epsilon$  that occurs prior to ZAP-70 recruitment to the TCR (see Fig. 6.2 in Chapter 6) (Straus and Weiss, 1992; Gauen et al., 1994; Iwashima et al., 1994; van Oers and Weiss, 1995; Weil et al., 1995). High-affinity binding of ZAP-70 to  $\zeta$  and CD3 $\epsilon$  requires the cooperative binding of both ZAP-70 SH2 domains (Hatada et al., 1993; Wange et al., 1993; Gauen et al., 1994; Iwashima et al., 1994; Isakov et al., 1995). However, association of ZAP-70 with the phosphorylated ITAM-containing subunits of the TCR alone is insufficient to induce ZAP-70 kinase activity (van Oers et al., 1994; Madrenas et al., 1995). ZAP-70 itself must be phosphorylated at specific tyrosine residues to increase its catalytic function (Watts et al., 1994; Chan et al., 1995; Neumeister et al., 1995; Wange et al., 1995a, 1995b). Tyrosine phosphorylation of ZAP-70 is mediated by Src family PTKs and by autophosphorylation activity (Watts et al., 1994; Chan et al., 1995; Neumeister et al., 1995; Wange et al., 1995a). Much of the increase in ZAP-70 catalytic function following TCR stimulation is associated with specific phosphorylation of tyrosine residue 493 by Lck (Watts et al., 1994; Chan et al., 1995). However, ZAP-70 enzymatic activity is also negatively regulated by phosphorylation of the adjacent tyrosine residue 492 (Chan et al., 1995; Wange et al., 1995a; Zhao and Weiss, 1996). Additional tyrosines within interdomain B bridging the SH2 and kinase domains of ZAP-70 are also phosphorylated and function as positive regulators of TCR signaling; these include tyrosine 315 (the putative binding site for the Vav guanine nucleotide exchange factor) and tyrosine 319, which may interact with PLC $\gamma$ 1 and Lck (Zhao and Weiss, 1999; Wu et al., 1997; Di Bartolo et al., 1999; Williams et al., 1999; Gong et al., 2001). In contrast, phosphorylation of tyrosine 292 within interdomain B of the ZAP-70 protein inhibits TCR signaling by serving as a binding site for the ubiquitin ligase Cbl, which targets ZAP-70 for ubiquitination and degradation (Lupher et al., 1996; Rao et al., 2000).

Following ZAP-70 phosphorylation and activation, multiple downstream signaling events occur that result in T cell activation. Phosphorylated ZAP-70 triggers recruitment of other molecules to the signaling complex, resulting in transduction of the TCR-mediated signal. Specific *in vivo* substrates for ZAP-70 include LAT and SLP-76 (Wardenburg et al., 1996; Raab et al., 1997; Williams et al., 1998, 1999; Zhang et al., 1998). Recruitment to the signaling complex is most likely mediated by the SH2 domains contained within each protein. Additional SH2 domain-containing signaling molecules recruited to the TCR via interactions with ZAP-70 or ZAP-70 substrates include PLC $\gamma$ 1, Cbl, Vav, Grb2, SOS, Gads, Itk, Ras-GTP, and the p85 subunit of PI3 kinase (Duplay et al., 1994; Katrav et al., 1994; Neumeister et al., 1995; Straus et al., 1996; Wardenburg et al., 1996; Wu et al., 1997; Finco et al., 1998; Yablonski et al., 1998; van Oers, 1999; Yablonski and Weiss, 2001). Formation of these protein complexes at the plasma membrane results in signal amplification and culminates in the transcription of genes involved in T cell activation, such as interleukin (IL)-2.

**Table 14.1.** Clinical Findings in Eight Patients with ZAP-70 Deficiency

Findings	Number of Affected Children
<i>Infections</i>	
Bacterial (otitis media, pneumonia)	4
<i>P. jiroveci</i> pneumonia	3
Cytomegalovirus retinitis or other infection	2
Parainfluenza pneumonitis	1
Chronic diarrhea or rotaviral enteritis	6
Severe or disseminated varicella	1
Oral or cutaneous candidiasis	3
<i>Failure to Thrive</i>	4
<i>Physical Findings</i>	
Presence of lymph tissue	5
Hepatosplenomegaly	1
Chronic eczematoid rash	2
Thymic shadow on chest X-ray	8

### Clinical and Pathologic Manifestations of ZAP-70 Deficiency

Eight children from five families were originally described with SCID due to ZAP-70 deficiency (Arpaia et al., 1994; Chan et al., 1994b; Elder et al., 1994; Gelfand et al., 1995). These patients included six children from three genetically isolated Mennonite kindreds and two children from separate, unrelated (Hispanic and Caucasian) families, who were both products of consanguineous relationships. Similar to other forms of SCID, each affected child presented within the first 2 years of life with a history of recurrent infections and failure to thrive (Table 14.1) (Roifman et al., 1989; Monafó et al., 1992; Elder et al., 1995; Gelfand et al., 1995). Seven of these children are well following allogeneic bone marrow transplantation (BMT); one child of Mennonite background died 2 months after BMT (Monafó et al., 1992). Additional patients with ZAP-70 deficiency have since been described and have had similar clinical presentations (Matsuda et al., 1999; Noraz et al., 2000; Elder et al., 2001; Toyabe et al., 2001).

Most ZAP-70-deficient patients have detectable lymphoid tissue along with their normal or elevated peripheral blood lymphocyte counts. Thymic histology in ZAP-70 deficiency is remarkable for normal structural organization and normal percentages of double-positive and single-positive CD4<sup>+</sup> thymocytes. In contrast, there are very few, if any, single-positive CD8<sup>+</sup> cells (Gelfand et al., 1995; Roifman et al., 1989).

### Laboratory Findings in ZAP-70 Deficiency

All patients have normal to elevated numbers of circulating lymphocytes (Table 14.2). Phenotypic analysis of their peripheral blood lymphocytes by flow cytometry reveals normal or increased percentages of CD3<sup>+</sup> (38%–80%) and CD4<sup>+</sup> T cells (37%–75%) because of the lack of CD8<sup>+</sup> T cells (0%–3%) (Roifman et al., 1989; Monafó et al., 1992; Elder et al., 1995, 2001; Gelfand et al., 1995; Matsuda et al., 1999; Noraz et al., 2000). Expression of T cell surface proteins other than CD8 is normal. In those patients in whom human leukocyte antigen (HLA) typing and Southern blot analysis have been performed, the peripheral blood T cells were demonstrated to be polyclonal and not maternal in origin (Arpaia et al., 1994; Elder et al., 1995). Absent

proliferative responses to alloantigen and to a variety of mitogens in vitro, including phytohemagglutinin (PHA), pokeweed mitogen (PWM), concanavalin A, *Candida albicans*, and anti-CD3 monoclonal antibody (MAb), are noted on testing of patient lymphocytes, confirming the diagnosis of SCID. Lack of response to *Candida* skin testing and failure to reject an allogeneic skin graft were also demonstrated in one ZAP-70-deficient patient (Roifman et al., 1989). NK cell numbers and activity are relatively normal (Elder et al., 1994). All patients have normal numbers of B cells, but some differences in the level of B cell function have been noted between patients. One affected child from a Mennonite family was able to make specific antibodies to tetanus and had normal levels of serum immunoglobulins (Roifman et al., 1989), and another child had IgE reactive with food allergens, but did not demonstrate atopy or intestinal symptoms related to food ingestion (Toyabe et al., 2001). In contrast, most patients have low-serum IgG and lack specific antibody production, necessitating monthly intravenous immunoglobulin administration (Elder et al., 1995, 2001; Gelfand et al., 1995).

In the original eight patients with ZAP-70 deficiency, the markedly abnormal distribution of peripheral T cell subsets and the absence of T cell proliferation to any stimulus transduced by the TCR led to further studies that documented defects within the proximal TCR signaling pathway, later proven to be due to absence of ZAP-70 function. The patients' T lymphocytes exhibited diminished or absent [Ca<sup>2+</sup>]<sub>i</sub> mobilization after stimulation with anti-CD3 MAb (Arpaia et al., 1994; Chan et al., 1994b; Gelfand et al., 1995; Elder et al., 2001). Furthermore, induction of most cytoplasmic tyrosine phosphoproteins was defective after co-cross-linking of the TCR on patient T cells with either anti-CD3 or a combination of anti-CD4 and anti-CD3 MAbs (Arpaia et al., 1994; Elder et al., 1995, 2001). In contrast to their absence of cell proliferation to TCR-mediated stimuli, ZAP-70-deficient lymphocytes proliferate normally to phorbol myristic acetate (PMA) plus ionomycin, agents that bypass proximal TCR signaling events by mimicking actions of the second messengers Ras and [Ca<sup>2+</sup>]<sub>i</sub>, respectively. In addition, IL-2 production is detected when lymphocytes are stimulated with PMA plus ionomycin, in contrast to the lack of detectable IL-2 production when T cells are incubated with anti-CD3 or PHA (Arpaia et al., 1994; Elder et al., 1995).

### Molecular Basis of ZAP-70 Deficiency

In most affected patients, ZAP-70 protein is not detected by immunoblot (Arpaia et al., 1994; Chan et al., 1994b; Elder et al., 1994; Gelfand et al., 1995; Matsuda et al., 1999; Noraz et al., 2000; Toyabe et al., 2001). In contrast, normal levels of other PTKs are present in patient T cells. Additional studies in one patient demonstrated that Lck function was normal: it could be coprecipitated with CD4, was inducibly phosphorylated in response to cross-linking of surface CD3 and CD4, and exhibited normal autophosphorylation activity in vitro (Elder et al., 1995). Fyn kinase activity was shown to be intact in vitro in two Mennonite kindreds as well (Arpaia et al., 1994). One child with SCID, born to a consanguineous union, had undetectable ZAP-70 mRNA levels, but his underlying mutation(s) have not yet been identified (Gelfand et al., 1995). In contrast, the remaining patients have normal levels of full-length ZAP-70 mRNA compared to controls.

At least eight separate mutations in the gene encoding ZAP-70 (gene symbol *ZAP70* or *SRK*, Syk-related tyrosine kinase) have been identified in affected children (Arpaia et al., 1994; Chan

**Table 14.2.** Laboratory Findings in Patients with ZAP-70 Deficiency

<i>Tests</i>	<i>Range of Patient Values</i>	<i>Normal Range</i>
<i>Lymphocyte Phenotype</i>		
Absolute lymphocyte count	4.0–20.0 × 10 <sup>9</sup> /l	3.5–8.0 × 10 <sup>9</sup> /l
CD3 <sup>+</sup> cells	38%–80%	53%–85%
CD4 <sup>+</sup> cells	37%–75%	25%–68%
CD8 <sup>+</sup> cells	0%–10%	12%–40%
CD3 <sup>+</sup> CD8 <sup>+</sup> cells	0%–3%	12%–37%
TCRα/β <sup>+</sup> cells	53%–79%	50%–85%
TCRγ/δ <sup>+</sup> cells	0.2%–?%	1%–12%
CD3 <sup>+</sup> CD69 <sup>+</sup> cells	0%–3%	25%–55%
CD16 <sup>+</sup> CD56 <sup>+</sup> cells	5%–13%	5%–29%
CD8 <sup>+</sup> /CD56 <sup>+</sup> cells	1%–10%	8%–27%
CD19 <sup>+</sup> cells	13%–41%	6%–24%
<i>Serum Immunoglobulin Levels</i>		
IgG (pre-IVIG)	63–1870 mg/dl	340–1210 mg/dl
IgA	39–160 mg/dl	10–50 mg/dl
IgM	67–170 mg/dl	40–200 mg/dl
Isohemagglutinins	0–<1:1 titer	0–1:128 titer
Specific antibody production	1 pt (levels not reported)	
<i>Lymphocyte Proliferative Function</i>		
Mitogens (PHA, PWM)	0–1,077 cpm	35,000–230,000 cpm
Soluble antigen (tetanus, candida)	0–704 cpm	1300–89,000 cpm
Alloantigen (MLC)	124–4620 cpm	14,000–150,000 cpm
Anti-CD3	185–900 cpm	21,000–93,300 cpm
IL-2	1280–19,759 cpm	1390–5900 cpm
PMA	15,882–50,322 cpm	1645–110,000 cpm
PMA plus ionomycin	39,308–187,000 cpm	26,649–168,000 cpm
PMA plus IL-2	100,000–134,000 cpm	64,000–120,000 cpm
SAC (B cell mitogen)	5000–21,679 cpm	5000–17,000 cpm
<i>IL-2 Production</i>		
PHA, anti-CD3	none	
PMA plus ionomycin	normal	
NK cell cytotoxicity	20%–30%	20%–50%

<b>Mutant allele</b>	<b>DNA Mutation</b>	<b>Consequence to Protein</b>
1	13 bp deletion (nts 1719–1731)	Deletion/frameshift/premature termination after 35 codons (K504_P508delsX35)

**Figure 14-1.** Schematic depiction of wild-type ZAP-70 protein and the identified mutant alleles. GenBank accession number is L05148 for the human AP-70 cDNA sequence.

et al., 1994b; Elder et al., 1994, 2001; Matsuda et al., 1999; Noraz et al., 2000; Toyabe et al., 2001). Interestingly, most mutations occur within the kinase domain of the ZAP-70 protein and significantly affect both protein stability and catalytic activity (Fig. 14.1).

### ZAP-70 Mutation Analysis

Pedigree analyses have confirmed that ZAP-70 deficiency is an autosomal recessive genetic syndrome and that affected children have failed to inherit a normal allele of the *ZAP70* gene, located on human chromosome 2q12 (Chan et al., 1994b). The molecular defects reported to date are listed in Figure 14.1. All six children from the three genetically related Mennonite families inherited at least one mutant *ZAP70* allele with a splicing error due to a G-to-A transition within an intron, generating a new splice acceptor site upstream of the normal splice site. Specifically, three children from two families were homozygous for a 9 bp insertion (CTTGAGCAG) into the coding sequence after nucleotide 1832. This mutation results in the addition of three amino acid residues, leucine, glutamic acid, and glutamine (LEQ), within the ZAP-70 catalytic domain following residue 541 (K541insLEQ) (Arpaia et al., 1994). Three children from the remaining Mennonite family inherited this mutant allele along with a second mutant allele and were thus compound heterozygotes for two *ZAP70* mutations (Chan et al., 1994b). The second mutation in these Mennonite cases is a C-to-A transition at position 1763, which results in a serine-to-arginine substitution at amino acid 518 (S518R) within a highly conserved region of all Syk family PTK catalytic domains.

In a fourth affected and unrelated family, a single patient with ZAP-70 deficiency was homozygous for a 13 bp deletion at nucleotides 1719 to 1731 (Elder et al., 1994). This deletion results in a translational frameshift after residue 503 and introduces a premature stop 35 codons downstream, yielding a mutant protein truncated by 82 amino acids (K504\_P508delfsX35). Interestingly, two siblings from an unrelated family were recently found to be homozygous for a C-to-T transition at position 1729 that results in an alanine-to-valine substitution at residue 507 (A507V), which is within the 13 bp deletion sequence (Noraz et al., 2000).

One Japanese patient with CD8 deficiency was a compound heterozygote for temperature sensitive mutations in *ZAP70*: a C-to-A transition at position 448 that results in a proline-to-glutamine substitution at residue 80 (P80Q), and an A-to-T transition at position 1923 that substitutes a leucine for methionine at amino acid 572 (M572L) within the ZAP-70 protein (Matsuda et al., 1999).

Most recently, two infants with SCID were demonstrated to have inherited a homozygous missense mutation within the highly conserved DLAARN motif in the ZAP-70 kinase domain (Elder et al., 2001; Toyabe et al., 2001). In one child, the mutation was a C-to-T transition at bp 1602, which results in an arginine-to-cysteine conversion at residue 465 (R465C). Unlike other described ZAP-70 mutations, this mutation only modestly affected protein stability, but it abrogated ZAP-70 catalytic function. Moreover, R465C is comparable to the mutation (R464C) that spontaneously arose in the inbred Strange (ST) mouse colony (Wiest et al., 1997). In contrast to ST mice, which lack any single-positive thymocytes and peripheral T cells, the R465C patient had typical findings of ZAP-70 deficiency and lacked only circulating CD8<sup>+</sup> T lymphocytes (Elder et al., 2001). This patient's case provides the first description of identical mutations in ZAP-70 having distinct T cell developmental consequences in

humans and mice. Subsequently, an unrelated patient was determined to be homozygous for a G-to-A transition at position 1603, resulting in an arginine-to-histidine (R465H) conversion at the same critical residue within the DLAARN motif (Toyabe et al., 2001). In contrast to the previous case and ST mice, this patient lacked ZAP-70 protein expression.

With the exception of the mutation R465C, all identified mutations significantly decrease the stability of the ZAP-70 protein in vitro and when transfected into cell lines in vitro (Chan et al., 1994b; Elder et al., 1994; Matsuda et al., 1999; Noraz et al., 2000). Furthermore, most mutations that change the sequence of the kinase domain of ZAP-70 affect its enzymatic activity. In vitro kinase assays have confirmed that mutant forms of ZAP-70 are catalytically inactive (Chan et al., 1994b; Elder et al., 1994, 2001; Noraz et al., 2000).

### Functional Aspects of ZAP-70 Deficiency

The phenotype of ZAP-70 deficiency in humans presents a notable paradox: although a single signaling pathway had previously been assumed to be required for both thymic selection and peripheral T cell activation, the abundant CD4<sup>+</sup> T cells in this disorder, which presumably were selected positively in the thymus, are refractory to TCR-mediated activation in the periphery. Thymic tissue from three ZAP-70-deficient patients revealed mostly double-positive thymocytes and normal numbers of single-positive CD4<sup>+</sup> cells, but very few if any CD8<sup>+</sup> thymocytes (Roifman et al., 1989; Gelfand et al., 1995).

These results suggest that ZAP-70 is critical for CD8 selection and peripheral CD4<sup>+</sup> and CD8<sup>+</sup> T cell signaling, but is dispensable for CD4 selection in the thymus. One possible explanation for the presence of normal numbers of CD4<sup>+</sup> T cells is that the related PTK, Syk, which is expressed at higher levels in the thymus than in the periphery, may be able to rescue CD4 selection in the absence of ZAP-70 (Chan et al., 1994c; Gelfand et al., 1995). A role for Syk in thymocyte signaling is suggested by findings that double-positive thymocytes from one patient were able to mobilize  $[Ca^{2+}]_i$  upon CD3 cross-linking (Gelfand et al., 1995). Comparable induction of tyrosine phosphoproteins was also seen in a human T-cell leukemia virus (HTLV)-1-transformed CD4<sup>+</sup> thymocyte line from the same patient. This thymocyte line demonstrated higher basal levels of Syk expression and increased Syk phosphorylation after TCR stimulation than in control HTLV-1-transformed thymocytes. Increased Syk activity in ZAP-70-deficient thymocytes may thus compensate at least in part for the lack of ZAP-70 function. The differential ability of Syk to replace ZAP-70 in CD4 vs. CD8 selection events may be related to the requirement for Lck in the recruitment of Syk family PTKs to the TCR and in their subsequent activation. Since more Lck is associated with the CD4 than with the CD8 coreceptor in double-positive thymocytes, CD4 cells may be preferentially selected if Syk is unable to fully substitute for loss of ZAP-70 function. Similarly, Syk activity, which is down-regulated in mature T cells, is insufficient to compensate for ZAP-70 deficiency in peripheral CD4<sup>+</sup> T cell signal transduction. Peripheral T cells from two ZAP-70-deficient patients were shown to express high levels of Syk and be capable of partial TCR signaling after long-term culture (Noraz et al., 2000). However, findings have been variable in freshly isolated ZAP-70-deficient T cells and suggest that survival of these cells does not necessarily depend on ZAP-70-mediated TCR signaling or on up-regulation of Syk expression (Elder et al., 2001; Toyabe et al., 2001).

Alternatively, the level of Syk activity required for peripheral T cell survival may be less than that required for propagation of TCR signals. Further studies are needed to characterize the antigen specificity and TCR repertoire of CD4<sup>+</sup> T cells in ZAP-70 deficiency and to clarify the role of Syk in thymocyte selection and peripheral T cell activation.

### Strategies for Diagnosis of ZAP-70 Deficiency

Patients with SCID characterized by variable hypogammaglobulinemia, relatively normal numbers of peripheral blood lymphocytes, normal or only modestly decreased T cells, but notable absence of CD8<sup>+</sup> T cells (<5%) should be screened for ZAP-70 deficiency. The diagnosis would be suggested by lack of T cell proliferation *in vitro* to TCR stimuli, such as PHA and anti-CD3 MAb, whereas proliferation to PMA plus ionomycin ought to be comparable to that of normal T cells. Further studies to confirm a proximal TCR signaling defect include defective  $[Ca^{2+}]_i$  mobilization and poor tyrosine phosphoprotein induction after stimulation through the TCR. In most cases, blotting for ZAP-70 protein will demonstrate lack of ZAP-70 protein expression. If phosphotyrosine induction is abnormal but ZAP-70 protein is present, cDNA or genomic DNA sequencing would be required to characterize the mutation(s). To date, cDNA sequencing has been used primarily to determine ZAP-70 mutations; however, as the structure of the human *ZAP70* gene is now available, single-strand conformational polymorphism analysis and genomic DNA sequencing undoubtedly will be used more often because less blood will be required from the affected child.

### Carrier Detection and Prenatal Diagnosis

If the ZAP-70 mutations are known in an affected proband, then both carrier detection in relatives and prenatal diagnosis of an at risk fetus can be performed. Individuals heterozygous for a mutant ZAP-70 allele are immunologically normal. Therefore, molecular techniques would be required to establish heterozygosity. However, since ZAP-70 deficiency is extremely rare and has primarily been demonstrated in consanguineous and genetically inbred families, carrier detection is useful for only a very few individuals in certain isolated population groups.

### Treatment and Prognosis

Patients with ZAP-70 deficiency require hematopoietic stem cell transplantation for cure of SCID. Six of the original ZAP-70-deficient patients who were successfully transplanted received one of the following regimens: (1) a histocompatible bone marrow transplant (BMT) from a sibling after conditioning with busulfan and cytoxan (BuCy) and antithymocyte globulin (ATG) (one child; A.H. Filipovich, personal communication); (2) a T cell-depleted BMT from a parent either without prior conditioning (one child; E.W. Gelfand, personal communication) or after cytoxan/ATG conditioning (one child; Elder et al., 1995) or after BuCy/ATG conditioning (one child; A.H. Filipovich, personal communication); (3) an HLA-matched unrelated BMT after BuCy/ATG conditioning (one child; A.H. Filipovich, personal communication); or (4) a partial HLA-matched unrelated BMT after BuCy/ATG conditioning (one child; A.H. Filipovich, personal communication). Mobilized peripheral blood stem cells from a parent have also been used with variable success to reconstitute ZAP-70-deficient children (Elder et al., 2001; Skoda-Smith et al., 2001; Toyabe et al., 2001). In one case, a paternal mobi-

lized peripheral blood stem cell transplant followed by treatment with anti-CD20 MAb (Rituximab) successfully reconstituted a ZAP-70-deficient child who had developed an Epstein-Barr virus (EBV)-negative non-Hodgkin's B cell lymphoma following attempted T cell-depleted maternal haploidentical BMT (Skoda-Smith et al., 2001). Monthly intravenous gammaglobulin therapy is required in most cases for variable periods of time after hematopoietic stem cell transplantation.

### Animal Model of ZAP-70 Deficiency

Genetically altered mice lacking the entire ZAP-70 locus exhibit markedly defective T cell activation and development (Negishi et al., 1995). In contrast to findings in ZAP-70-deficient patients, T cell ontogeny in ZAP-70 knockout mice is blocked at the double-positive stage of thymocyte differentiation. Thymocytes from mutant mice fail to mobilize  $[Ca^{2+}]_i$  after TCR cross-linking by anti-CD3 MAb, and neither single-positive CD4<sup>+</sup> nor CD8<sup>+</sup> thymocytes develop, and peripheral T cells are absent. These findings as well as the demonstration that single-positive CD4<sup>+</sup> and CD8<sup>+</sup> T cell development could be rescued by expression of a functional human ZAP-70 cDNA in mutant thymocytes suggest that ZAP-70 is required for selection of both major thymocyte subsets in mice (Negishi et al., 1995). A comparable lymphocyte phenotype is seen in ST mice, which develop SCID due to a spontaneously arising mutation (R464C) within the highly conserved DLAARN motif of ZAP-70 that is essential for PTK enzymatic function (Wiest et al., 1997). Analysis of TCR signaling in ST thymocytes demonstrates that R464C abrogates ZAP-70 kinase activity, but the mutant protein is expressed and can be phosphorylated. These results confirm that ZAP-70 function is absolutely required for TCR activation and development of mature murine T lymphocytes.

The absence of CD4<sup>+</sup> T cells in ZAP-70-deficient mice contrasts with their presence in humans with ZAP-70 deficiency. Although the nature of the underlying mutations in human ZAP-70 deficiency conceivably might allow for some residual PTK activity *in vivo*, the disparate effects of identical ZAP-70 mutations suggest instead that human and murine thymocytes have different dependencies on ZAP-70 function during development. As stated above, both ZAP-70 knockout and ST mice exhibit markedly defective T cell activation, and in contrast to findings in ZAP-70-deficient patients (Gelfand et al., 1995), ST murine thymocytes do not mobilize  $[Ca^{2+}]_i$  after TCR cross-linking (Negishi et al., 1995; Wiest et al., 1997). One explanation for this discrepancy is that the ability of Syk to contribute to pre-TCR and TCR signaling is substantially different between humans and mice; in particular, the level of Syk activity in double-positive thymocytes of ZAP-70-deficient mice may not be sufficient to rescue CD4 selection in the absence of ZAP-70. Although it remains to be established whether Syk expression is significantly higher in human than in mouse thymocytes, this explanation is supported by evidence that peripheral CD4<sup>+</sup> and CD8<sup>+</sup> T cell development in ZAP-70-deficient mice can be restored with human Syk transgene expression in the thymus (Gong et al., 1997). Moreover, in contrast to findings in murine double-positive thymocytes in which Syk expression is comparable to that seen in peripheral T cells, human double-positive thymocytes express significant levels of Syk and do not down-regulate this PTK to levels seen in peripheral T lymphocytes until after positive selection has commenced (Chu et al., 1999). As a consequence of its relative abundance in human double-positive thymocytes, Syk may partially compensate for loss of ZAP-70 during positive

selection in ZAP-70-deficient patients. However, final conclusions regarding the distinct phenotypes of mice and humans deficient in ZAP-70 await more detailed analyses of the comparative expression and function of the Syk and ZAP-70 PTKs.

### Lck Deficiency

In contrast to ZAP-70, in which SCID patients lack peripheral CD8<sup>+</sup> T cells, human Lck deficiency has been associated with a selective CD4 lymphopenia (Goldman et al., 1998; Hubert et al., 2000; Sawabe et al., 2001). The underlying genetic defects resulting in observed decreased expression of functional Lck protein in a small number of sporadic cases are unknown. The clinical presentation of patients with selective CD4 lymphopenia and Lck deficiency is variable and may include SCID or common variable immunodeficiency (Goldman et al., 1998; Hubert et al., 2000; Sawabe et al., 2001).

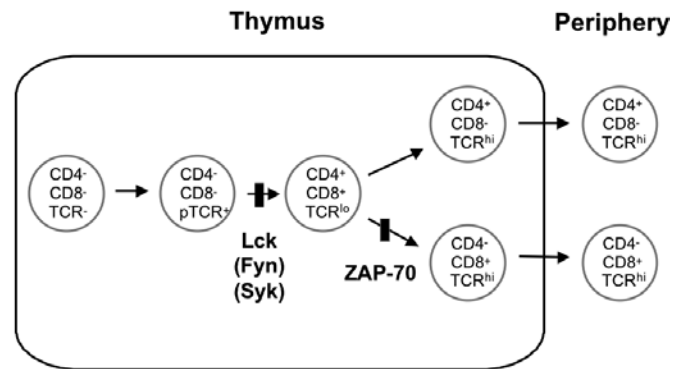

### Clinical and Laboratory Findings in Lck Deficiency

In addition to CD4 lymphopenia (range 4%–22%; 100–350 cells/mm<sup>3</sup>), affected individuals have decreased numbers of peripheral blood lymphocytes (780–1890 cells/mm<sup>3</sup>) and CD3<sup>+</sup> T cells (507–1200 cells/mm<sup>3</sup>); CD8<sup>+</sup> cell percentages and numbers are normal or increased (27%–65%, or 430–1058 cells/mm<sup>3</sup>). However, CD8<sup>+</sup> T cells from the Lck-deficient SCID patient poorly expressed the costimulatory molecule, CD28 (Goldman et al., 1998). Although mildly to significantly less responsive than control lymphocytes, Lck-deficient T cells do proliferate to mitogens, anti-CD3 MAb, and IL-2, and have demonstrated normal alloantigen responses (Goldman et al., 1998; Hubert et al., 2000; Sawabe et al., 2001). B cell and NK cell numbers are appropriate for age, but some patients have had panhypogammaglobulinemia and required intravenous immunoglobulin therapy.

Clinically, the single Lck-deficient child with SCID had infections similar to those of other children with combined primary immunodeficiencies and eventually was successfully treated with a BMT from a matched, unrelated donor (Goldman et al., 1998). One elderly adult with CD4 lymphopenia and decreased Lck function presented initially with cryptococcal meningitis (Hubert et al., 2000).

### Lck Mutation Analysis

The single child reported with Lck-deficient SCID was found to express an aberrantly spliced Lck mRNA lacking exon 7, which encodes the PTK ATP binding site and kinase domain (Straus and Weiss, 1992). Expression of a similar Lck mRNA lacking exon 7 is also found in the Jurkat cell line JCaM.1 (Straus and Weiss, 1992). As a result, the JCaM.1 cell line does not express Lck protein and exhibits profoundly defective proximal TCR signal transduction. A decreased but detectable amount of Lck protein was seen in the SCID patient's T cells by immunoblot; this signal was attributed to expression of the unstable mRNA lacking exon 7. Although less than in control lymphocytes, a significant amount of normal Lck mRNA was found in patient T cells as well. A relatively normal pattern of tyrosine phosphorylation was induced by TCR engagement despite defective expression of Lck; this is in obvious contrast to the JCaM.1 line (Straus and Weiss, 1992). Although TCR stimulation resulted in MAPK activation and [Ca<sup>2+</sup>]<sub>i</sub> mobilization at levels comparable to that of control cells, significant up-regulation of CD69 expression was

**Figure 14-2.** T cell ontogeny in humans. The developmental stages at which activities of certain protein tyrosine kinases (PTKs) have been identified as being critical for normal ontogeny are indicated.

not observed in the patient's CD8<sup>+</sup> T cells. The underlying genetic defect resulting in defective Lck expression has not yet been identified in this or any patient with selective CD4 lymphopenia and abnormal Lck expression or function.

### Conclusions and Future Directions

The defective TCR signaling observed in ZAP-70-deficient patients has established a critical role for a functional ZAP-70 PTK in normal TCR-mediated signal transduction. The failure of the TCR to mediate signals in thymocytes from mice deficient in ZAP-70 further supports the requisite role of ZAP-70 in TCR signal transduction. Despite findings that activation of Lck alone via co-cross-linking of CD4 or CD8 does not fully induce the PTK cascade and the other signaling reactions that occur as a result of TCR stimulation, a critical role for Lck in TCR signaling has been established on the basis of findings in mutant cell lines and Lck-deficient mice and one patient. These observations indicate that both Src and Syk family PTKs play unique and critical roles in TCR signal transduction.

In summary, TCR-associated PTKs are pivotally involved in distinct developmental events required for T cell maturation (Fig. 14.2). Lck and, to a lesser extent, Fyn are required for signaling in thymocytes; moreover, disruption of Lck severely affects peripheral T cell development and function in mice and humans. ZAP-70 deficiency has provided the first evidence that PTKs, and ZAP-70 in particular, are required for development of normal human T cell number and function. Further elucidation of the role of ZAP-70 in TCR signal transduction should be invaluable to the understanding of CD4 and CD8 selection in the thymus, as well as the pathogenesis of this form of SCID. Whether mutations in other molecules involved in TCR signaling produce abnormal T cell phenotypes in humans remains to be determined. Possible use of gene therapy as an alternative to BMT for cure of ZAP-70 deficiency remains to be explored.

### Acknowledgments

The author wishes to thank A. Weiss for his invaluable support and A.H. Filipovich, E.W. Gelfand, and S. Skoda-Smith for their assistance in the clinical and laboratory descriptions of ZAP-70-deficient patients.

## Human Interleukin-2 Receptor $\alpha$ Deficiency

CHAIM M. ROIFMAN

Regulation of the immune system requires communication among its cellular components. Such cell-to-cell interplay occurs in microenvironments in the lymphoid organs and sites of inflammation. A major mechanism of communication includes the secretion of a vast number of soluble mediators, of which the most extensively studied is interleukin-2 (IL-2). Originally identified as a T cell growth factor (Gillis and Smith, 1977a, 1977b) IL-2 was also later implicated in promoting growth of natural killer (NK) cells and B cells.

A better understanding of the effect of IL-2 was rendered by studying the structure of its receptor (IL-2R) and the signals generated by its perturbation. The IL-2R is multimeric, consisting of two obligate subunits, IL-2R $\beta$  (CD122) and IL-2R $\gamma$  or  $\gamma_c$  (CD132), and a variably expressed IL-2R $\alpha$  subunit (CD25) (Siegel et al., 1987; Wang and Smith, 1987; Waldmann, 1989; Kondo et al., 1994; Nakamura et al., 1994; Nelson et al., 1994). Similar to other cytokine receptor systems, IL-2R components are shared by other receptors including IL-4, -7, -9, and -15 (Leonard et al., 1994), accounting for some overlap in the function and characteristics of these lymphokines (see Chapters 9, 10).

Corresponding to which of the three IL-2R chains is expressed, different binding affinities for IL-2 can be recorded. The  $\alpha$  chain alone binds IL-2 with low affinity ( $K_d \sim 10$  nM), whereas IL-2R $\beta$  binds with an even lower affinity ( $K_d \sim 100$  nM) and the  $\gamma$  chain by itself has no measurable affinity. However, when coexpressed, the  $\alpha$  and  $\beta$  chains form an intermediate affinity complex ( $K_d \sim 30$  pM) (Arima et al., 1991; Anderson et al., 1995). Only the coexpression of all three chains forms the high-affinity IL-2R complex ( $K_d \sim 10$  pM) (Takeshita et al., 1992). Signaling activity through the IL-2R occurs with only two of the possible combinations of components. The combination of  $\beta$  and  $\gamma$  chains expressed on macrophages, resting T cells and NK cells, responds to high concentrations of IL-2, whereas the

complete  $\alpha\beta\gamma$  complex with the highest affinity can relay activation signals intracellularly at low concentrations of IL-2 (Smith, 1988). Indeed, because the phenotypes of IL-2 $^{-/-}$  and IL-2R $\alpha^{-/-}$  mice are almost identical (Schorle, et al., 1991; Willerford et al., 1995), most of the biologic effects of IL-2 are likely mediated through the high-affinity complex. Thus, the  $\alpha$  chain of the IL-2R appears critical for a full response to IL-2 in vivo.

### Interleukin-2 Receptor $\alpha$

Interleukin-2 receptor  $\alpha$  was the first chain of the IL-2R complex to be cloned (Leonard et al., 1984; Cosman et al., 1984; Nikaido et al., 1984). It is a 55 kDa protein with an extracellular portion containing 219 amino acid residues, a transmembrane segment of 19 residues, and a short cytoplasmic portion containing only 13 residues. Unlike the other chains of this receptor, IL-2R $\alpha$  has no similarity to the cytokine receptor superfamily, but it appears to have structural homology to the  $\alpha$  chain of the IL-15 receptor (Giri et al., 1995). The genes encoding IL-2R $\alpha$  and IL-15 $\alpha$  are located in proximity to each other on chromosome 10 in humans and chromosome 2 in mice (Anderson et al., 1995), which suggests that they may have arisen by gene duplication.

Of the three chains of the IL-2R, IL-2R $\alpha$  shows the most tightly regulated expression. During T cell development, IL-2R $\alpha$  is already expressed on the earliest triple-negative (CD3 $^{-}$ CD4 $^{-}$ CD8 $^{-}$ ) thymocytes (Godfrey and Zlotnick, 1993), but subsequently is dramatically down-regulated. Thymocytes do not express IL-2R $\alpha$  for the remainder of their development into T cells.

In resting, mature T cells IL-2R $\alpha$  is not expressed; it is induced by stimulation through the T cell receptor or by IL-1 and tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ) (Crabtree, 1989; Rothenberg, 1991). Similarly, mature B cells newly express IL-2R $\alpha$  following

stimulation through the B cell receptor (Jung et al., 1984; Tsudo et al., 1984; Waldmann et al., 1984). IL-2R $\alpha$  is also up-regulated in response to IL-2.

The regulation of IL-2R $\alpha$  gene expression appears to be dependent on several potent enhancers, including positive regulatory region I (PRRI) (Lin et al., 1990; Plaetinck et al., 1990), which binds NF- $\kappa$ B; the serum response factor; PRRII, which contains binding sites for Elf-1 and the chromatin-associated protein HMG-I; and PRRIII, which can bind Elf-1, HMG-1, and STAT5 (John et al., 1996; L'ecine et al., 1996).

### Clinical and Immunological Phenotype of IL-2R $\alpha$ Deficiency

To date, only two human subjects with IL-2R $\alpha$  deficiency have been identified; both were from the same family (Sharfe et al., 1997; Roifman, 2000; C. Roifman, unpublished observations). The parents of both patients were first cousins. The index patient, a male, presented with persistent thrush, *Candida* esophagitis, and cytomegalovirus (CMV) pneumonitis at 6 months of age (Table 15.1). By 8 months, chronic diarrhea and failure to thrive were associated with adenovirus gastroenteritis and frequent hospitalizations for exacerbations of pulmonary disease. Lymphadenopathy and hepatosplenomegaly became increasingly apparent during the second year of life, and by the third year he developed frequent otitis media, gingivitis, and chronic mandibu-

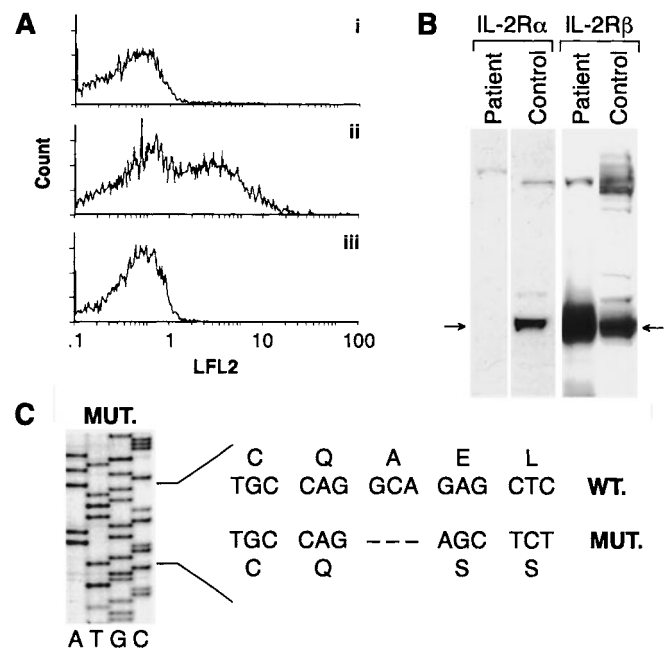

lar inflammation. While serum IgM and IgG levels were normal, IgA level was low. The absolute number of peripheral CD3<sup>+</sup> T cells was reduced, with a significant reduction in CD4<sup>+</sup> T cells. In vitro assays of peripheral lymphocyte function demonstrated reduced proliferation after stimulation by anti-CD3 (11% of control), phytohemagglutinin (20% of control), and other mitogens. Addition of exogenous IL-2 did not significantly rescue these proliferative responses. An allogenic skin graft from a healthy donor (negative for Epstein-Barr virus, CMV, HIV, and hepatitis B) was not rejected. Biopsies of lung and upper gastrointestinal tissue revealed dense lymphocytic infiltrates in the absence of infectious agents. The presentation was thus that of a combined immunodeficiency with increased susceptibility to viral, bacterial, and fungal infections, and evidence of dysregulated lymphocytic inflammatory disease.

### Absence of IL-2R $\alpha$ Chain (CD25) Expression

Epstein-Barr virus-transformed cells from these patients did not express detectable CD25 by flow cytometry, whereas EBV-transformed lines from normal individuals typically contain 20%–40% CD25-positive cells (Fig. 15.1A). Western blot analysis of lysates from peripheral blood lymphocytes confirmed the absence of CD25 protein (Fig. 15.1B). In contrast, expression of the common  $\gamma$  chain was normal and the IL-2R $\beta$  chain was elevated, possibly reflecting compensation for the lack of the  $\alpha$  chain, CD25.

**Table 15.1.** Clinical Immunological and Pathological Features of IL-2R $\alpha$  Deficiency

Factor	Clinical Manifestations
<i>Growth and Development</i>	Failure to thrive (decreased height and weight for age)
<i>Infections</i>	
Viral	CMV pneumonitis, adenovirus enteritis
Fungal	<i>Candida</i> stomatitis and esophagitis
Bacterial	Otitis media
<i>Lymphoid Tissue</i>	
Lymph nodes	Generalized lymphadenopathy
Liver/spleen	Hepatosplenomegaly with normal liver function
Thymus	Normal size
Factor	Laboratory and Pathological Features
<i>Markers</i>	
CD3 <sup>+</sup> cells	Reduced (<1000 cells/ml)
CD3 <sup>+</sup> , CD4 <sup>+</sup> cells	Reduced (300–450 cells/ml)
<i>Mitogenic Responses</i>	
Anti-CD3 and PHA	Markedly reduced (11% to 20% of normal)
<i>Tissue Pathology</i>	
Lymphocytic infiltrates	Heavy infiltrates in mandible, lungs, gastrointestinal tract, liver in absence of demonstrable infectious agents
<i>Thymus</i>	
Morphology	Loss of corticomedullary distinction, no Hassall's corpuscles
Immunohistochemistry	Lack of expression of CD1 and CD25 High bcl-2 expression Reduced apoptosis

**Figure 15.1.** (A) Epstein-Barr virus-transformed patient B lymphocytes (trace i) and normal control B lymphocytes (trace ii) were stained with anti-CD25 and analyzed by flow cytometry, demonstrating the absence of CD25 expression on patient cells (1.1% positive) compared with a normal control (44% positive). Isotype-matched antibody control staining of patient cells (1.8% positive) is shown in trace iii. (B) Western blot analysis demonstrates the absence of IL-2R $\alpha$  protein and elevated IL-2R $\beta$  expression in patient peripheral blood lymphocytes compared with normal. (C) A 4 bp deletion in the patient's CD25 gene results in a frameshift in protein translation. The sequence around the deletion (cDNA 60–64) is shown (MUT.) and compared with the sequence and reading frame of normal CD25 (WT.).

### Molecular Analysis

Two forms of CD25 cDNA were isolated from patient peripheral blood cells by reverse transcriptase-polymerase chain reaction, representing the full-length sequence (coding the active receptor) and a secondary splicing product lacking exon 4 (coding an inactive receptor) (Cosman et al., 1984; Leonard et al., 1984; Nikaido et al., 1984). Both forms of the patient's CD25 cDNA had a 4 bp deletion at cDNA 60–64, resulting in a translational frameshift (Fig. 15.1C). Predicted translation would proceed for only 20 amino acids before the deletion and resultant frameshift, with a further 25 irrelevant amino acids before termination. Thus even if this mRNA were stable, functional expression of CD25 would be effectively ablated. Consistent with autosomal recessive inheritance, the parents each demonstrated a normal and 4 bp-deleted allele.

### Requirement of IL-2R $\alpha$ for Normal Expression of CD1 in the Thymus

Atypically for profound cellular immunodeficiency, the thymus in IL-2R $\alpha$  deficiency was of normal size, although displaying no Hassall's corpuscles and a lack of distinct cortical-medullary demarcation (Color Plate 15.I). Whereas immunohistochemical staining of thymus sections showed normal expression of CD3, CD2, CD4, CD8, and class I and class II major histocompatibility complex (MHC) proteins, staining for CD1 was completely negative (Color Plate 15.I).

In the normal thymus, CD1a is highly expressed on cortical thymocytes and dramatically down-regulated upon progression into the medullary antigen-presenting region. Because the CD1a gene itself was normal, a failure to provide appropriate signals for CD1 up-regulation in thymocytes may explain this phenomenon. It is possible that rather than serving simply as a nonclassical antigen-presenting molecule, CD1a may participate in mediating interactions between thymocytes and thymic epithelium, and absence of CD1a may be related to the loss of the distinct corticomedullary boundary.

Normally the induction of CD1 expression in cortical thymocytes precedes a dramatic decrease in the cellular level of the bcl-2 protein (Alvarez-Vallina et al., 1993; Fujii et al., 1994; Gratiot-Deans et al., 1994; Vanhecke et al., 1995). The presence of bcl-2 acts to protect cells against programmed cell death, without promoting proliferation (Cory, 1995). Early, immature triple-negative thymocytes and more mature double-positive (CD1<sup>+</sup>, CD3<sup>hi</sup>, CD4<sup>+</sup>, CD8<sup>+</sup>) medullary thymocytes express high levels of bcl-2 and are relatively resistant to apoptosis (Fujii et al., 1994; Gratiot-Deans et al., 1994; Cory, 1995). To permit immature thymocytes to undergo positive and negative selection, both of which result in the induction of programmed cell death 95% of the time, a reduction in bcl-2 levels is believed to be required. Whereas normal thymocytes demonstrated distinct areas of low (cortical) and high (medullary) bcl-2 expression, staining of patient thymus sections revealed that all CD25-deficient thymocytes expressed high levels of bcl-2 protein (Color Plate 15.I). The lack of regulation of bcl-2 expression in CD25 deficiency suggests that bcl-2 expression may be dependent on downstream events following either CD1 or CD25 signaling.

Sakaguchi et al. (1995) reported that CD25<sup>+</sup> CD4<sup>+</sup> T cells maintain self-tolerance in mice by suppressing autoreactive cells. Indeed, even in the absence of thymic irregularities, autoreactive responses emerged in the absence of CD25<sup>+</sup> T cells. This finding suggests that the lymphocytic infiltrates observed in hu-

man CD25 deficiency could be autoimmune in nature. The persistence of high bcl-2 expression in cortical thymocytes supports this view; bcl-2 may permit some thymocytes bearing autoreactive T cell antigen receptors to escape deletion, as seen in some transgenic mice overexpressing bcl-2 (Siegel et al., 1992).

Normally, thymocytes expressing T cell receptors that bind avidly to an MHC molecule, which is presumably presenting self-derived antigens, are eliminated by apoptosis. Apoptosis in the CD25-deficient patient's thymus was low as demonstrated by decreased DNA degradation (Color Plate 15.1.) (Schmitz et al., 1991).

The heavy tissue infiltrates of lymphocytes found in a CD25-deficient patient suggest the involvement of autoreactive clones reminiscent of the oligoclonal expansion observed in multiple autoimmune disorders. Further, the higher than normal expression of bcl-2 in the thymus gland suggests that such autoreactive clones might escape selection because of reduced ability of these cells to undergo apoptosis. Thus IL-2R $\alpha$  appears to be critical for the physiologic negative selection of thymocytes. In its absence, autoreactive clones that normally should be destined to die by apoptosis fail to do so, and instead expand and cause damage to peripheral tissues.

In conclusion, a combination of at least two events, one intrathymic and another peripheral, may have combined to create the phenotype observed in humans with CD25 deficiency.

### IL-2R $\alpha$ -Deficient Mice

Targeted disruption of IL-2R $\alpha$  in the mouse showed that development of T and B cells appeared intact in these animals, including the distribution of thymocyte subpopulations in the thymus (Willerford et al., 1995). In addition, development of NK cells also appeared to be normal (Nelson and Willerford, 1998). However, as with IL-2 deficient mice, older IL-2R $\alpha$  knockout mice developed polyclonal expansion of peripheral T cells that highly expressed CD44 but had a low expression of CD62L. Activated B cells present in young animals initially led to hypergammaglobulinemia, but in older animals a progressive loss of B cells was noted. The major phenotype of IL-2R $\alpha$  knockout mice was autoimmune disease, including hemolytic anemia, severe colitis (reminiscent of human ulcerative colitis), and lymphadenopathy.

### Treatment

The lymphadenopathy and tissue infiltrates of the CD25-deficient patient were partially ameliorated by the administration of corticosteroids. However, to effect a cure an allogeneic bone marrow transplant was performed, using an HLA-matched sibling as the donor. Engraftment was rapid and a complete resolution of symptoms ensued. On follow-up, the patient was free of symptoms without any treatment; over 95% of peripheral blood mononuclear cells were of donor origin, and growth and development were appropriate for age.

## CD3 and CD8 Deficiencies

JOSÉ R. REGUEIRO and TERESA ESPANOL

Mature T cells detect the presence of antigens by way of a variable surface heterodimer (either  $\alpha\beta$  or  $\gamma\delta$ ) termed the *T cell receptor* (TCR) (Fig. 16.1). TCR molecules require association with a group of invariant proteins collectively called *CD3* and organized as dimers (Call et al., 2002). Since the first description of the T cell antigen receptor complex (TCR/CD3) in 1981, at least four different CD3 proteins have been reported: CD3 $\gamma$ ,  $\delta$ ,  $\epsilon$  and  $\zeta$ . CD3 proteins participate in TCR/CD3 assembly and surface expression. They also aid in the delivery of intracellular signals that drive T cell maturation or apoptosis in the thymus (see Chapter 4), and T cell activation, proliferation, and effector function or anergy/apoptosis after antigen recognition (see Chapter 6; Malissen et al., 1999). During early T cell development, some CD3 chains may act alone or assist immature TCR ensembles, such as those containing pre-TCR chains. CD3 chains lack intrinsic enzymatic activity for signal transduction. Rather, they rely on phosphorylation-dependent recruitment and activation of a number of cytosolic and transmembrane protein tyrosine kinases (PTK) and adaptors such as ZAP-70, Fyn, Lck, TRIM, LAT, SLP-76, and SIT (Schraven et al., 1999). Most  $\alpha\beta$  TCR-bearing T cells recognize processed peptides associated with major histocompatibility complex (MHC) molecules. This interaction is facilitated by the T cell coreceptor proteins CD4 and CD8, which show considerable affinity for the MHC but not peptide moiety. Coreceptor association thus increases the stability of TCR–MHC interactions extracellularly and recruits the crucial PTK Lck intracellularly through a conserved binding motif within its cytoplasmic tail, resulting in rapid T cell activation.

CD8 serves as a coreceptor for TCR recognition of MHC class I-associated peptides (Zamoyska, 1998), which leads to cytotoxic  $\alpha\beta$  T lymphocyte (CTL) activation and lysis of the antigen-presenting cell. This mechanism enables CTLs to recognize and eliminate infected cells, tumor cells, and allogeneic graft

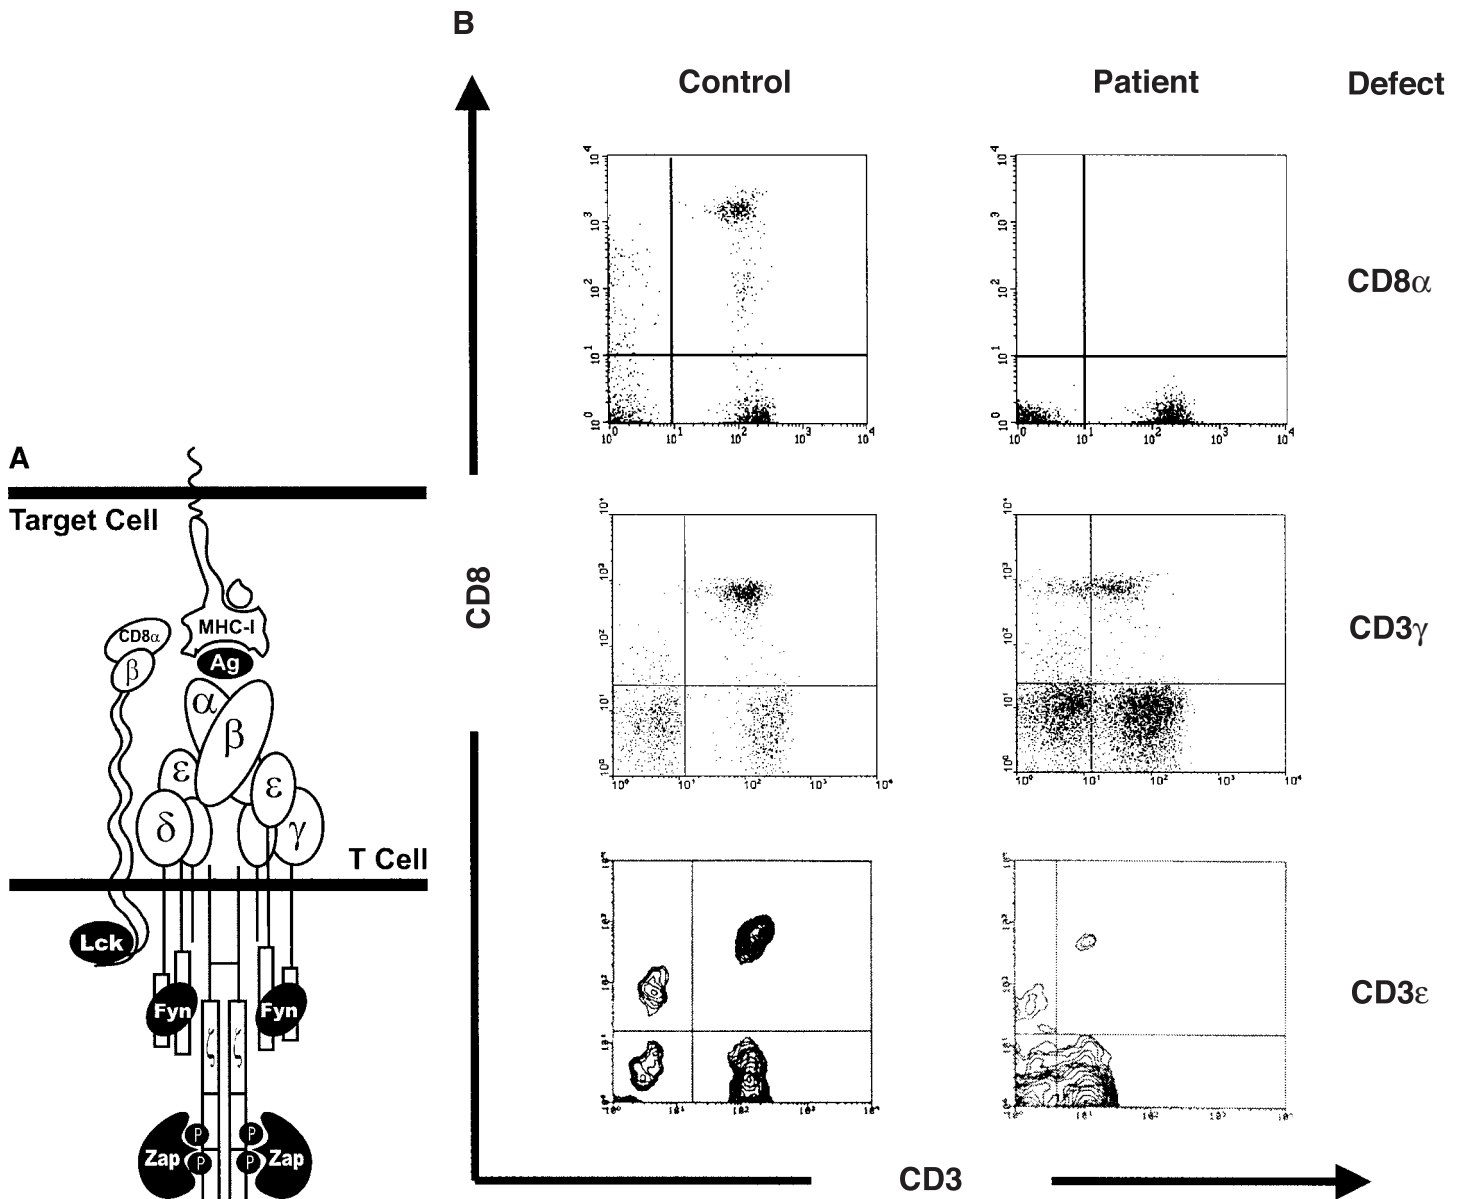

cells. CD8 molecules are expressed on the cell surface either as an  $\alpha\alpha$  homodimer (in natural killer [NK] cells, in intraepithelial  $\alpha\beta$  T cells, and in  $\gamma\delta$  T lymphocytes) or as an  $\alpha\beta$  heterodimer (in  $\alpha\beta$  T lymphocytes and thymocytes). Surface expression of CD8 $\beta$  is dependent on expression of CD8 $\alpha$ , as CD8 $\beta$  polypeptides are otherwise retained in the endoplasmic reticulum and degraded. Both chains ( $\alpha$  and  $\beta$ ) are composed of a single extracellular immunoglobulin-like domain (also present in CD3 $\gamma$ ,  $\delta$ , and  $\epsilon$ ), a membrane-proximal hinge region, a transmembrane domain, and a cytoplasmic tail (Fig. 16.1). Expression of CD8 is characteristic of CTLs and is critical for their progression through the process of positive selection during differentiation in the thymus. However, other cell types can also express CD8 molecules.

Because of the central role of T cells in specific immune responses and the central role of the TCR/CD3 complex in T cell function, the description of a human familial CD3 deficiency in 1986 was in many ways surprising due to its phenotypic spectrum (Regueiro et al., 1986). Four years later, a second CD3 deficiency was reported (Thoenes et al., 1990). As it turned out, the former was due to a selective CD3 $\gamma$  deficiency (Arnaiz-Villena et al., 1992) and became the first primary TCR immunodeficiency for which the genetic basis had been elucidated, whereas the latter was caused by a partial CD3 $\epsilon$  deficiency (Soudais et al., 1993). A further CD3 $\gamma$  deficiency case has been characterized biochemically and genetically (van Tol et al., 1997). Recently, complete CD3 $\delta$  or CD3 $\epsilon$  deficiencies have also been reported in patients with severe combined immunodeficiency (SCID) (Dadi et al., 2003; de Saint-Basile et al., 2004a). In addition, a human selective CD8 deficiency, caused by mutations in *CD8A*, has been reported (de la Calle-Martin et al., 2001). Taken together, CD3 and CD8 deficiencies provide insights into the redundant and unique roles of these transmembrane molecules for T cell antigen recognition and signal transduction.

In humans, CD3 deficiencies present as very rare autosomal recessive diseases characterized by a prominent TCR/CD3 expression defect that may be associated with a mild (CD3 $\gamma$ ) or severe (CD3 $\delta$ ,  $\epsilon$ ) peripheral blood T but not B or NK lymphopenia. It is caused by mutations in the genes encoding for CD3 $\gamma$  (Chr 11q23 *CD3G*); CD3 $\delta$  (Chr 11q23 *CD3D*); or CD3 $\epsilon$  (Chr 11q23.3 *CD3E*). Also, a CD3 $\zeta$  deficiency of French origin, with severe lung infections, low T cell counts, and low TCR/CD3 expression, has recently been characterized (de Saint-Basile et al., 2004b; A. Fischer, personal communication). A Dutch TCR/CD3 expression defect with SCID symptoms but no mutations in *CD3G*, *E* or *Z* has been reported but not fully characterized

(Brooimans et al., 2000). Human CD8 deficiency is also a very rare autosomal recessive disorder showing an absolute CD8 expression defect by mature peripheral blood T and NK lymphocytes. As a consequence, the  $\alpha\beta$  CTL lineage becomes CD4<sup>-</sup>CD8<sup>-</sup> (double negative, DN). It is caused by a point mutation (Gene Bank number AY039664) in the gene encoding for CD8 $\alpha$  (Chr 2p12 *CD8A*).

Mutation databases have been established at <http://bioinf.uta.fi/CD3Gbase>, [CD3Dbase](http://bioinf.uta.fi/CD3Dbase), [CD3Ebase](http://bioinf.uta.fi/CD3Ebase), and [CD8Abase](http://bioinf.uta.fi/CD8Abase). OMIM (Online Mendelian Inheritance in Man) sites can be found at <http://www3.ncbi.nlm.nih.gov/entrez/dispomim.cgi?id=186740> (for *CD3G*), 186790 (for *CD3D*), 186830 (for *CD3E*),

**Figure 16.1.** (A) Immunological synapse between a mature cytolytic  $\alpha\beta$ T lymphocyte and an antigen-presenting target cell. Variable  $\alpha\beta$ TCR heterodimers bind antigen (Ag) on major histocompatibility complex class I (MHC-I) molecules with aid from the CD8 $\alpha\beta$  coreceptor. CD3 dimers ( $\gamma\epsilon$ ,  $\delta\epsilon$ , and  $\zeta\zeta$ ) and CD8 dimers then recruit intracellular enzymes (Fyn, Zap, Lck) to initiate signal transduction. (B) Representative lymphocyte phenotypes of human CD8 $\alpha$ , CD3 $\gamma$ , and partial CD3 $\epsilon$

deficiencies (the latter from cultured cell blasts, reproduced with permission from Soudais et al., 1993). The lack of mature T cells in complete human CD3 $\delta$  or  $\epsilon$  deficiency precluded obtaining a similar histogram. (C) Lymphocyte phenotype of a human TCR/CD3 expression defect (Dutch patient DS, molecular basis still unknown) and of her healthy father, who showed 50% expression levels compared to controls.

## Clinical and Pathological Manifestations

### CD3 Deficiency

The incidence of CD3 deficiencies is very low; 13 patients (8 males, 5 females) have been reported in 7 unrelated kindreds (Table 16.1). Age of onset, when symptoms are present, is early in life (before 3 years of age), essentially as recurrent bacterial or viral respiratory infections (all patients), as well as otitis (individuals DSF, PT in Table 16.1). Bacterial infections included *Hemophilus influenzae* in individuals VSF and PT (lung, ear), and *Salmonella enteritidis* (stool) and *Yersinia enterocolitica* (blood) in VSF. Viral infections included adenovirus (P2, PI-3), cytomegalovirus (CMV) (P3, PI-2, PII-1), parainfluenza (VSF), and Epstein-Barr virus (EBV) (PIII-1). Fungus was detected through oral or perineal candidiasis (PI-2, PIII-1) and presence of aspergillus (PII-2). Other symptoms included chronic diarrhea (VSF, P3, PII-1, PIII-1); failure to thrive (PII-1, VSF); autoimmune enteropathy (VSF); respiratory distress (P2, P3); asthmatic bronchitis (DSF, FK); diarrhea, allergic rhinitis, atopic eczema, vitiligo, lymphocytary—most likely viral in nature—meningitis, and dilated cardiomyopathy (DSF); urinary tract infections, nonatopic hyperreactive airway, and maxillary sinusitis (FK); and chronic sinusitis (PT). The patients had no history of chronic pyogenic infections or eczema. No dysmorphic features or bone abnormalities were reported. Patients followed normal vaccination schedules without complications. Five of 13 patients are presently alive. The rest shared SCID features and died early in life, most likely as a consequence of viral infections. A gut biopsy of patient VSF at 18 months of age showed a flat mucosa with crypt hypertrophy consistent with celiac disease. A gluten-free diet-resistant malabsorption syndrome with gut epithelial cell autoantibodies (autoimmune enteropathy) was finally diagnosed. The autopsy demonstrated bilateral bronchopneumonia and the

presence of giant cells usually seen in Hecht's pneumonia, as well as mesenteric and mediastinic adenopathies. No thymus was evident on gross inspection, but microscopically the thymus rudiment ( $0.5 \times 1.2$  cm) and the lymph nodes, spleen, and bone marrow showed a marked lymphoid depletion, with no Hassal's corpuscles in the thymus, no plasma cells in the lymph nodes, and no lymphoid follicles in the spleen. Hassal's corpuscles were also absent in patients P1 and P3, despite a normal shadow on chest radiography. The Dutch patient with TCR/CD3 expression defect (DS), born to consanguineous parents, suffered two episodes of viral pneumonia at 7 months of age, and at 12 months showed SCID symptoms (failure to thrive, diarrhea, and *Pneumocystis carinii* pneumonia).

### CD8 Deficiency

To date, CD8 deficiency has only been described in a consanguineous Spanish family (Fig. 16.2). The proband, a 25-year-old male (EP, II-4 in Table 16.1), presented with repeated respiratory infections and had two asymptomatic sisters (II-5 and II-7). The patient had suffered repeated bronchitis and otitis media from childhood. Chest X-ray and computed tomography revealed disseminated bronchiectases. Sputum culture was positive for *Haemophilus influenzae*. Functional respiratory tests showed severe mixed ventilatory disturbance. The patient's clinical status improved after intravenous antibiotic therapy. He has required further admissions because of respiratory reinfections. The parents and the remaining siblings have had no relevant medical history.

## Laboratory Findings

### CD3 Deficiency

Table 16.1 summarizes the main laboratory findings in CD3 deficiencies, mostly at the time of diagnosis (see also Zapata et al., 2000). Some of the abnormal features, however, may not be stable over time. For instance, many T cell proliferative responses in

\*Two healthy female sibs showed similar results.

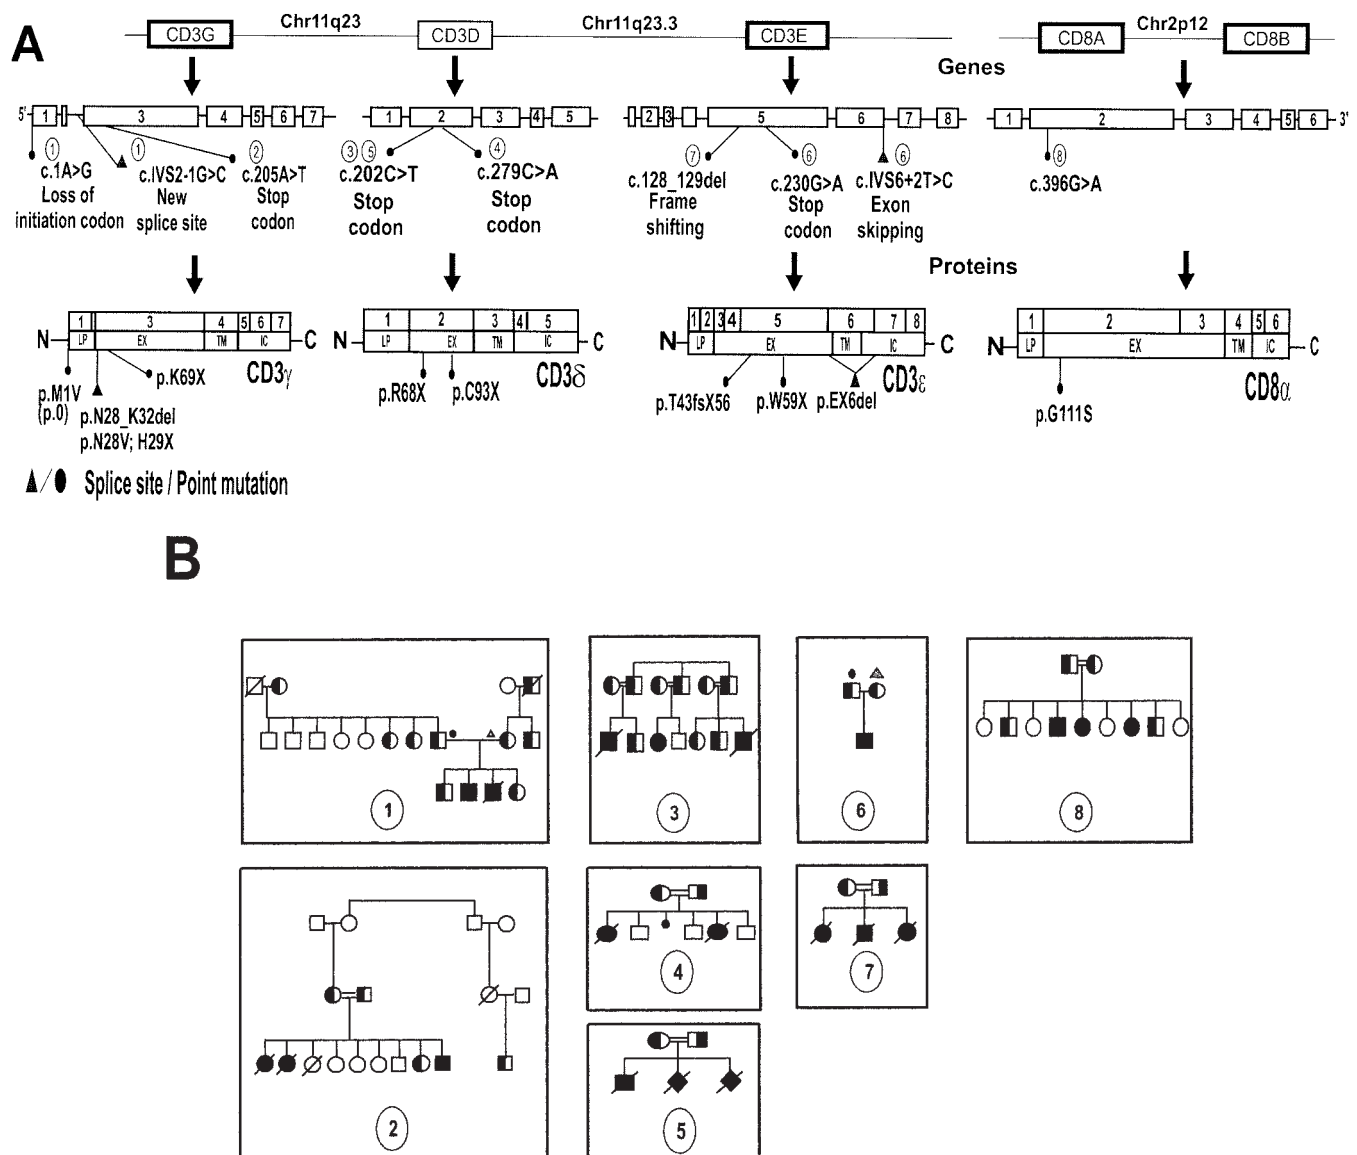

†After bone marrow transplantation.

‡T cell counts by use of TCR/CD3 antibodies are not reliable in CD3 defects because of the expression defect of the whole complex. ( $\alpha\beta + \gamma\delta$ ) T cells should be counted as CD2<sup>+</sup> CD16<sup>-</sup>, and  $\alpha\beta$  T cells as CD4<sup>+</sup> + CD8<sup>bright</sup> lymphocytes.

\*\*The father was also IgG2 deficient.

††Recent (2003) *in vitro* evaluation of PBL response to bacterial (tuberculin, tetanus toxoid, diphtheria) and viral (cytomegalovirus, herpes simplex virus, rubella, varicella, mumps, measles, influenza A and B) antigens was normal.

‡‡Low-titer thyroglobulin and thyroid peroxidase autoantibodies have been present since June 1999 (DSF). Gut epithelial cell, smooth muscle, and mitochondrial autoantibodies, and autoimmune hemolytic anemia (VSF), and low-titer microsomal and thyroglobulin autoantibodies (FK) were present.

**Figure 16.2.** (A) The human *CD3GDE* and *CD8AB* gene complexes (from Genatlas <http://www.dsi.univ-paris5.fr/genatlas>) and their mutations. LP, EX, TM, and IC indicate the leader peptide, extracellular, transmembrane, and intracellular domains, respectively. Nomenclature follows published recommendations ([http://archive.uwcm.ac.uk/uwcm/mg/docs/mut\\_nom.html](http://archive.uwcm.ac.uk/uwcm/mg/docs/mut_nom.html)). (B) Fate of each mutation along the family

trees. For nonconsanguineous families, the paternal and maternal mutations are indicated. Three untested deceased individuals are shown as presumed heterozygote (maternal grandfather in family 1) or homozygotes (two females in family 2, based on clinical data). Female 6 in family 8 was not tested. In family 5, two homozygote fetuses from terminated pregnancies were also studied.

patient DSF became normal as he grew older. Also, immunoglobulin levels and lymphocyte counts may fluctuate from infections. The most consistent laboratory finding (when peripheral blood T cells are present) is a TCR/CD3 expression defect on otherwise phenotypically normal and polyclonal CD4<sup>+</sup> and CD8<sup>+</sup> (bright, to exclude NK cells) lymphocytes (Fig. 16.1B). However, monoclonal-specific, CD3 chain-specific, and/or T cell subset-specific differences may be observed. Lymphocyte counts are grossly normal or slightly diminished in venous blood, but lymphocyte subset-specific imbalances may be observed, sometimes dramatically. These include absence of T cells (both CD4<sup>+</sup> and CD8<sup>+</sup>) in CD3δ or CD3ε deficiency (Dadi et al., 2003; de Saint-Basile et al., 2004a), or a very low number of CD45RA<sup>+</sup> T cells in CD3γ deficiency (Zapata et al., 2000), which suggests a defective supply of naive T cells from the thymus

(Mackall et al., 1993) or poor peripheral survival due to weak homeostatic TCR–MHC interaction (Freitas and Rocha, 2000). Normal numbers of CD45R0<sup>+</sup> T cells in CD3γ deficiency reflect a significant expansion of memory T cells, which are thought to be TCR-independent. TCR/CD3-induced T lymphocyte functions are very low, low, or normal, depending on the stimulus, whereas transmembrane stimuli (phorbol myristate acetate [PMA] + calcium ionophore) elicit normal responses. Skin tests with phytohemagglutinin (PHA), tetanus toxoid, PPD, or *Candida* are weak or absent. Some B cell functions may be low, manifested by serum IgG2 levels in two of three tested cases, isohemagglutinins in two of four, and in vivo responses to polysaccharides, but not to proteins. Immunoglobulin levels are generally normal, but may be low in SCID patients. Autoantibodies have been reported only in CD3γ deficiency. The Dutch TCR/CD3 expression defect

(Fig. 16.1C) showed some distinct laboratory features, such as a very severe T (particularly CD8<sup>+</sup>) lymphopenia.

### CD8 Deficiency

The main laboratory findings are shown in Table 16.1. Antibodies to tetanus, toxoplasma, mycoplasma pneumoniae, CMV, herpes zoster, herpes simplex, and rubella were present. Serologies to HIV and EBV, legionella pneumophila, aspergillus, and brucella were negative. Autoantibodies were negative. Lymphocyte phenotyping detected a total absence of surface CD8<sup>+</sup> ( $\alpha$  or  $\beta$ ) cells (Fig. 16.1B), presence of both CD3<sup>+</sup> ( $\alpha\beta$  and  $\gamma\delta$  T cells) and CD3<sup>-</sup> (NK cells), and a higher percentage of CD4<sup>-</sup> CD8<sup>-</sup> (DN) cells than that in normal donors. This increase was due to the rise in DN  $\alpha\beta$  T cells (16%; reference range, 0.1%–2%), with a large V $\beta$  repertoire and mostly CD3<sup>hi</sup> CD5<sup>+</sup> CD2<sup>+</sup> CD45RA<sup>+</sup> CD57<sup>+</sup> CD11b<sup>+</sup> CD28<sup>-</sup>. Upon stimulation, the DN T cells were positive for intracellular interferon- $\gamma$  (IFN- $\gamma$ ), but not for interleukin-2 (IL-2) or IL-4. The percentage of DN  $\gamma\delta$  T cells was normal (6%; reference range, 1%–8%). CD4<sup>+</sup> T cell, B cell, and NK cell percentage and absolute numbers were normal (Table 16.1). Intracellular CD8 $\beta$  was weakly positive.

### Family Studies

Siblings with likely symptoms of CD3 $\gamma$  and CD8 deficiencies were found within two probands' families. Upon careful investigation, a healthy CD3 $\gamma$ -deficient sibling (individual DSF in Table 16.1) did show early clinical symptoms starting at 12 months of age, such as bacterial infections, asthmatic bronchitis, allergic rhinitis, diarrhea, vitiligo, atopic eczema, otitis, lymphocytary meningitis, and a mildly dilated cardiomyopathy that was probably secondary to unrecorded viral infections (Allende et al., 2000). Computerized axial tomography at the age of 6 revealed the presence of a thymus (3 × 1.2 × 4.7 cm). In contrast to this individual, three female siblings of the Turkish proband died before the age of 2 from chickenpox (at 18 months), measles (at 15 months), and (probably) leukemia (at 11 months), respectively. A definitive diagnosis of CD3 $\gamma$  deficiency was not made, but the first two siblings might be considered to have had CD3 $\gamma$  deficiencies (Sanal et al., 1996). Heterozygotes for CD3 $\gamma$  or  $\epsilon$  deficiencies did not show TCR/CD3 expression defects, but the Dutch case did (Fig. 16.1C), suggesting a different molecular basis.

Two (females) of eight siblings of the CD8-deficient proband (EP) also lacked surface CD8<sup>+</sup> ( $\alpha$  or  $\beta$ ) expression and showed weak intracellular CD8 $\beta$  and high numbers of DN  $\alpha\beta$  T cells (10% and 4%, respectively). Immunoglobulin levels were normal in all siblings studied. Antibody responses to varicella zoster, tetanus, herpes simplex, and natural antibodies were also present in a tested heterozygote (II-2) and in a homozygote (II-7). Mean fluorescence intensity of CD8 $\alpha$  surface expression and soluble CD8 levels in serum (by ELISA) were decreased in the parents and in two heterozygous brothers (II-2 and II-8) but were normal in the remaining four siblings. These results indicate a good phenotype–genotype correlation (Fig. 16.2).

## Molecular Basis

### CD3 Deficiency

The lack of CD3 $\gamma$ ,  $\delta$ , or  $\epsilon$  impairs both  $\alpha\beta$  and  $\gamma\delta$  TCR/CD3 assembly and surface expression. The expression defect is more severe in CD3 $\epsilon$  (and probably CD3 $\delta$ ) than in CD3 $\gamma$  deficiency

(Fig. 16.1B). TCR $\alpha$  strictly associates with CD3 $\delta\epsilon$  dimers, whereas TCR $\beta$  has been shown to interact with  $\gamma\epsilon$  as well as  $\delta\epsilon$  dimers (Call et al., 2002). This finding may explain the differential effect of the lack of CD3 $\delta$  and  $\epsilon$ , compared to  $\gamma$ , on surface TCR/CD3 expression. T cell development was blocked in complete CD3 $\delta$  or  $\epsilon$  deficiency and impaired in human CD3 $\gamma$  deficiency, but not in partial CD3 $\epsilon$  deficiency. However, substantial numbers of mature T cells can be found in peripheral blood of CD3 $\gamma$ - or partially CD3 $\epsilon$ -deficient patients, who in fact can show several normal immunological responses in vivo and relatively mild clinical symptoms. Therefore, repertoire shaping during intrathymic selection seems to adjust to available TCR/CD3 levels to populate peripheral lymphoid organs with fairly functional T cells in these cases.

### CD8 Deficiency

Transfection studies were performed to establish a direct correlation between the mutation found in the CD8 immunoglobulin domain and the absence of any detectable CD8 antigen in homozygous family members. Wild-type and mutated CD8, as well as chimeric CD8 molecules (CD8 MUT/WT and WT/MUT), were subcloned into the *XbaI/SacI* sites of pCDL-SR $\alpha$ 296 vector (de la Calle-Martin et al., 2001). CD8 single-point mutants were generated by site-directed mutagenesis of the wild-type (wt CD8 > CD8<sup>ser111</sup> or CD8<sup>arg111</sup>) and mutated CD8 (mutant CD8 > CD8<sup>gly111</sup>). The different constructs were transiently transfected in COS-7 cells and analyzed 48 hours later by immunofluorescence. The results demonstrated that the presence of serine or another amino acid at position 111 (CD8<sup>ser111</sup> in the MUT/MUT and the MUT/WT construct) precludes CD8 expression, thereby suggesting that the presence of the evolutionary conserved glycine at this position may be important for appropriate folding of the protein. However, the lack of CD8 surface expression did not prevent development of a peripheral DN T cell lineage with functional features resembling CD8<sup>+</sup> T cells, such as IFN- $\gamma$  synthesis. Similar results have been reported in mice (see Animal Models, below).

## Functional Aspects

### CD3 Deficiency

CD3 $\delta$  and  $\epsilon$  are essential for  $\alpha\beta$  and  $\gamma\delta$  T cell development in humans, therefore, no mature T cells have been available for the functional analysis of TCR/CD3 complexes lacking those chains. The study of mature T cells lacking CD3 $\gamma$  or partially lacking CD3 $\epsilon$  has been complicated by two factors that hinder meaningful comparisons with normal individuals: (1) mild lymphopenia and/or differential T cell subset representation, and (2) defective surface expression of TCR/CD3 complexes. Nonetheless, it is clear that normal signaling is possible in vivo because antibody responses to T cell-dependent protein antigens were normal in these cases. Also, normal proliferative responses in vitro to certain antigens have been recorded (tetanus toxoid). Thus it seems that more subtle T lymphocyte functions will have to be studied in purified and/or cultured T cells.

Our studies in human CD3 $\gamma$ -deficient primary T cells, IL-2-dependent T cell lines, and herpesvirus saimiri-transformed T lymphocytes have indicated that CD3 $\gamma$  contributes to but is not absolutely required for the regulation of TCR trafficking in resting and antigen-stimulated mature T lymphocytes (Torres et al.,

2003). Despite its effects on TCR/CD3 expression (likely due to impaired recycling), CD3 $\gamma$  is not needed for several TCR/CD3-induced mature T cell responses, such as calcium flux, cytotoxicity, up- or down-regulation of several surface molecules, proliferation, and synthesis of certain cytokines (TNF- $\alpha$ ). In contrast, PMA-induced TCR/CD3 down-regulation and TCR/CD3-induced synthesis of other cytokines (IL-2) as well as adhesion and polarization were severely impaired (Perez-Aciego et al., 1991; Arnaiz-Villena et al., 1992; Pacheco-Castro et al., 1998; Torres et al., 2002). The lack of CD3 $\gamma$  caused a stronger impairment of  $\alpha\beta$ TCR/CD3 expression in CD8 $^{+}$  than that in CD4 $^{+}$  T cells in humans (Table 16.1) and in mice. We have shown that this is due to biochemical differences in the intracellular control of  $\alpha\beta$ TCR/CD3 assembly, maturation, or transport between the two lineages, which result in conformational lineage-specific differences regulated by activation or differentiation in both normal and CD3 $\gamma$ -deficient primary T cells (Zapata et al., 1999, 2004).

### CD8 Deficiency

Clinical manifestations, when present, are not severe, as shown in the murine homologue (see Animal Models, below). CD8 deficiency is thus compatible with life and less aggressive than HLA class I deficiencies. We believe that the absence of classical CD8 $^{+}$  CTL may be partially compensated for by the presence of a high percentage of  $\alpha\beta$  DN T cells in our patient, and by the cytolytic function of NK cells (Brown et al., 2001). The DN T cells were CD11b $^{+}$  CD57 $^{+}$  CD45RA $^{+}$  CD28 $^{-}$  IFN- $\gamma$  $^{+}$  IL-2 $^{-}$  IL-4 $^{-}$ , a phenotype associated with effector CD8 $^{+}$  CTL (Hamann et al., 1999). The high antibody titers to many viral infections (CMV, herpes zoster, herpes simplex, rubella) in the patient seem to demonstrate that he has been in contact with these viruses and is immunocompetent enough to overcome these infections. Although analysis of recent infections in the proband showed only those of a bacterial nature, viral infections suffered at an early age might have been responsible for the alveolar lesions that later became overinfected and produced bronchiectases, as has also been reported in TAP-deficient adult patients (de la Salle et al., 1999). Further studies will be required to establish the functional features of CD8-deficient CTL.

### Mutation Analysis

Mutation analysis was started by probing T cell RNA with CD3- or CD8-specific sequences. For CD3 $\delta$  deficiency, microarray analysis of thymocyte RNA revealed low specific transcript levels. In all cases, cDNA was synthesized and used to amplify and sequence CD3G, CD3D, CD3E, or CD8A. This process revealed the presence of point mutations or small deletions in all cases (Fig. 16.2A), which could be traced with mutation-specific oligonucleotides, restriction enzymes, or direct sequencing. Small deletions were due to splice site mutations, which were identified on genomic DNA by sequencing relevant exon boundaries. Six of eight CD3 mutations caused early protein truncation at the extracellular domain, one caused loss of the initiation codon, and another caused skipping of the transmembrane domain. As a consequence, no mature CD3 $\gamma$ ,  $\delta$ , or  $\epsilon$  proteins could be detected biochemically, and a TCR/CD3 expression defect ensued ( $\epsilon \geq \delta > \gamma$ , Fig. 16.1B). The CD8A point mutation caused a missense substitution in the immunoglobulin domain at a very conserved position. Thus no intracellular or surface CD8 $\alpha$  protein could be detected with several monoclon-

als, a finding suggesting that the mutant protein was degraded. CD8 $\beta$  surface expression is dependent on CD8 $\alpha$ , thus CD8 $\beta$  was also undetectable extracellularly, although it could be detected intracellularly.

### Strategies for Diagnosis

A definitive diagnosis of CD3 deficiency can be made in a male or female infant with a selective surface TCR/CD3 expression defect on mature peripheral blood T lymphocytes, or severe T lymphocytopenia, and mutations in CD3G, D, or E (or Z). CD8 deficiency is determined when either a male or female patient has an absolute surface CD8 expression defect on mature peripheral blood T and NK lymphocytes, high CD4 $^{-}$ CD8 $^{-}$  T cell numbers, and mutations in CD8A.

A probable diagnosis can be made in a male or female patient with selective T lymphocytopenia (T $^{-}$ B $^{+}$ NK $^{+}$  SCID) or selective surface TCR/CD3 or CD8 expression defect on mature peripheral blood T lymphocytes.

### Spectrum of Disease

Patients with CD3 or CD8 deficiency usually develop recurrent bacterial or viral respiratory infections as well as otitis. *Hemophilus influenzae* is frequently isolated. CD3-deficient SCID patients may develop fungal infections. The clinical course ranges from benign (CD3 $\gamma$ , partial CD3 $\epsilon$ , CD8 $\alpha$ ) to severe (CD3 $\delta$ , CD3 $\epsilon$ , CD3 $\gamma$ ), and asymptomatic siblings with CD3 $\gamma$  or CD8 deficiencies have been reported.

### Differential Diagnosis

CD3 and CD8 deficiencies need to be differentiated from deficiencies in (1) ZAP-70; (2) TAP; (3) MHC class I; (4) IL7R $\alpha$ ; (5) purine nucleoside phosphorylase (PNP); and (6) adenosine deaminase (ADA). CD3 $\gamma$  and CD8 deficiencies may be misdiagnosed as patients may be fairly healthy. Testing for percentage of CD3 cells may not be enough to detect mild CD3 deficiencies (Fig. 16.1B). Analysis of the mean fluorescence intensity is mandatory, as is use of a range of TCR/CD3-specific monoclonals. The expression defect is more severe in CD3 $\delta$  or CD3 $\epsilon$  than in CD3 $\gamma$  deficiency. Lymphopenia, when present, affects only T cells (defined as CD2 $^{+}$ CD16 $^{-}$ ), particularly CD45RA $^{+}$ , which are more thymus-dependent (Mackall et al., 1993). Biopsy specimens from lymphoid tissues should be thoroughly studied (Arnaiz-Villena et al., 1991; Dadi et al., 2003; de Saint-Basile et al., 2004a) and CD4 $^{+}$  and CD8 $^{+}$  T cells preserved (Perez-Aciego et al., 1991; Rodriguez-Gallego et al., 1996; Pacheco et al., 1998) and analyzed by immunoprecipitation (Alarcon et al., 1988; Perez-Aciego et al., 1991; Thoenes et al., 1992) and molecular biology techniques (Arnaiz-Villena et al., 1992; Soudais et al., 1993). In CD3 $\zeta$  deficiency, reversion of some T cell clones to normal expression was observed in vivo as a consequence of additional mutations in T cell precursors (de Saint-Basile et al., 2004b).

### Mode of Inheritance, Carrier detection, and Prenatal Diagnosis

CD3 and CD8 deficiencies are autosomal recessive disorders. Heterozygotes for CD3 deficiencies cannot be distinguished from normals by standard laboratory tests. Thus mutation analysis must be performed in each case, as explained above. In CD3 deficiencies, restriction fragment length polymorphism (RFLP)

analysis with *TaqI* and a *CD3E* probe (50% heterozygosity) or polymorphic markers may help to define *CD3GDE* haplotype inheritance for carrier detection and/or prenatal diagnosis, since recombinations within the *CD3* gene complex are rare. In contrast, carriers for CD8 deficiency can be determined by cytometry or ELISA, because the levels of membrane-bound and soluble CD8 have correlated strictly with the genotype of the family members (see Laboratory Findings, above). Similarly, both healthy parents of the Dutch patient with TCR/CD3 expression defect whose molecular basis is still undetermined showed half-normal CD3 expression levels (Fig. 16.1C).

### Treatment and Prognosis

The clinical manifestations and prognosis of CD3 and CD8 deficiencies are disparate even among siblings, ranging from early lethal SCID before 3 years of age (individuals VSF, P2, P3, II-1, II-2, III-1, I-2, I-3 in Table 16.1) to mild or no immunodeficiency and survival beyond 10 years of age (individuals PT, DSF, FK, EP in Table 16.1). Specific antibiotics were used in many cases, with clear clinical benefit. Lethality among CD3 deficiencies, however, may be high (8 of 13). Bone marrow transplantation was successfully performed in patient P1 with CD3 $\delta$  deficiency and in the Dutch patient (DS) with TCR/CD3 expression defect before 15 months of age. Haploidentical bone marrow grafts have frequently failed (patients PII-2, PIII-1, PI-2). Mild CD3 deficiencies have been treated with prophylactic intravenous immunoglobulin treatment (400 mg/kg/month) with (Deist et al., 1991) or without (van Tol et al., 1997) antibiotics. Bronchial asthma in patient FK was treated with ketotifen and cromolyn sodium between 3.5 and 7 years of age (Sanal et al., 1996). He has been using salbutamol sulphate and sodium chromoglycate intermittently since he was 7 to treat his nonatopic hyperreactive airway, and eformoterol with occasionally inhaled steroids for the last 7 months. A patient who had CD3 $\gamma$  deficiency with SCID (VSF) was treated with antibiotics but died, probably from a viral infection. The healthy Spanish CD3 $\gamma$  deficiency patient (DSF) was treated with antibiotics only when symptoms developed and received treatment for his dilated cardiomyopathy. The observation that most antibody responses were normal in vivo prompted a comprehensive vaccination program, excluding attenuated viruses, for this individual. No secondary effects were recorded. Thus, this approach may be helpful on a preventive basis for other mild CD3 deficiencies. Gene therapy protocols are being developed in vitro (Sun et al., 1997). However, transfer of CD3 $\gamma$  into mature T cells may disrupt their intrathymic fine-tuning (Pacheco-Castro et al., 2003). Lymphoid progenitors may be better targets in this case, although the selective advantage of transduced over untransduced T cells remains to be established.

### Animal Models

#### CD3 Deficiency

Single and multiple CD3 deficiencies have been created in mice through gene targeting of CD3 genes (reviewed by Malissen et al., 1999). Ablation of any CD3 protein essentially blocked T cell development, although at different intrathymic checkpoints and to a different extent. Indeed, all CD3 proteins, except CD3 $\delta$ , are required for T cell selection at the pre-TCR (TCR- $\beta$ ) checkpoint, with the following level of importance:  $\epsilon > \gamma > \zeta$ . Interestingly, CD3 $\delta$  is also dispensable for  $\gamma\delta$  T cell selection and for  $\gamma\delta$ TCR surface expression in mice (but not in humans; Dadi et al., 2003).

However, all CD3 chains, including CD3 $\delta$ , are required for T cell selection at the TCR $\alpha\beta$  checkpoint and for  $\alpha\beta$ TCR surface expression. The murine models of CD3 deficiency are similar to human CD3 deficiencies in some aspects ( $\epsilon > \gamma$  in  $\alpha\beta$ TCR expression, no peripheral T cells when CD3 $\delta$  is lacking), but not in others (peripheral blood T lymphocyte numbers are clearly higher in humans lacking  $\gamma$ ). However, comparisons between human and murine deficiencies must be made with caution, particularly when analyzing peripheral lymphocyte subsets. For instance, ZAP70- or CIITA-deficient humans show normal or significant numbers of peripheral CD4<sup>+</sup> T cells, respectively, and  $\gamma\epsilon$ - or JAK3-deficient humans have normal numbers of B cells, whereas their murine counterparts do not. This discrepancy could be explained if we consider that deficient humans, but not mice, available for analysis may constitute a small surviving subset of those produced and thus may show different phenotypes from those of mice grown in special germ-free facilities. Alternatively, peripheral lymphoid expansion mechanisms may differ between species. Also, comparing human venous blood with murine spleens or lymph nodes may be unsuitable: the spleen and lymph nodes of a human CD3 deficiency (individual VSF in Table 16.1) with normal venous blood lymphocyte counts were severely depleted, as observed in all murine CD3 deficiencies (see Clinical and Pathological Manifestations, above). CD3 gene inactivation in mice, even when kept in pathogen-free facilities, may cause pathological manifestations (enteropathy in CD3 $\zeta/\eta$ - or CD3 $\delta$ -deficient mice) that resemble those observed in some humans (CD3 $\gamma$  or  $\delta$  deficiency).

#### CD8 Deficiency

CD8 ( $\alpha$  or  $\beta$ ) knockout mice showed a severe reduction in MHC class I-restricted CTL development and function (Fung-Leung et al., 1991), but infections were mainly bacterial, with little incidence in survival. The CD8 glycoprotein plays an important role in the maturation and function of MHC class I-restricted T lymphocytes, but its presence does not appear to be essential for either CD8 lineage commitment or peripheral cytolytic function. It has been reported that TCR transgenic thymocytes from CD8 $\alpha$ -deficient mice were able to restore positive selection of CD8 lineage cells (as shown by CD8 $\beta$  expression) in the absence of surface CD8, thereby compensating for the lack of CD8 expression by increasing the affinity of TCR for the positively selecting ligand (Goldrath and Hogquist, 1997). It is therefore possible that in humans the DN cells are in fact MHC class I-restricted, high-affinity T cells with cytolytic functions.

### Concluding Remarks

Immature T lymphocytes cannot predict the isotype ( $\alpha\beta$  or  $\gamma\delta$  and surrogates thereof) or the specificity (MHC class I, MHC class II, CD1) of the particular TCR they will be endowed with. They may thus carry a range of adaptor CD3 chains capable of both supporting and signaling for different TCR ensembles in different phenotypic backgrounds. Indeed, the clear structural differences between the constant domains of  $\alpha\beta$  and  $\gamma\delta$  TCR involved in interactions with CD3 and other cell surface molecules strongly suggest that they may build different signaling complexes (Allison et al., 2001). Recently it has been shown that the  $\gamma\delta$  TCR does not contain CD3 $\delta$  but rather a differentially glycosylated form of CD3 $\gamma$  upon T cell activation (Hayes et al., 2002). In addition,  $\alpha\beta$  T lymphocytes carry appropriate coreceptors (CD4 and CD8) to increase the likelihood of being rescued in the event that their

TCR has low affinity for MHC class II or class I, respectively. CD3 and CD8 chains are thus first expressed and used by T cells early during their intrathymic development. Accordingly, CD3 and CD8 deficiencies strongly influence early T cell differentiation events in both humans and mice. However, available data from some human deficiencies (CD3 $\gamma$  and partial CD3 $\epsilon$ ) indicate that significant or normal numbers of T lymphocytes can populate the peripheral blood compartment despite their low TCR/CD3 surface levels or lack of CD8 expression, respectively (probably after a strong post-thymic expansion of selected, but polyclonal, cells). T cell clones that fulfil the functional requirements for intrathymic survival may display aberrant phenotypes in the periphery (abnormal TCR/CD3 complexes, DN cells), but when tested they have been shown to be functional *in vivo* and *in vitro*. The adaptative value of the CD3 (particularly  $\delta$  and  $\epsilon$ ) is nevertheless dramatically illustrated in SCID patients, whose survival is reduced without treatment. The healthy deficient siblings in CD3 $\gamma$  and CD8 $\alpha$  deficiencies reflect the high redundancy of the immune system, or perhaps the existence of undefined modifying genes in these individuals (Foster et al., 1998). Further functional studies in peripheral blood T cells in these cases should clarify the specific extracellular and intracellular structural and signaling roles of the absent proteins at the last developmental checkpoint along T cell differentiation—namely, antigen recognition.

### Note Added in Proof

Additional complete CD3 $\delta$ - and CD3 $\gamma$ -deficient patients with SCID symptoms have been characterized recently (Takada et al., *Eur J. Pediatr* 164: 311–314, 2005, and Recio et al., unpublished). Also the G111S mutation in the *CD8A* gene has been shown recently to generate an ectopic glycosylation site, which may cause the lack of surface CD8 protein (Vogt et al. *Nat Genet* 37:692–700, 2005).

### Acknowledgments

Antonio Arnaiz-Villena and Luis M. Allende (Hospital 12 de Octubre, Madrid), Oscar de la Calle-Martin (Hospital Sant Pau, Barcelona), and Manuel Hernandez (Hospital Vall d'Hebron, Barcelona) are joint coauthors of this work.

The following grants supported the work reviewed here: BFU2005-1738 (Dirección General de Investigación Científica), 8.3/21/01 and 570/04 (Comunidad Autónoma de Madrid), and BMC2002-3247 (Ministerio de Ciencia y Tecnología) to J.R.R. We thank Ozden Sanal (Hacettepe University Children's Hospital, Ankara, Turkey), Maarten J.M. van Tol (Leiden University Medical Center, The Netherlands), Alain Fischer (Hôpital Necker Enfants-Malades, Paris, France), Rik A. Brooimans (Wilhelmina Children's Hospital, University Medical Center Utrecht, The Netherlands), and Jesús Ruiz-Contreras and Julián Clemente (Hospital 12 de Octubre, Madrid) for patient updates and for sharing unpublished data, and Ramón Rodríguez, Juan G. Cabanillas, and A. Pacheco-Castro (Universidad Complutense, Madrid) for help with the figures.

# Molecular Basis of Major Histocompatibility Complex Class II Deficiency

WALTER REITH, BARBARA LISOWSKA-GROSPIERRE, and ALAIN FISCHER

Major histocompatibility complex class II (MHCII) molecules, also called human leukocyte antigens (HLA) in humans, are heterodimeric transmembrane glycoproteins consisting of  $\alpha$  and  $\beta$  chains. The different human MHCII isotypes (HLA-DR, HLA-DQ, and HLA-DP) are encoded by distinct  $\alpha$  chain and  $\beta$  chain genes that are clustered in the D region of the MHC on the short arm of chromosome 6. MHCII molecules play a pivotal role in the control of the immune system: they present exogenous peptide antigens to CD4<sup>+</sup> T lymphocytes, thereby leading to the antigen-specific T helper cell activation required for the initiation and propagation of adaptive immune responses. Given this essential function, it is not surprising that defects in the expression of MHCII molecules have profound immunopathological consequences.

Patients suffering from a rare primary immunodeficiency syndrome caused by the absence of MHCII expression were first identified in the late 1970s and early 1980s (Touraine et al., 1978; Schuurmann et al., 1979; Griscelli et al., 1980; Kuis et al., 1981; Touraine, 1981; Lisowska-Groszpiere et al., 1983; Hadam et al., 1984, 1986). The lack of MHCII expression results in a severe defect in both cellular and humoral immune responses to foreign antigens and is consequently characterized by an extreme susceptibility to viral, bacterial, fungal, and protozoal infections, primarily of the respiratory and gastrointestinal tracts (reviewed in Griscelli et al., 1993; Klein et al., 1993; Elhasid and Etzioni, 1996). Severe malabsorption with failure to thrive ensues, often leading to death in early childhood.

The disease was formally named *major histocompatibility complex class II deficiency* (MHCII deficiency) (Rosen et al., 1992) and has been assigned the MIM (Mendelian Inheritance in Man) number 209920. It is also frequently referred to as the bare lymphocyte syndrome (BLS). However, the term *BLS* was first

used to describe a defect in MHC class I (MHCI) expression in patients in which MHCII expression was not examined (Touraine et al., 1978), and it has been used synonymously for all defects involving expression of MHCI (BLS type I), MHCII (BLS type II), or both (BLS type III) (Touraine et al., 1992). Here we will discuss only the immunodeficiency syndrome associated with a constant and profound defect in MHCII expression, and we will thus use the term *MHCII deficiency*.

The disease is rare; fewer than 100 unrelated patients have been reported worldwide. The majority of patients are of North African origin (Algeria, Tunisia, Morocco) (Griscelli et al., 1993; Klein et al., 1993; Lisowska-Groszpiere et al., 1994). The remaining patients are of diverse ethnic backgrounds that include Spain, Italy, Turkey, France, Holland, the United States, Israel, Saudia Arabia, and Pakistan (Kuis et al., 1981; Haas and Stiehm, 1987; Clement et al., 1988; Hume et al., 1989; Casper et al., 1990; Hadam et al., 1984, 1986; Lisowska-Groszpiere et al., 1994; Peijnenburg et al., 1995). As expected for a rare disease, there is a high incidence of consanguinity in the affected families (Lisowska-Groszpiere et al., 1994).

MHCII deficiency has an autosomal recessive mode of inheritance. A comparison between the pattern of inheritance of the disease and the MHC genotype in affected families has demonstrated that the genetic lesions responsible for the MHCII-deficient phenotype lie outside of the MHC (de Preval et al., 1985; Griscelli et al., 1993). This finding suggested that the disease is due to defects in *trans*-acting regulatory factors required for expression of MHCII genes. Elucidation of the molecular defects responsible for MHCII deficiency has confirmed this. The affected genes are now indeed known to encode regulatory factors controlling transcription of MHCII genes. Four regulatory genes—*MHC2TA* (MIM number 600005), *RFXANK* (MIM number 603200), *RFX5*

(MIM number 601863), and *RFXAP* (MIM number 601861)—have been isolated and shown to be mutated in MHCII deficiency patients (reviewed in Masternak et al., 2000a; Reith and Mach, 2001).

### Clinical and Pathological Manifestations

Comprehensive accounts of the clinical and pathological manifestations associated with MHCII deficiency have been published previously (Griscelli et al., 1993; Klein et al., 1993; Elhasid and Etzioni, 1996). The major findings are summarized in Table 17.1. Clinical manifestations include primarily septicemia and recurrent infections of the gastrointestinal, pulmonary, upper respiratory, and urinary tracts. The patients are prone to bacterial, fungal, viral, and protozoal infections. Although the most frequently isolated bacteria were *Pseudomonas* and *Salmonella*, and the most frequent virus was cytomegalovirus (CMV), the type of infecting agent is by no means pathognomonic. Infections start within the first year of life; the mean age at first infection is 4.1 months. Subsequent evolution of the disease is characterized by an inexorable progression of the infectious complications until death ensues. Few children reach puberty; the majority die between the age of 6 months and 5 years. All of the pathological manifestations of MHCII deficiency are related to the infectious complications, and with the exception of the absence of MHCII expression there are no features that are specific for this particular immunodeficiency.

Bacterial infections in various locations are dominant. These include intestinal infections, pneumonitis, bronchitis, and septicemia. The most frequently isolated bacteria include *Pseudomonas*, *Salmonella*, *E. coli*, *Streptococcus*, and *Staphylococcus*. *Haemophilus* and *Proteus* species have also been isolated. In almost all patients, bacterial infections of the intestinal tract, together with *Candida albicans*, *Giardia lamblia*, and *Cryptosporidium* infection, are responsible for protracted diarrhea, malabsorption, and failure to thrive. Intestinal and hepatic involvement due to *Cryptosporidium* colonization appears to be more frequent in MHCII deficiency than it is in other immunodeficiencies. Protracted diarrhea is the most common gastrointestinal manifestation. Histological examinations of the intestinal

mucosa typically reveal a variable degree of villous atrophy. There is also frequently an intraepithelial infiltration by lymphocytes, macrophages, and some plasma cells, and a severe colitis.

Hepatic involvement is frequent, but the manifestations are not uniform. Many patients exhibit either symptoms suggestive of viral hepatitis, or hepatic involvement resulting from cholangitis, parenteral nutrition, and the use of hepatotoxic drugs. The most frequent cause of hepatitis is infection with CMV. Pseudosclerosing cholangitis is a frequent complication of chronic *Cryptosporidium* infection, and bacterial cholangitis due to *Pseudomonas*, *Enterococcus*, and *Streptococcus* infections have been diagnosed in a number of patients.

Recurrent bronchopulmonary infections have been observed in all patients. Many had one or more episodes of pneumonia. The infectious agents identified include viruses (CMV, respiratory syncytial virus, enterovirus), bacteria (*Streptococcus*, *Haemophilus*, *Staphylococcus*, *Pseudomonas*, *Proteus*), *Pneumocystis carinii*, and *Candida albicans*.

Neurological manifestations due to viral infections have been diagnosed in a number of patients. These include poliomyelitis, meningoencephalitis, and chronic lymphocytic meningitis caused by enterovirus, herpes simplex virus, or poliovirus vaccination. Coxsackie virus, adenovirus, and poliovirus were frequently responsible for meningoencephalitis. Two patients developed poliomyelitis despite previous vaccination with inactivated virus. Another patient died of postvaccinal poliomyelitis with encephalitis after vaccination with live attenuated virus.

Hematologic manifestations are characterized by neutropenia and severe autoimmune cytopenia.

The clinical features vary considerably from one patient to another. This variability does not show any correlation with the genetic heterogeneity in the cause of the disease (see below). Interestingly, several patients having an atypical clinical course have been identified (Hauber et al., 1995; Wolf et al., 1995; Wiszniewski et al., 2001; B. Lisowska-Groszpierska, unpublished data). Although these patients have classical MHCII deficiency, the clinical manifestations they suffer from are less severe or even absent, and their survival is considerably longer. Several patients over 20 years of age have been identified. The unusual capacity of these patients to cope with infections depends on genetic, immunological, and/or environmental differences that remain largely unknown.

**Table 17.1.** Clinical Manifestations

Manifestation	Patients	
	n	%
Repeated severe infections	63	(100)
Protracted diarrhea	54	(86)
Lower respiratory tract infections	54	(86)
Failure to thrive	46	(73)
Severe viral infections	40	(63)
Upper respiratory infections	35	(56)
Mucocutaneous candidiasis	19	(30)
Progressive liver disease	11	(17)
Cryptosporidiosis	11	(17)
Autoimmune cytopenia	4	(6)
Sclerosing cholangitis	6	(10)

Mean age at first infection is 4.1 months (range, 6 weeks to 12 months). Included are 43 patients from Hospital Necker-Enfants Malades, 1 patient from Hospital Robert Debré (Pickard et al., unpublished), 9 Tunisian patients (Bejaoui et al., 1998), and 10 patients reported by Saleem et al. (2000). Not included are four patients with an atypical clinical presentation in two unrelated families belonging to complementation group A (Quan et al., 1999; Wiszniewski et al., 2001).

### Laboratory Findings—Immunological Features

The immunological manifestations characteristic of MHCII deficiency (reviewed in Griscelli et al., 1993; Klein et al., 1993) are summarized in Table 17.2. All of the immunological manifestations can be accounted for by the absence of antigen presentation via MHCII molecules. The most striking and constant consequence of the defect in MHCII expression is, as expected, the absence of cellular and humoral immune responses to foreign antigens. All patients are unable to mount T cell-mediated immune responses to specific antigens, as assessed by delayed-type hypersensitivity skin tests. This correlates with an absence of T cell responses in vitro in the presence of antigens with which the patients had been immunized or sensitized to by infections. Also consistent with the absence of MHCII expression is the finding that lymphocytes from patients have a decreased capacity to stimulate HLA-nonidentical lymphocytes in the mixed lymphocyte reaction.

**Table 17.2.** Summary of Immunological Findings\*

<i>Factor Measured</i>	<i>Findings</i>	<i>Patients<sup>†</sup></i>
<i>HLA Class II Expression<sup>‡</sup></i>		
B cells	Absent (0%)	43/45
Monocytes	Residual (0–17%)**	6/37
PHA-activated T cells	Absent (0%)	32/37
	Residual (0–32%)**	5/37
<i>HLA Class I Expression<sup>‡</sup></i>		
Mononuclear cells	Reduced	29/37
<i>CD4<sup>+</sup> Lymphopenia</i>		34/39
<i>Lymphocyte Proliferative Response to</i>		
PHA	Normal	37/39
Antigen	Decreased	2/39
<i>Serum Immunoglobulins</i>		
IgG	Normal	6/30
	Decreased	24/30
IgM	Normal	9/40
	Decreased	28/40
IgA	Increased	3/40
	Normal	8/40
	Decreased	31/40
	Increased	3/40
<i>Antibody Production Response to:</i>		
Immunizations	Normal	1/20
	Decreased	2/20
	Negative	17/20
Microbial antigens	Decreased	5/27
	Negative	22/27

\*Data are from 44 patients treated at Hospital Necker-Enfants Malades and 1 patient from Hospital Robert Debré, between 1977 and 2001 (Pickard et al., unpublished data).

<sup>†</sup>Results for all parameters are not available for all 45 patients. Only results for the number of patients tested are provided.

<sup>‡</sup>Tested by fluorescence-activated cell sorting (FACS) or microscopy.

\*\*Numbers in parentheses indicate the percentage of “dull” stained cells.

Humoral immunity is severely impaired. Most patients are panhypogammaglobulinemic, almost agammaglobulinemic, or have a decrease in one or two immunoglobulin isotypes. Antibody responses to immunizations and infections by microbial agents are generally absent or strongly reduced. Interestingly, autoantibodies associated with autoimmune disorders have been found in several patients.

Patients have normal numbers of circulating T and B lymphocytes. In most patients, however, CD4<sup>+</sup> T cell counts are reduced, whereas CD8<sup>+</sup> T cell counts are proportionally increased. This reflects abnormal selection and maturation of CD4<sup>+</sup> T cells resulting from a lack of MHCII expression in the thymus. Surprisingly, however, the remaining CD4<sup>+</sup> T cell population appears to be phenotypically and functionally normal. The patient's CD4<sup>+</sup> T cells exhibit only relatively minor differences with respect to the normal TCR repertoire (Rieux Laucat et al., 1993; Henwood et al., 1996) and behave normally in terms of alloreactivity and proliferative responses to mitogens (Griscelli et al., 1993; Klein et al., 1993).

The immunological features summarized above vary considerably from one patient to another. It is remarkable, however, that this variability does not show any correlation with the genetic heterogeneity in the cause of the disease (see below).

## Molecular Basis

### Abnormal Expression of MHCII Molecules

The hallmark of MHCII deficiency is the absence of MHCII molecules on the surface of all cells that normally express them, and the demonstration of this lack of expression remains the mainstay of diagnosis. In normal individuals, two modes of MHCII expression, constitutive and inducible, are observed (reviewed in Glimcher and Kara, 1992; Guardiola and Maffei, 1993; Mach et al., 1996). Constitutive expression is largely restricted to professional antigen-presenting cells (B lymphocytes, cells of the monocyte/macrophage lineage, and dendritic cells) and epithelial cells in the thymus. Inducible expression, by contrast, can be observed in virtually all cell types in response to a variety of stimuli, of which the most potent and well known is interferon- $\gamma$  (IFN- $\gamma$ ). In MHCII-deficient patients, both the constitutive and inducible expression modes are abolished (reviewed in Griscelli et al., 1993; Klein et al., 1993). The absence of MHCII molecules concerns all professional antigen-presenting cells including B lymphocytes, cells of the macrophage/monocyte lineage such as Kupffer cells, and dendritic cells such as skin Langerhans cells. Activated T cells also remain MHCII negative. In addition, cells not derived from the bone marrow, such as thymic epithelial cells and endothelial and epithelial cells of the intestinal or bronchial mucosa, also lack MHCII molecules. Expression of MHCII cannot be restored in any cell type by IFN- $\gamma$ .

The inability of patients' cells to express MHCII molecules constitutively or in response to IFN- $\gamma$  has been demonstrated in vitro using peripheral blood lymphocytes (PBL), Epstein-Barr virus (EBV)-transformed B cell lines, interleukin-2 (IL-2)-dependent T cell lines, and primary or transformed fibroblasts derived from MHCII deficiency patients (de Preval et al., 1985, 1988; Lisowska-Grospierre et al., 1985; Griscelli et al., 1993; Klein et al., 1993). Studies on EBV-transformed B cell lines from patients indicated that expression of MHCII genes could not be detected at levels of the cell surface, intracellular protein, or mRNA (de Preval et al., 1985; Lisowska-Grospierre et al., 1985). In fibroblasts, the expression of MHCII genes cannot be induced by IFN- $\gamma$  (de Preval et al., 1988). The lack of constitutive and inducible expression concerns all MHCII genes (encoding the DR, DP, and DQ  $\alpha$  and  $\beta$  chains) (de Preval et al., 1985, 1988; Lisowska-Grospierre et al., 1985). In addition, there is a defect in expression of the invariant chain (*Ii*) gene (*CD74*) and the *HLA-DM* genes, which encode proteins required for antigen presentation by MHCII molecules (Cresswell, 1996; Alfonso and Karlsson, 2000); the *HLA-DMA* and *HLA-DMB* genes are silent and expression of the *Ii* gene is reduced (Nocera et al., 1993; Kern et al., 1995).

Although a complete absence of MHCII molecules is the general rule, certain patients appear to have a “leaky” phenotype (Griscelli et al., 1993; Klein et al., 1993). Low residual levels of MHCII expression have been observed in several patients on various cell types, including B cells, monocytes, activated T cells, Langerhans cells, intestinal endothelial cells, and thymic stromal and dendritic cells (Schuurman et al., 1985; Hadam et al., 1986; Klein et al., 1993). Very low levels of expression of certain MHCII genes have also been observed in EBV-transformed B cell lines and IFN- $\gamma$ -treated fibroblasts derived from several patients (Griscelli et al., 1993; Klein et al., 1993; Peijnenburg et al., 1995).

In addition to the profound defect in MHCII expression, a reduction in cell surface expression of MHCI and  $\beta$ 2 microglobulin

is observed on fresh PBL, cultured fibroblasts, SV40-transformed fibroblasts, and EBV-transformed B cell lines from MHCII deficiency patients (Touraine et al., 1978; Schuurmann et al., 1979; Griscelli et al., 1980; Hadam et al., 1984, 1986; Sabatier et al., 1996). A reduction in MHCI expression is observed to a variable degree in over 75% of the patients (Table 17.2) (Klein et al., 1993).

MHCII Deficiency Is Due to Regulatory Defects in MHCII Gene Transcription

Direct measurements of the transcriptional activity of MHCII genes have demonstrated that the lack of expression in patients is due to a deficiency in transcription (Reith et al., 1988). This finding suggested that the disease is due to defects in regulatory factors controlling transcriptional activation of MHCII genes. Direct evidence for this interpretation was provided by four independent observations. First, family studies demonstrated that the genetic lesions responsible for the disease do not cosegregate with the MHC (de Preval et al., 1985; Griscelli et al., 1993). Second, reporter genes fused to the DNA sequences controlling transcription of MHCII genes (see below) remain silent upon transfection into cells from patients (Hasegawa et al., 1993; Riley and Boss, 1993). Third, nuclear extracts from patients' cells are unable to activate transcription from MHCII promoters in in vitro transcription experiments (Durand et al., 1994). Finally, expression of endogenous MHCII genes of patients' cells can be reactivated in somatic cell fusion experiments (see below).

Genetic Heterogeneity in MHCII Deficiency

It is now clear that defects in several distinct MHCII regulatory factors can give rise to MHCII deficiency. This genetic heterogeneity was first demonstrated by means of somatic cell fusion

experiments performed with cell lines derived from different patients (Hume and Lee, 1989; Benichou and Strominger, 1991; Seidl et al., 1992; Lisowska-Grospierre et al., 1994). Several experimentally generated cell lines (Gladstone and Pious, 1978; Accolla, 1983; Calman and Peterlin, 1987) exhibiting an MHCII-negative phenotype indistinguishable from the patients' cell lines were also included in these studies. The results of these experiments indicate that the patients and experimentally derived cell lines can be assigned to four different complementation groups (Table 17.3, groups A to D), reflecting the existence of mutations in four distinct MHCII regulatory genes. Most patients (27 unrelated families) fall into complementation group B (reviewed in Masternak et al., 2000a). Group A contains patients from five different families (reviewed in Masternak et al., 2000a) as well as three experimentally derived mutants, most well-known one being RJ2.2.5 (Accolla, 1983). Group C contains patients from six families (reviewed in Masternak et al., 2000a). Group D was first defined by cell fusion experiments with the experimentally generated cell line 6.1.6 (Gladstone and Pious, 1978). Subsequent cell fusion experiments and isolation of the gene affected in 6.1.6 permitted the classification of patients from six unrelated families in this group (reviewed in Masternak et al., 2000a).

The spectrum of clinical manifestations and immunopathologies associated with the disease encompasses all four complementation groups (Klein et al., 1993; Griscelli et al., 1993). No distinctive phenotype restricted to one of these complementation groups has been identified. Despite the genetic heterogeneity in the cause of MHCII deficiency, the syndrome is therefore clinically homogeneous.

Atypical Form of MHCII Deficiency

Twin brothers (Ken and Ker) exhibiting an atypical and less severe form of MHCII deficiency have been described (Hauber

**Table 17.3.** Phenotypical, Biochemical, and Molecular Defects of MHCII Deficiency Patients and Regulatory Mutants from Complementation Groups A to D

		MHCII Deficiency Complementation Groups*

\*A–D, nomenclature for complementation groups used in Bénichou and Strominger (1991) and Lisowska-Grospierre et al. (1994); I–IV, alternative nomenclature used in Seidl et al. (1992).  
<sup>†</sup>Numbers are based on somatic cell fusion experiments and/or mutation analysis of the affected genes.  
<sup>‡</sup>Tested on at least one cell line in each complementation group.  
\*\*Also called RFX-B in Nagarajan et al. (1999).

et al., 1995; Wolf et al., 1995; Douhan et al., 1996). In contrast to the situation observed in the “classical” form of MHCII deficiency, defective expression in these patients does not concern all MHCII genes equally and does not affect all cell types to the same extent. In EBV-transformed B cells from these patients, the *HLA-DRB*, *HLA-DQB*, and *HLA-DPA* genes are silent whereas the *HLA-DRA*, *HLA-DQA*, and *HLA-DPB* genes are expressed. In mononuclear cells, by contrast, there is a significant level of *HLA-DRB*, *HLA-DQB*, and *HLA-DPA* gene expression. Moreover, impairment of the immune response is much less evident than in classical MHCII deficiency. In fact, investigations of MHCII-dependent immune functions in these patients indicate the presence of competent MHCII-positive antigen-presenting cells (Hauber et al., 1995; Wolf et al., 1995). Characterization of the genetic defect in these patients has demonstrated that they do not represent a fifth complementation group, as was initially believed. They belong in fact to complementation group C (Nekrep et al., 2002).

### Biochemical Heterogeneity in MHCII Deficiency

MHCII expression is regulated primarily at the level of transcription by a short DNA segment situated immediately upstream of the transcription initiation site of each MHCII gene (reviewed in Benoist and Mathis, 1990; Mach et al., 1996). This promoter proximal region contains four *cis*-acting DNA elements—called the S, X, X2, and Y boxes—that are highly conserved in their sequence and in their organization with respect to orientation, order, and spacing relative to each other (Fig. 17.1A). This conservation is apparent not only in all MHCII genes from all species that have been examined but also in the invariant chain and *DM* genes. Finally, a similar region is also found in the promoters of the MHC I and  $\beta 2$  microglobulin ( $\beta 2m$ ) genes (van den Elsen et al., 1998).

In the hope of elucidating the molecular mechanisms controlling transcription of MHCII genes and identifying the regulatory genes that are mutated in MHCII deficiency, numerous studies were performed to identify and isolate DNA binding proteins that interact specifically with MHCII promoters (reviewed in Mach et al., 1996). These studies led to the identification of several key transcription factors, particularly the X box binding complex called *RFX* (regulatory factor X) (Reith et al., 1988).

*RFX* is a protein complex that was first identified in nuclear extracts from MHCII-positive B cell lines on the basis of its ability to bind in vitro to the X box of MHCII promoters (Reith et al., 1988). It has been purified to near homogeneity by affinity chromatography and shown to be a heteromeric protein consisting of three subunits of 75 kDa, 36 kDa, and 33 kDa (Durand et al., 1994; Masternak et al., 1998). The DNA-binding activity of this *RFX* complex has been analyzed extensively by in vitro studies using nuclear extracts prepared from MHCII deficiency cell lines and from the experimentally generated regulatory mutants (Reith et al., 1988; Stimac et al., 1991; Herrero-Sanchez et al., 1992; Hasegawa et al., 1993; Durand et al., 1994). Based on the presence or absence of *RFX* binding activity, two types of mutant cells were recognized (Table 17.3, Fig. 17.1); *RFX* binding activity is normal in cell lines classified in complementation group A but is deficient in cell lines assigned to complementation groups B, C, and D (reviewed in Mach et al., 1996). The lack of *RFX* binding activity in cells from complementation groups B–D

**Figure 17.1.** Molecular defects in MHCII deficiency. MHCII promoter occupancy and transcription status in normal B cells (A) and in B cells from complementation groups A to D (B–E). Open boxes represent the S, X, X2, and Y sequences. RFX, X2BP, and NF-Y bind to the X, X2, and Y boxes to form a nucleoprotein complex called the *MHCII enhancosome*. Proteins binding to the S box remain poorly characterized. The MHCII enhancosome forms a “landing pad” for CIITA. Cooperative protein–protein interactions between RFX, X2BP, and NF-Y are indicated by double-headed arrows. Arrowheads represent DNaseI hypersensitive sites. *MHC2TA* is mutated in complementation group A. Mutations in *MHC2TA* do not modify promoter occupation in vivo. In complementation groups B, C, and D, the 75 kDa (RFX5), 33 kDa (RFXANK), and 36 kDa (RFXAP) subunits of RFX are mutated. A deficiency in RFX leads to a bare promoter in vivo.

is specific since other known MHCII promoter binding proteins are detected normally in these cells (Reith et al., 1988; Stimac et al., 1991; Herrero-Sanchez et al., 1992; Hasegawa et al., 1993). The absence of *RFX* is functionally relevant because MHCII promoter activity can be restored to normal levels in in vitro transcription experiments when transcriptionally silent extracts from cells in groups B and C are supplemented with purified *RFX* (Durand et al., 1994).

Examination of DNase I hypersensitive sites (Gonczy et al., 1989) and in vivo footprint experiments (Kara and Glimcher,

1991, 1993) have revealed that the lack of RFX binding activity observed in vitro correlates with a bare promoter in vivo (Table 17.3, Fig. 17.1), (reviewed in Mach et al., 1996). In RFX-positive cells (normal MHCII-positive B cells as well as B cells from complementation group A), MHCII promoters exhibit characteristic DNaseI hypersensitive sites and are occupied by DNA-binding proteins in vivo. In RFX-deficient B cells (complementation groups B–D), on the other hand, the DNaseI hypersensitive sites are missing and all of the MHCII promoter elements, including the X, X2, and Y boxes, are unoccupied.

### The Gene Affected in Complementation Group A

A genetic approach based on cDNA expression cloning was developed to identify the genes affected in MHCII deficiency (Steimle et al., 1993). This approach is based on functional complementation of the genetic defects. Briefly, cell lines established from patients, or experimentally generated cell lines, were transfected with cDNA expression libraries and cells carrying cDNA clones capable of restoring MHCII expression were selected for. This approach was first successful in the case of RJ2.2.5 (Accolla, 1983), an experimentally generated cell line from complementation group A. Complementation of RJ2.2.5 led to isolation of the MHCII transactivator CIITA, a novel 1130–amino acid protein (Steimle et al., 1993).

Transfection with the CIITA cDNA restores expression of all MHCII isotypes (DR, DQ, DP) to wild-type levels in cell lines from complementation group A (Steimle et al., 1993). It also restores normal expression of the *Ii* (CD74), *HLA-DMA*, and *HLA-DMB* genes in these cells (Chang and Flavell, 1995; Kern et al., 1995).

The human *MHC2TA* gene is localized on chromosome 16 (16p13), and the corresponding mouse gene is situated in a syntenic region of mouse chromosome 16. This localization is in accordance with the findings that regulatory genes present on human and mouse chromosomes 16 are required for expression of MHCII genes (Accolla et al., 1986; Bono et al., 1991).

### The Gene Affected in Complementation Group B

The gene affected in complementation group B, which contains the largest number of patients (Table 17.3), was isolated by a biochemical approach based on purification of the RFX complex. It was baptized *RFXANK* (Masternak et al., 1998) because it contains four ankyrin repeats. Ankyrin repeats constitute a well-known protein–protein interaction motif. The same gene was subsequently also called *RFX-B* (Nagarajan et al., 1999). *RFXANK* encodes the 33 kDa subunit of the RFX complex (Fig. 17.1). Transfection of the *RFXANK* cDNA restores RFX binding activity and thus reactivates expression of all MHCII isotypes (DR, DQ, DP) in cell lines from patients in complementation group B (Masternak et al., 1998; Nagarajan et al., 1999). The chromosomal localization of *RFXANK* is 19p12.

### The Gene Affected in Complementation Group C

The same complementation approach used to isolate CIITA was successful in elucidating the molecular defect leading to a lack of RFX binding activity in patients from complementation group C. Complementation of a cell line derived from patient SJO

(Casper et al., 1990) led to the isolation of a cDNA encoding the 75 kDa subunit of RFX (Fig. 17.1) (Steimle et al., 1995). The gene was called *RFX5* because it encoded the fifth member of a family of X box binding proteins sharing a highly characteristic DNA binding domain (DBD) (Steimle et al., 1995; Emery et al., 1996). This RFX DBD has been strongly conserved in evolution and has been identified in a variety of different proteins having diverse regulatory functions in organisms ranging from yeast to humans (Emery et al., 1996). The structure of the DBD of one member of the RFX family (RFX1) has been determined and shown to belong to the winged helix subfamily of the helix–turn–helix (HTH) proteins (Gajiwala et al., 2000). Surprisingly, the RFX1 DBD binds DNA in a fashion that is radically different from that observed for all other known HTH proteins (Gajiwala et al., 2000). The amino acids implicated in site-specific binding of the RFX1 DBD are strongly conserved in RFX5, implying that the latter interacts with its X box target site in a similar fashion (Gajiwala et al., 2000).

Transfection of the *RFX5* cDNA restores RFX binding activity and thus reactivates expression of all MHCII isotypes (DR, DQ, DP) in cell lines from patients in complementation group C (Steimle et al., 1995). It also restores expression of the *Ii* (CD74), *HLA-DMA*, and *HLA-DMB* genes in these cells (Kern et al., 1995).

The human *RFX5* gene is situated in a subcentromeric region of the long arm of chromosome 1 (Villard et al., 1997b). The corresponding mouse gene maps to a syntenic region of chromosome 3.

### The Gene Affected in Complementation Group D

The experimentally generated cell line 6.1.6 (Gladstone and Pious, 1978) was initially the only representative of complementation group D (Hume and Lee, 1989; Benichou and Strominger, 1991; Seidl et al., 1992; Lisowska-Grospierre et al., 1994). The gene affected in 6.1.6 was isolated and shown to encode a novel protein corresponding to the 36 kDa subunit of the RFX complex (Fig. 17.1) (Durand et al., 1997). This protein was called RFX-associated protein (RFXAP) because it is a subunit of the RFX complex but does not contain the DBD characteristic of the RFX family of DNA binding proteins (Durand et al., 1997). Transfection of the *RFXAP* cDNA restores RFX binding activity and thus reactivates expression of all MHCII isotypes (DR, DQ, DP) in the 6.1.6 cell line.

Isolation of the *RFXAP* gene permitted the identification of MHCII deficiency patients belonging to complementation group D. Transfection of the *RFXAP* cDNA was found to complement cell lines derived from several patients (Durand et al., 1997; Villard et al., 1997a). The *RFXAP* gene is localized on the long arm of chromosome 13 (Villard et al., 1997a).

### The Molecular Defect in Atypical Patients

Surprisingly, the gene affected in the atypical twins has recently been shown to be *RFX5*, thereby placing these patients in complementation group C (Nekrep et al., 2002). The defect is a point mutation changing a critical DNA contact residue within the DBD of *RFX5*. The unusual pattern of residual MHCII expression and atypical phenotype of these patients are probably a result of the mutation not compromising binding of RFX to all MHCII promoters to the same extent (Nekrep et al., 2002).

## Function of the Affected MHCII Regulatory Factors

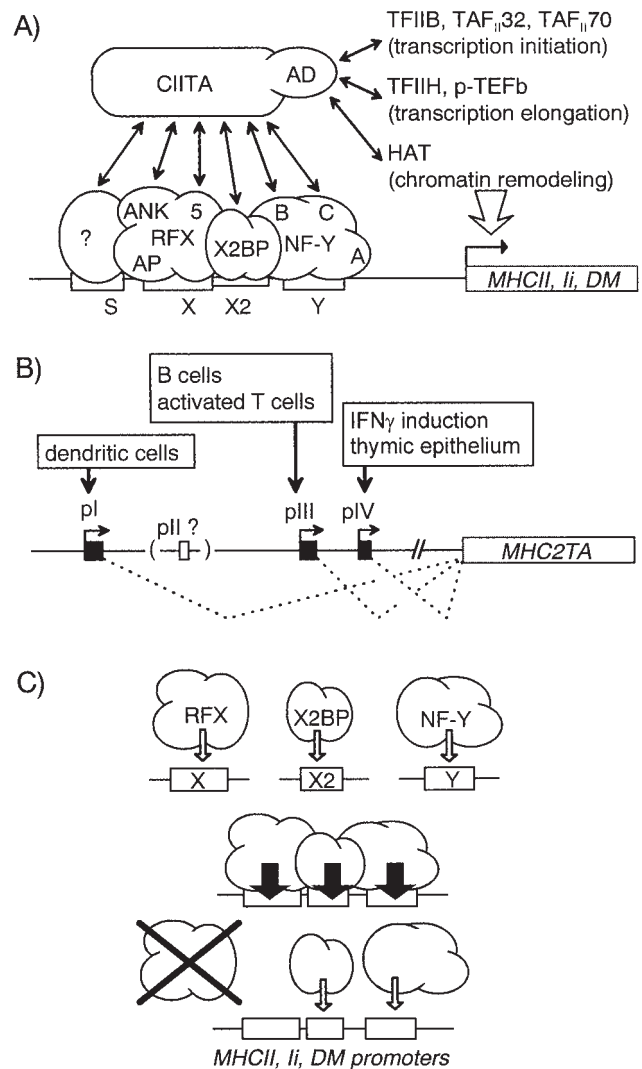

### Structure and Mode of Action of CIITA

The primary sequence of CIITA exhibits four major features of interest (see Fig. 17.3A) (reviewed in Harton and Ting, 2000; Reith and Mach, 2001; Ting and Trowsdale, 2002). First, the N terminus of the protein contains a region rich in acidic amino acids. Second, downstream of this acidic region lie three segments rich in proline, serine, and threonine. Third, there is a centrally placed GTP binding domain that contains three characteristic sequences, a motif involved in nucleotide binding, a magnesium binding site, and a sequence believed to confer GTP binding specificity. Finally, there is a leucine-rich repeat (LRR)-based protein-protein interaction motif near the C terminus of the protein. All four features are required for the function of CIITA.

CIITA does not contain a recognizable DNA-binding domain and does not have affinity for DNA. Yet chromatin immunoprecipitation experiments have demonstrated that CIITA is physically associated in vivo with MHCII promoters and with the promoters of the *Ii*, *HLA-DM*, *MHCI*, and  $\beta 2m$  genes (Hake et al., 2000; Masternak et al., 2000b, 2003; Beresford and Boss, 2001; Masternak and Reith, 2002). Recruitment of CIITA to MHCII promoters is mediated by multiple protein-protein interactions with DNA-bound factors (Fig. 17.2A). Factors bound to the S, X, X2, and Y boxes are all required for recruitment of CIITA (DeSandro et al., 2000; Hake et al., 2000; Masternak et al., 2000b; Zhu et al., 2000).

Once tethered to MHCII promoters, CIITA activates transcription via N-terminal transcription activation domains (Fig. 17.2A) (reviewed in Harton and Ting, 2000; Reith and Mach, 2001; Ting and Trowsdale, 2002). The acidic and proline/serine/threonine-rich regions in the N terminus of CIITA resemble the transcription activation domains found in transcription factors. Moreover, they can activate transcription when fused to heterologous DNA-binding proteins and can be replaced by activation domains from other transcription factors (Riley et al., 1995; Zhou and Glimcher, 1995). How these domains of CIITA function to activate transcription remains an open question. Three different but not mutually exclusive mechanisms have been proposed (Fig. 17.2A). First, CIITA can contact the general transcription factors TFIIB, hTAF<sub>II</sub>32, and hTAF<sub>II</sub>70, and may therefore activate transcription initiation by recruiting the general transcription machinery (Fontes et al., 1997; Mahanta et al., 1997; Masternak and Reith, 2002; Masternak et al., 2003). Second, CIITA may affect promoter clearance or transcription elongation by interacting with such factors as TFIIF or P-TEFb (Mahanta et al., 1997; Kanazawa et al., 2000). Finally, CIITA may facilitate chromatin remodeling at the promoter by recruiting coactivators having histone acetylase activity (Kretsovali et al., 1998; Fontes et al., 1999; Spilianakis et al., 2000; Beresford and Boss, 2001; Masternak and Reith, 2002; Masternak et al., 2003).

Analysis of the intracellular distribution of CIITA has shown that a substantial portion of the protein is localized in the nucleus. Several regions within CIITA have been implicated in nuclear targeting of the protein. First, three nuclear localization signals have been identified. One of these lies within the region deleted in patient BLS-2 (see Fig. 17.3A) (Cressman et al., 1999). Second, the GTP-binding domain appears to be required for nuclear import (Harton et al., 1999). Finally, a detailed mutational analysis of the LRR region has shown that it is important for directing CIITA to the nucleus (Hake et al., 2000).

**Figure 17.2.** Function of CIITA and RFX. (A) CIITA is a non-DNA-binding coactivator that functions via protein-protein interactions (double-headed arrows). CIITA is tethered to the promoters by contacts with a poorly defined S box binding factor (?), the RFXANK and RFX5 subunits of RFX, X2BP (CREB), and the B and C subunits of NF-Y. CIITA is believed to activate transcription by recruiting other factors via its N-terminal activation domains (AD). Candidate factors include TFIIB, TAF<sub>II</sub>32, TAF<sub>II</sub>70, TFIIF, p-TEFb, and HAT (histone acetyl transferases). The roles of these factors in transcription initiation and elongation and in chromatin remodeling are indicated. (B) Cell type-specific and inducible expression of MHCII and related genes is controlled at the level of transcription of the *MHC2TA* gene. Transcription of *MHC2TA* is controlled by four independent promoters (pI, pII, pIII, and pIV) preceding four alternative first exons. These promoters exhibit different cell type specificity and responsiveness to IFN- $\gamma$ . pII is not conserved in the mouse and its specificity is not known. (C) RFX participates in cooperative binding interactions required for promoter occupation in vivo. RFX, X2BP, and NF-Y have only low affinity (thin open arrows) for their respective target sites when bound on their own (top). This affinity is strongly enhanced (thick solid arrows) when the proteins bind cooperatively to the same DNA fragment (middle). In RFX-deficient cells, cooperative binding is lost and the promoters remain unoccupied in vivo (bottom).

CIITA shares a similar architecture and low sequence homology with a family of proteins containing a nucleotide-binding domain (NBD) coupled to a C-terminal LRR domain (reviewed in Harton and Ting, 2000; Harton et al., 2002). Although the

**Figure 17.3.** Mutations in MHCII deficiency. (A) Mutations in *MHC2TA* have been characterized in five unrelated patients and one experimentally generated cell line (RJ2.2.5). The ATP/GTP-binding domain, the leucine-rich repeat domain (LRR), the acidic region (DE), and the proline/serine/threonine-rich regions (P/S/T) are indicated. (B) Mutations in *RFXANK* have been characterized in 27 unrelated patients. The region containing ankyrin repeats is indicated. (C) Mutations in *RFX5* have been characterized in six unrelated patients and one experimentally generated cell line (G1B). The DNA-binding domain (DBD) and a proline-rich region (P) are indicated. (D) Mutations in *RFXAP* have been characterized in the experimentally generated 6.1.6 cell line and in six unrelated patients. Acidic (DE), basic, and glutamine (Q)-rich regions are indicated. In each case, the repercussion of the mutation on the

functions of many of these proteins are unknown, several have functions that are very different from that of CIITA. Conservation of the NBD-LRR domain organization in proteins having very different functions is intriguing. It is tempting to speculate that the similar structure of these proteins reflects an analogy in their mode of action.

Several studies have shown that CIITA can self-associate to form homomeric complexes. Although there is some controversy concerning the precise sequences that mediate self-association, the LRR and GTP binding domains have been implicated. (Kretsovali et al., 2001; Linhoff et al., 2001; Sisk et al., 2001). There is growing evidence that self-association is important for CIITA function, but there is as yet no consensus on its precise role.

### Function and Expression of CIITA

MHCII genes, and the *Ii* (CD74), *HLA-DMA*, and *HLA-DMB* genes required for antigen presentation by MHCII molecules, are the major target genes of CIITA. In addition, CIITA contributes to, but is not essential for, expression of the MHC I and  $\beta 2m$  genes (Gobin et al., 1997; Martin et al., 1997; van den Elsen et al., 1998). It is unlikely that CIITA plays an essential role in other systems, because all of the clinical manifestations exhibited by patients in which the *MHC2TA* gene is mutated can be attributed to the deficiency in MHC expression.

CIITA functions as a “master regulator” controlling cell type specificity, induction, and level of MHCII expression (reviewed in Harton and Ting, 2000; Reith and Mach 2001; Ting and Trowsdale, 2002). This is clearly demonstrated by the following findings.

1. The *MHC2TA* gene is expressed in a cell type-specific manner that correlates closely with MHCII expression.
2. Constitutive expression of MHCII genes in B cells is determined by constitutive expression of CIITA (Steimle et al., 1993).
3. CIITA expression is essential for the activation of MHCII gene transcription in response to IFN- $\gamma$ , and induction of MHCII expression by IFN- $\gamma$  is mediated by induction of CIITA expression (Chang et al., 1994; Chin et al., 1994; Steimle et al., 1994).
4. Differentiation of B cells into mature plasma cells is accompanied by the loss of MHCII expression, a process believed to be mediated by a dominant repression mechanism. This loss of MHCII expression has been shown to result from silencing of the *MHC2TA* gene (Silacci et al., 1994).
5. It has long been a puzzle that MHCII gene expression is induced in activated human T cells but not in activated mouse T cells. This discrepancy has been shown to be due to a species-specific difference in CIITA expression; CIITA is expressed in activated human T cells but not in activated mouse T cells (Chang et al., 1996b).
6. Repression of MHCII expression in trophoblast cells is caused by inhibition of CIITA expression (Morris et al., 1998, 2000).
7. The level of MHCII expression is modulated by the level of CIITA. Analysis of a large number of human and mouse cell lines and tissues has demonstrated that there is a tight quantitative correlation between the level of MHCII expression and that of CIITA expression. In addition, experimental modulation of CIITA expression using a tetracycline-inducible system has shown that the level of CIITA expression directly determines the level of MHCII expression (Otten et al., 1998).

protein is indicated schematically. Most mutations lead to internal deletions or C-terminal truncations. For JER (Lennon-Dumenil et al., 2001) only the truncated protein derived from the major splice variant is shown. Asterisks (Fern, SaE, G1B, FZA, Ken/Ker) indicate missense mutations. Mutations are described in detail in Masternak et al. (2000a).

8. Finally, an important emerging concept is that a variety of pathogens have developed the ability to inhibit CIITA expression—and thus MHCII expression—as a strategy to evade recognition by the immune system. Examples include CMV, varicella-zoster virus, *Mycobacterium bovis*, and *Chlamydia* (Miller et al., 1998; Le Roy et al., 1999; Wojciechowski et al., 1999; Zhong et al., 1999; Abenroth et al., 2000). This last point emphasizes the functional importance of CIITA as an essential immunomodulator.

Expression of the *MHC2TA* gene is directed by at least four independent promoters (I, II, III, and IV), which precede four alternative first exons (Fig. 17.2B). These promoters differ in their cell type specificity and response to IFN- $\gamma$  (Muhlethaler-Mottet et al., 1997, 1998). It is thus the differential activity of the different CIITA promoters that ultimately determines the cell type specificity and inducibility of MHCII gene expression (reviewed in Harton and Ting, 2000; Reith and Mach, 2001; Ting and Trowsdale, 2002). Promoter I is used in dendritic cells (Muhlethaler-Mottet et al., 1997; Landmann et al., 2001). Promoter III primarily drives expression of CIITA in B cells and activated T cells, but also contributes to expression in dendritic cells. Promoter IV is essential for IFN- $\gamma$ -induced expression in non-bone marrow-derived cells and for expression in epithelial cells of the thymic cortex (Waldburger et al., 2001, 2003).

### Function and Mode of Action of RFX

In contrast to CIITA, the RFX complex is expressed ubiquitously in all cell types examined, even in MHCII-negative cells. However, like CIITA, the MHCII, *Ii* (*CD74*), *HLA-DMA*, and *HLA-DMB* genes are the major target genes of RFX. RFX is also implicated in expression of MHCI and  $\beta 2m$  genes (Gobin et al., 1998; van den Elsen et al., 1998). It is unlikely that RFX plays a major essential role in other systems because the clinical manifestations in patients characterized by a defect in RFX (groups B, C and D) can all be attributed to the deficiency in MHC expression.

In vivo footprint experiments (Kara and Glimcher, 1991, 1993) and DNaseI hypersensitivity studies (Gonczy et al., 1989) have shown that the entire MHCII promoter, including the X, X2, and Y boxes, are unoccupied in RFX-deficient patients (Table 17.3, Fig. 17.1). This indicates that occupation of the promoter by DNA-binding factors such as the X2 box binding protein X2BP (Hasegawa and Boss, 1991), which has been shown to contain CREB (Moreno et al., 1999), and the Y box binding protein NF-Y (Mantovani, 1999) is dependent on binding of RFX to the adjacent X box. An explanation for these findings has been provided by in vitro binding studies demonstrating that RFX binds cooperatively with X2BP(CREB) and NF-Y to form a higher-order protein/DNA complex containing all three proteins (Fig. 17.2C) (Durand et al., 1994; Reith et al., 1994a, 1994b; Moreno et al., 1995; Louis-Plence et al., 1997). This nucleoprotein complex has recently been coined the *MHCII enhanceosome* (Masternak et al., 2000b). In the MHCII enhanceosome, the interactions of RFX, X2BP(CREB), and NF-Y with their respective target sites are strongly stabilized (Reith et al., 1994a, 1994b; Moreno et al., 1995; Louis-Plence et al., 1997). This stabilization is sufficiently strong to permit recruitment of RFX, X2BP(CREB), and NF-Y to all MHCII promoters, even to those that contain only very low-affinity binding sites for these proteins (Reith et al., 1994a; Louis-Plence et al., 1997). These cooperative binding interactions are essential for stable occupation of MHCII promoters in vivo (Wright et al., 1994). The bare promoter phenotype observed in groups B, C, and D is thus a direct consequence of the deficiency in RFX (Figs. 17.1 and 17.2C).

In addition to enhancing stability, the cooperative binding interactions between RFX, X2BP(CREB), and NF-Y are highly specific (W. Reith, unpublished data). For example, cooperative binding is not observed between RFX and proteins such as c-Jun and c-Fos, which are known to be able to bind to the X2 box in vitro, or between X2BP(CREB) and other X box binding proteins such as RFX1. This specificity ensures that RFX, X2BP(CREB), and NF-Y, rather than other related DNA binding proteins capable of recognizing the same DNA sequences, are recruited to MHCII promoters in vivo.

The fact that occupation of the MHCII promoter requires cooperative binding interactions between RFX, X2BP(CREB), NF-Y, and possibly other unidentified proteins, such as those recognizing the S box, explains the observation that the order, orientation, and spacing of the S, X, X2, and Y regulatory sequences are highly conserved in MHCII promoters and are critical for their activity (Vilen et al., 1991, 1992; Reith et al., 1994b).

### Mutation Analysis

At the present time, six different mutations of the *MHC2TA* gene have been characterized in five unrelated BLS patients (Fig. 17.3A) (reviewed in Masternak et al., 2000a). One of these is a nonsense mutation leading to a severely truncated protein lacking the last two-thirds. Four of the mutations lie near the C terminus of the protein, in the vicinity of the protein-protein interaction domain consisting of LRRs. One of the latter is a missense mutation, while the other three are splice site mutations leading to the skipping of short in-frame exons. The most recent mutation to be identified is a missense mutation lying at amino acid 469 (Wiszniewski et al., 2001). The mutations affecting the two alleles of *MHC2TA* in the in vitro-generated RJ2.2.5 cell line have also been defined: one allele contains a large deletion within the CIITA gene (Fig. 17.3A), while the second allele is deleted entirely.

To date, eight different mutations of the *RFXANK* gene have been characterized in 27 unrelated patients (Fig. 17.3B) (reviewed in Masternak et al., 2000a). All mutations affect the integrity of the ankyrin repeat region. One is a missense mutation lying within the third repeat. The other six are nonsense mutations, deletions, or splice site mutations leading to proteins lacking all or part of the ankyrin repeat region. One of the mutations has been found in 21 unrelated patients, indicating the existence of a founder effect (Wiszniewski et al., 2000).

Mutations disrupting the *RFX5* gene have been identified in five classical patients in complementation group C (Fig. 17.3C) (reviewed in Masternak et al., 2000a). All are nonsense mutations or splice site mutations leading to the synthesis of severely truncated RFX5 proteins lacking the DBD and/or the C-terminal moiety of the protein. The atypical twins exhibiting an unusual mild form of MHCII deficiency have a point mutation in the DBD of RFX5 (Ken and Ker, Fig. 17.3C) (Nekrep et al., 2002). A mutation within RFX5 has also been identified in G1B, which is an in vitro-generated MHCII regulatory mutant. The RFX5 gene in G1B contains a missense mutation situated just upstream of the DNA binding domain (Brickey et al., 1999).

Only three different mutations disrupting the *RFXAP* gene have been identified in six unrelated families in complementation group D (Fig. 17.3D) (reviewed in Masternak et al., 2000a). Each allele of the *RFXAP* gene in the 6.1.6 cell line contains a frameshift mutation resulting from the insertion of a single G nucleotide (Fig. 17.3D) (Durand et al., 1997). All of these mutations lead to the synthesis of severely truncated RFXAP proteins.

Strategies for Diagnosis

Early diagnosis is critical because it increases the chances of successful bone marrow transplantation (BMT). Young children presenting with clinical and immunological features typical of MHCII deficiency should be referred by their physicians to specialized centers as soon as possible. The decisive criteria for the diagnosis of MHCII deficiency are the absence of MHCII expression and the inability to produce specific antibodies in response to immunization. These parameters should be tested in children having recurrent upper respiratory tract infections, diarrhea, and failure to thrive. Additional criteria warranting an investigation of MHCII expression include hypogammaglobulinemia and the absence of delayed-type hypersensitivity (DTH) skin tests.

Mode of Inheritance, Carrier Detection, and Prenatal Diagnosis

MHCII deficiency is inherited as an autosomal recessive disease. Carriers are healthy and exhibit no known phenotype. Considering the rarity of the disease, carrier detection is of no interest unless a consanguineous union is envisaged despite genetic counseling. In this case it could be performed either by using polymorphic markers flanking the affected gene or by a direct search for known mutations. Given the severity of MHCII deficiency, prenatal diagnosis in affected families is a valid ethical option. Previously, prenatal diagnosis has been carried out safely between the 20th and 22nd week of gestation by analyzing MHCII expression on fetal leukocytes obtained by means of an umbilical vein puncture guided by echography (Durandy et al., 1987). However, characterization of the mutations affecting the *MHC2TA*, *RFXANK*, *RFX5*, and *RFXAP* genes in families from complementation groups A, B, C, and D now offers a better option for prenatal diagnosis. The presence of these mutations could be assessed directly on trophoblastic cells obtained from a chorionic villi biopsy.

Treatment and Prognosis

Treatment of infections and other complications can at best reduce the frequency and severity of the clinical problems associated with MHCII deficiency. The optimal symptomatic care available consists of the prophylactic use of antibiotics, intravenous administration of immunoglobulins, and parenteral nutrition. However, these means do not prevent progressive organ dysfunction and death. In the absence of curative treatment—namely, BMT—prognosis is poor. As indicated in Table 17.4, the majority of patients who do not undergo BMT die at a young age from various infections, with or without autoimmune manifestations. Only a minority of patients characterized by a less severe clinical picture survives beyond the age of 14 years. Protracted diarrhea, malnutrition, the requirement for total parenteral nutrition, and the associated complications are the major causes of progressive clinical deterioration. There is no obvious difference in prognosis for patients belonging to the four different genetic complementation groups. The leaky phenotype characteristic of atypical patients is associated with a better outcome (Hauber et al., 1995; Wolf et al., 1995).

As for other combined immunodeficiency disorders, allogeneic BMT is currently the only available curative treatment for MHCII deficiency. The outcome of BMT in patients with MHCII

Table 17.4. Outcome with and without Bone Marrow Transplantation (BMT)

Without BMT (14 Patients)		After BMT (27 Patients)	
Outcome	n	Outcome	n
Chronic diarrhea	14	Well 1–11 years after BMT	11
Pneumonia	13	Persistent immunodeficiency	1
Meningoencephalitis	5	Death <2 months after BMT	7
Hepatitis, cholangitis	6	Death <1 year after BMT	12
Sepsis	7	Death >1 year after BMT	3
Autoimmunity	4		
Death at age 6 months to 16 years	10		

Patients from Hospital Necker-Enfants Malades.

deficiency is summarized in Table 17.4. The success rate is relatively poor since less than half of the patients were cured by the procedure (Table 17.4; Klein et al., 1995). Results were much better in patients undergoing BMT before the age of 2 years, probably because the viral burden and organ dysfunction are less intense (Klein et al., 1995). When an HLA-identical sibling is available, the chances of success are fairly good. They are considerably lower when BMT is performed with matched unrelated donors or with partially HLA-compatible related donors. Although several patients have now been cured by BMT with such non-HLA-identical donors (Klein et al., 1995), the success rate remains lower than in other immunodeficiency syndromes. The two main obstacles are intractable persistent viral infections caused by a long-lasting T cell immunodeficiency, and graft failure or rejection resulting from the allogeneic response in patients being normal.

Four conclusions can be drawn from our current experience with BMT in MHCII deficiency (Klein et al., 1995). First, despite the lack of MHCII expression, the risk of graft-versus-host disease is similar to that observed in patients with other forms of immunodeficiency. Second, CD4<sup>+</sup> T cell counts remain low (albeit functional) in long-term survivors because of defective MHCII expression by the thymic epithelial cells of the host. Third, the lack of MHCII expression in nonhematopoietic cells does not appear to be detrimental for patients having undergone successful allogeneic BMT. Finally, given the invariably fatal course of typical MHCII deficiency and the poor outcome of BMT performed after the age of 2–4 years, it is highly recommended that BMT be performed in young children independent of whether an HLA-identical sibling is available.

Now that the four genes affected in MHCII deficiency have been identified, gene therapy has become a potential alternative to BMT. Introduction of the wild-type *MHC2TA*, *RFXANK*, *RFX5*, or *RFXAP* genes into the hematopoietic stem cells of patients in complementation groups A, B, C, and D, respectively, would represent a logical therapeutic strategy. It should be mentioned, however, that current gene therapy protocols remain hampered by the inefficiency of gene transfer into human hematopoietic stem cells. Moreover, in normal individuals MHCII expression is tightly controlled in a cell type-specific and inducible manner, and ectopic or nonphysiological levels of MHCII expression induced by the transgene should therefore be avoided in these patients. This should not represent a major problem in gene therapy with *RFX5*, *RFXANK*, and *RFXAP*, which are expressed ubiquitously at relatively constant levels in all cell types. Expression of CIITA is, on the other hand, tightly regulated. Correct expression of a *MHC2TA* transgene will be difficult to obtain unless the

endogenous promoters of the *MHC2TA* gene are used. *Mhc2ta* and *Rfx5* knockout mice (see below) will be invaluable for evaluating the feasibility of gene therapy for MHCII deficiency.

### Mouse Models for MHCII Deficiency

There are no spontaneous animal models for MHCII deficiency. However, three mouse models have been constructed by gene targeting. The first model to become available was the MHCII knockout mouse, which reproduced many of the immunopathological features of the human disease, including hypogammaglobulinemia, decreased CD4<sup>+</sup> T cell counts, and a deficiency in cellular and humoral immune responses to foreign antigens (reviewed in Dardell et al., 1994; Grusby and Glimcher, 1995). A more faithful model reproducing the molecular defect exhibited by patients in complementation group A has been obtained by gene targeting of the mouse *Mhc2ta* gene (Chang et al., 1996a; Williams et al., 1998; Itoh-Lindstrom et al., 1999). The phenotype exhibited by the *Mhc2ta* knockout mouse is very similar to that of human MHCII deficiency patients. Both constitutive and IFN- $\gamma$ -induced MHCII expression is strongly reduced. The mice are consequently impaired in CD4<sup>+</sup> T cell-dependent immune responses and their immune system is severely compromised. The only major difference from the human disease concerns the mature CD4<sup>+</sup> T cell population; the number of mature CD4<sup>+</sup> T cells is drastically reduced in *Mhc2ta* knockout mice whereas only a minor reduction is observed in MHCII deficiency patients (see below). A third model reproducing the molecular defect exhibited by patients in complementation group C has been constructed by disruption of the mouse *Rfx5* gene (Clausen et al., 1998). The phenotype of *Rfx5* knockout mice is similar to that of *Mhc2ta* knockout mice. Constitutive and IFN- $\gamma$ -inducible MHCII expression is strongly affected. There is also a severe reduction in the number of mature CD4<sup>+</sup> T cells.

### Unresolved Issues and Future Directions

#### Residual MHCII Expression

Both the CIITA and RFX5 knockout mice exhibit residual MHCII expression in certain tissues and cell types (reviewed in Reith and Mach, 2001), which implies that there must be RFX5- and/or CIITA-independent pathways for MHCII expression in specific cellular compartments. The precise pattern of residual expression differs between the two mice. RFX5<sup>-/-</sup> mice retain MHCII expression in the thymic medulla and significant, albeit weak, expression on a fraction of splenic and bone marrow-derived dendritic cells, and on B cells activated in vitro with lipopolysaccharide (LPS) and/or IL-4 (Clausen et al., 1998). In contrast, residual MHCII expression in CIITA<sup>-/-</sup> mice concerns primarily dendritic cells in the lymph nodes, B cells in germinal centers, and a subset of thymic epithelial cells (Chang et al., 1996a; Williams et al., 1998). This difference in residual expression pattern is surprising because the human disease is phenotypically homogeneous. Leaky expression has been observed in cells from certain BLS patients, but no characteristic residual expression pattern distinguishing RFX5-deficient patients from those with defects in CIITA have been described. This discrepancy could reflect species-specific differences in the respective roles of the two MHCII regulatory genes. However, because of the rarity and severity of the disease, only relatively few patients from defined complementation groups have been studied in detail

with respect to residual MHCII expression. Consequently, it is also possible that the phenotypic differences observed in the mouse system exist in the human disease as well but have escaped attention until now.

#### Modest Reduction in CD4<sup>+</sup> T Lymphocytes

Normal development of mature CD4<sup>+</sup> T lymphocytes requires the expression of MHCII molecules on cortical thymic epithelial cells (Viret and Janeway, 1999). The fact that the CD4<sup>+</sup> T cell population is almost completely absent in MHCII, *Mhc2ta*, and *Rfx5* knockout mice is consistent with this finding (Dardell et al., 1994; Grusby and Glimcher, 1995; Chang et al., 1996a; Clausen et al., 1998). It is therefore quite surprising that the levels of CD4<sup>+</sup> T lymphocytes are only mildly reduced in MHCII deficiency patients (Griscelli et al., 1993; Klein et al., 1993). This discrepancy between MHCII deficiency and the existing mouse models for the human disease remains unresolved. One possible explanation is that, in humans, mutations in *MHC2TA* or *RFX5* genes may permit a low residual level of MHCII expression on cortical epithelial cells of the thymus, and this residual expression is sufficient to drive positive selection of CD4<sup>+</sup> T lymphocytes. In this context it may be relevant that residual MHCII expression in the thymus has indeed been described in certain patients (Schuurman et al., 1985; Griscelli et al., 1993). A subset of thymic epithelial cells retaining the ability to express MHCII molecules has also been observed in *Mhc2ta* knockout mice (Chang et al., 1996a) and in *Rfx5* knockout mice (Clausen et al., 1998). An alternative explanation could be that CD4<sup>+</sup> T cell selection in humans can be driven by alternative mechanisms that differ from those most prominent in the mouse. Interestingly, an analysis of the CD4<sup>+</sup> T cell repertoire in MHCII deficiency patients has revealed alterations suggesting that CD4<sup>+</sup> T cells in these patients may have escaped the normal selection processes in the thymus (Henwood et al., 1996). It should be mentioned, however, that the same alterations were not observed in another study (Rieux Laucat et al., 1993).

#### Therapeutic Modulation of MHCII Expression

RFX5, RFXANK, RFXAP, and CIITA exhibit two features that are unusual for transcription factors. First, mutations in these factors almost completely abolish MHCII expression, indicating that they are essential and that no major bypass or alternative pathways can compensate for their absence. Second, they are highly specific for the *MHCII*, *Ii*, and *DM* genes. These characteristics suggest that inhibition of the synthesis or activity of CIITA, RFXANK, RFXAP, and RFX5 should result in a highly selective and efficient down-regulation of MHCII expression. This down-regulation would have profound effects on the control of the immune response. CIITA, RFXANK, RFXAP, and RFX5 may thus represent prime targets for novel immunomodulatory drugs having wide applications in situations such as organ transplantation and autoimmune diseases.

#### Acknowledgments

The literature cited here is only a small selection of all the contributions that have been made to the fields of MHCII gene regulation and the molecular basis of MHCII deficiency. We sincerely apologize to all colleagues whose work we have been unable to cite for reasons of lack of space. We thank all past and present members of our laboratories for helpful discussions and their contributions to the work reviewed here.

## Peptide Transporter Defects in Human Leukocyte Antigen Class I Deficiency

HENRI DE LA SALLE, LIONEL DONATO, and DANIEL HANAU

Human leukocyte antigen (HLA) class I molecules present peptides derived from proteins that are synthesized in the cell to cytotoxic  $\alpha\beta$  CD8<sup>+</sup> T lymphocytes. In this way, these molecules are involved in immune responses against intracellular pathogens and cancer cells. Although these molecules should a priori be essential to immune defense and thus to survival, a few cases have been described of children or adults who live with a defect in the expression of HLA class I molecules.

HLA class I deficiency, also called *type I bare lymphocyte syndrome* (BLS), is detected when HLA class I molecules on lymphocytes cannot be typed by serological methods because of their low expression at the plasma membrane. Complete HLA class I deficiency has never been reported, which suggests that low expression of class I molecules may be sufficient to ensure immune responses against pathogens; while total deficiency would be lethal. The first case of HLA class I deficiency was identified at a time when HLA class II typing techniques were unreliable. This case was later found to be an HLA class II deficiency associated with low expression of class I molecules (type III BLS) (Touraine et al., 1978; Sabatier et al., 1996), resulting from a defect in the RFXAP transcription factor (Durand et al., 1997). Two cases without immunodeficiency were subsequently described in a nonconsanguineous family (Payne et al., 1983). One was discovered when bone marrow transplantation was being considered to treat aplastic anemia, and the second was a younger brother who displayed the same defect of HLA class I expression and was healthy. Four other cases were identified in patients who had first-cousin parents and suffered from unexplained lung disease (Maeda et al., 1985; Sugiyama et al., 1986; de la Salle et al., 1994). Apart from one patient who experienced recurrent fever (Sugiyama et al., 1986), these patients did not seem to be abnormally susceptible to viral infections. Moreover,

when complete clinical data were available, they appeared to have been healthy during the first years of life. Thus, the pathology associated with type I BLS appears not to be a direct consequence of the deficiency—i.e., an expected susceptibility to viral infections or cancer—but rather a result of secondary effects. Because of this absence of a direct link between clinical manifestations and deficiency, the discovery of the first cases of type I BLS was fortuitous. Since the first genetic and clinical descriptions of two patients in 1994, other HLA class I-deficient individuals have been discovered among previous and new clinical cases.

### Clinical and Pathological Manifestations

Only 20 well-documented cases of HLA class I molecule deficiency with normal expression of class II molecules have been identified; 13 of them result from a defect in the transporter of peptides associated with antigen processing (TAP) (Table 18.1). Contrary to types II and III BLS, which are characterized by the early onset of severe combined immunodeficiency, HLA class I deficiencies do not lead to any particular pathological manifestations during the first years of life. Pathology of the gut (diarrhea) is not observed, unlike in type II or III BLS. The clinical course of the known cases (reviewed in Gadola et al., 2000), summarized in Table 18.1, varies among individuals. A chronic inflammatory lung disease, developing generally in late childhood, is the most common, though not requisite, trait of TAP-deficient patients. It begins with infections with *Hemophilus influenza* during the first decade of life, is confined to the respiratory tract, and extends from the upper to lower airways. Other bacterial pathogens may also be found (*Streptococcus pneumoniae*, *Klebsiella*, *Pseudomonas aeruginosa*). The high frequency of nasosinus involvement and nasal polyposis, uncommon for noncystic

<sup>†</sup>Reference in which mutation is described.

fibrosis in children, is noteworthy. The pathology inevitably evolves to a respiratory insufficiency resulting in bronchiectasis, emphysema, panbronchiolitis, or bronchial obstruction. In the early stages of the disease, computerized tomography (CT) scans of the chest may show bronchiolectasis, which later leads to bronchiectasis (Fig. 18.1). Hypoxemia can occur during infectious exacerbation. Skin lesions have been described in several patients and start with local inflammation, most often on the legs, developing into necrotizing granulomas. These lesions may be related to vasculitis (Watanabe et al., 1987; Plebani et al., 1996; Teisserenc et al., 1997). In a number of cases, lesions occurring in the upper respiratory tract led to mutilation of the mid-face (Moins-Teisserenc et al., 1999). One of these patients did not display inflammation of the airways. Recently, two adults without inflammatory lung disease were also described, one totally asymptomatic and the other with minor skin lesions on one leg (de la Salle et al., 2002). Definitive healing of the skin lesions has never been reported, except in this last case. Two other TAP1-deficient brothers were recently identified in our laboratory (de la Salle, unpublished results). In contrast to all previ-

ously described TAP-deficient individuals, these patients have unrelated parents, who nevertheless share a rare HLA haplotype. One of the patients is 14 years old and asymptomatic. The other patient is 15 and suffered a retinal toxoplasmosis, which, despite surgery, led to the loss of one eye.

The two HLA class I-deficient brothers described by Payne et al. were free of lung and upper-airway disease, although respiratory involvement could not be excluded because the patients were young, no ear-nose-throat or pulmonary investigations had been carried out, and long-term data were lacking. One of these children suffered from unexplained anemia but recovered under prolonged corticosteroid treatment. Another case has since been discovered in France (de la Salle, unpublished data). As shown in the next section, this type of deficiency is not caused by a TAP defect.

Finally, a moderate HLA class I deficiency resulting from a tapasin defect was recently characterized. Although the patient did not display any of the symptoms associated with TAP deficiency, he suffered from chronic primary glomerulonephritis (Yabe et al., 2002).

**Figure 18.1.** Chest CT scans. (Top) Bronchiolectasis in a 15-year-old TAP2-deficient patient. Patchy opacities spread out along the bronchovascular axes within the right middle lobe. (Bottom) Bilateral bronchiectasis in patient's eldest sister. Lesions extend to the right middle lobe, lingula, and left lower lobe and probably represent a later stage of the disease.

### Molecular Basis of TAP Deficiency

Classical HLA class I molecules are composed of a polymorphic heavy chain, encoded by HLA-A, HLA-B, and HLA-C genes, associated with  $\beta$ 2-microglobulin ( $\beta$ 2m). The assembly of heavy chains with  $\beta$ 2m (Creswell et al., 1999) occurs in the lumen of the endoplasmic reticulum under the control of chaperone molecules such as calnexin, calreticulin, and thiol oxidoreductase Erp57. After assembly the complexes are loaded with peptides derived from degradation of intracellular proteins. The peptides are transported from the cytosol into the lumen of the endoplasmic reticulum by TAP, a protein composed of two subunits, TAP1 and TAP2. These proteins belong to the ATP-binding cassette (ABC) family of transporters, which display common features in the cytoplasmic domain. The cytoplasmic part includes two sites (Walker sites A and B) involved in ATP binding and necessary for the transport of substrates (the structure of ABC

transporters is reviewed in Schneider and Hunke, 1998). However, in the case of TAP, the ATP binding site of TAP1 is dispensable (Kartunen et al., 2001). The N-terminal halves of the TAP subunits form their luminal and transmembrane domains. In general, peptide loading depends on interaction of the TAP1 subunit with a complex comprised of class I heavy chains,  $\beta$ 2m and calreticulin, an interaction controlled by tapasin (TAP-associated glycoprotein).

Studies in tumor and mutant cell lines have shown that defective HLA class I expression may arise from the down-regulation of HLA class I genes or TAP genes, or from the absence of  $\beta$ 2m, TAP, or tapasin. In TAP-deficient cell lines, most HLA class I molecules remain blocked between the endoplasmic reticulum and the *cis*-Golgi compartment and therefore stay endoglycosidase H sensitive and unsialylated. The HLA class I heavy chain/ $\beta$ 2m complexes are peptide-free and unstable at 37°C, resulting in poor expression of HLA class I molecules on the cell surface. In the absence of TAP, the presentation of most peptides of intracellular origin is blocked, although TAP-independent presentation of some antigens can occur. The genes encoding the TAP subunits are located in the HLA class II genetic region on chromosome 6 and are polymorphic; up to six TAP1 and four TAP2 human alleles having been described to date (<http://www.anthonynolan.com/HIG/nomenc.html>). Calnexin is not essential for normal expression of HLA class I molecules (Scott and Dawson, 1996). In contrast, the processing of these molecules is altered in the tapasin-defective 721.220 cell line, in a manner similar to that in TAP-deficient cells, the effect of the mutation depending on the biophysical characteristics of the HLA variants. Thus, in transfected 721.220 cells, depending on the alleles, HLA class I molecules are more or less retained in the endoplasmic reticulum (Greenwood et al., 1994).

Genetic and biochemical studies of HLA class I deficiencies have revealed three kinds of defect. In two cases (Payne et al., 1983), molecular genetic analyses demonstrated that HLA class I genes were constitutively poorly expressed in lymphocytes (Sullivan et al., 1985). This deficiency was probably not linked to chromosome 6, as the two brothers had inherited different HLA haplotypes and the causative genetic defect has not yet been elucidated. In most instances of the second type of HLA class I deficiency, the patients were born to consanguineous parents. When HLA typing could be performed, patients were shown to be HLA homozygous, which suggests that the genetic defect was carried on chromosome 6 (Table 18.1). Biochemical studies of cell lines derived from these patients showed that their HLA class I heavy chains remained unsialylated (Maeda et al., 1985; de la Salle et al., 1994, 1999). Most of the heavy chains remained endoglycosidase H sensitive, whereas HLA class I molecules were unstable at 37°C (de la Salle et al., 1994, 1999, 2002; Teisserenc et al., 1997). All of these properties point to a defect in the peptide loading of HLA class I molecules. Additional complementation experiments demonstrated that the deficiencies resulted from a defect in either TAP1 or TAP2 (Table 18.1 and Fig. 18.2). Three mutations have been characterized in the TAP1 and four in the TAP2 gene; the MIM (Mendelian Inheritance in Man) numbers for these deficiencies are 170260 and 170261. All the mutations generate truncated subunits, and those in the transmembrane domains may be expected to have profound effects on the TAP complex. It has been shown that the amount of TAP2 protein is decreased in TAP1-deficient cell lines (Furukawa et al., 1999a, Moins-Teisserenc et al., 1999). In one patient, a mutation occurred in the ATP-binding domain of the TAP2 subunit (de la Salle et al., 2002). The third type of HLA class I deficiency identified arose

**Figure 18.2.** Structure of TAP1 and TAP2 genes and positions of known mutations. The Genbank accession numbers of the normal sequences are given. The exons are shown as boxes. Wavy boxes correspond to the luminal and transmembrane domains of the subunits and shaded boxes to the cytosolic ABC homology domains. The amino acid

(aa) positions and sequences of the mutated codons are as follows: 3, aa 273, GAC to GA-; 4, aa 260, GGG to GG-; 5, aa 326, AGG to -GG; 7, aa 274, CGA to TGA; 8, aa 219, CGA to TGA; 10, aa 543, GTG to -TG; 12, aa 522, TAC to TAG. The numbering of the mutations corresponds to the reference numbers in Table 18.1.

from a tapasin defect. In this patient, HLA class I expression was reduced 10-fold. Additional biochemical and immunological investigations have not been reported.

### Functional Aspects

#### Expression of HLA Class I Molecules

The expression of HLA class I molecules can be quantified by flow cytometry after staining of the cells with a pan-anti-HLA class I monoclonal antibody such as W6/32. On peripheral blood mononuclear cells (PBMCs) of the two individuals described by Payne et al., the expression of HLA class I molecules was reduced 10-fold, whereas this expression was normal on platelets (Sullivan et al., 1985). The latter observation would appear to contradict the fact that HLA typing could not be performed on platelets (Payne et al., 1983). Epstein-Barr virus-transformed B (EBV-B) cell lines derived from the patients progressively expressed higher levels of HLA class I molecules after a few weeks of culture. In an analogous case, we observed that the PBMCs of a 2-year-old child displayed low HLA class I expression while the EBV-B cell line gradually expressed higher levels of these molecules, although still 10 times less than normal EBV-B cells. Additional experiments demonstrated that HLA class I genes were induced in activated T cells, their expression being up-regulated by tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ) and interferon- $\alpha$  (IFN- $\alpha$ ) or IFN- $\gamma$  (de la Salle, unpublished observations). Thus, in this type of deficiency, HLA class I genes can be induced by inflammatory cytokines. As a result, HLA class I-mediated immune responses can be increased when necessary and, for this reason, the defect may be qualified as conditional. Although HLA class I expression in other tissues of these individuals has not been documented, it is remarkable that the expression of HLA class II molecules is normal.

On the surface of cells from TAP-deficient patients, the expression of HLA class I molecules is reduced 100-fold (de la Salle et al., 1994, 1999; Teisserenc et al., 1997) and the same level of reduction is found on lymphocytes, monocytes, neutrophils, and skin fibroblasts. This expression was slightly increased on lymphocytes and fibroblasts through treatment with IFN- $\alpha$  or IFN- $\gamma$ , whereas TNF- $\alpha$  induced weak up-regulation on fibroblasts only. These observations probably reflect merely the capacity of these cytokines to up-regulate HLA class I genes. A similar effect was reported when the PBMCs of another patient were incubated with phytohemagglutinin (PHA) and IFN- $\gamma$

(Plebani et al., 1996). Two adults with a TAP2 deficiency were recently described who surprisingly expressed five times more HLA class I molecules than those in other TAP-deficient patients (de la Salle et al., 2002). This discrepancy results from a moderate TAP-independent cell surface expression of probably empty HLA-B7 molecules, which is 20% that on normal HLA-B7 cells. Interestingly, one of these individuals had mild symptoms, whereas the other was asymptomatic.

HLA class I molecules were found to be absent from the skin of TAP-deficient patients (Hanau et al., 1994). Immunohistochemical studies of skin biopsies from two other patients showed that these molecules were not expressed in normal skin but were present in skin lesions. In one case, HLA class I expression was lower than that in skin from normal individuals (Watanabe et al., 1987), whereas in the other case the location of these molecules within cells or at the cell surface was uncertain (Plebani et al., 1996).

#### Soluble HLA Class I Molecules

Soluble HLA class I molecules circulate in plasma (normal values, 160 ng to 3  $\mu$ g/ml) and are observed in HLA class I-deficient patients, although at relatively low levels. TAP-deficient patients and the child described above who had a low but inducible HLA class I expression on lymphocytes displayed 0.15 and 0.31  $\mu$ g/ml of soluble HLA class I molecules, respectively (de la Salle, unpublished data).

#### Expression of Nonclassical HLA Class I Molecules

Nonclassical HLA class I molecules are composed of a nonpolymorphic heavy chain associated with  $\beta$ 2m, and unlike the ubiquitous classical HLA class I molecules, the nonclassical molecules are expressed only on specialized cells. In particular, CD1 molecules are expressed on dendritic cells, including epidermal Langerhans cells. In two TAP-deficient patients, immunocytochemical staining of skin biopsies showed HLA class I molecules to be undetectable but CD1a antigens to be normally expressed on Langerhans cells. Flow cytometry further demonstrated that CD1 antigens were present at normal levels on dendritic cells derived in vitro from monocytes (Hanau et al., 1994). In another case, CD1a molecules were likewise normally expressed on epidermal Langerhans cells in biopsies taken from nonlesional skin, but were not detectable in biopsies taken from

ulcers (Plebani et al., 1996). This absence of CD1a from lesion biopsies might only result from the local inflammation and not be linked to the genetic defect.

Another important HLA class I-like molecule is HLA-E, which presents, in a TAP-dependent manner, peptides derived from signal peptides of classical HLA class I molecules. This protein interacts with the NKG-2A/CD94 inhibitory receptor expressed on natural killer (NK) cells and a subset of T cells and thereby acts as a sensor in the biosynthetic pathway of HLA class I molecules. HLA-E/NKG-2A/CD94 interactions suppress the cytolytic responses of NK and T cells and their cytokine release. Surprisingly, through immunofluorescence techniques, HLA-E was found to be expressed on the PHA-induced T cell blasts but not on the EBV-B cells of a TAP-deficient patient (Furukawa et al., 1999a). Because of the confidential distribution of the anti-HLA-E monoclonal antibody used in the study, these results could not be challenged except in one case where HLA-E molecules were shown to be nearly undetectable on the surface of PBMCs and EBV-B cells (Matamoros et al., 2001).

### T Lymphocyte Subpopulations

Experiments in transgenic mice have shown that the positive selection of  $\alpha\beta$  CD8<sup>+</sup> T cells is dependent on interaction of their T cell receptor with HLA class I molecules expressed on thymic epithelial cells. Consequently, MHC class I-deficient mice have very low numbers of CD8<sup>+</sup> T cells. Most analyses of T cell subpopulations in type I BLS patients have been limited to determination of the ratio of CD8<sup>+</sup> to CD4<sup>+</sup> T cells. This ratio frequently appears to lie within normal values (Maeda et al., 1985; Sugiyama et al., 1986; Plebani et al., 1996; Teisserenc et al., 1997; Moins-Teisserenc et al., 1999), although the absolute number of T cells decreased progressively in one case (Plebani et al., 1996). No data are available on T cell subsets in the patients described by Payne et al. In the apparently similar case identified in our laboratory, the numbers of CD4<sup>+</sup> and CD8<sup>+</sup>  $\alpha\beta$  T lymphocytes were normal (unpublished observations).

T cell subpopulations have been analyzed in PBMCs from some TAP-deficient patients (de la Salle et al., 1994, 2002; Moins-Teisserenc et al., 1999). In two cases (Table 18.2) the ratio of CD8<sup>+</sup> to CD4<sup>+</sup> T cells in patient 1 appeared to be somewhat diminished compared to that in normal individuals. Approximately one-third of T cells were  $\gamma\delta$  T cells, one-third of which were CD8<sup>+</sup>. A high proportion of CD8<sup>+</sup> T cells expressed  $\gamma\delta$  receptors and the absolute number of CD8<sup>+</sup>  $\alpha\beta$  T cells was low, although it was significantly higher than that in MHC class I-deficient transgenic mice. In contrast, the proportion of CD8<sup>+</sup>  $\alpha\beta$  T cells in PBMCs of this patient's younger brother (patient 2), who was considered at the time to be healthy, was very low whereas the number of  $\gamma\delta$  T cells was normal. Soon after identification of the deficiency, patient 2 also developed lung pathology. During progression of the disease, an expansion of  $\alpha\beta$  CD8<sup>+</sup> and  $\gamma\delta$  T cells was observed, a finding suggesting that these two subsets can be recruited in immune responses. An expansion of  $\gamma\delta$  T cells has been observed in several but not all cases (Moins-Teisserenc et al., 1999; de la Salle et al., 2002; Matamoros et al., 2001). Because a large proportion of CD8<sup>+</sup> cells may correspond to HLA-unrestricted  $\gamma\delta$  T cells in type I BLS patients, relevant assessment and interpretation of CD8<sup>+</sup> T cell frequencies and CD8<sup>+</sup>-to-CD4<sup>+</sup> ratios are possible only by analyzing exclusively  $\alpha\beta$  T cells. On this basis, the numbers of CD8<sup>+</sup>  $\alpha\beta$  T cells appear to be generally decreased, although they sometimes remain within the lower limits. Finally, the repertoire of CD8<sup>+</sup>  $\alpha\beta$

**Table 18.2.** Evolution of T Cell Subpopulations in TAP-Deficient Patients

Lymphocyte Subpopulations	Patient 1		Patient 2	
CD8 <sup>+</sup>	22.5	16	5	16.5
CD4 <sup>+</sup>	42.5	43	60.5	53
CD4 <sup>+</sup> CD8 <sup>+</sup>	7.5	10	0.3	1
$\alpha\beta$	45	59	60	69
$\alpha\beta$ CD8 <sup>+</sup>	11	15	2.4	11
$\alpha\beta$ CD8 <sup>+</sup> CD4 <sup>+</sup>	<1	<1	<1	<1
$\gamma\delta$	27	16	5	11
$\gamma\delta$ CD8 <sup>+</sup>	11	6	1.2	5
NK	11	8.5	5	8

Results are given as percentages of total lymphocyte population and were obtained on two different blood samples taken at a 2-year interval. Patient 2 was considered to be healthy when the first sample was taken but suffered from chronic lung inflammation at the time of the second one.

T cells is oligoclonal and quite similar to that of CD4<sup>+</sup> cells (de la Salle, unpublished observations). This finding suggests that the deficiency has only a weak incidence in the CD8<sup>+</sup> T cell repertoire.

### Lymphocyte Natural Killer Subpopulations

The number of NK cells seems to stay within normal ranges in HLA class I-deficient patients, varying from lower to higher values, depending on the individual (de la Salle et al., 1994, 2001; Moins-Teisserenc et al., 1999; Furukawa et al., 1999a; Matamoros et al., 2001). A study of the phenotype of NK cells in two TAP2-deficient patients showed that these cells express the type III receptor for IgG (CD16) and the CD56 adhesion molecule. In addition, 40% to 50% of NK cells were found to express high levels of CD56, compared to less than 10% in normal subjects. In TAP<sup>+</sup> individuals, these cells must be activated with IL-2 to become cytotoxic.

The cytolytic activity of NK cells is controlled by a balance of activating and inhibitory receptors (Moretta et al., 2000), and the latter receptors block the cytolytic process when they interact with HLA class I molecules on the target cells. Resting TAP-deficient NK cells display a normally diverse repertoire of inhibitory receptors (Zimmer et al., 1998; Furukawa et al., 1999c). Levels of expression of these receptors are similar to those on normal cells, except for the NKG-2A/CD94 and ILT2 receptors, which were found to be overexpressed on NK cells but not on T cells in three cases (Zimmer et al., 1998 and unpublished observations; Matamoros et al., 2001). This overexpression of NKG-2A/CD94 was not found in another study (Furukawa et al., 1999b), whereas in the two patients from the first study, it seemed to decrease with age or improvement of clinical status (unpublished data). The inhibitory receptors negatively regulate the cytolytic activity of TAP<sup>+</sup> NK cells and are therefore functional.

In a more recent study (Markel et al., 2004), the repertoire of inhibitory receptors on NK clones derived from three patients from the same family was compared to that on NK clones from an unaffected sister. The number of clones expressing higher levels of inhibiting receptors was increased on TAP<sup>+</sup> clones. Interestingly, whereas TAP<sup>+</sup> NK cells rarely express the carcinoembryonic antigen-related cell adhesion molecule 1 (CEA-CAM1), an inhibitory receptor, most of the TAP<sup>+</sup> clones express this molecule.

This work demonstrates that the repertoire of inhibitory receptors on the activated NK cells of these patients is unique.

The repertoire of most activating receptors is also normal on peripheral TAP<sup>-</sup> NK cells (Vitale et al., 2002). Thus, these cells express receptors involved in the killing of tumor cells (NKP30, 40, and 46) or virally infected cells (NKG2-D). On polyclonal NK cell lines derived from TAP-deficient patients, the repertoire of activating receptors nevertheless displays some abnormality, since the expression of NKP80 is low on many cells. Moreover, the same abnormality is observed at a clonal level. Triggering of these receptors induces normal cytolytic responses, except for 2B4 and NKP80, which were found to be functional on only a limited number of NK clones. Hence, the deficiency appears to have an observable incidence on a restricted spectrum of NK receptors and only in some cells.

### Humoral Immune Response

The effects of HLA class I deficiency on the levels of immunoglobulin (Ig) classes and subclasses have not yet been fully investigated. Hypergammaglobulinemia with low levels of IgG2 and an absence of IgG4 was observed in one case (Plebani et al., 1996) and IgG2 deficiency was found in another (Matamoros et al., 2001).

Titration of antibodies in the sera of two TAP2-deficient patients showed them to have been infected by most common viruses: measles, mumps, herpes, cytomegalovirus, influenza, varicella, and EBV (Donato et al., 1995). Since these viral infections did not lead to an exaggerated pathology or require special care, the TAP-independent immune responses of these individuals must be to some extent efficient. This contrasts with the pathologies of herpes, cytomegalovirus, and EBV observed in patients lacking NK cells (Biron et al., 1989) or with diminished NK cell activity (Caligiuri et al., 1987). The fact that TAP-deficient patients can have high titers of antibodies against measles, mumps, herpes, cytomegalovirus, or varicella suggests that antibodies are important in their immune defense against these viruses. High levels of antiviral antibodies have not been reported in all patients. Moreover, normal titers of antibodies against EBV, respiratory syncytial virus, and influenza were found (Donato et al., 1985; unpublished data), which would suggest that cell-mediated immune responses are effective against these three viruses. In contrast, vaccinations failed to induce antibody responses to polysaccharides (Matamoros et al., 2001). Antibodies against herpes and EBV were detected in serum from one case of "conditional" HLA class I deficiency (de la Salle, unpublished observations).

### Cell-Mediated Immune Responses

The cytotoxicity of TAP-deficient NK and T cells has been investigated in several patients. Although resting NK cells did not appear to kill the HLA class I-negative K562 cells classically used in NK cytotoxicity assays, they were able to mediate a weak antibody-dependent cytotoxicity. After activation *in vitro* with IL-2 or IL-12, these NK cells killed K562 cells, but not other HLA class I-negative cells such as Daudi or 721.221 cells (Furukawa et al., 1999c). When TAP-deficient NK cells were stimulated with EBV-B cells and IL-2, they proliferated and developed cytotoxicity against several target cells in the same manner as NK cells from normal donors, although with lower efficiency. More importantly, these activated cells were cytotoxic to autologous EBV-B cells and skin fibroblasts. Cytokines, which increase HLA

class I expression and consequently protect normal fibroblasts from lysis by activated autologous NK cells, did not protect the TAP-deficient cells (Zimmer et al., 1999). This reactivity toward autologous EBV-B cells and fibroblasts is mediated by an NK cell subset expressing high levels of NKP46 (Vitale et al., 2002). Thus, it would appear that *in vivo* the NK cells of these patients can be activated by cytokines released during antiviral responses, while the activated NKP46 bright NK cells are aggressive to surrounding uninfected cells.

In contrast, activated TAP-deficient NK cells do not kill autologous T cell blasts, whereas less than 10% of TAP<sup>+</sup> NK cell clones are unable to kill TAP<sup>-</sup> T cell blasts. This tolerance of autologous T cells in TAP-deficient patients could be mediated by an inhibitory receptor expressed by all TAP<sup>-</sup> NK cells, but by no more than a few TAP<sup>+</sup> NK cells (Vitale et al., 2002). This hypothesis was confirmed by the demonstration that CEA-CAM1 is expressed by most of the activated TAP<sup>-</sup> NK cells and inhibits the lysis of autologous PHA T cell blasts by homotypic interaction (Markel et al., 2004).

Autoreactive  $\gamma\delta$  T cells have also been described in TAP-deficient patients. Interestingly, biopsies of skin lesions revealed the presence of foci of activated NK cells and  $\gamma\delta$  T cells in the dermis, suggesting a role of these cells in the development of skin lesions (Moins-Teisserenc et al., 1999).

TAP-independent anti-EBV  $\alpha\beta$  T cell responses have been demonstrated in two cases of TAP deficiency. In one study, a cytotoxic CD8<sup>+</sup>  $\alpha\beta$  T cell clone was characterized that recognized a peptide of latent membrane protein 2 (LMP2) presented by HLA-B molecules (de la Salle et al., 1997). The LMP2 antigen was also found to be presented by HLA-A2 on TAP-deficient cell lines (Lee et al., 1996). More recently, an anti-EBV T cell clone recognizing the EBV transcription factor BMFR1 presented by HLA-B7 was isolated from another TAP-deficient patient (de la Salle et al., 2002). Therefore, CD8<sup>+</sup>  $\alpha\beta$  T cells can contribute to immune responses against viruses in TAP-deficient patients through recognition of TAP-independent antigens presented by classical HLA class I molecules.

### A Model for the Pathology

At first glance, the absence of susceptibility to viruses and predominance of pulmonary bacterial infections in TAP-deficient patients may appear surprising. Our analysis nevertheless demonstrates that cytotoxic CD8<sup>+</sup>  $\alpha\beta$  T cells recognizing TAP-independent viral antigens can be stimulated *in vivo* and suggests that activated NK cells could also play a role in immune defense. These cell-mediated cytotoxic responses are less efficient than in normal individuals because (1) TAP-independent antigens are more rare and (2) the activated NK cells are less cytotoxic than those from normal subjects. Although a higher production of antibodies may partly compensate for these weaker cell-mediated responses, the overall immune response is unlikely to be sufficient. Consequently, TAP deficiency should lead to a delayed clearance of viral infections, as observed in  $\beta$ 2m-deficient animals (Raulet, 1994).

Several viruses, including respiratory syncytial virus, are known to induce synthesis of IL-8, a chemoattractant for neutrophils and for a subpopulation of T lymphocytes. Because the lungs are probably more subject to viral infections than other tissues, these organs would be attacked (1) by the viruses inefficiently cleared and (2) by proteolytic enzymes released from neutrophils present in large numbers due to the sustained production of IL-8. Activated NK cells, and probably also cytotoxic CD8<sup>+</sup>  $\alpha\beta$  or  $\gamma\delta$

T cells expressing NK inhibitory receptors, could further kill uninfected HLA class I-deficient autologous cells because of the absence of counterregulation by the inhibitory receptors. This would lead to destruction of ciliary cells and fibrosis of the lungs, with the result that bacteria and/or bacterial endotoxins would be inefficiently eliminated, thereby increasing the chemotaxis of neutrophils and maintaining a state of chronic inflammation in the lungs. It has been shown that cystic fibrosis patients display inflammation of the lungs that involves an associated increased neutrophil count within the first weeks of life, several years before the appearance of lung insufficiency (Kahn et al., 1995). Similarly, the progressive degradation of lung tissues of TAP-deficient patients is probably mediated by neutrophils and may begin long before any observable pathology.

One poorly understood aspect of the pathology is the development of skin lesions at any age and only in some patients. No pathogens could be detected in these lesions (Gadola et al., 2000). The activated NK and  $\gamma\delta$  T cells present in inflamed tissues, which kill autologous cells in TAP-deficient patients, may be involved in this process. Histological studies support this hypothesis (Moins-Teisserenc et al., 1999).

### Strategies for Diagnosis

HLA class I deficiency is generally diagnosed by serological HLA typing, but it can also be easily identified by flow cytometric analysis of PBMCs labeled with the anti-class I monomorphic monoclonal antibody W6/32. This test should also be carried out on PBMCs from other members of the family (parents and co-laterals). The type of defect, particularly whether it involves transcription or assembly of HLA class I molecules, may be investigated in a few experiments. In consanguineous families HLA typing can reveal linkage of the deficiency to chromosome 6. Stimulation of T lymphocytes with allogeneic PBMCs, PHA, and IL-2 will show whether HLA class I expression can be induced, indicating whether the defect is transcriptional. If the expression of HLA class I molecules remains low on activated T cells, intracellular class I molecules can be analyzed by metabolic labeling of proteins with  $^{35}\text{S}$ -methionine, immunoprecipitation of cell lysates with W6/32, optional treatment of the immunoprecipitates with neuraminidase, and separation of the proteins by isoelectric focusing. This test will give information on the sialylation of HLA class I heavy chains and their association with  $\beta 2\text{m}$ . Absence of sialylation would strongly suggest a defect of peptide loading. In this case, infection of a cell line derived from the patient with a recombinant vaccinia virus expressing either TAP1, TAP2, or both subunits (constructed by Russ et al., 1995), followed by flow cytometry of cells stained with W6/32, will determine whether the deficiency results from a TAP defect.

### Treatment and Prognosis

Bronchiectasis and bacterial colonization of the respiratory tract lead to chronic respiratory failure and a strong reduction in life expectancy. As in cystic fibrosis and other inherited dysfunctions of the respiratory mucosae, the evolution of bronchiectasis is closely linked to the bacterial charge. Since no specific therapy can yet be proposed for HLA class I-deficient patients, the only way to limit the inflammatory process and hence the neutrophil-mediated lung damage is to strongly treat and, if possible, prevent the episodes of bronchial infection. When the diagnosis is made in infancy—for instance, in the case of early

detection in the family of a known patient—nurseries and other infant communities should be avoided to reduce the risk of early viral contamination. Immunizations against measles, pertussis, and influenza must be carefully controlled and exposure to tobacco smoke in the home environment should be prohibited. Bacteriological examination of the sputum is mandatory as soon as bacterial colonization becomes effective to provide guidelines for antimicrobial therapy. *Haemophilus influenzae* and *Streptococcus pneumoniae* strains, which are commonly found in repeated sputum tests from such patients, can be treated with oral antibiotics ( $\beta$ -lactamines, macrolides, penicillinase inhibitors), while intravenous treatment can be useful in the event of a major bacterial inoculum (bronchorrhea). Some other types of gram-negative bacilli such as enterobacteria and nonmucoid *Pseudomonas aeruginosa* strains may also be found in sputum and require intravenous administration of third-generation  $\beta$ -lactamines and aminoglycosides. Low doses of erythromycin have been reported to improve and stabilize chronic inflammation of the respiratory tract in a patient treated for 19 years (Furukawa et al., 2000; Azuma et al., 2001). This antibiotic is also an inhibitor of neutrophil functions and used in the treatment of diffuse pan-bronchiolitis in Far-East countries, which supports the hypothesis that lung disease of TAP-deficient patients is mediated by neutrophils.

A long-term policy for antimicrobial therapy is difficult to define, as the bronchial colonization does not immediately endanger the survival of these HLA class I-deficient individuals. However, continuous or alternate use of oral antibiotics becomes necessary when bronchiectasis develops. Regular intravenous administration of high-dose antibiotics increases patients' level of comfort and probably slows their progressive functional impairment. One of the cases followed in Strasbourg was diagnosed when the patient was 12. At this time the bacterial charge was of major concern, requiring continuous oral antibiotics and some intravenous treatment during infectious exacerbations. This policy did not induce any bacterial resistance and enabled stabilization of the bronchiectasis. The bronchorrhea gradually disappeared and antibiotics were withdrawn at the age of 20 with no further functional impairment, as is the usual pattern in bronchiectasis caused by noncystic fibrosis.

Pulmonary function tests, which should be performed at regular intervals, will initially show bronchial obstruction unresponsive to inhaled bronchodilators. Inhaled corticosteroids have been tried at this stage, but without clear clinical benefit. Overdistention of the chest and chronic respiratory failure occur secondarily and lead to end-stage disease.

Computed tomography (CT) scans and 99m-Tc-technetium pulmonary scintigraphies are useful tools for assessment of bronchiectasis. If localized lesions are suspected, preoperative bronchography and surgical lobectomy should be considered, although to our knowledge no HLA class I-deficient patient has to date undergone thoracic surgery. Since the mucosal injuries of type I BLS also involve the upper airways, nasal endoscopy and a sinus CT scan can be proposed in the case of suspected sinusitis with nasosinus polyps. The treatment of such lesions is either surgical (polypectomy, ethmoidectomy) or medical (local washing, high-dose topical corticosteroids), or requires both types of intervention. Surgical treatment of chronic sinusitis was reported to accelerate the nasal disease in one case (Gadola et al., 2000), but not in another (Azuma et al., 2001). Chronic otitis media must be carefully checked on regular audiograms and tympanograms. Surgical operations should only be performed under high doses of intravenous antibiotics. Use of tympanostomy

tubes necessitate prolonged antibiotic therapy to avoid middle ear suppuration.

The skin ulcers are difficult to cure. Trials with IFN- $\alpha$  or IFN- $\gamma$  made the lesions worse, and skin grafting was followed by the reappearance of lesions at the same sites (Willemsen et al., 1995). Only basic antiseptic care can be recommended (Gadola et al., 2000).

### Animal Models

MHC class I-deficient transgenic mice have been generated by disrupting the genes encoding  $\beta 2m$  (Koller et al., 1990; Zijlstra et al., 1990), the TAP1 subunit (Van Kaer et al., 1992), or tapasin (Grandea et al., 2000). Findings obtained with the first two models are discussed in detail in three reviews (Raulet, 1994; Ljunggren et al., 1996; Hoglund et al., 1997). These two deficient strains express low levels of MHC class I molecules on the plasma membranes and have very low absolute numbers of CD8 $^{+}$   $\alpha\beta$  T cells. In  $\beta 2m$ -deficient mice, CD8 $^{+}$   $\alpha\beta$  T cells can reject allogeneic tumor cells and syngeneic tumor cells expressing minor antigens (Apasov and Sitkovski, 1994). The mice can fight viral infections but with lower efficiency than that of normal animals. Thus, attenuated influenza viruses are cleared more slowly and virulent strains inflict a higher rate of mortality.  $\beta 2m$ -deficient mice, by contrast, cannot eliminate Theiler's virus although they survive early infection. The mechanisms of resistance to these and other viruses, such as Sendai virus, rotavirus, reovirus, and herpes simplex virus, appear to involve CD4 $^{+}$  T cells and antibody production. More recent studies have analyzed the immune responses of TAP-deficient mice. In these animals, HSV gB-specific cytotoxic T cells were induced by immunization with a recombinant vaccinia virus or naked DNA, but not following HSV infection (Paliard et al., 2001). TAP-deficient animals were more susceptible to infection by the intracellular pathogen *Mycobacterium tuberculosis* (Behar et al., 1999). In contrast, they were not particularly susceptible to tumor formation (Johnsen et al., 2001). NK cells from  $\beta 2m$ -deficient mice displayed reduced cytotoxicity but could be activated in vivo by viral infection (Su et al., 1994; Tay et al., 1995). TAP-deficient mice have been widely studied to characterize the development of CD8 $^{+}$   $\alpha\beta$  T cells (reviewed in Ljunggren et al., 1996). Their NK cells, like those of  $\beta 2m$ -deficient mice, display reduced activity (Ljunggren et al., 1994).

### Future Directions

Most of the identified HLA class I deficiencies result from a defect in one of the two TAP subunits. Although the associated lung and skin pathologies are highly characteristic, some individuals remain asymptomatic for decades, hence the true frequency of the disease is unknown. Therefore, HLA class I deficiency should be more systematically investigated in cases of unexplained chronic inflammation of the respiratory tract that lead to development of nasal polyps, granulomatous lesions of the midface or legs, bronchiectasis, or chronic bacterial infection of the lungs, notably with *Haemophilus influenzae*. On the other hand, the fact that TAP-deficient adults can be healthy indicates that TAP deficiency could come to the fore in atypical situations. In the absence of clinical data on "conditional" HLA class I deficiencies, the discovery of such defects is at present incidental. It will be necessary to collect data on the health status of these individuals and elucidate the genetic defect(s) responsible for their deficiency.

The process of lung degradation in HLA class I deficiency is likewise not yet fully understood. Efficient methods of treating the lung disease need to be developed, for example, through testing of drugs modulating neutrophil activity. The etiology of the skin lesions requires investigation, as does effective care of these lesions. Interestingly, the lesions of one patient transiently regressed when she was pregnant (Furukawa et al., 2000), as is often observed for other clinical manifestations of autoimmune diseases. This regression suggests that favorable regulatory responses controlling NK and T cell activity are induced during pregnancy and remain to be discovered. Finally, the influence of HLA class I deficiency on the production of antibacterial antibodies requires clarification.

At a more fundamental level, as suggested by our own studies of anti-EBV T cell responses in TAP-deficient patients, analysis of antiviral responses mediated by CD8 $^{+}$   $\alpha\beta$  T cells in these individuals might lead to the identification of a large number of viral proteins presented in a TAP-independent manner. Such observations could provide insight into the molecular bases and physiological relevance of these TAP-independent presentation pathways.

## CD40, CD40 Ligand, and the Hyper-IgM Syndrome

RAIF S. GEHA, ALESSANDRO PLEBANI, and LUIGI D. NOTARANGELO

Immunodeficiency with hyper-IgM (HIGM) is a rare congenital disorder, characterized by recurrent infections and very low levels of serum IgG, IgA, and IgE, with normal or elevated IgM (Notarangelo et al., 1992). Both primary and acquired forms of the disease have been reported. Among primary HIGM, X-linked (Krantman et al., 1980; Benkerrou et al., 1990), autosomal recessive (Pascual-Salcedo et al., 1983; Benkerrou et al., 1990; Revy et al., 2000; Ferrari et al., 2001; Imai et al., 2003b), and possibly autosomal dominant (Beall et al., 1980; Brahmi et al., 1983) variants are known, accounting for genetic heterogeneity. Acquired HIGM may be secondary to congenital rubella (Schimke et al., 1969; Espanol et al., 1986; Benkerrou et al., 1990), neoplasia (Raziuddin et al., 1989), or use of antiepileptic drugs (Mitsuya et al., 1979). The disease, originally named *dysgammaglobulinemia*, was first described in 1961 in a 15-year-old boy with recurrent pneumonia, meningitis, and lymphadenopathy (Burtin, 1961), and in two male brothers with a history of recurrent bacterial infections (Rosen et al., 1961).

The primary immunological defect in HIGM had long remained elusive. On the basis of immunoglobulin profile and demonstration that peripheral B lymphocytes from patients with HIGM uniquely express IgM and/or IgD at the cell surface (Schwaber et al., 1981; Levitt et al., 1983), it was originally hypothesized that B lymphocytes from HIGM patients have an intrinsic inability to undergo immunoglobulin isotype switch (Geha et al., 1979; Levitt et al., 1983). However, the observation that patients with the X-linked form of the disease (XHIGM) are uniquely prone to opportunistic infections (Hong et al., 1962) suggested a T cell defect despite laboratory evidence for a humoral immune deficiency. The hypothesis of a primary T cell defect in XHIGM was elegantly supported by studies of Mayer et al. (1986), who demonstrated that B cells from XHIGM patients can be driven to secrete immunoglobulins of various iso-

types in the presence of pokeweed mitogen when cocultured with “helper T lymphoblasts” from a patient with a Sezary-like syndrome.

Experiments aimed at characterizing the helper T cell signals involved in B cell differentiation led to the discovery that monoclonal antibodies to CD40 (a surface protein constitutively expressed on B cells) are able to induce isotype switch in the presence of appropriate costimulatory cytokines (Rousset et al., 1991; Zhang et al., 1991). The gene encoding the natural ligand for CD40 (CD40L, also designated CD154) was cloned first in the mouse (Armitage et al., 1992) and then in humans (Graf et al., 1992; Hollenbaugh et al., 1992; Lederman et al., 1992; Gauchat et al., 1993a). CD40L was shown to be a surface molecule transiently expressed on activated T cells, mainly belonging to the CD4<sup>+</sup> subset (Lane et al., 1992). The *CD40L* gene (also designated tumor necrosis factor superfamily member 5, or *TNFSF5*) was mapped to the X chromosome region q26 (Graf et al., 1992), where the XHIGM locus had been assigned (Padayachee et al., 1992, 1993), and was thus investigated as a candidate gene for XHIGM. Indeed, within a few weeks, five groups independently demonstrated that mutations of the *CD40L/TNFSF5* gene account for XHIGM (MIM #308220) (Allen et al., 1993a; Aruffo et al., 1993; DiSanto et al., 1993; Fuleihan et al., 1993b; Korthauer et al., 1993).

More recently, another group of HIGM patients have been identified whose clinical and immunological features are similar to those of XHIGM, but with an autosomal recessive inheritance (Ferrari et al., 2001). In these patients, mutations of the *CD40* gene (CD40 deficiency; MIM #606843) have been identified, as discussed below. These findings reinforce the importance of the fundamental role that CD40L–CD40 interaction and downstream signaling events play in regulating T cell–dependent B cell responses.

An X-linked HIGM phenotype may also be associated with ectodermal dysplasia (MIM #300291); this disease (described in more detail in Chapter 36) is due to mutations of the *IKK- $\gamma$*  (*NEMO*) gene, involved in nuclear factor (NF)- $\kappa$ B activation (Zonana et al., 2000; Döffinger et al., 2001; Jain et al., 2001).

While defects of CD40L, CD40, and NEMO also affect immune cells other than B lymphocytes (e.g., T lymphocytes and dendritic cells), some forms of HIGM syndrome reflect intrinsic B cell defects that impair the processes of class switch recombination (CSR) and somatic hypermutation (SHM). In particular, Revy et al. (2000) have shown that an autosomal recessive variant of HIGM (activation-induced cytidine deaminase [AID] deficiency; MIM #605258) is due to mutations of the activation-induced cytidine deaminase (*AICD*) gene that is selectively expressed in germinal-center B cells and participates in immunoglobulin isotype switching and somatic hypermutation. In contrast to patients with mutations of CD40L, those with mutations of AID have enlarged lymph nodes and tonsils, with prominent germinal centers, and suffer mainly from recurrent bacterial but not opportunistic infections. Similar features are also observed in patients with the uracil-*N*-glycosylase (UNG) deficiency (MIM #608106), an enzyme also involved in CSR and SHM (Imai et al., 2003b). Finally, at least one other variant of autosomal recessive HIGM with defective CSR has been recognized (selective CSR deficiency), but its gene defects remain obscure (Imai et al., 2003a).

In this chapter, we will focus on CD40L and CD40 defects. Deficiencies of AID, UNG, and NEMO will be discussed in Chapters 20 and 36, respectively.

## Biology of CD40 and CD40 Ligand

### CD40

CD40, a 50 kDa glycoprotein, is a member of the tumor necrosis factor receptor (TNFR) family of surface molecules. The gene, *TNFRSF5* (\*109535), encodes a type I transmembrane protein of 277 amino acids (a.a.) (Stamenkovic et al., 1989). CD40 is expressed on all B cells, but also on other cells that include follicular dendritic cells, thymic epithelial cells, some endothelial and epithelial cells, and neurons. CD40 plays an important role in B cell survival, growth, and differentiation. CD40 ligation on the surface of B cells in the presence of interleukin-4 (IL-4) initiates proliferation and growth and induces homotypic cell adhesion and up-regulation of the expression of CD23, CD54, CD80, CD86, and lymphotoxin- $\alpha$  on B cells. CD40 ligation also up-regulates Fas expression on B cells, making them susceptible to killing by Fas ligand<sup>+</sup> (FasL<sup>+</sup>)-activated T cells (Banchereau et al., 1994; van Kooten and Banchereau, 2000). However, CD40 also delivers an antiapoptotic signal to B cells by inducing antiapoptotic genes that include Bcl-xL and A20 (Ishida et al., 1995; Sarma et al., 1995). Recently it has been shown that C4 binding protein (C4BP), a regulator component of the classical complement pathway, binds directly to CD40 on human B cells at a site that differs from that used by CD40L. Engagement of CD40 by C4BP triggers signaling pathways similar to those triggered by CD40L, as demonstrated by the fact that this interaction induces proliferation, up-regulation of CD54 and CD86 expression, and IL-4-dependent IgE isotype switching in normal B cells (Brodeur et al., 2003). These findings unequivocally suggest that C4BP is an activating ligand for CD40 and establish a novel interface between complement and B cell activation.

### CD40 and isotype switching

Heavy-chain class switching results from deletional recombination between characteristic repetitive sequences (switch regions) located 5' of the C $\mu$  gene and of each C $H$  gene, except C $\delta$ . IL-4 and IL-13, the switch factors for IgE, induce the transcription of a 1.8 kb  $\epsilon$  germ-line mRNA that initiates 5' of the S $\epsilon$  region. This transcript is sterile, as it is not translated into a functional protein. Induction of a mature 2.0 kb  $\epsilon$ mRNA and of IgE protein synthesis requires a second signal, provided by T cells, via CD40L-CD40 interactions (Oettgen, 2000). CD40<sup>-/-</sup> mice fail to undergo T cell-dependent isotype switching and fail to develop germinal centers following immunization with T cell-dependent antigens (Castigli et al., 1994; Kawabe et al., 1994). Similar results were obtained in mice with disrupted *CD40L* genes (Xu et al., 1994; Borrow et al., 1996). Crosslinking of CD40 induces the expression of activation-induced deaminase (AID), which plays a critical role in isotype switching. B cells from AID<sup>-/-</sup> mice and from patients with AID deficiency are unable to undergo isotype switching (Muramatsu et al., 2000; Revy et al., 2000). Several molecules that play a role in DNA repair have been found to be important or essential for isotype switching; these include Ku70, Ku80, DNA-PK, Msh2, and others (Stavnezer, 2000).

### Structure of CD40 receptor complex

The intracellular sequences of murine and human CD40 are shown below:

Mu: 216KRVVKKPRDNEMLPPAARRQDPQEMEDYPGH-----NTA  
 APVQETLHGCQPVTQEDGKESRLSVQERQVTDLSLRPLV  
 Hu: 216KKVAKKPTNKAPHP-----KQEPQE INFPDDLPGS---NTA  
 APVQETLHGCQPVTQEDGKESRISVQERQ

The intracellular domain of human CD40, which starts at a.a. 216 from the initiating methionine, has a binding site for Jak3 in its proline-rich Box 1 membrane proximal region (a.a. 222–229), a binding site for tumor necrosis factor receptor-associated factor 6 (TRAF6) that spans the sequence KQEPQE (a.a. 230–236) (Ishida et al., 1996), and a consensus core binding sequence, Px-QxT (a.a. 250–254), that binds TRAF2 and TRAF3 directly (Cheng et al., 1995; Pullen et al., 1998; Lee et al., 1999; Sutherland et al., 1999). Amino acid residues surrounding this core sequence are also involved in TRAF2,3 binding. The sites of TRAF2 and TRAF3 binding overlap but are not identical. Indeed, mutation of Pro250 to Ala destroys TRAF2 binding but does not affect TRAF3 binding. The reverse is true for mutations of L255, Q263, and E264. These mutations destroy TRAF3 binding but do not affect TRAF2 binding. Furthermore, the C-terminal 18 a.a., which contain the sequence PxxQxD, contribute to TRAF2 but not to TRAF3 binding (Ye et al., 1999). There is a debate as to whether TRAF6 binds directly to CD40. It has been suggested that an adaptor protein, possibly related to MyoD88, that links the IL-1 receptor recruited protein IRAK to TRAF6 facilitates TRAF6 binding to CD40. TRAF1 is probably recruited to CD40 by TRAF2, whereas TRAF5 is recruited by TRAF3 (Leo et al., 1999).

The intracellular domain of murine CD40 also starts at a.a. 216 from the initiating methionine. Like human CD40, it has a proline-rich membrane proximal region (a.a. 222–230). More importantly, it has a highly conserved putative TRAF 6 binding sequence, RQDPQE (a.a. 234–239), and a 32-a.a. stretch (a.a. 247–278) that is 100% homologous to a.a. 246–277 of human CD40 (shaded sequence above). This stretch contains the PxQxT core motif (a.a. 251–255) and all the residues that have been shown to differentially influence TRAF2 and TRAF3 binding.

Murine CD40 has an additional C-terminal 11–a.a. sequence (a.a. 279–289) that is not present in human CD40. Murine CD40, like its human counterpart, binds TRAF2, TRAF3, and TRAF6.

#### Signal transduction following CD40 engagement

CD40 ligation causes an increase in protein tyrosine phosphorylation (Ren et al., 1994; Faris et al., 1994), enhanced association of CD40 with TRAF proteins (Pullen et al., 1999), activation of NF- $\kappa$ B, AP-1, STAT3, and STAT5 transcription factors (Berberich et al. 1994; Hanissian et al., 1997; Iciek et al., 1997; Revy et al., 1999), and activation of the mitogen-activated protein (MAP) kinases Erk, JNK, and p38 (Li et al., 1996). Jak3 activation is thought to mediate STAT activation by CD40 (Karras et al., 1997). CD40 ligation also causes the recruitment of CD40 into lipid rafts (Hostager et al., 2000; Vidalain et al., 2000). There is evidence that CD40, like TNFR1, may already be trimerized by its extracellular pre-ligand association domain (PLAD) (Chan et al., 2000; Kaykas et al., 2001). CD40 ligation by membrane-bound trimeric CD40L causes a higher degree of oligomerization and, most importantly, a conformational change that results in its translocation with associated TRAF proteins to lipid rafts.

A truncated derivative of TRAF2 lacking an amino-terminal RING finger domain is a dominant-negative inhibitor of NF- $\kappa$ B activation mediated by CD40 (Rothe et al., 1995). An 11–a.a. motif in the intracellular domain of CD40 that spans the core Px-QxT TRAF2,3 binding sequence was found to be sufficient for the activation of Jun, p38, and NF- $\kappa$ B. TRAF6 has been reported to synergize with TRAF2 in NF- $\kappa$ B activation (Lee et al., 1999; Tsukamoto et al., 1999). However, in another study TRAF6 was found not to be important for NF- $\kappa$ B activation in B cells (Jalukar et al., 2000). Furthermore, a CD40 mutant that binds TRAF2 but not TRAF3 (or TRAF5) was shown to activate NF- $\kappa$ B. This finding, together with the inability of TRAF1 to activate NF- $\kappa$ B, suggests that TRAF2 is the most important element in CD40-mediated activation of NF- $\kappa$ B. However, the mechanism of NF- $\kappa$ B activation by TRAF2 is still unclear. Oligomerization of the TRAF2 effector domain results in specific binding to MEKK1, a protein kinase capable of activating JNK, p38, and the IKK complex (Baud et al., 1999). TRAF2 has also been found to bind to the kinase NIK, which can also phosphorylate and activate the IKK complex. TRAF2 also binds to RIP, a protein that is central to NF- $\kappa$ B activation by TNFR1 and to the protection of cells from TNF-mediated death. RIP was recently found to bind to MEKK3, which then phosphorylates and activates IKK (Wang et al., 2001). It has been shown that TRAF6 functions as an E3 ubiquitin ligase to catalyze, together with Ubc13/Uev1A, the synthesis of polyubiquitin chains linked through lysine-63 (K63) of ubiquitin and the activation of a TAK1–TAB1/2 complex, which phosphorylates and activates IKK (Deng et al., 2000; Yang et al., 2000; Shuto et al., 2001). Blockade of this polyubiquitin chain synthesis prevents TRAF6-mediated activation of IKK. However, TRAF6 does not appear to activate NF- $\kappa$ B in B cells (Jalukar et al., 2000).

Data from knockout mice and from patients with IKK $\gamma$ /NEMO mutations (Zonana et al., 2000; Döffinger et al., 2001; Jain et al., 2001) strongly suggest that NF- $\kappa$ B plays an important role in CD40-mediated isotype switching. The point mutation in NIK in *aly* mice and null mutations in IKK $\alpha$  are associated with low-serum IgG and absent-serum IgA. B cells from p50, RelA, c-Rel, p52, and IKK $\alpha$  knockout mice, but not from RelB knockout mice, have defects in class switching and in germinal center formation (Sha, 1998). TRAF2 $^{-/-}$  mice die perinatally but TRAF2 $^{-/-}$  TNFR1 $^{-/-}$  and TRAF2 $^{-/-}$  TNF $^{-/-}$  double-mutant mice are viable

(Yeh et al., 1997). Isotype switching to IgG is impaired in TRAF2 $^{-/-}$  TNFR1 $^{-/-}$  mice. This finding further supports the idea that a pathway consisting of TRAF2-mediated activation of NF- $\kappa$ B in CD40-activated B cells is critical for isotype switching. Importantly, both type 1 (p50-dependent) and type 2 (p52-dependent) NF- $\kappa$ B signaling pathways are triggered following CD40 activation and contribute to the gene expression and biological program unique to CD40 in B cell activation (Zarnegar et al., 2004).

TRAF6 and TRAF2 have been reported to be involved in JNK and p38 activation by CD40 (Reinhard et al., 1997; Song et al., 1997; Leo et al., 1999). Both synergize in the activation of JNK, but TRAF6 appears to be the most important factor for activation of p38 (Leo et al., 1999). TRAF3 has been reported to activate the JNK and p38 pathways (Grammer et al., 1998). There is also evidence for a TRAF-independent pathway of CD40-mediated JNK activation. A deletion mutant of TRAF6 lacking the NH2-terminal domain acted as a dominant-negative mutant to suppress ERK activation by full-length CD40 and by a deletion mutant of CD40, only containing the binding site for TRAF6 in its cytoplasmic tail (Kashiwada et al., 1998). This result suggests that TRAF6 may be the most important element in CD40-mediated activation of ERK. A model for CD40 signaling is presented in Figure 19.1.

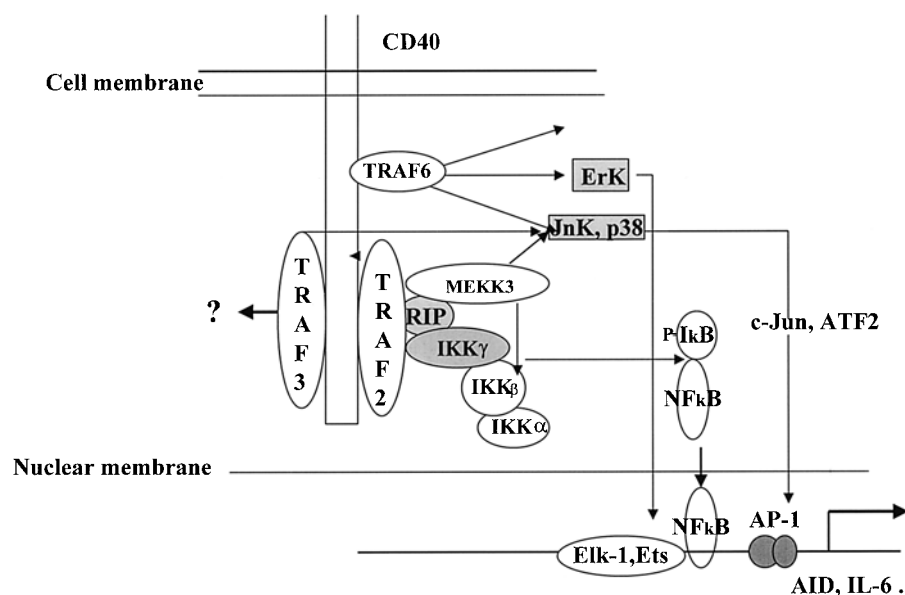

Finally, the redox factor APE/Ref-1 has been reported to act as a key signaling intermediate in response to CD40-mediated B cell activation. Upon CD40 cross-linking, APE/Ref-1 translocates from the cytoplasm to the nucleus, where it modulates the DNA-binding activity of the Pax5 and EBF transcription factors. APE/Ref-1 appears to be required for CD40-mediated Pax5 activation, as the repression of APE/Ref-1 protein production is able to block CD40-induced Pax5 binding activity (Merluzzi et al., 2003).

#### CD40 Ligand

The murine CD40L has been identified and the gene cloned as an EL4 thymoma cell surface molecule that binds to soluble CD40 (Armitage et al., 1992). Subsequently, the human *CD40L* gene (*TNFSF5*, 300386) was cloned from activated T cells (Graf et al., 1992; Hollenbaugh et al., 1992; Spriggs et al., 1992). Independently, Lederman and coworkers identified a subclone of Jurkat T cells that is able to provide contact-dependent helper function to B cells (Lederman et al., 1992); this molecule has since been cloned and confirmed to be CD40L (CD154, also referred to as *gp39*). The human cDNA has an open reading frame of 783 base pairs (bp) that codes for a type II membrane protein 261 a.a. long. The extracellular domain is 215 a.a. long, the transmembrane domain is 24 a.a. in length, and the intracellular domain is 22 a.a. long. The extracellular domain immediately proximal to the transmembrane region has a putative proteolytic cleavage site (His-Arg-Arg-Leu), which suggests that the extracellular domain may be “shed.” Molecular modeling of CD40L based on the crystal structure of TNF indicates that a.a. residues 189–209 are critical for the binding of CD40L to CD40 (Peitsch and Jongeneel, 1993).

Detailed organization of the murine (Tsitsikov et al., 1994) and human (Villa et al., 1994; Shimadzu et al., 1995) *CD40L* genes has been reported. The gene consists of five exons. Exon 1 encodes for the 5′ untranslated region and the first 52 a.a., including 22 a.a. of the intracytoplasmic tail, 24 a.a. of the transmembrane domain, and 6 a.a. of extracellular domain. Exons 2, 3, and 4 encode a.a. 53–96, a.a. 97–114, and a.a. 115–135 a.a.,

**Figure 19.1.** Hypothetical model of CD40 signaling. CD40 ligation causes enhanced association of CD40 with tumor necrosis factor receptor-associated factor (TRAF) proteins. Oligomerization of TRAF2 effector domain results in specific binding to MEKK3, a kinase capable of activating JNK, p38, and the IKK complex. TRAF2 also binds to RIP, a protein central to NF- $\kappa$ B activation. Subsequently, RIP binds to MEKK3, which then activates the IKK complex. JNK and p38 are also activated by CD40-activated TRAF6. TRAF6 is known to be the most important element in CD40-mediated activation of ERK. JNK and p38 transduce their activation signal to the nucleus through c-Jun and ATF2, whereas ERK binds to Elk-Ets binding sites. As a result of CD40-mediated signaling, a number of critical genes involved in terminal B cell differentiation and inflammation (such as AID and IL-6) are transcribed.

respectively. Exon 5 encodes the rest of the protein (a.a. 136–260) and the 3' untranslated region. There is no homology in the position of the exons between CD40L and any of the known genes from the TNF family, but in all these genes the sequence encoding the receptor binding domain is located in the last exon. Sequences up to 1.5 kb upstream from the murine gene lack the TATAA or CCAAT boxes but have an Sp1 sequence, six nuclear factor of activated T cells (NFAT)-like sequences, and one OAP-like site. The 3' untranslated region of the murine gene has two adjacent microsatellite repeats (a 50-bp-long CT and a 90-bp-long CA repeat) as well as two ATTTA elements that are putatively responsible for the stability of mRNA.

Several studies have illustrated the importance of CD40 and its ligand, CD40L, in humoral immunity. Recombinant CD40L mimics the action of CD40 monoclonal antibody (MAb) and is able to stimulate B cell proliferation in the presence of phorbol myristate acetate (PMA) and to induce immunoglobulin synthesis (Spriggs et al., 1992; Lane et al., 1993). Immunoglobulin secretion by B cells is highly modulated by cytokines. In the presence of recombinant CD40L, IL-2 and IL-10 induce specifically the secretion of IgM, IgG1, and IgA (Durandy et al., 1993) whereas IL-4 is necessary for the secretion of IgG4 and IgE. Antibody to CD40L can block T cell-dependent B cell activation (Noelle et al., 1992a, 1992b). Likewise, soluble CD40, a product of the fusion of cDNA segments encoding the extracellular domain of CD40 to genomic DNA segments encoding human IgG1, inhibits IgE synthesis (Fanslow et al., 1992). Immunization of mice with KLH (a thymus-dependent antigen) or DNP-Ficoll (a thymus-independent antigen) induces the expression of CD40L by T helper (TH) cells, and this induction coincides with the development of cytokine-producing cells. Through the use of immunocytochemical techniques, it was elegantly demonstrated that CD40L cells and cytokine-producing cells are juxtaposed in the lymphoid organs (Van den Eertwegh et al., 1993). Short-term treatment with anti-CD40L antibody suppressed the immune response against these antigens, but adoptive transfer of cells from anti-CD40L-treated mice could fully reconstitute TH function in irradiated recipient mice, showing that immune suppression does not involve clonal anergy or deletion (Foy et al., 1993). Thus it appears that CD40L expression is essential for both thymus-dependent and thymus-independent antigens.

However, in mice with targeted disruption of the *CD40* or *CD40L* gene, only the antibody response against the T-dependent antigen is impaired. This finding suggests that stimulation via CD40/CD40L may not be critical for antibody responses to T-independent antigens, at least in the murine model.

Soluble CD40L also acts as T cell growth factor, being a costimulatory molecule for both  $\alpha/\beta$  and  $\gamma/\delta$  T cells (Armitage et al., 1993; Fanslow et al., 1994; Ramsdell et al., 1994). In the presence of submitogenic concentrations of Con A, phytohemagglutinin (PHA), CD3 MAb, or MAbs to the T cell receptor (TCR), addition of soluble CD40L increased the expression of CD25 and CD69. CD40L is also essential for the activation of macrophage effector function by T cells. CD40L<sup>-/-</sup> mice are less effective in stimulating allogenic macrophages to produce inflammatory cytokines and reactive nitrogen intermediates (Stout et al., 1996).

#### Regulation of CD40 ligand expression

*CD40L* is a highly inducible gene and is mainly expressed by CD4<sup>+</sup> T cells, although polymerase chain reaction (PCR) products have been identified using mRNA derived from CD8<sup>+</sup> cells, monocytes, and natural killer (NK) cells (Cocks et al., 1993). In addition, mast cells, basophils (Gauchat et al., 1993b), and eosinophils (Gauchat et al., 1995) have been shown to express functional CD40L on their surface. The T cell expression of CD40L is well regulated; resting T lymphocytes do not express CD40L. In  $\alpha/\beta$  T cells, CD40L mRNA becomes detectable as early as 1 hour after stimulation with PMA and ionomycin, peaks at 3 hours, and disappears by 24 hours. Surface CD40L is detected as early as 3 hours after stimulation with PMA and ionomycin, peaks at 6 hours after stimulation, starts to decline by 8 hours, and is barely detectable by 16 hours. However, murine TH cells activated by anti-CD3 displayed sustained expression of CD40L, showing 50% of the maximal staining even 24 hours poststimulation, but fell rapidly by 48 hours (Castle et al., 1993; Roy et al., 1993). Simultaneous engagement of the T cell costimulatory molecule CD28 by MAb enhances CD40L expression (Klaus et al., 1994; Ding et al., 1995). Highly purified peripheral blood  $\gamma/\delta$  T cells also express CD40L after stimulation (Horner et al., 1995). The kinetics of mRNA synthesis and surface

expression closely resembles that of  $\alpha/\beta$  T cells, but the levels are much lower. Although the physiological significance of this observation needs to be assessed, it suggests a mechanism by which  $\gamma/\delta$  T cells might be able to provide helper function in isotype switching.

Mature thymocytes express functional CD40L on their surface, and CD40 is also functionally expressed on thymic epithelial cells and dendritic cells, a finding suggesting that the CD40/CD40L system may play a role in T cell development. Indeed, negative selection of endogenously expressed antigens and superantigens were blocked by the administration of antibodies to CD40 ligand, illustrating a role for CD40 ligand in thymic selection (Foy et al., 1995).

CD40L expression is developmentally regulated. Immature CD4<sup>+</sup> CD8<sup>+</sup> human thymocytes obtained from infants (3 months to 2 years of age) failed to express CD40L upon activation. In contrast, CD4<sup>+</sup> thymocytes, but not CD8<sup>+</sup> thymocytes, expressed CD40L and could induce B cells to undergo isotype switching to IgE in the presence of IL-4 (Fuleihan et al., 1995). Newborn T cells were found to be deficient in CD40L expression and in their ability to induce isotype switching in B cells (Brugnoni et al., 1994; Fuleihan et al., 1994a; Durandy et al., 1995; Nonoyama et al., 1995). The ability of T cells to express CD40L improved by 1 month of age and reached a plateau by late adolescence (Brugnoni et al., 1996). In keeping with this finding, infants below 6 months of age tend to express low amounts of CD40L compared to that in older subjects (Gilmour et al., 2003).

Cyclosporin A (CsA) inhibits the surface and mRNA expression of CD40L in human (Fuleihan et al., 1994b) and murine (Roy et al., 1993) T cells. CsA is a naturally occurring immunosuppressant that binds to its cellular receptor(s), cyclophilin, forming a complex that inhibits the activity of the phosphoprotein phosphatase calcineurin. Calcineurin dephosphorylates the cytoplasmic subunit of the transcription factor, NFAT, which translocates into the nucleus to form the functional NFAT complex and regulates the expression of the gene encoding IL-2 (Jain et al., 1993). The transcription of CD40L mRNA and the surface expression of the protein is inhibited by pretreatment of T cells with CsA in a dose-dependent manner. The ability of CsA analogues to inhibit CD40L expression correlated with the affinity of the cyclophilin drug complex to calcineurin and not with the affinity of the drug to cyclophilin. These results suggest that transcription factors activated by calcineurin, such as NFAT, regulate the transcription of the *CD40L* gene. This regulatory mechanism was borne out experimentally as described below.

The corticosteroid hydrocortisone up-regulates CD40L mRNA expression in peripheral blood mononuclear cells (PBMCs) and surface expression of CD40L in PBMCs as well as in purified populations of T and B cells. Furthermore, hydrocortisone induces IgE synthesis in IL-4-stimulated normal human B cells but fails to induce IgE synthesis in B cells from CD40L-deficient patients. Disruption of CD40L-CD40 interaction by soluble CD40-Ig fusion protein or anti-CD40L MAb blocked the capacity of hydrocortisone to induce IgE synthesis in normal B cells. Up-regulation of CD40L mRNA and induction of IgE synthesis by hydrocortisone were inhibited by the steroid hormone receptor antagonist RU-486 (Jabara et al., 2001). These results indicate that ligand-mediated activation of the glucocorticoid receptor (GR) up-regulates CD40L expression in human lymphocytes. It is possible that hydrocortisone acts by inducing GR binding to glucocorticoid-responsive elements present in the CD40L promoter.

**Table 19.1.** NFAT-Like Sequences in Murine and Human *CD40L* Gene Promoter/Enhancer Region

Orientation Relative to ORF	Sequence	Position From Transcription Start Site
<i>Murine</i>

NM, NFAT motifs; NLM, NFAT-like motifs; ORF, open reading frame; +, orientation same as that of ORF; -, opposite orientation.

The organization of the murine and human *CD40L* genes shows remarkable conservation even in the 5' upstream regulatory sequences. The transcription originates from a G residue 68 bp upstream from the A of the initiation codon in both species (Tsitsikov et al., 1994; Schubert et al., 1995). Within 1.2 kb from the transcription start site, the mouse gene has four motifs that contain the invariant TTTTCC sequence found in the two NFAT binding motifs (NM) and two NFAT-like motifs (NLM) of the murine IL-2 gene (Table 19.1). The NM-1, NM-2, and the NLM-1 motifs are conserved in the human gene; however, the NM-3, NM-4, and NLM-2 motifs are not. It may be noted that the position and orientation of the NFAT binding motifs in the human gene are identical to those of the equivalent NFAT motifs in the murine gene. A detailed study of the most proximal NM sites in the murine system showed that this sequence formed two complexes on electrophoretic mobility shift analyses (EMSA) and that mutation of the TTTTCC sequence but not of the flanking sequences abolished the capacity to inhibit complex formation (Tsytyskova et al., 1996). Both complexes were sensitive to CsA and contained NFATc and NFATp as revealed by supershift analyses. Short (18 bp) oligonucleotides containing the NFAT sites were not supershifted by antisera to Fos and Jun proteins; however, long oligonucleotides (30 bp) bound to AP-1 proteins (Fos and Jun). Trimers of the proximal NFAT (long oligonucleotides) homologous sites were transcriptionally active. These results suggest that NFATp and/or related proteins play an important role in expression of the *CD40L* gene. Similar results have been obtained with human CD4 cells (Schubert et al., 1995).

### Clinical and Pathological Manifestations of CD40 Ligand Deficiency

Most patients with CD40L deficiency (XHIGM) present in infancy with recurrent upper and lower respiratory tract infections and have a unique predisposition to *Pneumocystis carinii* pneumonia (PCP) (Levitt et al., 1983; Benkerrou et al., 1990; Notarangelo et al., 1992; Banatvala et al., 1994; Conley et al., 1994; Kraakman et al., 1995). In some cases, PCP may even mark the clinical onset of the disease (Marshall et al., 1964; Ochs and Wedgwood, 1989; Levy et al., 1997; Winkelstein et al., 2003). The frequency of PCP in XHIGM varies from 31.7% to

48.1% in the European and U.S. series of patients (Winkelstein et al., 2003; L. Notarangelo et al., unpublished observation). Lung infections may also be due to cytomegalovirus, cryptococcus, and mycobacteria, including bacillus Calmette-Guerin (Levy et al., 1997). In some cases, disseminated cryptococcosis, histoplasmosis, or mycobacterial infection may ensue (Kyong et al., 1978; Tu et al., 1991; Banatvala et al., 1994; Hostoffer et al., 1994; Iseki et al., 1994; Tabone et al., 1994; Levy et al., 1997).

Diarrhea, a frequent finding, occurs in over 50% of XHIGM patients (Notarangelo et al., 1992; Levy et al., 1997; Winkelstein et al., 2003) and may become chronic, requiring total parenteral nutrition to avoid severe growth failure. Chronic watery diarrhea is often associated with *Cryptosporidium* infection (Stiehm et al., 1986) that may also contribute to sclerosing cholangitis—a severe and often fatal complication (DiPalma et al., 1986; Banatvala et al., 1994; Hayward et al., 1997; Levy et al., 1997; Winkelstein et al., 2003). The incidence of liver and biliary tract disease increases with age (Hayward et al., 1997).

Oral ulcers and proctitis are common manifestations (Hong et al., 1962; Kyong et al., 1978; Rieger et al., 1980; Benkerrou et al., 1990; Notarangelo et al., 1992; Banatvala et al., 1994; Macchi et al., 1995) and are usually associated with neutropenia, either chronic (Aruffo et al., 1993; Levy et al., 1997) or cyclic (Notarangelo et al., 1992; Wang et al., 1994; Shimadzu et al., 1995).

Patients with mutations of CD40L are at increased risk for neoplasms, most often lymphomas (Filipovich et al., 1994) but also liver/biliary tract and gastrointestinal tumors, which are rarely observed in other primary immunodeficiencies (Facchetti et al., 1995; Hayward et al., 1997). Autoimmune manifestations may occur in X-linked forms of HIGM but more so in autosomal forms. These may lead to arthritis, thrombocytopenia, hemolytic anemia, hypoparathyroidism, or immune complex-mediated nephritis (Pascual-Salcedo et al., 1983; Benkerrou et al., 1990; Hollenbaugh et al., 1994). Anemia is present in about 25% of XHIGM patients (Notarangelo et al., 1992) and may be secondary to chronic infections or to parvovirus B19-induced red blood cell aplasia. The latter may even be the only manifestation of disease in patients with a mild phenotype (Seyama et al., 1998a).

Severe neurological involvement has also been reported (Banatvala et al., 1994; Levy et al., 1997; Ziegner et al., 2002). Meningoencephalitis due to enterovirus infection may occur, despite regular administration of intravenous immunoglobulins (IVIG) (Cunningham et al., 1999; Halliday et al., 2003).

Lymph nodes of XHIGM patients lack germinal centers (Rosen et al., 1961; Hong et al., 1962; Stiehm and Fudenberg, 1966; Facchetti et al., 1995) (Color Plate 19. I). This is the consequence of ineffective CD40–CD40L interaction in the extrafollicular areas, resulting in poor recruitment of germinal-center precursors. In addition, severe depletion and phenotypic abnormalities of follicular dendritic cells have been reported in XHIGM that may contribute to poor antigen trapping and result in inefficient rescue of the few germinal-center B cells from apoptosis (Facchetti et al., 1995). Bone marrow examination in patients with concurrent neutropenia often reveals a block of myeloid differentiation at the myelocyte/promyelocyte stage (Hong et al., 1962; Kyong et al., 1978; Benkerrou et al., 1990; Notarangelo et al., 1992). By contrast, serum levels of granulocyte colony-stimulating factor (G-CSF) in neutropenic XHIGM patients are normal or elevated (Wang et al., 1994).

A European registry of CD40L-deficient patients has been organized that includes clinical, immunological, and molecular data. The registry is fully accessible through at [\[uta.fi/CD40Lbase/index2.html\]\(http://uta.fi/CD40Lbase/index2.html\). A similar registry has been set up in the United States by USIDnet.](http://bioinf</a></p>

## Laboratory Findings

### Immunoglobulin levels

Like all forms of HIGM, XHIGM is characterized by markedly reduced serum IgG, IgA, and IgE with normal to elevated IgM levels and a normal number of circulating B cells (Geha et al., 1979; Levy et al., 1987; Notarangelo et al., 1992; Winkelstein et al., 2003). Variability of IgM serum levels has been reported among affected members of the same family, indicating that increased IgM may reflect chronic antigenic stimulation rather than the direct effect of a molecular defect (Krocze et al., 1994).

In a series of 56 XHIGM patients, the majority (53%) had normal IgM serum levels at the time of diagnosis (Levy et al., 1997). It appears that IgM serum levels increase with age, particularly if initiation of IVIG substitution therapy is delayed (Levy et al., 1997). In a recent study, however, as many as one-quarter of patients with confirmed CD40L deficiency had low concentrations of serum IgM, indicating that even low-serum IgM should not preclude testing for CD40L deficiency (Gilmour et al., 2003). Although serum levels of IgG, IgA, and IgE are normally very low, exceptional cases with elevated IgA, IgE, or even IgG have been reported in patients with severe defects in the CD40L gene (Levy et al., 1997; L. Notarangelo, unpublished observation), indicating that environmental and/or additional molecular mechanisms other than CD40L are involved in isotype switch.

Levels of specific antibodies of the IgM isotype (e.g., iso-hemagglutinins, Forssman antibodies) are normal (Rosen et al., 1961; Kyong et al., 1978; Benkerrou et al., 1990). Immunization with T-dependent antigens (e.g., bacteriophage  $\phi$ x174) leads to reduced primary and secondary IgM antibody responses, whereas there is little or no production of IgG-specific antibodies following recall immunization (Stiehm and Fudenberg, 1966; Benkerrou et al., 1990; Nonoyama et al., 1993). In addition, analysis of V<sub>H</sub> gene segments in patients with CD40L mutations has revealed a lower frequency of somatic mutations in IgM-expressing B cells than that in controls (Chu et al., 1995; Razanajaona et al., 1996). This finding is in keeping with the observed lower affinity of antibodies produced by XHIM patients in response to vaccination.

Defects of immunoglobulin isotype switching and of somatic mutations are a direct consequence of the underlying genetic defect. Because of the inability to express functional CD40L trimers, activated T cells are unable to provide a key helper signal for terminal B cell differentiation. The functional integrity of XHIGM B cells, by contrast, initially suggested by the historical experiments performed by Mayer et al. (1986), is best illustrated by intact CSR and the production of IgG, IgA, or IgE upon in vitro coculture of PBMCs with anti-CD40 MAb (or soluble CD40L) and appropriate cytokines, such as IL-4 and IL-10 (Allen et al., 1993a; Aruffo et al., 1993; Durandy et al., 1993; Fuleihan et al., 1993a; Korthauer et al., 1993; Callard et al., 1994; Saiki et al., 1995).

### B and T lymphocytes

The demonstration of normal numbers of circulating B cells allows differentiation from X-linked agammaglobulinemia. As a rule, circulating B cells from XHIGM patients express IgM

**Table 19.2.** Synopsis of Laboratory Findings in X-Linked Form of Hyper-IgM (CD40L Deficiency)

Assay	Typical Phenotype	Percent of XHIGM Patients Showing Phenotype*
<i>Immunological Features</i>		
Serum IgG	<2 SD below normal range	100
Serum IgA (mg/dl)	Undetectable	93
Serum IgM (mg/dl)	Normal	53 (at diagnosis) <sup>†</sup>
	Elevated	47 (at diagnosis) <sup>†</sup>
Antibody response to T-dependent antigens ( $\phi \times 174$ )	Lack of specific IgG production	100 <sup>‡</sup>
B cell count	Normal	90
CD4 <sup>+</sup> cell count	Normal	94
CD8 <sup>+</sup> cell count	Normal	98
Proliferative response to PHA	Normal (>50,000 cpm)	93
Proliferative response to T-dependent antigens	Often reduced (<5000 cpm)	37
CD40L expression**		
As assessed with CD40-Ig	Absent	Nearly 100 <sup>††</sup>
As assessed with MAbs	Usually absent	95
As assessed with polyclonal antiserum	Detectable in some cases	23
<i>Hematological Features</i>		
Neutropenia	Generally present (mostly chronic)	68
Anemia	Often present	32

\*Unless differently specified, data are from Levy et al. (1997).

<sup>†</sup>Elevated levels of IgM are detected in 70% of patients during follow-up.

<sup>‡</sup>From Nonoyama et al. (1993).

\*\*From a series of 22 patients analyzed at the Department of Pediatrics, University of Brescia, Italy.

<sup>††</sup>Activated CD4<sup>+</sup> T cells from patients with missense mutations in intracytoplasmic or transmembrane domains of CD40L may occasionally react with CD40-Ig (Seyama et al., 1998b).

and/or IgD, but not other isotypes (Levitt et al., 1983; Benkerrou et al., 1990). Since CD40L–CD40 interaction is essential for memory B cell generation, the number of circulating IgD–CD27<sup>+</sup> switched memory B cells is strongly diminished in patients with CD40L mutations (Agematsu et al., 1998).

In spite of the T cell nature of the defect in XHIGM, the number and distribution of T cell subsets are normal, although the proportion of CD45R0<sup>+</sup> primed T cells is reduced (Jain et al., 1999). In vitro proliferative responses to mitogens are also normal in these patients (Benkerrou et al., 1990; Ameratunga et al., 1997; Levy et al., 1997). In contrast, in vitro proliferative response to antigens is often reduced (Ameratunga et al., 1997; Levy et al., 1997). A defect in TH1 responses has been reported, with reduced secretion of interferon- $\gamma$  (IFN- $\gamma$ ) and failure to induce antigen-presenting cells to synthesize IL-12 (Jain et al., 1999; Subauste et al., 1999). Finally, T cells from patients with CD40L mutations are unable to provide help for the antibody response to polysaccharide antigens. This deficit further contributes to the susceptibility to infections observed in patients with XHIGM (Jeurissen et al., 2004). A summary of laboratory features typically observed in XHIGM is shown in Table 19.2.

### Molecular Basis of CD40 Ligand Deficiency

By means of linkage analysis, the XHIGM locus was originally assigned to Xq24–27 (Mensink et al., 1987) and subsequently mapped to Xq26.3–27 (Padayachee et al., 1992, 1993). Cloning of the human *CD40L/TNFSF5* gene and coincidental mapping to the same region of the X chromosome (Graf et al., 1992) were

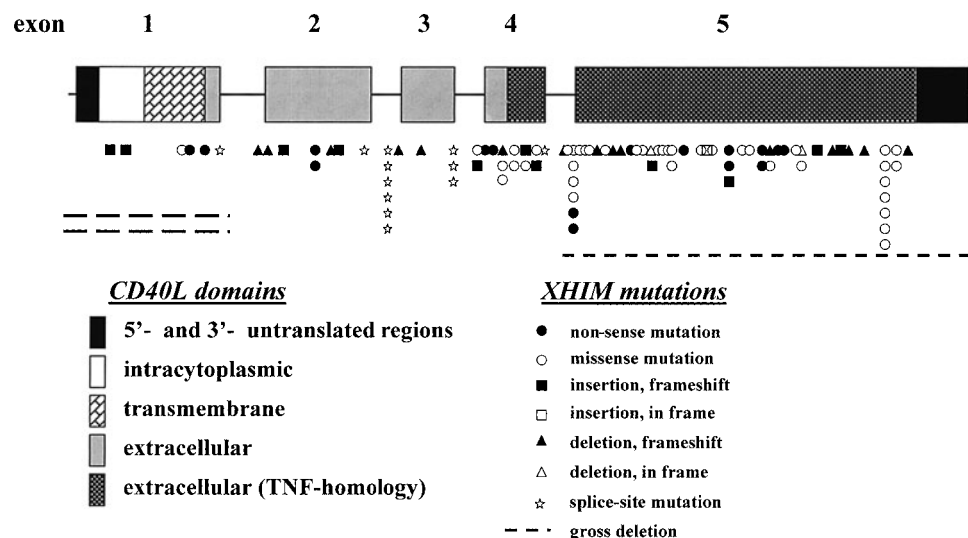

soon followed by the recognition that mutations of *CD40L* account for XHIGM (Allen et al., 1993a; Aruffo et al., 1993; DiSanto et al., 1993; Fuleihan et al., 1993b; Korthauer et al., 1993). More accurate mapping (Pilia et al., 1994) and elucidation of the organization of the *CD40L/TNFSF5* gene (Villa et al., 1994; Shimadzu et al., 1995) have since been provided. The human *CD40L/TNFSF5* gene encompasses about 13 kb of genomic DNA and is organized in five exons and four introns. Definition of the exon–intron boundaries has enabled a search for mutations at the genomic level (Villa et al., 1994; Lin et al., 1996).

### CD40L mutations

Since 1993, a long list of distinct mutations of the *CD40L/TNFSF5* gene have been identified in multiple unrelated XHIGM families. Figure 19.2 illustrates the mutations identified in 128 patients included in the European CD40Lbase Registry. Although mutations may affect the entire gene, they are unequally distributed and the majority are located in exon 5, which contains most of the TNF-homology domain (Hollenbaugh et al., 1992).

Missense mutations are the most common cause of the disease. In addition, one single amino acid change (Arg81Trp) that does not lead to diminished CD40 binding or to clinical or immunological abnormalities has been described and should therefore be considered a rare polymorphism (Bajorath et al., 1996). In some cases, for example, the Trp140stop mutation, premature termination is compatible with expression of a truncated molecule at the cell surface, as shown by staining with polyclonal anti-CD40L antibody (Korthauer et al., 1993; Seyama et al., 1998b). Small insertions or deletions are also common; these

**Figure 19.2.** Description of CD40L mutations identified in 128 patients enrolled in the European CD40Lbase Registry. The various mutations reported in families with X-linked form of hyper-IgM syndrome are shown with different symbols, as indicated in the figure, and aligned along the CD40L cDNA schema.

may be due to polymerase slippage, occurring at sites of nucleotide duplications or tandem repeats in the CD40L sequence (Macchi et al., 1995). A few patients with two different mutations have been described (Aruffo et al., 1993; Grammer et al., 1995; Lin et al., 1996).

The finding that several apparently unrelated families share mutations at the same codon has led to the hypothesis that hot-spot mutations in the *CD40L/TNFSF5* gene exist. In particular, several families have been reported with mutations affecting codon 140 (Korthauer et al., 1993; Iseki et al., 1994; Macchi et al., 1995; Saiki et al., 1995; Bajorath et al., 1996; Notarangelo et al., 1996; Seyama et al., 1998b; Lee et al., 2005) or with the Leu155Pro mutation (Allen et al., 1993a; Lin et al., 1996; Notarangelo et al., 1996) or the Thr254Met substitution (Bajorath et al., 1996; Notarangelo et al., 1996; Lee et al., 2005). Recurrence of mutations at these codons is not due to the presence of CpG dinucleotides.

Investigation of the effect of amino acid substitutions on CD40L expression and function, studied through several approaches, has contributed to definition of the role that single residues play in determining folding, assembling, and CD40-binding properties of CD40L. For some naturally occurring mutations, transfectants that express surface membrane or soluble forms of mutant CD40L molecules have been generated. The mutagenized recombinants fail to bind CD40-Ig or to induce B cell proliferation and immunoglobulin secretion in the presence of IL-4 (Allen et al., 1993a; Aruffo et al., 1993).

#### Functional aspects of CD40L deficiency

Human CD40L belongs to the TNF family (Hollenbaugh et al., 1992). Interestingly, when one considers the missense mutations that affect the TNF-like domain of CD40L, a remarkable proportion (9 out of 24, or 37.5%) affect residues that are identical between CD40L and TNF, whereas the sequence identity between these molecules in the region is only 24.7%. Despite the rather limited sequence identity of the CD40L TNF-like domain with TNF (27.3%), the homology is sufficient to allow computer modeling based on the crystal structures available for TNF and for the TNF/TNFR complex (Jones et al., 1989; Eck and Sprang, 1991; Banner et al., 1993). Thus, models have been generated for

murine (Peitsch and Jongeneel, 1993) and human (Bajorath et al., 1995a, 1995b; Notarangelo et al., 1996) CD40L, and an X-ray structure of the extracellular portion of human CD40L has been produced (Karpusas et al., 1995). Analogous to TNF, CD40L forms a trimer and exhibits a remarkably similar overall fold, with the extracellular portion assuming the shape of a truncated pyramid (Karpusas et al., 1995). A disulfide bond between Cys178 and Cys218 stabilizes the top of the molecule. The CD40 binding site consists of a shallow groove formed between two monomers. Buried and solvent-accessible residues of the CD40L molecule have been identified (Bajorath et al., 1995a, 1995b; Karpusas et al., 1995). Interestingly, of several residues predicted to be directly involved in CD40 binding, only one (Gly144) has been found mutated in an XHIGM patient (Macchi et al., 1995). In addition, only a few residues (Lys143, Tyr145, Tyr146, Arg203, and Gln220) appear to be really critical for CD40 binding, as shown by in vitro mutagenesis studies (Bajorath et al., 1995a, 1995b). The crystal structure of the extracellular portion of CD40L has indeed shown that both hydrophobic and hydrophilic residues form the surface of the CD40 binding site (Karpusas et al., 1995). In addition, a number of buried residues appear to be important for proper monomer folding and trimer formation. The location of mutations that occur in XHIGM patients has been compared to that in the CD40L model. Ser128 and Glu129 (which have both been reported to be mutated) lie close to Lys143 in the three-dimensional structure. Since Lys143 is involved in CD40 binding, it is likely that mutations at codons 128 and 129 disturb ligand-receptor interaction (Karpusas et al., 1995; Bajorath et al., 1996). Similarly, Val126 and Leu155 (also mutated in XHIGM) participate in the formation of a hydrophobic core that is very close to residues 143–145, which are involved in CD40 binding; it is predicted that these mutations also affect the CD40 binding property of CD40L. Finally, three additional mutations (Thr147Asn, Thr211Asp, Gly250Ala) involve residues that are either buried (Thr147) or exposed (Thr211, Gly250) and are located at the interface between monomers; they participate in the formation of three equivalent CD40 binding sites, one per interface between monomers. Mutation at these residues should also affect CD40 binding (Bajorath et al., 1996).

However, the majority of missense mutations reported in XHIGM do not involve the CD40 binding site. The amino acids affected may participate in the generation of the hydrophobic core, so mutations at these residues compromise core packing and folding of the monomer (this is the case for Trp140Arg, Trp140Cys, Trp140Gly, Leu232Ser, Ala235Pro, Val237Glu, Thr254Met, and Leu258Ser) (Bajorath et al., 1996). Alternatively, they may involve buried residues at the interface between monomers; mutations at these sites are likely to disturb trimer formation, as predicted for Ala123Glu, Tyr170Cys, Tyr172His, and Gly227Val (Karpus et al., 1995; Bajorath et al., 1996). Finally, the single amino acid substitution Met36Arg in the transmembrane domain of CD40L introduces a polar residue in a very hydrophobic sequence, thus inhibiting membrane expression of the protein (Korlhauer et al., 1993).

### Strategy for Diagnosis

The diagnosis of XHIGM is usually accomplished by demonstrating in vitro the inability of activated patient CD4<sup>+</sup> T cells to express functional CD40L (CD154) molecules, as assessed by binding soluble CD40-Ig chimeric constructs. Monoclonal antibodies to CD40L are often used to stain activated CD4<sup>+</sup> T cells in flow cytometry assays. However, false-negative results may be obtained because occasionally monoclonal antibodies recognize mutant forms of CD40L expressed at the cell surface. This phenomenon is even more common when polyclonal antisera to CD40L are used in the staining procedure, as they may recognize even truncated forms of the protein (Seyama et al., 1998b). Therefore, polyclonal antisera to CD40L should not be used for diagnosis. Although rare, even the chimeric CD40-Ig molecule may bind to mutant CD40L, particularly in patients with missense mutations in the transmembrane or cytoplasmic domains, which are permissive for membrane protein expression (Seyama et al., 1998a, 1998b; Lee et al., 2005). Ultimately, mutation analysis at the *CD40L/TNFSF5* locus may be required for a definitive diagnosis.

A number of critical factors should be considered when performing diagnostic assays for XHIGM. First, appropriate controls for T cell activation (e.g., expression of CD69) should be included. This is particularly important to distinguish XHIGM from common variable immunodeficiency (CVID); a subgroup of CVID patients have defective CD40L expression in the context of a broader T cell activation defect (Farrington et al., 1994). Second, because CD40L is preferentially expressed by activated CD4<sup>+</sup> cells (Lane et al., 1992), the proportion of CD4<sup>+</sup> T cells in the patient should be analyzed. This is particularly important when a more simple whole-blood assay is used to evaluate CD40L expression (Gilmour et al., 2003). It has been recognized that activated T cells from patients with major histocompatibility complex (MHC) class II deficiency fail to express CD40L because of the markedly reduced proportion of CD4<sup>+</sup> T lymphocytes (Callard et al., 1994). Third, the age of the proband has to be considered. There is ample evidence showing that expression of CD40L by activated neonatal T cells is physiologically reduced (Brugnoni et al., 1994; Fuleihan et al., 1994a; Durandy et al., 1995; Nonoyama et al., 1995), making flow cytometry unsuitable for diagnosis of XHIGM in neonates. Defects of CD40L could not be demonstrated in autosomal forms of HIGM (Callard et al., 1994; Oliva et al., 1995), therefore, analysis of CD40L expression is particularly important for the correct diagnosis of sporadic HIGM in males, as it

allows distinction between XHIGM and autosomal forms of HIGM.

As mentioned above, definitive confirmation of CD40L deficiency can be achieved through molecular studies. Investigation of mutations at the DNA level has become possible following elucidation of the genomic structure of the *CD40L/TNFSF5* gene (Villa et al., 1994; Shimadzu et al., 1995). This information has in turn allowed diagnosis even when viable lymphocytes for studying CD40L expression are not available.

### Carrier Detection and Prenatal Diagnosis

In contrast to carriers of other X-linked immunodeficiencies (e.g., X-linked agammaglobulinemia [XLA]; X-linked severe combined immunodeficiency [X-SCID]; Wiskott-Aldrich Syndrome [WAS]), carrier females of XHIGM exhibit a random pattern of X inactivation. This was originally established in mature, IgG- and IgA-positive B lymphocytes (Hendricks et al., 1990), indicating the integrity of the B cell machinery for isotype switching. Following the demonstration that XHIGM is caused by mutations of the *CD40L/TNFSF5* gene, it was shown that two populations of circulating T lymphocytes (one expressing the wild-type CD40L allele and the other expressing the mutated one) are present in XHIGM carriers (Hollenbaugh et al., 1994). In carriers with skewed lyonization, no clinical or immunological abnormalities are found, indicating that limited CD40L expression is sufficient to induce isotype switching and normal generation of memory B cells (Callard et al., 1994; Hollenbaugh et al., 1994). However, extreme lyonization with selective expression of the mutant form of CD40L may result in an overt clinical phenotype (de Saint Basile et al., 1999).

Carrier detection is best achieved with molecular assays targeted at the *CD40L/TNFSF5* locus. In families with clear X-linked inheritance linkage analysis can be performed, taking advantage of two sets of hypervariable microsatellites at the 3' untranslated region of the *CD40L/TNFSF5* gene (Allen et al., 1993b; DiSanto et al., 1993, 1994; Gauchat et al., 1993a; Ramesh et al., 1994; Shimadzu et al., 1995). Whenever the mutation is known, DNA sequencing, with a search for heterozygosity for the specific mutation, is the most simple and direct way to attempt carrier detection (Villa et al., 1994; Shimadzu et al., 1995; Lin et al., 1996). Occasionally, heterozygosity for the mutation (e.g., carrier detection) can also be performed at the cDNA level, as for splice-site mutations that cause exon skipping (DiSanto et al., 1993; Hollenbaugh et al., 1994).

In families with clear X-linked inheritance, prenatal diagnosis can be safely attempted at 10 weeks gestation on chorionic villi DNA by means of segregation analysis with hypervariable microsatellites at the 3' untranslated region of the *CD40L* gene (DiSanto et al., 1994). Characterization of organization of the *CD40L/TNFSF5* gene allows prenatal diagnosis even in families with sporadic presentation, provided that the mutation is known (Villa et al., 1994).

Despite the reduced ability of activated T cells from neonates to express CD40L (Brugnoni et al., 1994; Fuleihan et al., 1994a; Durandy et al., 1995; Nonoyama et al., 1995), surface membrane CD40L was detected on activated T cells from 19 to 28-week-old fetuses (Durandy et al., 1995). However, because of the obviously complex developmental control of CD40L expression, staining for CD40L on fetal cord blood T lymphocytes should not be used as the sole technique for prenatal diagnosis of XHIGM.

**Figure 19.3.** Cumulative survival curve of 128 patients with the X-linked form of hyper-IgM enrolled in the European Registry. The number of patients at various ages is shown at the bottom of the panel.

### Treatment and Prognosis

The long-term prognosis of XHIGM appears to be worse than that in other forms of congenital hypogammaglobulinemia, for example, XLA. The cumulative survival curve for 128 XHIGM patients enrolled in the European Registry is shown in Figure 19.3, with 30 of 128 patients having died. The mortality is somewhat lower in the U.S. series (8 deceased out of 79 subjects), possibly reflecting a lower incidence of sclerosing cholangitis and irreversible liver damage (Winkelstein et al., 2003). The main causes of death include infections early in life and, later on, severe liver disease and malignant tumors (Hayward et al., 1997; Levy et al., 1997).

The complex array of clinical manifestations and the increased risk of opportunistic infections and chronic neutropenia require multiple therapeutic approaches. Regular infusion of IVIG (400–600 mg/kg every 21 to 28 days) is the most important form of treatment. It significantly reduces the severity and frequency of infections (Levy et al., 1997) and may occasionally correct neutropenia (Banatvala et al., 1994; Levy et al., 1997). In view of the higher risk for severe clinical manifestations, patients suffering from XHIGM often require more aggressive treatment. Continuous prophylaxis with cotrimoxazole has been advocated to prevent PCP (Notarangelo et al., 1992; Banatvala et al., 1994) and has in fact proven effective (Levy et al., 1997). Long-term treatment with amphotericin B and flucytosine are necessary for cryptococcosis (Iseki et al., 1994; Tabone et al., 1994). Patients with severe neutropenia may benefit from treatment with recombinant G-CSF; in some cases, this approach has caused a change from chronic to cyclic neutropenia (Wang et al., 1994; Shimadzu et al., 1995). Total parenteral nutrition may be necessary in patients with protracted diarrhea and malabsorption, particularly if these are due to *Cryptosporidium* (Benkerrou et al., 1990). *Cryptosporidium* infection should be prevented by using filtered or sterile water and treated with azithromycin or nitazoxanide. Early detection of *Cryptosporidium* infection is best achieved by PCR-based amplification of stool DNA and microscopy of bile fluid (McLauchlin et al., 2003).

Despite these efforts, the mortality rate remains high (Levy et al., 1997), as illustrated in Figure 19.3. Therefore, more radical forms of treatment have been proposed. Successful hematopoietic stem cells transplantation (HSCT) from a human leukocyte antigen (HLA)-identical sibling or matched unrelated donor (Thomas et al., 1995; Levy et al., 1997; Bordigoni et al., 1998;

Scholl et al., 1998; Kato et al., 1999; Kawai et al., 1999; Gennery et al., 2000; Duplantier et al., 2001) or partially matched cord blood (Ziegner et al., 2001) have been reported. However, in a recent series of 38 XHIGM patients treated by HSCT, a high mortality rate (31.6%) was observed (Gennery et al., 2004). In all cases, death was from infections. Importantly, preexisting lung disease was associated with a poor outcome. Nonmyeloablative HSCT has been successfully used in an XHIGM patient with severe liver disease (Jacobsohn et al., 2004). It should be noted that lack of a strict genotype–phenotype correlation in XHIGM prevents selection for bone marrow transplantation of those patients at high risk for mortality.

While attempts to treat severe liver disease (sclerosing cholangitis, cirrhosis) with liver transplantation usually fail because of relapse of the disease in the transplanted organ (Hayward et al., 1997; Levy et al., 1997), more promising results have been achieved in severely ill patients with a combined bone marrow and cadaveric orthotopic liver transplantation (Hadzic et al., 2000).

The recognition that expression of the *CD40L/TNFSF5* gene is under tight regulatory control makes gene therapy a less viable option, particularly since deregulated expression of CD40L in transgenic mice has been shown to result in tumor development (Brown et al., 1998; Sacco et al., 2000). Use of lentiviral vectors might enable insertion of autologous regulatory gene elements (Barry et al., 2000), thus making gene therapy–based treatment with acceptable risks possible in the future. However, the finding that mutant forms of CD40L interact with wild-type molecules and prevent expression of functional trimers (Seyama et al., 1999; Su et al., 2001) raises further doubts that gene therapy could become an effective form of treatment for XHIGM. These problems may be circumvented by *trans*-splicing (a process by which two different pre-mRNAs are joined by the cellular splicing apparatus), which allows complementation of the gene defect while preserving the natural regulation and cell specificity of CD40L expression. Indeed, this strategy has been successfully used to correct a murine model of CD40L deficiency (Tahara et al., 2004).

### Clinical and Pathological Manifestations of CD40 Deficiency

Defective expression of CD40 by B lymphocytes (CD40 deficiency, HIGM3) has been detected in four children from three unrelated families with autosomal recessive HIGM (Ferrari et al., 2001; Kutukculer et al., 2003). Clinical and immunological data at presentation (Table 19.3) were very similar to those observed in XHIGM, but autosomal recessive inheritance was indicated by parental consanguinity and by the fact that three of the four patients are female. Patient 1, an 8-year-old Italian girl, suffered from PCP at 4 months of age and had another episode of pneumonia at age 2, when she was found to be panhypogammaglobulinemic and was started on IVIG treatment. Patients 2 and 3 are first cousins from a multiply related Arabian family. Patient 2 is a 5-year-old male who suffered from recurrent pneumonia, hypogammaglobulinemia with elevated IgM, and neutropenia. Patient 3 is a 7-year-old female who also experienced recurrent lower respiratory tract infections. She was diagnosed with HIGM at 8 months of age, and substitution treatment with IVIG was started. At 3 years of age, she was admitted to a pediatric intensive care unit for severe interstitial pneumonia. Patient 4, a 12-month-old Turkish girl born to consanguineous parents, was hospitalized for respiratory distress. She developed necrotizing pneumonia caused by *Pseudomonas aeruginosa* and

**Table 19.3.** Clinical and Immunological Features of Four Patients with CD40 Deficiency

	Patient 1	Patient 2*	Patient 3*	Patient 4
<i>Clinical Features</i>				
Current age (years)/gender	8/F	5/M	7/F	Deceased/F
Age at onset (months)	4	6	8	12
Recurrent URTI/LRTI	+	+	+	+

CD8 (%)	13	24	19	34
CD19(%)	16	19	20	35
CD40 (%)	0	0	0	0
In vitro response to PHA (cpm)	124,200	122,000	138,000	115,000

\*Patient 2 and Patient 3 are first cousins.

PCP, *Pneumocystis carinii* pneumonia; PHA, phytohemagglutinin; URTI/LRTI, Upper and lower respiratory tract infections.

chronic watery diarrhea due to *Cryptosporidium parvum*, which was also isolated from tracheal aspirates, indicating disseminated infection. She received a matched-sibling stem cell transplantation but died of cardiorespiratory arrest at day 16 post-transplant. All four children had very low levels of IgG and IgA, and two had increased serum IgM levels. Lymphocyte numbers and subset distributions were normal, as were in vitro proliferative responses to mitogens. In contrast to observations consistently seen in XHIGM, B cells from these patients could not be induced to secrete IgG and IgA upon in vitro activation with anti-CD40 MAb and IL-10, a result indicating a B cell intrinsic defect.

### Functional Aspects of CD40 Deficiency

Immunophenotypic analysis showed that circulating B cells and monocytes lacked surface membrane CD40. The protein was also undetectable intracellularly in patient 1 (as shown by Western blot analysis of lymphoblastoid B cell lines), whereas an aberrant pattern of migration of the CD40 protein was detected in patient 2. Mutation analysis showed that patient 1 was homozygous for a silent mutation (A-to-T substitution at nucleotide 408, corresponding to the fifth nucleotide of exon 5). However, this mutation involves and disrupts an exonic splicing enhancer, thus preventing incorporation of exon 5 in the mRNA. Consequently, cDNA from this patient lacked 94 nucleotides (matching exon 5), resulting in frameshift and premature termination. Patients 2 and 3 were both homozygous for a C-to-T change at nucleotide 247, resulting in a nonconserved Cys83-to-Arg amino acid substitution. The mutation in patient 4 occurred at position –2 of the acceptor site of intron 3; the resulting use of a cryptic splice site caused a 6 bp deletion in exon 4.

Further investigation of the functional consequences of CD40 deficiency showed that both memory B cell generation and somatic mutation were affected. Dendritic cells, cultured with TNF- $\alpha$  or with lipopolysaccharide (LPS) combined with IFN- $\gamma$ , displayed a consistent defect in their ability to induce proliferation

of allogeneic T cells and secretion of IFN- $\gamma$ . The defective costimulatory activity of dendritic cells derived from patients with CD40 deficiency was associated with lower cell surface levels of MHC class II antigen and with a decreased release of IL-12. These findings support the notion that CD40 deficiency is not an exclusive defect of humoral immunity but should be considered a combined defect of B and T cell compartments (Fontana et al., 2003).

### Strategy for Diagnosis

The diagnosis of CD40 deficiency is usually made by demonstrating the inability of peripheral blood B cells to constitutively express CD40 molecules, assessed by staining with MAbs to CD40 in patients with clinical features and an immunoglobulin profile suggestive of HIGM. Cytofluorimetric analysis could be considered a reliable technique, as all patients reported with mutations of the *CD40* gene lacked expression of CD40 at the cell surface. However, the possibility of false-negative results, due to recognition of mutant CD40 molecules by the monoclonal antibody, exists. Furthermore, because CD40 is expressed as a trimer, is it theoretically possible that heterozygous mutations that allow expression of CD40 but affect its function may result in an HIGM phenotype through a dominant-negative effect. Ultimately, diagnosis of CD40 deficiency requires mutation analysis.

### Treatment and Prognosis

Management of patients with CD40 deficiency is similar to that outlined for patients with CD40L deficiency. Treatment includes regular infusions of IVIG, PCP prophylaxis, water purification measures to prevent *Cryptosporidium* infection, and monitoring of liver status by ultrasound scanning and biochemical analysis. Compared to CD40L deficiency, the benefits of HSCT in CD40 deficiency are less obvious and remain to be proven, as this strategy would not correct defective CD40 expression on non-hematopoietic cells. Successful immune reconstitution has been

recently achieved in a fifth patient with CD40 deficiency by means of hematopoietic stem cell transplantation from a matched sibling (E. Mazzolari, L. Notarangelo, and N. Kutukculer unpublished observation).

## Animals Models of CD40 and CD40L Deficiency

### Gene Disruption

#### Mice with disruption of the CD40L gene

CD40L<sup>-/-</sup> mice exhibit normal percentages of B and T cell subpopulations but display selective deficiencies in humoral immunity. Basal serum immunoglobulin isotype levels are significantly lower than in normal mice, and IgE is undetectable. Furthermore, CD40L-deficient mice fail to mount secondary antigen-specific responses to immunization with T-dependent antigens. By contrast, they produce antigen-specific antibody of all isotypes except IgE in response to thymus-independent antigens. These results underscore the requirement of CD40L for T cell-dependent antibody responses (Renshaw et al., 1994; Xu et al., 1994). Moreover, Ig class switching to isotypes other than IgE can occur in vivo in the absence of CD40L, a phenomenon supporting the notion that alternative B cell signaling pathways regulate responses to thymus-independent antigens.

CD4<sup>+</sup> T cells from CD40L<sup>-/-</sup> mice were fourfold less effective than normal T cells in activating the nitric oxide response in allogeneic macrophages. CD40L<sup>-/-</sup> T cells fixed with paraformaldehyde after a 6-hour activation period, a time point at which CD40L dominates the macrophage-activating capability of T cells, failed to activate the production of inflammatory cytokines (TNF- $\alpha$ ) or the generation of reactive nitrogen intermediates. After 24 hours of activation, however, both CD40L<sup>-/-</sup> and normal T cells could induce similar but weak responses from activated macrophages (Stout et al., 1996). These studies demonstrate that CD40L<sup>-/-</sup> mice have a deficient T cell-dependent macrophage-mediated immune response. However, CD40L-deficient mice are able to generate normal primary cytotoxic T cell responses (in spite of a defective humoral response) to a viral infection (Whitmire et al., 1996).

CD40L<sup>-/-</sup> mice are susceptible to *Pneumocystis carinii* infection (as are CD40<sup>-/-</sup> mice). Treatment of wild-type mice with soluble CD40L-fusion protein evokes a pulmonary inflammatory response that is not observed in identically treated CD40<sup>-/-</sup> mice (Wiley et al., 1997). This finding supports evidence that ligation of CD40 results in inflammatory responses and that soluble CD40L is a potent inflammagen that may be important for protection against *P. carinii* infection.

Finally, when injected with *Cryptococcus neoformans*, CD40L<sup>-/-</sup> mice show increased fungal growth in the brain, associated with reduced production of IL-12, IFN- $\gamma$ , and nitrites (Pietrella et al., 2004).

#### Mice with disruption of the CD40 gene

CD40<sup>-/-</sup> mice have normal numbers of T and B cells, indicating that CD40 is not essential for B cell development. Their B cells fail to proliferate and undergo isotype switching in response to soluble CD40 ligand (sCD40L) and IL-4 but respond normally to LPS in the presence of IL-4. CD40<sup>-/-</sup> mice completely fail to mount an antigen-specific antibody response or to develop germinal centers following immunization with T cell-dependent antigens, but they respond normally to the T cell-independent

antigens. The most noticeable alteration in the serum immunoglobulin levels of young CD40<sup>-/-</sup> animals is absence of IgE and severe decrease of IgG1 and IgG2a (Castigli et al., 1994; Kawabe et al., 1994). These results indicate an essential role of CD40-CD40L interactions in the antibody response to T cell-dependent antigens and in isotype switching.

B cells deficient in CD40 expression are unable to elicit the proliferation of allogeneic T cells in vitro. More importantly, mice immunized with CD40<sup>-/-</sup> B cells become tolerant to allogeneic MHC antigens as measured by a mixed lymphocyte reaction and cytotoxic T cell assay. The failure of CD40<sup>-/-</sup> B cells to serve as antigen-presenting cells in vitro is corrected by the addition of anti-CD28 MAb. Moreover, LPS stimulation, which up-regulates B7 expression, reverses the inability of CD40<sup>-/-</sup> B cells to stimulate an alloresponse in vitro and abrogates the capacity of these B cells to induce tolerance in vivo (Hollander et al., 1996). These results suggest that CD40 engagement by CD40 ligand expressed on antigen-activated T cells is critical for the up-regulation of B7 molecules on antigen-presenting B cells that subsequently deliver the costimulatory signals necessary for T cell proliferation and differentiation.

In addition to susceptibility to *Pneumocystis carinii* infection, CD40-deficient mice are also prone to *Mycobacterium avium* infection (Florido et al., 2004). Furthermore, when inoculated with the defective murine leukemia retrovirus LP-BM5def, CD40<sup>-/-</sup> mice become infected and show virus expression similar to that in wild-type mice. However, unlike the wild-type mice, CD40-deficient mice do not develop symptoms of immunodeficiency, lymphoproliferation, and the typical histological changes in the lymphoid tissue (Yu et al., 1999). These results show that the CD40-CD40L interaction in vivo is essential for anergy induction and the subsequent development of immunodeficiency and pathologic expansion of lymphocytes.

Recently it has been shown that CD40<sup>-/-</sup> adult mice develop neuronal cell dysfunction and gross central nervous system abnormalities with age. These findings suggest that CD40 signaling plays an important role in normal neuronal cell maintenance and confers resistance to aging-induced stress (Tan et al., 2002).

## Conclusion

Detailed clinical, molecular, and immunological analysis of patients with XHIGM has been instrumental in unraveling the complex effects that CD40L (CD154) exerts in vivo upon interaction with CD40. For many years considered a prototypic humoral immunodeficiency, XHIGM is now viewed as a combined defect of cognate immunity. Similarly, CD40-CD40L interaction, originally thought to play a major role in terminal B cell differentiation only, is now widely recognized as a key signal in a variety of biological systems, particularly TH1-related inflammatory responses. Not surprisingly, anti-CD40L MABs are coming into clinical practice as a potent anti-inflammatory drug (Durie et al., 1993) and as a powerful tool to prevent graft rejection and graft-vs.-host disease (Durie et al., 1994). Furthermore, recent observations indicate that CD40L is indeed a real cytokine, as it may also be released in an active, secretory form. It is expected that this profound change in perspective may lead to further therapeutic approaches based on disruption of CD40-CD40L interaction. Soluble CD40L is presently being explored at the National Institutes of Health (NIH) as a possible form of treatment for XHIGM. However, it remains to be seen if continuous administration of CD40L is safe and effective.

Since the first edition of this text, much has been written on the molecular pathophysiology of autosomal recessive HIGM syndromes. The genetic heterogeneity has been well documented. In patients with mutations of the *AICD* or the *UNG* gene, the disease is intrinsic to B cells, and the overall clinical manifestations are compatible with defective CSR and SHM (see Chapter 20). In contrast, patients with a mutation of CD40 are clinically and immunologically indistinguishable from patients with CD40L deficiency. This observation confirms the critical role that CD40L–CD40 interaction plays in protecting patients from not only bacteria but also opportunistic pathogens.

# Autosomal Hyper-IgM Syndromes Caused by an Intrinsic B Cell Defect

ANNE DURANDY, PATRICK REVY, and ALAIN FISCHER

The study of inherited hyper-IgM syndromes (HIGM) has greatly contributed to our understanding of the normal processes of antibody maturation, because these syndromes have in common a defect in immunoglobulin (Ig) class switch recombination (CSR), as demonstrated by normal or elevated serum IgM levels. This is in contrast to absent or strongly decreased levels of the other immunoglobulin (Ig) isotypes. Antibody maturation leads to the production of antibodies of different isotypes and formation of B cell receptors (BCR) with high affinity for antigen. This event usually takes place in the secondary lymphoid organs (spleen, lymph nodes, tonsils) in an antigen- and T lymphocyte-dependent manner. When mature (but still naive) IgM<sup>+</sup>IgD<sup>+</sup> B cells, after emigrating from the bone marrow (or fetal liver), encounter an antigen that is specifically recognized by their BCR, they proliferate vigorously and give birth to a unique lymphoid formation, the germinal center. In this location, B cells undergo the two major events of maturation: CSR and somatic hypermutation (SHM).

## Class Switch Recombination and Somatic Hypermutation

Class switch recombination is a process of DNA recombination between two different switch (S) regions located upstream of the constant (C) regions, while the intervening DNA is deleted by forming excision circles (Iwasato et al., 1990; Matsuoka et al., 1990; von Schwedler et al., 1990; Kinoshita and Honjo, 2000; Manis et al., 2002). Replacement of the C<sub>μ</sub> region by a C<sub>γ</sub> region from another class of Ig results in the production of antibodies of different isotypes (IgG, IgA, and IgE) with the same variable (V) region and thus the same antigen specificity and affinity. The different Ig isotypes vary in activities (half-life, binding to Fc receptors, ability to activate the complement system) and tissue localization (IgA is secreted by mucosal

membranes). Thus CSR is necessary for an optimal humoral response against pathogens.

Through SHM, missense mutations and, less frequently, deletions or insertions are introduced into the V regions of immunoglobulins. This process is triggered by activation of the BCR and signaling via CD40 (Storb et al., 1998; Jacobs et al., 2001). These mutations occur at a high frequency in the V regions and their proximal flanks ( $1 \times 10^{-3}$  bases/generation). SHM is required as a basis for the selection and proliferation of B cells expressing a BCR with a high affinity for antigen in close interaction with follicular dendritic cells (Rajewsky, 1996; Frazer et al., 1997). The CSR and SHM processes occur simultaneously in germinal centers, but neither is a prerequisite for the other because IgM may be mutated whereas IgG or IgA can remain unmutated (Kaartinen et al., 1983; Jacob and Kelsoe, 1992).

Three successive steps are required for the process of CSR and SHM:

1. Transcription of the targeted DNA (S and V regions). In S regions, this step leads to the formation of RNA–DNA hybrids, known as stable R-loops, on the template DNA strand, leaving the single non-template strand accessible for cleavage (Bransteitter et al., 2003; Chaudhuri et al., 2003; Dickerson et al., 2003; Ramiro et al., 2003; Yu et al., 2003).
2. DNA cleavage. During CSR, single-stranded DNA breaks result in double-stranded DNA breaks (DSB) by a mechanism currently unknown. It has been suggested that the template DNA strand may also be attacked in transcription bubbles (Bransteitter et al., 2003), resulting in scattered DSB, eventually processed by exonucleases and error-prone polymerases into blunt DSB. This error-prone DNA processing is suggested by the high frequency of mutations found in S<sub>μ</sub>-S<sub>γ</sub> junctions (Chen et al., 2001). In V regions, single-stranded DNA breaks are either directly repaired or processed into scattered DSB. Alternatively, recent data suggest that blunt DSB could occur spontaneously in V regions and secondarily lead to scattered DSB (Catalan et al., 2003; Zan et al., 2003).

3. DNA repair. The mechanisms involved in DNA repair differ for CSR and SHM. During CSR, histone H2AX is phosphorylated, and the repair protein 53BP1 and the complex MRE11/RAD50/NBS1 are recruited at DSB in repair foci. Thereafter, the DNA repair machinery joins S $\mu$  and S $\alpha$  sequences by means of the widespread, constitutively expressed nonhomologous end-joining (NHEJ) enzymes, including the KU proteins that act on DNA blunt DSB (Rolink et al., 1996; Casellas et al., 1998; Manis et al., 1998). In contrast, SHM DNA repair does not require the NHEJ complex (Bemark et al., 2000), but probably the error-prone polymerases  $\eta$  and  $\zeta$  (Zan et al., 2001) and the mismatch repair (MMR) enzymes (Cascalho et al., 1998; Wiesendanger et al., 1998; Kenter, 1999; Schrader et al., 1999; Evans and Alani, 2000).

CSR and SHM are initiated by T and B cell interaction, involving CD40 ligand (CD40L or CD154), a molecule transiently expressed on activated CD4<sup>+</sup> T cells, and CD40, constitutively expressed on B lymphocytes. The CD40L-CD40 interaction is required for B cell proliferation, germinal center formation, CSR, and SHM, as demonstrated by the phenotype of patients with loss of function of either the *CD40L* (Aruffo et al., 1993; DiSanto et al., 1993) (see Chapter 19) or *CD40* gene (Ferrari et al., 2001). The role of the CD40 activation pathway in antibody maturation has been underscored by the recent demonstration of a profound immune deficiency, including the HIGM phenotype, as the result of defective nuclear factor- $\kappa$ B (NF- $\kappa$ B) signaling following CD40 activation. This is illustrated by the fact that hypomorphic mutations in the zinc finger domain of the nuclear factor- $\kappa$ B essential modulator gene (also called *NEMO* or *IKK $\gamma$* ) (Zonana et al., 2000; Döffinger et al., 2001; Jain et al., 2001) or mutation producing a gain of function of the NF- $\kappa$ B inhibitor I $\kappa$ B $\alpha$  (Courtois et al., 2003) result, respectively, in a syndrome of X-linked or autosomal dominant anhydrotic ectodermal dysplasia (AED) associated with a T cell immunodeficiency and the HIGM condition.

HIGM syndromes with an autosomal recessive mode of inheritance have been described over the years by a number of investigators (Callard et al., 1994; Conley et al., 1994; Durandy et al., 1997). This condition is characterized by a specific B cell defect, resulting in increased susceptibility to bacterial infections (but not to opportunistic infections) that can be easily controlled by regular intravenous Ig (IVIG) substitution. Lymphadenopathy is frequent (50%–75%) and autoimmunity is reported in 25% of patients. SHM is found to be either normal or defective, according to the molecular defect. B cells are intrinsically defective; although they normally proliferate, they are unable to undergo CSR after activation by CD40L and cytokines. The precise delineation of the defects leading to abnormal CSR allowed the definition of molecularly defined autosomal recessive HIGM conditions.

### Activation-Induced Cytidine Deaminase (AID) Deficiency

The activation-induced cytidine deaminase (*AICDA*) gene (\*605257) was first identified in mice (Muramatsu et al., 1999) and cloned by subtractive hybridization between murine lymphoma CH12F-2 B cells with and without induction of CSR in vitro. The *AICDA* RNA transcripts are detected only in B cells undergoing CSR or SHM either in vivo (in germinal center B cells) or in vitro (Muramatsu et al., 1999; Revy et al., 2000; Diaz and Casali, 2002; Faily et al., 2002; Papavasiliou and Schatz, 2002). The activation-induced cytidine deaminase (AID) protein is structurally similar (34% amino acid sequence identity) to the apoB mRNA-editing enzyme APOBEC-1. RNA editing is widely used to create new functional RNAs from a single gene. APOBEC-1 edits ApoB mRNA by deamination of a cytosine into a uracil

residue at a specific site, resulting in a stop codon. ApoB100 and ApoB48, the translation products of the unedited and edited apoB mRNAs, respectively, have entirely different functions and expression profiles (Navaratnam et al., 1993; Teng et al., 1993; Mehta et al., 2000). APOBEC-1 requires an auxiliary factor (ACF) for the site-specific editing of apoB mRNA. This auxiliary factor is widely expressed, including in tissues that do not express APOBEC-1 (Navaratnam et al., 1993; Teng et al., 1993; Yamanaka et al., 1994).

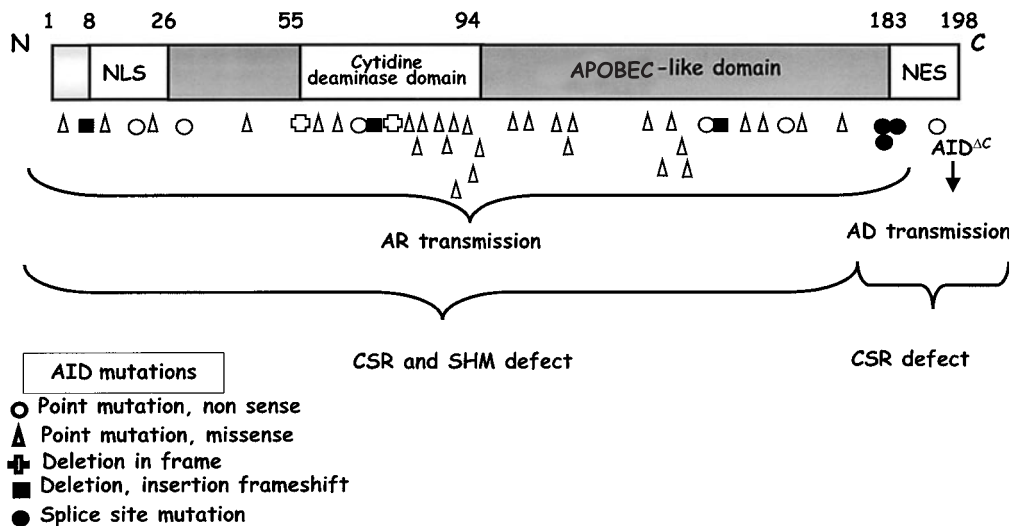

The open reading frame of the *AICDA* cDNA encodes a 198-residue protein with a molecular mass of approximately 24 kDa. This protein contains an active site for cytidine deamination, whose the sequence is conserved throughout the large cytidine deaminase family, and has been shown to display cytidine deaminase activity in vitro (Muramatsu et al., 1999). The C-terminal domain also contains a leucine-rich region that may be important for protein-protein interaction. This region is thought to bind accessory factors required for AID activity and may be important in AID tetramerization (Dickerson et al., 2003). Recently, a nuclear localization signal (NLS) and a nuclear export signal (NES) have been described in the N and C termini of the molecule (Ito et al., 2004), although the function of this NLS is still debated (Brar et al., 2004; McBride et al., 2004). An APOBEC-1-like domain is also described but its exact function remains unknown (Fig. 20.1).

AID-deficient patients and AID<sup>-/-</sup> mice display a defect in both CSR and SHM, which demonstrates the crucial role of AID in both these processes required for B cell terminal differentiation. The mechanism of action of AID, however, remains open to debate. Because the sequence of AID is similar to that of the RNA-editing enzyme APOBEC-1, originally it was proposed that AID edits an mRNA encoding a substrate common to CSR and SHM, probably an endonuclease (Chen et al., 2001; Kinoshita and Honjo, 2001; Honjo et al., 2002). The recently described requirement for de novo protein synthesis downstream of AID expression in CSR, compatible with the synthesis of a recombinase, is consistent with the RNA-editing model (Doi et al., 2003).

However, recent data strongly indicate that AID exerts a DNA-editing activity. Following the transfection of *E. coli*, AID deaminates deoxycytidine (dC) residues within DNA into deoxyuridine (dU) (Petersen-Mahrt et al., 2002). Subsequently, several groups have demonstrated in cell-free assays a direct role for AID on single-stranded DNA but not on double-stranded DNA, RNA-DNA hybrids, or RNA (Bransteitter et al., 2003; Chaudhuri et al., 2003; Dickerson et al., 2003; Ramiro et al., 2003). The transcription of S regions increases AID activity (Ramiro et al., 2003; Shinkura et al., 2003), probably by generating the secondary structures required for this activity (Yu et al., 2003). R loops are generated by the formation of RNA-DNA hybrids on the template DNA strand, rendering the single nontemplate strand a target for AID to generate the first lesion required for DNA cleavage. Although these observations provide strong evidence that AID has DNA-editing activity, they were obtained in nonphysiological conditions (overexpression in *E. coli*, using in vitro assays) in which the well-known RNA-editing protein APOBEC-1 exerts a similar effect (Harris et al., 2002; Petersen-Mahrt and Neuberger, 2003).

### Clinical and Pathological Manifestations of AID Deficiency

Four reports describing AID deficiency (MIM #605258) have been published in the literature (Minegishi et al., 2000; Revy et al., 2000; Quartier et al., 2004; Lee et al., 2005). Although the onset of symptoms occurs during early childhood (mean age, 5 years), the diagnosis is frequently established at a later age.

**Figure 20.1.** Schematic representation of activation-induced cytidine deaminase (AID) and localization of mutations in AID deficiency. Mutations are scattered throughout the entire gene. Each symbol represents a unique mutation. Mutations in the C-terminal domain do not affect somatic hypermutation (SHM). A mutation of the C-terminal region

(AID<sup>ΔC</sup>) results in truncation of the last nine amino acids of the nuclear export signal (NES) and is responsible for an autosomal dominant (AD) form of HIGM. AR, autosomal recessive; CSR, class switch recombination; NLS, nuclear localization signal.

According to clinical data from 51 AID-deficient patients, all presented with recurrent bacterial infections; more than half (58%) had respiratory tract infections, with 14% of the patients reporting bronchiectasis. Gastrointestinal infections were observed in 27%, sometimes related to persistent *Giardia* infections. Such infections may result in failure to thrive. Infections of the central nervous system (e.g., meningitis) have been reported in 25% of AID-deficient patients, often associated with inadequate Ig substitution. One case each of herpes virus encephalitis and poliomyelitis have been described. Two adult patients died prematurely, one of pulmonary hemorrhage at 47 years of age, the other of septicemia at age 63.

A striking lymphoid hyperplasia is present in the majority (75%) of patients, affecting predominantly the cervical lymph nodes and tonsils. In one case, mesenteric lymph node hyperplasia resulted in intestinal obstruction. Hepatosplenomegaly has been reported in 10% of the patient cohort. Other manifestations include arthritis (12%) and autoimmune manifestations (hemolytic anemia, thrombopenia, and autoimmune hepatitis) (21%); autoantibodies of the IgM isotypes are detectable in some cases. Systematic lupus erythematosus, diabetes mellitus, and Crohn's disease have been reported in one patient each (Table 20.1).

### Laboratory Findings in AID Deficiency

All patients had normal or elevated IgM at the time of diagnosis and markedly diminished or, most often, undetectable serum levels of IgG and IgA. In some patients, 7S IgM can be demonstrated. In agreement with the aberrant serum immunoglobulin levels, antigen-specific (vaccine or infectious agents) antibodies of the IgG isotype were not detectable. When analyzed, IgM isohemagglutinins and antipolysaccharide IgM antibodies were present. IgM serum levels often diminish after Ig substitution, a finding suggesting that increased IgM reflects chronic antigenic stimulation rather than a direct effect of the AID deficiency.

Numbers of peripheral blood T cells (CD3<sup>+</sup>) and T cell subsets (CD4<sup>+</sup> and CD8<sup>+</sup>) as well as in vitro T cell proliferation to mitogens and antigens are normal. Peripheral blood B cells

(CD19<sup>+</sup>) are normal in number and express wild-type CD40 in normal concentrations. All CD19<sup>+</sup> B cells coexpress sIgM and sIgD, in contrast to age-matched controls, who have a population of CD19<sup>+</sup> B cells that express sIgG or sIgA and not sIgM/sIgD.

Soluble CD40-L (sCD40L)-induced B cell proliferation in vitro is normal. However, in vitro activation of B lymphocytes by sCD40L and interleukin-4 (IL-4), which induces IgE production in controls and CD40L-deficient patients (Durandy et al., 1993), is ineffective in AID-deficient patients. Under the same culture conditions, S-region transcription is normally induced, whereas DNA DSB are not detected in S<sub>μ</sub> regions, providing evidence that the CSR defect is located downstream from transcription and upstream from DNA cleavage (Catalan et al., 2003). A normal fraction (20%–50%) of B cells express the CD27 marker, which indicates mutated memory B cells, even if limited to the IgM<sup>+</sup>/IgD<sup>+</sup> B cell compartment (Klein et al., 1998). However, the frequency of SHM on CD19<sup>+</sup>CD27<sup>+</sup> B cells is dramatically reduced. Thus, AID deficiency leads to not only lack of CSR but also defective SHM (Revy et al., 2000) (Table 20.2).

Most of the patients exhibit enlarged secondary lymphoid organs, which may require surgical resection (tonsils) or biopsy (cervical lymph nodes); histological evaluation shows marked follicular hyperplasia. Germinal centers are giant, being 2 to more than 10 times larger than those from control reactive lymph nodes (Plate 20.I). The mantle zone and interfollicular areas appear thin. The giant germinal centers contain a normal follicular dendritic cell network and B cells that are PNA<sup>+</sup>, CD38<sup>+</sup>, CD23<sup>+</sup>, CD83<sup>+</sup>, CD95<sup>+</sup>, CD40<sup>+</sup>, IgM<sup>+</sup>, Bcl2<sup>+</sup>, and Ki67<sup>+</sup>. Strikingly, many germinal-center B cells coexpress sIgD, in contrast to normal reactive germinal centers, in which IgD<sup>+</sup> B cells are rarely found. The high proliferation index of germinal-center B cells is associated with a dense network of macrophages filled with apoptotic bodies giving a starry-sky appearance. The characteristic markers and size of the germinal-center B cells identify them as proliferating (Ki67<sup>+</sup>) germinal-center founder cells (CD38<sup>+</sup>, sIgM<sup>+</sup>, sIgD<sup>+</sup>), prone to undergo SHM and selection (Lebecque et al., 1997). Occasional CD27<sup>+</sup> B cells as well as IgM- and IgD-expressing

plasma cells are found in germinal centers and T cell areas; however, neither IgG- nor IgA-expressing plasma cells are observed.

### Molecular Basis of AID Deficiency

Because the analysis of informative pedigrees suggested an autosomal recessive inheritance, genetic mapping was attempted by studying the segregation of polymorphic microsatellite markers in several consanguineous families. Random screening of the genome indicated that disease segregation was compatible in all studied families with the telomeric region of the short arm of chromosome 12 at p13 with a multipoint LOD score of 10.45

(Revy et al., 2000). Recombination analysis defined the critical genetic interval as a 4.5 cM region, in which a gene coding for AID had recently been localized (Muto et al., 2000). The human *AICDA* gene encompasses about 10 kb of genomic DNA and is organized in five exons and four introns. Definition of the exon–intron boundaries allowed a search for mutations at the genomic level. Deleterious mutations were found in all regions of the gene, including the cytidine deaminase domain (Minegishi et al., 2000; Revy et al., 2000; Quartier et al., 2004; Lee et al., 2005).

Forty different mutations have been found in 45 families, most often as homozygous defects (29 families), less frequently as

**Figure 20.2.** Schematic representation of uracil-*N*-glycosylase (UNG) and localization of mutations in UNG deficiency. Mutations affect the catalytic domain of both UNG1 (mitochondrial isoform) and UNG2 (nuclear isoform).

compound heterozygous mutations (16 families). They include missense mutations (28 families), nonsense mutations, and small deletions (6 families) (Fig. 20.1). In addition, deletions of the entire coding region (3 families) or splice-site mutations (3 families) leading to either a longer RNA transcript or to frameshift and premature stop codon were reported. The same mutations were found in a number of unrelated families of the same ethnic origin (e.g., French Canadians, Turkish); analysis of flanking polymorphic markers in these families indicated a common ancestral origin of the mutation (Minegishi et al., 2000; Revy et al., 2000).

Several mutations, located in the C-terminal part of the *AICDA* gene, were recently shown to result in defective CSR, whereas SHM is not affected (Ta et al., 2003). This observation suggests that, in addition to its cytidine deaminase activity, AID acts on CSR by binding a CSR-specific cofactor. Because mutations are normally found in  $S\mu$  regions, a defect in targeting AID to the S regions is unlikely and a defect in DNA repair can be suspected (Barreto et al., 2003). Another unexpected finding recently reported (Kasahara et al., 2003; Imai et al., 2005) is that a heterozygous nonsense mutation, also located in the C-terminal domain, results in the loss of the nine last amino acids of NES (AID<sup>ΔC</sup>) and a variable HIGM condition transmitted as an autosomal dominant disease (Fig. 20.1). Haploinsufficiency is highly unlikely because subjects heterozygous for AID deficiency always exhibit normal Ig levels. Two nonexclusive explanations for this dominant effect have been proposed: (1) the mutated allele, which is devoid of a normal nuclear export signal, accumulates in the nucleus, overriding the wild-type allele (Ito et al., 2004), or (2) in order to induce CSR, AID has to form homodimeric or multimeric complexes while the mutated allele cannot multimerize (Ta et al., 2003).

## Uracil-*N* Glycosylase (UNG) Deficiency

### Uracil-*N* Glycosylase

Uracil-*N*-glycosylase belongs to the family of uracil-DNA-glycosylases capable of deglycosylating uracil residues that are misintegrated into DNA. Each of the two different UNG promoters creates a different isoform: UNG1 (305 amino acids), which is mitochondrial and ubiquitously expressed, and UNG2 (314 amino acids), which is nuclear and expressed in proliferating cells, including B cells undergoing CSR. The catalytic domain binds the replication protein RPA and the proliferating cell nu-

clear antigen (PCNA) in a multimolecular complex involved in DNA base excision repair (Fig. 20.2). According to a model proposed by Petersen-Mahrt and Neuberger (2002), AID deaminates cytosine into uracil residues on single-stranded DNA. Following the deglycosylation and removal of uracil residues by UNG, an abasic site is created that can be attacked by an apyrimidinic endonuclease (APE), leading to single-stranded DNA breaks. The processing and repair of the DNA nicks complete both CSR and SHM. In the absence of UNG, this pathway is impaired, resulting in defective CSR and abnormal SHM. The presence of SHM with a skewed pattern of G/C residues may arise from the replication of U/G lesions in the absence of U removal. MMR enzymes may also recognize and repair these lesions, introducing mutations on neighboring nucleotides that result in transitions and transversions of A/T residues (Petersen-Mahrt et al., 2002; Rada et al., 2002). Alternatively it has been proposed that rather than UNG's enzymatic activity on DNA, the UNG protein is required for CSR by its involvement in the recruitment of DNA repair molecules or its role in folding the CSR-induced DSB (Honjo et al., 2004). However, this hypothesis does not explain the defect in DSB formation within  $S\mu$  regions observed in UNG-deficient B cells (Imai et al., 2003b).

### Clinical and Pathological Manifestations of UNG Deficiency

To date, only three UNG-deficient patients (MIM #608106, gene \*191525) have been reported (Imai et al., 2003b); two were diagnosed during childhood, the other as an adult. All three patients have had a history of frequent bacterial infections of the respiratory tract that are easily controlled by regular IVIG infusions. Lymphadenopathy was observed in two of three patients, one with impressive enlargement of mediastinal lymph nodes. The adult patient has developed Sjögren syndrome in recent years. The absence of metabolic abnormality suggests that UNG deficiency is compensated in mitochondria by other uracil-DNA glycosylases (Table 20.1).

### Laboratory Findings in UNG Deficiency

At the time of diagnosis, all three patients presented with HIGM, defined by markedly diminished serum levels of IgG and IgA and an increased serum level of IgM. No antibodies of the IgG isotype were detected to vaccines nor to infectious agents.

Peripheral blood T cell and T cell subset numbers as well as in vitro T cell proliferation to mitogens and antigens were normal. Peripheral blood B cells (CD19<sup>+</sup>) were normal in number, expressed CD40, which was of wild type, and coexpressed sIgM and sIgD with a normal fraction expressing CD27.

When cultured in the presence of sCD40-L, B cells proliferate normally but fail to undergo CSR and secrete IgG, IgA, or IgE in the presence of appropriate cytokines. As in AID deficiency, the CSR defect occurs downstream from S-region transcription and upstream from DSB in S $\mu$  regions.

Somatic hypermutations were found in normal frequency in CD19<sup>+</sup>CD27<sup>+</sup> B cells but exhibited a biased pattern. Almost all mutations are transitions at G/C residues (G>A, C>T), although transitions and transversions are equally present on A/T nucleotides (Table 20.2).

The association of an HIGM phenotype with UNG deficiency, together with the description of a mild CSR defect and a similarly biased SHM in UNG-deficient mice, provides a strong argument for DNA-editing activity of AID (Di Noia and Neuberger, 2002; Rada et al., 2002).

### Molecular Basis of UNG Deficiency

Four different mutations affecting the catalytic domain of UNG1 and UNG2 have been found. Two patients have small deletions leading to a premature stop codon (homozygous mutation in one patient born in a consanguineous family and two heterozygous mutations in the other). The third patient carries a homozygous missense mutation (Fig. 20.3). UNG expression and function were defective in Epstein-Barr virus (EBV) B cell lines, providing evidence for the lack of any compensatory UNG-DNA glycosylase activity, at least in B cells.

### Hyper-IgM Syndromes with Unknown Molecular Defect(s)

Not all cases of HIGM due to an intrinsic B cell defect are related to AID or UNG deficiency. Although most of these cases are sporadic, the mode of inheritance observed in a few multiplex or consanguineous families is compatible with an autosomal recessive pattern. The clinical phenotype is similar to that of AID deficiency, including increased susceptibility to bacterial infections of the respiratory and gastrointestinal tracts. Lymphoid hyperplasia is milder and less frequent (50%), consisting of moderate follicular hyperplasia without the giant germinal centers typical of AID deficiency (Table 20.1).

The CSR defect appears to be milder, as residual serum levels of IgG can be detected in some patients. While isohemagglutinins and IgM antipolysaccharide antibodies are present in normal amounts, IgG antibodies against immunization antigens or infectious agents cannot be detected. Upon activation with sCD40L and cytokines, B cells proliferate but do not undergo CSR (Table 20.2).

The definition of the precise location of the CSR defect has led to the delineation of two distinct groups.

#### Class Switch Recombination Defect Located Upstream from S Region DNA Cleavage

We are following a subgroup of 16 patients with an HIGM phenotype characterized by good prognosis, lack of autoimmune manifestations, and no increased risk of lymphoma or other malignancies. No CSR-induced DSB occur in S $\mu$  regions of patients' B cells, although both AID and UNG transcripts are normally ex-

pressed. The defect, located downstream from S-region transcription and upstream from the S-region DNA cleavage, is restricted to CSR, as SHM is normal in both frequency and pattern in the CD27<sup>+</sup> B cell subset, which is represented in normal numbers.

This type of HIGM could thus be caused by a direct or indirect impairment of AID targeting on S regions. Although targeting factors of AID are presently unknown, they most likely exist because AID deaminates cytosines only in the S and V regions in B cells. AID shares sequence similarity with the RNA-editing enzyme APOBEC-1, which is only expressed in the gut and requires a cofactor, ACF (APOBEC-1-cofactor), which targets APOBEC-1 on a unique C residue in ApoB mRNA. In addition, specific switch factors have been described in CSR-activated B cells. Although their role remains elusive, it has been proposed that these cofactors act as docking proteins for the recruitment of the recombinase complexes to DNA-specific regions (Shanmugam et al., 2000; Ma et al., 2002).

#### Class Switch Recombination Defect Located Downstream from S Region DNA Cleavage

This condition has been found in 15 patients thus far (Imai et al., 2003a). The prognosis of this HIGM subgroup is complicated by the occurrence of autoimmune manifestations that were found in 4 of 15 patients and were sometimes life threatening (severe autoimmune hemolytic anemia). Double-strand breaks are normally detected in S $\mu$  regions in CSR-activated B cells, suggesting a defect downstream from DNA cleavage. The subsequent step, DNA repair, is impaired because excision circles and functional transcripts of switched isotypes cannot be detected. The normal presence of DSB and of mutations in S $\mu$  regions rules out a defect in AID-targeting to S regions. SHM is present in normal frequency and pattern in the purified CD27<sup>+</sup> B cell population. However, the CD27<sup>+</sup> B cell count is decreased compared to that of controls (<10% of the B cell population).

Two hypotheses can account for this unique phenotype: (1) a defect in survival signals delivered to switched B cells—this does not fit with the observed defective in vitro CSR—and (2) a DNA repair defect, because CSR-induced DSB occur normally. CSR and SHM are known to use different pathways for DNA repair. NHEJ enzymes and the MRE11/hRad50/NBS1 protein complex have been shown to be involved in CSR DNA repair (Rolink et al., 1996; Casellas et al., 1998). Nevertheless, a defect in one of these proteins is unlikely given the phenotype of patients carrying mutations in *MRE11* or *NBS1* genes (ataxia-like disease or Nijmegen breakage syndrome, respectively; see Chapters 29 and 30). A defective CSR with normal SHM has been reported in H2AX and 53BP1 knockout mice (Petersen et al., 2001; Manis et al., 2004; Ward et al., 2004) but a defect in one of these genes has been ruled out in our patients by sequence analysis. Thus, other DNA repair factor(s) have to be considered, including the undefined cofactor that binds to the C-terminal part of AID. Two of our 15 patients have developed Hodgkin lymphoma. Although the number is small, this observation is compatible with a DNA repair defect, which could facilitate illegitimate recombination leading to oncogene activation.

#### Strategy for Diagnosis of Hyper-IgM Syndrome Due to an Intrinsic B Cell Defect

Like all patients with the diagnosis of HIGM, this group of patients with an intrinsic B cell defect is defined by markedly diminished serum levels of IgG and IgA and a normal or increased

level of IgM. Assessment of CD27<sup>+</sup> B cell count and analysis of the frequency and pattern of SHM allow identification of these different autosomal recessive HIGM conditions (Table 20.2). A pre-diagnosis is required for optimal prognosis assessment.

Other HIGM syndromes not caused by a B cell-specific abnormality are associated with T cell defects, which strongly worsens the prognosis. Defects of CD40L and CD40 are excluded by assessing membrane expression of these two molecules and/or direct gene sequencing (see Chapter 19). A defect in the NF- $\kappa$ B activation pathway (due to mutations in *NEMO*, also designated IKK- $\gamma$ , or in I $\kappa$ B $\alpha$ ) is often responsible for an HIGM phenotype characterized by a T cell defect and frequently associated with hypohidrotic ectodermal dysplasia (see Chapter 36).

Other causes of HIGM that should be excluded are the following:

1. Ataxia telangiectasia (AT), in which elevated IgM can develop before the onset of neurological manifestations (Meyts et al., 2003). It has been proposed that the HIGM condition in AT is caused by a T cell activation abnormality (Gatti et al., 1991) or, more likely, by a B cell defect, since AT-mutated (*ATM*), the gene responsible for this syndrome, plays a role in CSR (but not SHM) DNA repair (Pan-Hammarstrom et al., 2003; see Chapter 29).
2. Congenital rubella, in which a defect of T cell activation leads to defective CD40L expression on CD4<sup>+</sup> T cells (Kawamura et al., 2000).
3. Patients with major histocompatibility complex (MHC) class II deficiency have diminished expression of CD40L by activated CD4<sup>+</sup> T cells and can present with elevated serum IgM (Nonoyama et al., 1998; see Chapter 17).
4. An HIGM phenotype has been observed as part of a syndrome associated with microcephaly, mental retardation, and combined immunodeficiency. B cells from these patients are unable to proliferate in response to CD40 signaling and BCR activation. In spite of progressive B cell lymphopenia, serum IgM levels remain elevated. Circulating CD4<sup>+</sup> lymphocytes are limited to expression of the memory marker CD45RO and the T cell proliferative response to mitogens is defective. These features suggest a DNA repair defect not restricted to the B cell compartment (A. Durandy, unpublished observation).

### Prenatal Diagnosis

Prenatal diagnosis can be performed by sequence analysis of the *AID* or *UNG* gene with genomic DNA obtained from the fetus. Prenatal diagnosis could raise ethical problems since the prognosis is generally good and nearly all patients reach adulthood with only a few recurrent bacterial infections, provided that prophylactic treatment with IVIG is started early and given on a regular basis. However, other life-threatening complications (autoimmunity, lymphoma) can occur.

### Prognosis and Treatment

As soon as the diagnosis of HIGM is established, treatment with regular IVIG infusions (400–600 mg/kg every 21–28 days) must be initiated with the aim of maintaining a trough IgG level of 700–800 mg/dl. This protocol results in a significant reduction in the severity and frequency of infections and often reduces or even normalizes serum IgM levels. However, the lymphoid hyperplasia does not seem to be reduced by IVIG therapy.

With adequate prophylactic treatment, patients with HIGM due to intrinsic B cell deficiency are protected from infections and can reach adulthood without developing bronchiectasis. Surprisingly, they do not appear to be unusually susceptible to enteroviral infections, a serious complication observed in patients with X-linked agammaglobulinemia (Quartier et al., 2000; see also Chapter 21). This observation suggests a protective role of IgM (even without SHM) as a first barrier against some pathogens.

Autoimmunity has been reported in AID deficiency and in the HIGM condition characterized by a CSR defect located downstream from the S-region cleavage. Both conditions are characterized by an SHM defect (in the latter condition the B cell memory subset is decreased). In contrast, autoimmunity has not been reported in the HIGM condition characterized by a CSR defect located upstream from the S-region cleavage, in which both SHM and memory B cell numbers are normal. Autoimmunity could thus be related to defective SHM. It may be that autoimmunity, initiated by germ-line Ig sequences, is caused by the lack of negative selection in germinal centers.

A more serious complication, the occurrence of tumors, has to be considered for the prognostic assessment. The subgroup of HIGM characterized by a CSR defect located downstream from the S-region cleavage may be directly related to a DNA repair defect and patients could become susceptible to an increased risk of malignancy. UNG is part of the DNA base excision repair and is thus involved in the repair of spontaneously occurring base lesions as part of a major antimutagenic defense strategy. Interestingly, UNG-deficient mice develop B cell lymphomas when aging (Nilsen et al., 2003), so UNG deficiency may predispose to malignancies in adulthood (Table 20.3).

### Animal Models of AID and UNG Deficiencies

No naturally occurring mutants defective in AID or UNG have been described in animals. However, AID- and UNG-deficient mice, as well as AID-transgenic mice, have been generated by gene-targeting techniques.

**Table 20.3.** Main Clinical and Laboratory Findings in Hyper-IgM Syndrome Due to an Intrinsic B Cell Defect

Molecular Defect	Transmission	S DNA Cleavage	B CD27 <sup>+</sup>	SHM Frequency	Autoimmunity	Lymphoma
AID	AR	–	+	–	+	–
AID-C ter	AR	Not done	+	+	–	–
AID <sup>Ac</sup>	AD	+	+	+	–	–
UNG	AR	–	+	+	–	?
Other HIGM	AR	–	+	+	–	–
Other HIGM	AR	+	Diminished	+	+	+

AD, autosomal dominant; AR, autosomal recessive; SHM, somatic hypermutation.

\*In six of seven patients.

†Normal in frequency in the diminished B CD27<sup>+</sup> population.

### AID-Deficient Mice

The phenotype of AID<sup>-/-</sup> mice resembles completely that observed in patients and is associated with the three main features of AID deficiency:

1. Defective CSR *in vivo* and *in vitro*. The CSR defect has been shown to occur downstream from S-region transcription and upstream from the occurrence of repair foci at DSB on the Ig locus (Petersen et al., 2001).
2. Defective somatic hypermutation.
3. Giant germinal-center formation in spleen and lymph nodes with accumulation of IgM<sup>+</sup>/IgD<sup>+</sup>/PNA<sup>+</sup> proliferating B cells (Muramatsu et al., 2000).

### AID-Transgenic Mice

AID-transgenic mice express mutations in the T cell receptor, a finding indicating that aberrantly and overexpressed AID can exert its activity outside the B cell compartment. All of these mice develop tumors affecting the lymphoid compartment (T lymphoma) and nonlymphoid tissues (e.g., epithelium of respiratory bronchioles). Interestingly, these transgenic mice do not develop B cell lymphomas, an observation suggesting that AID activity and/or nuclear localization can be regulated effectively only in B cells (Okazaki et al., 2003).

### UNG-Deficient Mice

UNG-deficient mice have been generated to study the effects of base excision repair defects on the incidence of tumors (Nilsen et al., 2000). No striking biologic effects could be shown, most likely because of compensatory mechanisms provided by other uracil-N glycosylases. A more recent study of CSR and SHM provided evidence for a mild *in vivo* and a profound *in vitro* CSR defect. The remaining CSR observed *in vivo* is likely related to MMR enzymes, which are known to be involved in CSR in mice (Rada et al., 2002). This study also showed a normal frequency of SHM that exhibit a skewed pattern. Since all mutations at G/C residues are transitions, likely occurring on U/G nucleotides after replication, mutations observed on A/T residues could be the consequence of the recognition and repair of U/G lesions by MMR. Both observations, confirmed by similar data in humans (although the CSR defect is much more pronounced in UNG-deficient patients), are a strong argument for a DNA-editing activity of AID.

Without exception, UNG-deficient mice develop B lymphomas when aging, an observation that could reflect the lack of compensatory uracil-DNA glycosylases in B cells (Nilsen et al., 2003). Another adverse consequence has been reported in UNG-deficient mice: compared with wild-type mice, postischemic brain injury is much more severe, a complication likely related to the mitochondrial DNA repair defect (Endres et al., 2004).

### Conclusions

The ongoing investigation of inherited HIGM syndromes is shedding new light on the process of antibody maturation in human B cells. This is especially true for the evaluation of HIGM due to an intrinsic B cell defect, which has illustrated the complex mechanisms involved in both events of B cell maturation—CSR and SHM. On the basis of clinical phenotypes, the following mode of action of AID and UNG is proposed: AID, at center stage of CSR and SHM, deaminates cytosine nucleotides to uracil in S and V

regions of Ig genes. The integrated uridine nucleosides are deglycosylated and removed from DNA by UNG, resulting in an abasic site that becomes a target for an endonuclease. This DNA cleavage step appears to be sufficient for SHM, at least on G/C residues, but not for CSR, which require DSB. Beyond its cytidine deaminase activity, AID requires specific cofactors. A CSR-specific cofactor, which could be involved in DSB DNA repair, is expected to bind to the C-terminal part of multimeric AID. It is likely that the molecular definition of the HIGM entity caused by a CSR defect located downstream from S-region cleavage will lead to the identification of this cofactor. Taken together, these observations indicate that AID acts in a multimolecular complex composed of individual partners that have yet to be defined. The precise diagnosis of these HIGM conditions, in addition to contributing to a better understanding of the antibody maturation processes, provides science-based guidelines for better prognosis assessment and treatment management.

## X-Linked Agammaglobulinemia: A Disease of Btk Tyrosine Kinase

C. I. EDVARD SMITH, ANNE B. SATTERTHWAITE, and OWEN N. WITTE

X-linked agammaglobulinemia (XLA) is caused by a B lymphocyte differentiation arrest and was originally described in 1952 by the American physician Dr. (Colonel) Ogden C. Bruton. XLA is frequently recognized as the prototype primary immunodeficiency (PID) (Rosen et al., 1984) and was the first human immune disorder in which an underlying defect was clearly identified. The locus designation is *BTK* and the Mendelian Inheritance in Man (MIM) number is 300300. XLA is characterized by an increased susceptibility to extracellular bacterial infections (Lederman and Winkelstein, 1985; Sideras and Smith, 1995; Ochs and Smith, 1996). Enteroviral infections also frequently run a severe course, often resist therapy, and have therefore become increasingly important (Lederman and Winkelstein, 1985; McKinney et al., 1987; Ochs and Smith, 1996; Plebani et al., 2002). Through different approaches, the gene affected in XLA was isolated simultaneously by two groups and found to encode a novel cytoplasmic tyrosine kinase designated *Bruton's agammaglobulinemia tyrosine kinase*, or Btk (Tsukada et al., 1993; Vetrie et al., 1993).

Bruton's initial report described an 8-year-old boy highly susceptible to bacterial infections, in particular *Streptococcus pneumoniae*, from the age of 4 1/2 years. As reviewed in greater detail (Sideras and Smith, 1995; Smith and Notarangelo, 1997), the analysis of serum through electrophoresis, which had only recently been applied in a clinical setting, revealed the absence of detectable immunoglobulins (Ig). This finding prompted Bruton to coin the term *agammaglobulinemia*, a name that has been kept in spite of the observation that minute and sometimes even considerable amounts of Ig are detectable in XLA patients. Bruton not only realized that there was a connection between the absence of Ig and the susceptibility to infections, he also initiated substitution treatment with subcutaneous  $\gamma$ -globulin and demonstrated its efficacy.

It has been noticed that the patient initially described by Bruton had some characteristics that are not typical for classical XLA (reviewed in Sideras and Smith, 1995). However, certain patients with XLA, as confirmed by mutation analysis, have demonstrated a mild disease phenotype similar to or even milder than that of Bruton's case (Vihinen et al., 1995a, 1996b, 2001; Bykowski et al., 1996; Jones et al., 1996; Hashimoto et al., 1999; Stewart et al., 2001; Wood et al., 2001; Plebani et al., 2002). In a collaborative study, Bruton and coworkers reported on additional patients in whom the diagnosis of XLA seems indisputable (Bruton et al., 1952); but, more importantly, the original report inspired a great number of investigators to look for patients with antibody deficiency. As a result, within a few years, many patients were identified worldwide with not only XLA but also many other forms of Ig abnormality (reviewed in Good et al., 1962). The recognition of different forms of antibody deficiency disease was a gradual process, and it was not until the early 1970s that a classification as we know it today was generally accepted (Cooper et al., 1973).

In the 1950s the relationship between lymphocytes and plasma cells was still debated, and studies on XLA were crucial to this analysis (Good and Zak, 1956). More than a decade later, Naor et al. (1969) first described absence of antigen-binding cells in patients with XLA. This observation was followed by a number of investigations using technologies based on fluorochrome-labeled anti-Ig preparations that conclusively demonstrated a B lineage differentiation defect (reviewed in Sideras and Smith, 1995; Smith and Notarangelo, 1997). Over the years, hematopoietic cells other than B lymphocytes have been characterized in XLA. Although occasional reports have described non-B lineage cells to be affected, only granulocytopenia has been a frequent finding, and this is secondary to infections (Janeway, 1954; Koslowski and Evans, 1991; Sideras and Smith, 1995; Farrar et al., 1996). Thus, in spite

**Figure 21.1.** Schematic representation of B lymphocyte development and the differentiation block/growth arrest in XLA. The broken line represents a partial block and the filled line an almost total block in B lineage differentiation in XLA (modified from Mattsson et al., 1996). The thin broken line demonstrates the second block affecting B cell differentiation as detected in mice with a targeted deletion of the *Btk* gene (Hendriks et al., 1996).

of the demonstration that *Btk* is expressed outside the B cell lineage (Tsukada et al., 1993; de Weers et al., 1993; Smith et al., 1994a, Müller et al., 1999), there is no evidence demonstrating that a functional defect in non-B cells contributes to the XLA phenotype.

XLA is characterized by an increased susceptibility to infections, with onset most often during the first year of life, when transferred maternal Ig has been catabolized. Analysis of serum demonstrates a pronounced decrease in Ig levels of all isotypes; IgA is usually undetectable. There is a virtual absence of humoral response to recall antigens. B lymphocyte and plasma cell numbers are markedly decreased, whereas T lymphocyte subsets show a relative increase. The defect is caused by a differentiation arrest confined to the B cell lineage (Fig. 21.1), distinguishing XLA from several other Ig deficiencies. B lineage cells in all organs are affected, resulting in a reduced size of lymph nodes and tonsils.

The defective gene encodes a cytoplasmic tyrosine kinase designated *Btk*. Mutation analysis will confirm the diagnosis and may be used to identify healthy carriers. Treatment consists of antibiotics to combat ongoing infections and  $\gamma$ -globulin substitution as prophylaxis.

## Clinical and Pathological Manifestations

### Incidence

The incidence of XLA has been investigated in several ethnic populations (Sideras and Smith, 1995). Most of these studies were performed during the 1980s prior to the cloning of many of the genes defective in primary Ig deficiencies, including the *BTK* gene, thus preventing definitive diagnosis (reviewed in Sideras and Smith, 1995). Furthermore, these investigations were usually not specifically aimed at studying XLA but were general surveys of PID, often carried out for the first time on a national basis. Thus, several parameters may have influenced the actual patient numbers identified. An incidence for XLA of about 5 in  $10^6$  individuals was frequently reported. Ethnic differences were considered, since in the Japanese survey by Hayakawa et al. (1981) only 56 XLA cases were reported. Low numbers were found also in Malaysia (Noh et al., 1995) and in black populations in the United States and South Africa. However, lethal X-linked traits are believed to occur by de novo mutations in approximately one-third of the cases (Haldane, 1935; Chase and Murphy, 1973), a finding arguing against incidence variations in mutation frequency among different ethnic populations. In support of this notion, the number of Japanese patients with verified mutations in the *BTK* gene has increased considerably (Kanegane et al., 2001). However, even if racial differences in incidence do not exist, delayed diagnosis in non-Caucasians has been reported (Conley and Howard, 2002).

### Onset of Symptoms and Age at Diagnosis

Onset of symptoms, mainly manifested as respiratory and/or gastrointestinal tract infections, is normally within the first year of life, after the disappearance of maternal IgG transported across the placenta. In a survey of 96 North American patients with XLA, Lederman and Winkelstein (1985) noted that 25% had symptoms by the age of 4 months, 50% by 8 months, 75% by 12 months, and 90% by 18 months. In a British study comprising 44 patients with XLA, symptoms did not present in 40% of affected boys during their first year of life and 20% remained asymptomatic until the age of 3–5 years, whereas in common variable immunodeficiency (CVID), a biphasic distribution was found with symptoms beginning at 1–5 and 16–20 years, respectively (Hermaszewski and Webster, 1993). In an Italian study of 73 patients with mutation-verified XLA the mean age of onset of symptoms was 2 years (Plebani et al., 2002). In reports from recent years there seems to be a tendency toward later onset of symptoms. This phenomenon may be caused by a generous contemporary usage of more efficient antibiotics. As expected, there was no difference in age when symptoms appeared between familial and sporadic cases of XLA (Lederman and Winkelstein, 1985; Hansel et al., 1987), although diagnosis may be delayed among sporadic cases.

Lederman and Winkelstein (1985) reported a mean age at diagnosis of 2½ years in familial and 3½ in sporadic cases. Hansel et al. (1987) found 2½ years to be the average age of diagnosis among 69 patients not subdivided according to familial or nonfamilial cases, whereas Plebani et al. (2002) found 3.5 years to be the mean age. Hansel et al. (1987) and Plebani et al. (2002) reported that earlier diagnosis was made in more recent years, perhaps reflecting the rarity of an initial diagnosis being made later than during childhood. This development is likely to continue, especially in familial cases, because of the availability of mutation analysis. However, some patients with mutation-verified diagnosis do not present with symptoms until much later in life (Vihinen et al., 1995, 1996b, 2001; Hashimoto et al., 1999, Wood et al., 2001), whereas others have symptoms but are not diagnosed until later for other reasons (Stewart et al., 2001; Morwood et al., 2004). It is noteworthy that onset may also vary among individuals within the same family carrying the same mutation (Wedgewood and Ochs, 1980), demonstrating that other factors may influence this process.

The presenting symptoms in XLA vary among patients. Pneumonia, otitis media, and diarrhea are frequent clinical presentations. Sinusitis, conjunctivitis, and pyoderma are also prevalent (Table 21.1). Hematogenic dissemination of the infection may result in septicemia, meningitis, septic arthritis, or osteomyelitis. Thus, a highly increased frequency of infections is seen in all organ systems, with the possible exception of the urinary tract, in which infections seem to be limited to *Mycoplasma* or, more

**Table 21.1.** Infections in Patients with X-Linked Agammaglobulinemia

Presenting Infection	Patients in Each Study (%)			
	Lederman and Winkelstein (1985) (n = 96)	Hansel et al. (1987) (n = 69)	Hermaszewski and Webster (1993) (n = 44)	Plebani et al. (2002) (n = 73)
Ear, nose, and throat	75	22	52	50
Pneumonia	56	67	32	39
Gastrointestinal infection	35	16	11	13
Bacterial skin infection	28	DC*	14	27
Meningitis	10	17	5	4
Septicemia	10	dc	7	6
Osteomyelitis	3	dc	5	—

Modified from Sideras and Smith (1995).

rarely, *Chlamydia* species. Arthritis, affecting large joints, was found in about 20% of patients, central nervous system (CNS) infections in 4%–16%, and septicemia in 6%–10% of patients before or at the time of diagnosis (Lederman and Winkelstein, 1985; Hansel et al., 1987; Hermaszewski and Webster, 1993; Plebani et al., 2002), although the presenting symptoms are rarely limited to a single manifestation. Conley and Howard (2002) found a high frequency of *Pseudomonas* infections in children diagnosed before the age of 12 months, one of whom died prior to diagnosis. Hansel et al. (1987) reported that hypogammaglobulinemia was initially misdiagnosed as juvenile chronic arthritis in two children and delays in diagnosis were noticed in several others presenting with arthritis.

In sum, the onset and type of symptoms may vary extensively. Most patients will show an increased frequency of infections during their first year of life, whereas a few may be asymptomatic until adolescence.

### Pathology of Lymphoid Organs

The B lineage defect is manifested as a virtual absence of B lymphocytes and plasma cells in all organs. In the affected newborn, lymphoid hypoplasia may not be apparent, since in healthy infants the antigen-induced expansion of B lymphocytes in secondary lymphoid organs has not yet taken place. Adenoids and tonsils are frequently rudimentary and lymph nodes are reduced in size. Secondary lymphoid organs, such as lymph nodes and appendix, lack germinal centers and follicles (Good, 1954; Sideras and Smith, 1995). In the lamina propria of the gut, plasma cells are typically absent in patients with XLA, this is not the case in most other primary immunodeficiencies (Ochs et al., 1972; Ament et al., 1973; Buckley and Rowlands, 1973). A low number of plasma cells in the gut is also a typical finding in CVID. However, biopsies of lymphoid organs for diagnostic reasons are now rarely indicated, with the exception of sampling for isolation of an infectious agent.

Analysis of bone marrow has revealed a maturation block between terminal deoxynucleotidyl transferase (TdT) C $\mu$ -negative early pre-B cells and C $\mu$ -positive pre-B cells (Campana et al., 1990; Nomura et al., 2000). The severity of the block is variable, thus normal pre-B cells can develop in some patients. The proliferative activity of these pre-B cells is impaired, however (Pearl et al., 1978; Campana et al., 1990; Noordzij et al., 2002a). Furthermore, although the differentiation block is manifested in the early stages of B lymphocyte development, it is likely that the

defect in XLA also affects the later stages of B cell development (Conley, 1985). Experiments in mice indicate that this is indeed the case (Hendriks et al., 1996).

### Spectrum of Infections

Bacterial respiratory tract and gastrointestinal infections are the predominant manifestations of XLA, as they are of other antibody deficiencies. What distinguishes XLA from most other humoral defects is the increased frequency of chronic enteroviral infections. Pyogenic bacteria, such as *Hemophilus influenzae*, *Streptococcus pneumoniae*, and *Staphylococcus aureus*, for which antibodies act as opsonins, typically cause infections. In normal individuals, antibody binding to microorganisms contributes to the inflammatory reaction, which causes the clinical symptoms. Because XLA patients lack antibodies, clinical symptoms are often mild and do not reflect the severity of the infections. As in other immunodeficiencies, infections typically are recurrent or chronic in nature. Another hallmark of XLA is the observation that infections are often found in more than one location and may be atypical, such as *Mycoplasma*-associated arthritis.

Lederman and Winkelstein (1985) reported that 71% of investigated XLA patients presented with chronic infections. Chronic pulmonary disease was found in almost half of the patients, complicated in some by hypoxemia and cor pulmonale. Hearing loss secondary to chronic otitis media and meningoencephalitis as well as delayed speech acquisition also occurred frequently. However, patients diagnosed early in life and receiving adequate treatment rarely developed sensory-neurologic complications caused by bacterial infections. It should also be noted that certain XLA patients have a mutation extending from the *BTK* gene into the adjacent *TIMM8A* (formerly *DDP*) gene causing sensory-neurologic manifestations (see Chromosomal Region Containing the *BTK* gene, below).

Chronic progressive encephalitis caused by enteroviral infection is an often fatal complication of XLA patients, who are uniquely susceptible to enteroviruses causing meningoencephalitis. This disease is described in more detail in below. Bacterial infections, found in all patients displaying antibody deficiency, are discussed briefly in the following section and in more detail in Chapters 43 and 46.

Other viral infections, such as measles, and infections with intracellular microorganisms, such as *Mycobacteria* or the protozoan *Toxoplasma gondii*, run a normal course that is not different from that in immunologically normal individuals. For

these infectious agents cellular immunity is believed to constitute the main defense. Patients with XLA seem not to be infected by Epstein-Barr virus (EBV), a finding pointing to the crucial role of B lymphocytes for this virus (Faulkner et al., 1999). Infections with *Pneumocystis carinii*, a major pathogen in patients with impaired cellular immunity, may occur in XLA, although rarely (Alibrahim et al., 1998; Dittrich et al., 2003). Increased susceptibility to other fungal infections has not been reported (see also Miscellaneous Infections, below).

### Bacterial infections

Bacterial infections are the major complications in XLA and other antibody deficiencies (Lederman and Winkelstein, 1985; Stiehm et al., 1986; Spickett et al., 1991; Hermaszewski and Webster, 1993; Ochs and Smith, 1996). The typical sites of infections are presented in Table 21.1. In a survey of patients with XLA, Lederman and Winkelstein (1985) reported that respiratory tract and/or gastrointestinal tract infections caused the presenting symptoms in 91% of patients. Similar findings were obtained by Hermaszewski and Webster (1993).

The most frequently observed organisms include *H. influenzae*, a chronic sputum isolate in 82% of cases; *S. aureus*, in 27%; and *S. pneumoniae*, in 21% (Lederman and Winkelstein, 1985). In chronic conjunctivitis, *H. influenzae* was found in more than half of the investigated patients. In septic arthritis, *H. influenzae* and *S. pneumoniae* were most frequently reported prior to diagnosis, whereas a viral etiology was predominantly observed after the diagnosis of XLA had been established; *Mycoplasma* species were isolated in some cases. A similar pattern was noted in bacterial meningitis, with *H. influenzae* and *S. pneumoniae* being the predominant organisms prior to diagnosis, followed by a higher frequency of viral agents in diagnosed patients. In septicemia *Pseudomonas* was the most frequently isolated microorganism, with *H. influenzae*, *S. pneumoniae*, and *S. aureus* being isolated less consistently.

Infections with the nonsporulating gram-negative rod *Campylobacter jejuni* have been reported to cause gastrointestinal disease, erysipelas-like skin lesions, pericarditis, and recurrent fever in patients with XLA (Kerstens et al., 1992; Rafi and Matz, 2002). The diarrhea may be of long duration, but in some cases patients are asymptomatic (Melamed et al., 1983; van der Meer et al., 1986; Chusid et al., 1987; Hermaszewski and Webster, 1993; Schuster et al., 1996). Excretion of *C. jejuni* in the stool, which in untreated non-immune-deficient subjects normally persists for 2–3 weeks, may be prolonged. As for many other bacterial species, human serum is bactericidal for *Campylobacter* isolates and antibodies seem to constitute an important line of defense (Blaser et al., 1985; Cover and Blaser, 1989). Infection with fastidious organisms such as *H. cinaedi* (previously known as *C. cinaedi*) has been reported in XLA (reviewed in Simons et al., 2004). The presentation was hyperpigmented macules, without increased local warmth, fever, or any other signs of illness.

Systemic *Ureaplasma urealyticum* infections or infections with other *Mycoplasma* species are also frequent and may primarily cause symptoms in the respiratory tract, joints, and urogenital tract (Stuckey et al., 1978; Webster et al., 1978; Lederman and Winkelstein, 1985; Roifman et al., 1986; Gelfand, 1993; Hermaszewski and Webster, 1993). These organisms are often difficult to identify, and the course of disease may be prolonged, with an insidious onset. Symptoms may be severe, with accompanying weight loss. Significantly milder symptoms are associated with *Mycoplasma* infections of the respiratory tract compared to normal individuals, and there are minimal or no changes on chest X-ray despite

prolonged periods of cough (Foy et al., 1973). Combined infections of *Mycoplasma* and other bacterial species may also contribute to disease severity. Urogenital tract infections can cause urethral strictures and result in epididymitis and prostatitis (Hermaszewski and Webster, 1993; Ochs and Smith, 1996).

### Enterovirus infections

Most viral infections run a normal course in XLA (Janeway et al., 1953; Lederman and Winkelstein, 1985; Ochs and Smith, 1996). However, enteroviral infections frequently cause chronic meningoencephalitis often associated with a dermatomyositis/fasciitis-like syndrome in patients with agammaglobulinemia. Thus, although viral infections are the hallmark of abnormalities in cellular immunity, enteroviral infections are found in patients with severe agammaglobulinemia, particularly in XLA. The most comprehensive review in the field describes 42 patients with antibody deficiency, 18 of whom have classic XLA and 14 with clinical features typical for XLA but devoid of a family history (McKinney et al., 1987). Enteroviral disease presenting with a similar clinical picture to that in XLA was also seen in some patients with CVID and in patients with thymoma and hypogammaglobulinemia. However, the frequency of patients affected was considerably lower than in XLA. Hermaszewski and Webster (1993) reported a 10-fold increased risk in patients with XLA compared to those with CVID. Also, in CD40 ligand defects enteroviral meningoencephalitis has been reported (Cunningham et al., 1999). In agammaglobulinemia caused by mutations in the  $\mu$  heavy-chain gene, resulting in undetectable B cells, chronic enteroviral infection seems to occur as frequently as in XLA, although the number of identified patients is still limited (Lopes Granados et al., 2002). Recently, enteroviral meningoencephalitis was reported after treatment with monoclonal antibodies directed against the B lymphocyte cell surface antigen CD20 (Quartier et al., 2003).

The reason for this high susceptibility is unknown, but it may be the result of the virtual complete absence of antibodies in XLA, compared to several other Ig deficiencies. As for most viral infections, immunoglobulins have a protective effect against enteroviruses, as demonstrated over 60 years ago (Kramer, 1943; Hammon et al., 1952). Alternatively, the lack of B lymphocytes may impair the removal of viral particles, impede antigen presentation, or affect other parameters in the immune defense. Enteroviral infection is frequently manifested as chronic encephalomyelitis (McKinney et al., 1987) and insidious onset of neurologic symptoms and altered cognitive function are typical. Almost any symptom in an agammaglobulinemic patient may be caused by an enteroviral infection of the CNS.

*Types of enteroviruses causing disease in XLA.* Echovirus is the predominant pathogen among the enteroviruses causing meningoencephalitis in agammaglobulinemic patients. Coxsackieviruses A and B have also been reported to cause disease (McKinney et al., 1987; Lederman and Winkelstein, 1985). Patients with agammaglobulinemia are also highly susceptible to poliovirus infection, as reviewed by Wyatt (1973), who calculated that vaccine-associated poliomyelitis was increased by a factor of  $10^4$  in this patient category. Lederman and Winkelstein (1985) observed one case of poliovirus vaccination-associated death in their survey. Hermaszewski and Webster (1993) reported one patient with paralytic poliomyelitis and one who suffered foot drop following oral polio virus vaccination, and McKinney et al. (1987) described two patients with paralytic poliomyelitis prior to their echoviral infections. Sarpong et al. (2002) reported one patient

who survived infection with wild poliomyelitis in childhood many years before the diagnosis of XLA was made. Vaccine-associated poliomyelitis may also occur in nonvaccinated individuals, since the oral live vaccine may spread in the population (Hidalgo et al., 2003). McKinney et al. (1987) reported a close correlation between the prevalence of echoviral serotypes in agammaglobulinemic patients and that observed in the general population. During the period 1970–1983, the most common echoviral serotypes in both populations were 11, 9, and 30 (Strikas et al., 1986).

*Clinical features and investigation of enteroviral infection in agammaglobulinemia.* In XLA patients demonstrating neurological symptoms, enteroviral infection should always be suspected. Agammaglobulinemic patients developing meningoencephalitic enteroviral disease often present with slowly progressing neurologic symptoms, including ataxia, loss of cognitive skills, and paresthesias. Some patients show an acute onset with fever, headache, and seizures. Nearly all patients display pleocytosis in their cerebrospinal fluid (CSF), with a predominance of lymphocytes. Leukocyte numbers are usually  $<10^3$  cells/mm<sup>3</sup>, and protein concentration is typically between 0.5 and 5 g/l (McKinney et al., 1987). Imaging with magnetic resonance imaging (MRI) or computed tomography (CT) scanning was found to be normal initially in patients with early encephalopathy, thus having a limited diagnostic value. Cultures for enterovirus are frequently negative. However, the use of reverse-transcription polymerase chain reaction (PCR) has improved the identification of enterovirus in the CNS (Rotbart, 1990; Zoll et al., 1992; Rotbart et al., 1994), including patients with XLA (Webster et al., 1993; Rudge et al., 1996). Bacterial infections of the CNS have to be differentiated from the less common, fulminant, acute-onset encephalomyelitis caused by enteroviruses. Since bacterial infections in XLA generally respond well to prompt treatment with antibiotics, it is important to exclude a bacterial origin.

Enteroviral infection may also present as a dermatomyositis-like syndrome associated with dissemination of enterovirus (McKinney et al., 1987; Thyss et al., 1990). This form of the disease is characterized by peripheral edema, erythematous rash, and evidence of inflammation in skin and muscle biopsy specimens. The infection in the CNS seems to occur prior to dissemination of the virus. Edema or myositis with fasciitis may be found as the only manifestation of viral dissemination. Enteroviral hepatitis resulting in hepatomegaly and an increase in liver enzymes such as alanine aminotransferase are frequently seen in affected patients, usually associated with erythematous rashes and fever.

Most patients with long-standing enteroviral disease have similar symptomatology. More than half will show weakness, hearing loss, headache, lethargy/coma, seizures, ataxia, or paresthesias. Personality changes appear to be common, including depression and emotional lability, and the interval between onset of viral infection in the CNS and the appearance of overt symptoms may be considerable (McKinney et al., 1987).

*Pathology of enteroviral disease in X-linked agammaglobulinemia.* Histological examination of enteroviral meningoencephalitis demonstrates meningeal inflammation with perivascular mononuclear cell infiltrates and edematous thickening of the leptomeninges (McKinney et al., 1987; Rudge et al., 1996). Cerebral edema is extensive and diffuse encephalitis with glial reaction including microglial nodules and focal neuronal degeneration is evident. Astrogliosis in association with perivascular lymphocytic cuffs and elongated microglial cells have also been observed. In

**Figure 21.2.** Whole brain section of a patient with XLA having an enteroviral infection presumably contracted at 8 years of age. Autopsy performed at 17 years of age, after several years of progressing dementia, shows severe thinning of the cerebral cortex, reduced subcortical and deep white matter, and marked dilatation of the lateral ventricles (reproduced from Rudge et al., 1996).

particular the cerebellum but also the brain stem and the spinal cord show loss of neurons. Eventually, most patients display profound cerebral atrophy with enlargement of the ventricles, which can be detected with CT. At autopsy the histologic appearance is sometimes consistent with that seen in an end-stage, severe encephalitic process of long duration (Fig. 21.2). Some patients do not show features of encephalitis but instead have evidence of long-standing leptomeningitis.

Hepatic involvement is manifested as centrilobular congestion and periportal lymphocytic infiltrates. Lymphocytic infiltrates may be found in multiple organs, including heart, lung, and kidney, whereas enteroviral infections in normal individuals do not become chronic. Furthermore, XLA patients may not only become chronically infected but also excrete enterovirus for extended periods of time (McKinney et al., 1987). As reported in a recent workshop (Halsey, 2002), 17 persons with B cell immune deficiency disorders, primarily XLA or CVID, who excreted polio vaccine viruses for 6 months or more, sometimes for many years, have been identified over the past 40 years. Most of these patients became paralyzed from the viruses, often after several years of poliovirus excretion. To this end, a recent Italian study found long-term excretors to be rare (Fiore et al., 2004). No effective therapy has been identified; some affected individuals have spontaneously stopped excreting polioviruses after several years.

*Treatment and prevention of enteroviral disease.* Initial attempts using high-dose treatment or intraventricular delivery of immunoglobulins were considered successful (Mease et al., 1981; Erlendsson et al., 1985; reviewed in McKinney et al., 1987; Misbah et al., 1992). However, treatment failures have been reported (Johnsson et al., 1985) and long-term follow-up has demonstrated that the enteroviral infection is not always eradicated, although in selected patients all symptoms disappeared when receiving adequate Ig treatment (Mease et al., 1985; Crennan et al., 1986; Rudge et al., 1996). Quartier et al. (1999, 2000) treated three patients with enteroviral meningoencephalitis. Residual IgG levels were increased to 31–63 g/l—i.e., considerably higher levels than

those in healthy controls. In two patients clinical symptoms and CSF abnormalities resolved. The third patient died despite intraventricular infusion of Ig through an Omayo reservoir.

It has been suggested that high-dose intravenous immunoglobulin (IVIG) substitution therapy slows the development of cerebral disease. However, the number of patients is limited, rendering statistical evaluation impossible (Erlendsson et al., 1985; Mease et al., 1985). It has been considered important to try and identify the virus causing the infection to select Ig preparations with high specific antibody titers (H.D. Ochs, J.M. Puck, personal communication). Some practitioners prefer intrathecal delivery, whereas others use the IV route. Liese et al. (1992) reported that neither low- nor high-dose IVIG therapy improved the clinical course and that intraventricular administration of IVIG was ineffective. Misbah et al. (1992) have suggested that the significant clinical improvement seen in their patient following high-dose IVIG may have been due to an anti-inflammatory effect. Oral treatment with ribavirin had no effect. These authors also recommend the use of serial CSF albumin-level determinations to monitor the blood-brain barrier permeability.

As of 2003, and 2005, respectively two patients treated with a combination of Ig therapy and pleconaril (Quartier et al., 2000) have shown no signs of recurrence of the enteroviral infection with a follow-up of >4 and >6 years (P. Quartier, personal communication). Pleconaril treatment was found to cause clinical improvement in 78% of patients with potentially life-threatening enterovirus infection, including 12 of 16 with chronic enterovirus meningoencephalitis (Rotbart and Webster, 2001). Recently, a mutation in polio virus was found to accompany reduced susceptibility to pleconaril in a patient with CVID, known to be a long-term excretor of the virus (MacLennan et al., 2004).

There is clinical evidence that substitution therapy resulting in high serum levels of IgG protects against enteroviral meningoencephalitis, because the frequency of patients developing this infection has decreased over the years (Liese et al., 1992; Misbah et al., 1992; A.D.B. Webster, personal communication). Liese et al. (1992) did not find symptoms of chronic encephalitis in any of eight patients in whom high-dose IVIG was started before the age of 5 years. Rudge et al. (1996) have suggested that Ig treatment resulting in serum IgG levels maintained above 8 g/l may provide protection. However, although this is the general trend, fatal enteroviral infections may still occur during high-dose Ig substitution therapy (Misbah et al., 1992; Quartier et al., 1999). It could be anticipated that rare forms of enteroviruses would be more prone to cause infections because  $\gamma$ -globulin preparations would lack neutralizing antibodies.

#### Miscellaneous infections

Gastrointestinal infection caused by the flagellate *Giardia lamblia* has been found in many patients with XLA, although it appears to be more common in CVID (Ochs et al., 1972; Hermaszewski and Webster, 1993; Lavilla et al., 1993). The infection may cause abdominal pains, diarrhea, and malabsorption. *P. carinii* infection has been identified in most forms of PID but is more common in patients with a defect in cellular immunity (Masur et al., 1989; Walzer, 1991). Infections may preferentially occur in XLA patients who are debilitated or otherwise compromised (Lederman and Winkelstein, 1985). A recent outbreak of *P. carinii* pneumonia in a colony of mice specifically lacking B lymphocytes caused death in more than 50 of the animals (Marcotte et al., 1996). Although species differences may exist, this finding further indicates that humoral immunity to this protozoan is of importance (see also Spectrum of Infections, above).

#### Arthritis

Arthritis is frequently observed in XLA. It may be the presenting symptom and has been mistaken for chronic juvenile arthritis (Hansel et al., 1987). The arthritis is normally nonseptic, monoarthritic, and affects the large joints, causing hydroarthritis with relatively little pain (McLaughlin et al., 1972; Ochs and Smith, 1996). The arthritis frequently responds to  $\gamma$ -globulin treatment (Webster et al., 1976; Plebani et al., 2002) and there is usually no apparent joint destruction. Residual IgG levels of >8 g/l were associated with improvement of clinical symptoms, whereas in patients with 5–8 g/l recurrences were seen (Quartier et al., 1999). The erythrocyte sedimentation rate is normal, as are serological tests for rheumatoid factor and antinuclear antibodies. (Because these patients essentially lack immunoglobulins, autoantibody analysis is of no value.) The cause of the arthritis is frequently unknown, since an infectious origin has not been verified. Lederman and Winkelstein (1985) reported arthritis, including polyarthritis, in 20% of XLA patients. Less than half of the episodes were due to acute pyogenic infections. Conley and Howard (2002) reported pneumococcal arthritis in two patients diagnosed after >40 months of age. Enteroviruses or *Mycoplasma* species have also been identified in affected joints from some patients (Ackerson et al., 1987; Hermaszewski and Webster, 1993). Recently, an atypical case of rheumatoid arthritis with infiltrating CD8 cells was reported (Verbruggen et al., 2005).

#### Autoimmunity

In contrast CVID (Cunningham-Rundles et al., 1987; Hermaszewski et al., 1991), XLA does not seem to predispose to autoimmune disorders (Sideras and Smith, 1995). Type 1 diabetes has only been reported in a single patient with XLA, but this finding suggests that humoral immunity is not required for development of this form of autoimmunity (Martin et al., 2001). Whether humoral immunity may still contribute to the disease process in humans is not known, but in the animal diabetes model, nonobese diabetic (NOD) mice, this is the case. As mentioned in the Arthritis section above, a case of rheumatoid arthritis in XLA has also been reported (Verbruggen et al., 2005).

#### Allergic Reactions

Few allergic reactions have been reported in XLA patients. After repeated treatment with intravenous infusions of ceftriaxone for an *H. influenzae* infection, a child developed diffuse, maculopapular rash with minimal pruritus, hyperthermia, flushing, and lethargy (Collins and Assa'ad, 2002). A skin biopsy showed the presence of infiltrating CD4<sup>+</sup>, CD45RO<sup>+</sup> memory T cells in the absence of detectable IgE.

#### Tumors

Predisposition to tumors is the hallmark of several PIDs, such as the Wiskott-Aldrich syndrome and ataxia-telangiectasia (Filipovich et al., 1994; Smith and Notarangelo, 1997). In XLA this relationship is less obvious (Sideras and Smith, 1995; Ochs and Smith, 1996), although 4.2% of a total of 500 patients with neoplasia in a primary immunodeficiency disease registry were reported to have XLA (Filipovich and Shapiro, 1991). Lymphoreticular malignancies may be slightly increased (Kersey et al., 1973; Lederman and Winkelstein, 1985; Filipovich et al., 1994). The incidence of rectosigmoid cancer has been suggested

to show a 30-fold increment, and mortality was 59-fold greater in a survey of 52 Dutch patients (van der Meer et al., 1993). Rectosigmoid cancer was also observed in a Swedish (Sideras and Smith, 1995) and a North American patient (H.D. Ochs, personal communication). Glutathione-S-transferase activity, possibly reflecting detoxification capacity, in gastrointestinal mucosa was found to significantly correlate with tumor incidence in humans, and decreased levels were also identified in patients with XLA (Grubben et al., 2000). However, the causal relationship to XLA, if any, remains elusive, and human adenocarcinoma cell lines were found not to express Btk (Smith et al., 1994a). Two patients with pituitary adenoma have been identified (Hermaszewski and Webster, 1993; Ochs and Smith, 1996). In case reports, von Recklinghausen disease was noticed at the age of 33 (Hirata et al., 2002) whereas extranodal cytotoxic T cell lymphoma was observed in another patient (Kanavaros et al., 2001). These findings indicate that there is a minor increase in malignancies in patients with XLA.

Lavilla et al. (1993) and Paller (1995) have suggested that complete gastrointestinal studies and examination for lymphomas should be performed regularly in all patients with XLA. In view of the minor increase in tumor frequency seen in XLA, most investigators seem to favor a more modest approach (H.D. Ochs; A.D.B. Webster; J.W.M. van der Meer, personal communication). However, owing to the high frequency of atrophic gastritis, pernicious anemia, and gastric adenocarcinoma in CVID (Kinlen et al., 1985; Cunningham-Rundles et al., 1987), it seems reasonable to implement careful monitoring with regular endoscopic screening of XLA patients in whom atrophic gastritis was diagnosed. The risk of cancer of the stomach in nonimmunodeficient patients with pernicious anemia who suffer from chronic gastritis and achlorhydria was estimated to be increased by a factor of 3 (Elsborg and Mosbech, 1979).

As discussed in the section Animal Models below, a mutation resulting in the substitution of arginine at position 41 with glutamine, designated BTK\*, has a transforming capacity (Li et al., 1995). This effect is manifested in transduced fibroblast 3T3 cells and also in the form of IL-5-independent growth of a pro-B cell line. Initial studies of patients with various forms of B lymphoid tumors did not indicate any abnormal expression of Btk (Katz et al., 1994; Vorechovsky et al., 1994b). Furthermore, an increased frequency of chromosomal aberrations in the Xq22 region (in which the BTK gene is located) has to date not been reported in B lineage tumors. However, in a recent report, defective expression of Btk in acute lymphoblastic leukemia was reported, although the biological significance, if any, of this phenomenon is unknown (Goodman et al., 2003).

### Causes of Death

Among 170 patients observed by Lederman and Winkelstein (1985), Hermaszewski and Webster (1993) and Ochs and Smith (1996), 29 deaths were recorded (Table 21.2). The major cause of death was viral infections, which occurred in about half the patients. Enteroviral infections predominated, with echoviruses being the major agent causing disseminated disease, including meningoencephalitis. The disease progression is characterized by slow deterioration with increasing loss of cerebral function. Chronic pulmonary disease, amyloidosis, septicemia with osteomyelitis, and inflammatory bowel disease were other causes of death. Approximately one-third of the deaths reported by Lederman and Winkelstein (1985) were caused by cardiorespiratory failure, secondary to chronic pulmonary disease and corpul-

**Table 21.2.** Cause of Death in X-Linked Agammaglobulinemia\*

Cause of Death	Patients (n)	Age at Death (Years)
Pulmonary infections (acute, chronic)	9	Mean 20 (10–27)
<i>Enterovirus infections</i>		
ECHO	10	12 (6–23)
Coxsackie	1	28
Polio (attenuated vaccine)	1	4
Adenovirus infections	1	14
Hepatitis	3	12 (10–24)
Staphylococcus (pericarditis/sepsis)	2	23 (20–26)
Amyloidosis	1	Unknown
Inflammatory bowel disease	1	Unknown

\*Premature death occurred in 30 of 170 XLA patients studied longitudinally in the United States and Canada ( $n = 96$ ) (Lederman and Winkelstein, 1985), Great Britain ( $n = 44$ ) (Hermaszewski and Webster, 1993), and Seattle, WA ( $n = 30$ ) (H.D. Ochs unpublished data).

Reproduced from Ochs and Smith (1996).

monale. Hermaszewski and Webster (1993) reported a single patient who died from respiratory disease. This patient did not suffer from corpulmonale. Iatrogenic disease in the form of hepatitis C contracted during globulin substitution treatment was fatal in one patient. However, patients with XLA normally seem to develop a less fulminant hepatitis than that in CVID patients (Hermaszewski and Webster, 1993; Bjørø et al., 1994; J. Björkander, personal communication). As discussed elsewhere in this chapter, malignancies constitute a rare cause of death in XLA.

### Laboratory Findings

The laboratory findings characteristic for XLA reflect the B lineage defect and are manifested as severely decreased numbers of B lymphocytes and absence of serum immunoglobulins (Table 21.3). Rarely, XLA patients may have near-normal or normal Ig levels and numbers of B lymphocytes. In these patients analysis of the spectrum of antibodies and investigation of antigen-specific antibody responses are recommended (Table 21.3).

**Table 21.3.** Characteristic Laboratory Findings in Patients with X-Linked Agammaglobulinemia

Serum Ig levels*	IgM	IgG	IgA
g/l	<0.1	<2	Often undetectable
Isohemagglutinins†	Undetectable		
Antibody responses to foreign antigens†	Undetectable or markedly reduced		
Peripheral blood‡	CD19	CD20	Surface Ig <sup>+</sup>
B lymphocyte markers	<2%	<2%	<2%

\*Normal values vary somewhat among different laboratories, but are typically as follows: IgM: 0.5–2 g/l; IgG, 7–16 g/l; IgA: 0.5–3 g/l in adults. Normal values for IgA may vary extensively until adolescence. The IgG level is typically >4 g/l at all ages. In the newborn it is similar to what is seen in adults, as a consequence of placental transfer; it will thereafter decrease until about 6 months of age.

†Analysis is not obligatory for diagnosis. However, analysis is recommended in patients having essentially normal Ig levels. For definitive diagnosis of XLA, mutation analysis has to be carried out.

‡Normal values vary somewhat among different laboratories, but are typically 5%–20%, corresponding to  $0.08\text{--}0.4 \times 10^9$  cells/l. As surface Ig determination may be influenced by Fc receptor binding, the inclusion of CD marker analysis is recommended.

**Figure 21.3.** Schematic representation of the Btk protein. Boxes represent functional regions or domain structures. The protein is composed of the following domains: PH (pleckstrin homology), TH (Tec homology),

SH3 (Src homology 3), SH2 (Src homology 2) and kinase (SH1). The numbers denote amino acids numbered from the N-terminus. For simplicity the linker regions between functional domains are not denoted.

**Molecular Basis of X-Linked Agammaglobulinemia**

**The Gene Defective in X-Linked Agammaglobulinemia Encodes a Tyrosine Kinase**

The molecular basis of XLA was identified using two different modes of gene cloning: positional cloning by applying cDNA selection on yeast artificial chromosomes from the implicated region, and investigation of novel protein tyrosine kinases (PTKs) expressed in B lymphocytes (Tsukada et al., 1993; Vetrie et al., 1993). These studies demonstrated that a gene, *BTK*, encoding a novel cytoplasmic PTK was defective in XLA. PTKs are enzymes that catalyze the phosphorylation of tyrosine residues in proteins with ATP or other nucleotides as phosphor donors and belong to the enzyme classification (EC) group EC 2.7.1.112. PTKs are subdivided into receptor PTKs, which are membrane-spanning proteins such as the receptor for platelet-derived growth factor (PDGF), and cytoplasmic, or nonreceptor PTKs, exemplified by the cellular homologue of Rous sarcoma virus, c-Src (Manning et al., 2002). The current estimate of human PTKs is 58 receptor PTKs and 32 nonreceptor PTKs.

When the *BTK* gene was isolated, it was also the first time a cytoplasmic PTK was implicated in a hereditary human disease. Subsequently, mutations in the genes encoding both the Jak3 and Zap-70 cytoplasmic kinases have been shown to cause PID (see Chapters 10 and 14, respectively).

Btk is composed of 659 amino acids with a total molecular weight of 77 kDa; the corresponding mRNA is normally found as a single species of 2.7 kb (Tsukada et al., 1993; Vetrie et al., 1993; Smith et al., 1994b). Btk carries three domains, which are also found in Src. These are from the C terminus, the kinase domain of about 280 amino acids, also referred to as *Src homology 1* (SH1); a region of about 100 residues, which binds to phosphorylated tyrosine residues, designated *SH2*; and a domain of about 65 amino acids known to interact with proline-rich stretches, referred to as *SH3*, as depicted in Figure 21.3 (Pawson, 1995).

In addition, Btk contains two regions in the N terminus, designated *Pleckstrin homology* (PH), with 140 amino acids, and *Tec homology* (TH), containing approximately 80 residues (Fig. 21.3). The PH domain is found in more than 100 proteins and is believed to have a membrane-targeting function (Salim et al., 1996; Rameh et al., 1997). The TH region is composed of an extension of the PH domain, designated the *Btk motif* (27 residues), and a proline-rich stretch (Vihinen et al., 1994b; Smith et al., 1994b). The Btk motif in the TH region has been shown to bind a Zn<sup>2+</sup> ion (Vihinen et al., 1997b). This region was named after Tec, which was the first member to be identified in the family of PTKs to which Btk belongs (Mano et al., 1990). The other family members are Itk (also called Tsk and Emt) and Bmx (also called Etk). The kinase Txk (also Rlk) lacks the PH domain but is related to the Tec family of kinases. For comprehensive reviews of the Tec family see Smith et al. (2001) and Takesono et al. (2002).

**Chromosomal region containing the *BTK* gene**

The human *BTK* gene is located on the long arm of the X chromosome in a region designated Xq22.1 (Fig. 21.4). It is transcribed in a telomere (→) centromere direction (Vorechovsky et al., 1994a) and the human gene encompasses 37.5 kb (Hagemann et al., 1994; Ohta et al., 1994; Rohrer et al., 1994; Sideras et al., 1994) as depicted in Figure 21.4. Use of cDNA selection technology enabled identification of several RNA species expressed from this region in B cells and in B cell progenitors (Vorechovsky et al., 1994a). A deletion extending into the closest flanking gene, the centromerically located gene initially referred to as *DXS1274E*, was found in a family with XLA and sensorineural deafness (Vorechovsky et al., 1994a). Mutations in this gene, later renamed *DDP* (deafness dystonia protein) and then officially called *TIMM8A*, because it encodes a conserved mitochondrial protein, were found to cause Mohr-Tranebjaerg syndrome (Jin et al., 1996). Subsequently, patients with various deletions extending from the *BTK* gene into the *DDP* gene have been reported (Richter et al., 2001). A map of this chromosomal region is depicted in Figure 21.4.

**Figure 21.4.** Physical map of the Xq22.1 region showing the *BTK* gene and adjacent genes (top) and how they are transcribed. Deletions encompassing the 3' end of the *BTK* gene and extending into the *TIMM8A* gene cause XLA and Mohr-Tranebjaerg syndrome. Below is the organization of the *BTK* gene, showing the 19 exons. Filled squares represent translated exonic regions.

### Genomic organization of the *BTK* gene

*Btk* was the first member of the Tec family for which the genomic organization was established. The related *TXK* gene, which encodes a kinase lacking a PH domain, has shown an organizational pattern similar to that of *BTK* (Ohta et al., 1996). The human *BTK* gene comprises 19 exons, including a 5' untranslated region (exon 1) and a 3' exon containing both the C-terminal coding and a 3' untranslated part (Hagemann et al., 1994; Ohta et al., 1994; Rohrer et al., 1994; Sideras et al., 1994), as depicted in Figure 21.4. The sizes of the exons vary from 55 to 560 bp, and the introns range from 164 bp to 9 kb. In the mouse, a similar genomic organization was observed (Sideras et al., 1994), the difference being mainly an increased size of introns 4 and 12. The number of exons was identical in humans and mice, as were the exon–intron boundaries. Furthermore, the human, mouse, and rat *Btk* proteins are highly conserved, being 98%–99% identical at the amino acid level (Sideras et al., 1994; Lindvall et al., 2005).

The promoter region of the *BTK* gene was initially inferred from sequence motifs in the DNA stretch 5 of the start site (Sideras et al., 1994). Through functional analysis of this region, binding sites for members of two families of transcription factors have been identified—namely, Sp1 and Spi-1/PU.1, respectively (Himmelman et al., 1996; Müller et al., 1996, 1999). Tissue specificity seems to be provided by the Spi-1/PU.1 factors, which are selectively expressed among hematopoietic cells. *Btk* is expressed in all hematopoietic cells with the exception of T cells and plasma cells. This indicates that the *BTK* gene is turned on early during differentiation, and *Btk* expression has been observed in cells carrying the early progenitor marker CD34 (Smith et al., 1994a).

The first mutations identified resulted from amino acid substitutions in the kinase domain (Vetrie et al., 1993). However, mutations have been found scattered all over the gene, afflicting all the domains of the protein.

### Functional Aspects of *Btk* Signaling

Multiple receptors connect to *Btk* in B and non-B hematopoietic cell types.

#### Immunoglobulin-Based Receptors

The ordered rearrangement of immunoglobulin heavy-chain segments and expression of associated signaling molecules like Ig $\beta$  (CD79b) is a critical step in the production and selection of diverse immature B lineage cells. The transition from pro-B to pre-B phenotype cells can be induced by cross-linking of the CD79b molecule, even in cells from *Rag2* knockout mice that lack productive Ig rearrangements. However, in *Btk/Rag2* double-knockout mice this induced transition does not occur, a result supporting a role for *Btk* in one of the earliest steps in B lineage development (Kouro et al., 2001).

Proper assembly and signaling from the pre-B cell receptor is needed to progress through B cell development for selection of the heavy chain repertoire and to signal for light-chain rearrangements (Conley et al., 2000). *Btk* and other signaling molecules including Lyn, Syk, BLNK (also known as SIp-65), phosphatidylinositol 3-kinase (PI3K), Vav, and PLC $\gamma$ 2 can all be associated in a lipid raft signaling complex with the pre-B cell receptor (Guo et al., 2000) necessary for effective Ca<sup>2+</sup> signaling.

The most intensively studied receptor on the surface of B lineage cells is the Ig receptor complex, or B cell receptor (BCR), which contains both heavy and light chains and the associated

signaling molecules, Ig $\alpha$  and Ig $\beta$ . Peripheral resting B cells with a IgM<sup>low</sup>/IgD<sup>high</sup> phenotype are reduced in numbers in X-linked immunodeficiency (Xid) mice and nearly absent in most patients with XLA. Activation by cross-linking with anti-immunoglobulin is defective in Xid B cells, with failure to sustain a strong flux of Ca<sup>2+</sup> and progress through the cell cycle. Early steps downstream of BCR activation include tyrosine phosphorylation of the immunoreceptor tyrosine-based activation motif (ITAM) sequences on Ig $\alpha$  and  $\beta$  by Src family kinases (predominantly Lyn). This eventually results in the assembly of a membrane-associated signaling complex that includes Lyn, Syk, PI3K, PLC $\gamma$ 2, BLNK, and *Btk* (reviewed in Fruman et al., 2000) (Fig. 21.5). The joint activity of these proteins in a common complex or pathway is strongly supported by the striking finding that knockouts causing absence of *Btk*, PLC $\gamma$ , BLNK, and the p85 form of PI3K all show the common phenotype of the Xid mouse (reviewed in Fruman et al., 2000; Leitges et al., 1996; Fruman et al., 1999; Hashimoto et al., 1999; Jumaa et al., 1999; Minegishi et al., 1999; Pappu et al., 1999; Suzuki et al., 1999; Wang et al., 2000; Xu et al., 2000).

BCR cross-linking and Lyn activation also activates PI3K, resulting in the production of inositol lipids that bind to PH domain-containing proteins such as *Btk* and stabilize their membrane association (Fukuda et al., 1996; Salim et al., 1996; Li et al., 1997a, 1997b; Rameh et al., 1997; Bolland et al., 1998; Scharenberg et al., 1998; Nore et al., 2000). This lipid–enzyme interaction may also directly influence the kinase activity of *Btk* (Saito et al., 2001). Pathways that deplete these PI3K-generated lipids, like activation of the SHIP phosphatase via inhibitory receptors, antagonize the assembly and stability of the BCR-directed signalosome complex (Bolland et al., 1998; Scharenberg et al., 1998). A recent addition to the PI3K pathway is the phosphatidylinositol-4-phosphate 5-kinases (PIP5Ks) (Saito et al., 2003). This signaling assembly is thought to segregate to a specialized lipid domain or raft critical for efficient and sustained signaling.

Lyn and other Src family kinases can transphosphorylate *Btk* on tyrosine 551, located within the kinase activation loop, resulting in a dramatic increase in enzyme activity (Rawlings et al., 1996). This process is followed by autophosphorylation at tyrosine 223 within the SH3 domain (Park et al., 1996), resulting in stronger downstream signaling by altering binding interactions of the SH3 domain (Morrogh et al., 1999) and relieving negative control of *Btk*. Several *Btk* SH3-binding partners have been identified. Some, such as Sab, interact with the SH3 domain and serve to inhibit the kinase activity (Yamadori et al., 1999). An attractive model to consider for further analysis is an inactive pool of *Btk* existing in the cytoplasm with a bound regulator released upon kinase activation and autophosphorylation within the SH3 domain. This two-step activation mechanism is highly conserved among the Tec family of kinases in mammals (Heyeck et al., 1997) and similar interactions are seen for Src and Tec family kinases in *Drosophila* (Guarnieri et al., 1998; Roullet et al., 1998). Antibodies specific for the phosphotyrosine-modified sequences around residues 551 and 223 of *Btk* have been useful in defining the pathway of activation and inactivation of *Btk* and demonstrating that the active fraction of *Btk* moves into the receptor signaling complex (Wahl et al., 1997; Nisitani et al., 1999).

#### Postreceptor Control of *Btk* Activity

A variety of mechanisms to control *Btk* activity within the cytoplasm and signalosome structure have been described. Like other tyrosine kinases, *Btk* can be directly activated inside of cells by

**Figure 21.5.** Schematic representation of signaling pathways in which Btk has been implicated. Since Btk may be found in different subcellular locations, this is also depicted.

the addition of strong oxidizing agents such as hydrogen peroxide (Qin et al., 2000). This seems to effect the function of Btk in coordinating the transphosphorylation of PLC $\gamma$  to regulate  $\text{Ca}^{2+}$  flux and other signals (Qin and Chock, 2001).

Serine phosphorylation of Btk by PKC $\beta$  can down-regulate its tyrosine kinase activity (Yao et al., 1994; Kang et al., 2001). However, the phenotype of a *Pkcb* knockout is almost identical to that of the Xid mouse at the whole-animal level (Leitges et al., 1996). These findings may relate to the need to maintain an optimal dose and timing of activation for Btk within the B cell. Alternatively, PKC $\beta$  may be part of a feedback loop to limit the extent of Btk signaling. PKC $\beta$  is activated downstream of PLC $\gamma$ 2, which itself is regulated by Btk (Humphries et al., 2004). Thus, PKC $\beta$  may be required to transmit Btk signals in addition to down-regulating them.

#### Selected Cytokine and Other Classes of Receptors Require Btk for Signaling in B Lineage Cells

The interleukin-5 (IL-5) receptor mediates important growth and developmental choices for the B and eosinophil cell lineages in the mouse. Although this class of receptors acts predominantly through the activation of specific members of the Jak family of kinases to transphosphorylate Stat proteins to activate gene expression, the IL-5  $\alpha$  subunit can also activate Src family kinases and Btk (Sato et al., 1994; Pazdrak et al., 1995). Certain Jak family kinases have been reported to directly phosphorylate Btk (Takahashi-Tezuka et al., 1997). Studies with the Xid mouse strain have shown that full-signal responses through this receptor in B cells require the function of Btk (Hitoshi et al., 1993; Koike et al., 1995). Similarly, function of the IL-10 receptor on B cell survival and activation is Btk-dependent (Go et al., 1990).

Other receptors of quite different types, including CD38 (Kikuchi et al., 1995; Santos-Argumedo et al., 1995; Yamashita et al., 1995), RP105 (Miyake et al., 1994), CD72 (Venkataraman et al., 1998), and CD40 (Hasbold and Klaus, 1994), have been

linked to Btk by showing defective signaling in Xid B cells under some experimental conditions. Failure to efficiently transmit signals from some or all of these receptors likely contributes to the Xid phenotype, although the relative requirement for each signaling pathway has not been defined.

#### Activation of Btk by Receptors in Non-B Cells

Btk is broadly expressed among hematopoietic cell types with the exception of T cells (Smith et al., 1994a). Important receptors, such as the Fc $\epsilon$  receptor of mast cells, which mediates degranulation responses via IgE and allergen complex-induced binding, have been clearly linked to Btk activation by genetic and biochemical criteria (Kawakami et al., 1994; Hata et al., 1998a; Setoguchi et al., 1998). Although Xid mice and XLA patients demonstrate competent mast cell responses through this receptor, Btk appears to play an important quantitative role in the efficiency of the response (Hata et al., 1998b). Sustained  $\text{Ca}^{2+}$  flux influenced by Btk and other members of the Tec family of kinases appears crucial for these events (Kawakami et al., 2000).

A very different type of receptor activation is exemplified by the collagen-mediated activation of platelet aggregation via non integrin glycoprotein receptors. Although Xid mice and XLA patients show no gross defect in blood clotting, Btk is clearly activated by this mechanism and likely plays an additive role with other Tec family kinases in mediating effective platelet activation (Quek et al., 1998).

#### Cross-Talk Between the G Protein-Coupled Receptor Family and Btk

The largest family of receptors in the human or mouse genomes is the multimembrane spanning G protein-coupled receptors that mediate an enormous range of cellular responses (Gether, 2000). Activation of one of these receptors results in signaling through a specific subset of the G $\alpha$  and G $\beta/\gamma$  components of the heterotrimeric G protein complex. The range of downstream

signals is broad, with activation of downstream second messengers and transcriptional responses. Several reports have connected activation of G protein subunits to activation of Btk by a direct protein interaction mechanism (Tsukada et al., 1994; Langhans-Rajasekaran et al., 1995; Bence et al., 1997; Jiang et al., 1998b). Most studies have used either cotransfection analysis or in vitro activation assays to monitor changes in the phosphorylation status of Btk or its specific activity as a tyrosine kinase. Associations between the activity of  $G\alpha_{12}$  (Jiang et al., 1998b) and  $G\alpha_q$  (Bence et al., 1997; Ma and Huang, 1998) subtypes and  $G\beta/\gamma$  subunits (Tsukada et al., 1994; Langhans-Rajasekaran et al., 1995) with Btk have been noted. There is some genetic evidence from transfection studies that shows the quantitative importance of such cross-talk between G protein-coupled receptors and Btk signaling (Satterthwaite et al., 2000). This is an important area for future study. Furthermore, activation of G protein-coupled receptors stimulate PI3K activation, which recruits Btk to the cell membrane (Nore et al., 2000), linking it to small GTPases.

### Downstream Signaling Events Mediated by Btk

The broad range of receptors that require Btk for effective signal transduction and the Xid-like phenotype generated by loss-of-function mutations affecting PLC $\gamma$ 2, BLNK, PI3K, and PKC $\beta$  presage the complexity of assigning a precise and limited set of downstream signals to Btk. Since evidence exists to support Btk's participation in a "signalosome"-type complex for receptors like the BCR, one must first define those signals regulated by the complex. The clearest signal is the regulated increase in intracytoplasmic calcium following BCR receptor engagement. A strikingly common cellular phenotype for loss-of-function mutants of Btk and the other molecules mentioned above is the loss of sustained calcium flux by oscillatory calcium pumps using capacitive-type mechanisms (Rigley et al., 1989; Takata et al., 1995; Takata and Kurosaki, 1996; Kurosaki and Kurosaki, 1997; Fluckiger et al., 1998; Ishiai et al., 1999; Jumaa et al., 1999; Pappu et al., 1999; Wen et al., 2004).

The tyrosine phosphorylation of PLC $\gamma$  by several enzymes including Btk and Syk is known to activate calcium flux through the production of inositol 1, 4, 5-triphosphate (IP3) and diacylglycerol (DAG) (Humphries et al., 2004) through release of  $Ca^{2+}$  from intracellular stores, primarily in the endoplasmic reticulum. In a yet-to-be-defined mechanism, this released  $Ca^{2+}$  and other signals control capacitive (or store operated) channels that regulate the sustained influx of  $Ca^{2+}$  from the extracellular fluid (reviewed in Scharenberg and Kinet, 1998). Candidates for these capacitive pumps have been defined (Harteneck et al., 2000). The sustained flux of  $Ca^{2+}$  would be expected to influence a broad range of cellular events including specific transcription factor activation, and cytoskeletal rearrangement needed for entry into S phase.

A variety of cytoplasmic molecules have been linked to Btk by physical or genetic means, including Wiskott-Aldrich syndrome protein (WASP) (Guinamard et al., 1998), Cbl (Cory et al., 1995), Akt (Craxton et al., 1999; Kitaura et al., 2000), phospholipase D (Hitomi et al., 2001), Ras (Deng et al., 1998), JNK (Kawakami et al., 1997, 1998; Deng et al., 1998; Hata et al., 1998b; Jiang et al., 1998a), Bcl-2 (Woodland et al., 1996), and Bcl-x (Anderson et al., 1996; Solvason et al., 1998). This collection implicates a broad variety of signal transduction processes as working with Btk. These include the mitogen-activated protein kinase (MAPK) cascades, antiapoptotic pathways, and regulators of the cytoskeleton. The precise and quantitative role of Btk in these processes,

compared to that of other factors, is hard to assess at this point in time.

### Role of Btk in the Nucleus

Through its actions in the cytoplasm, some signals from Btk should influence processes within the nucleus. Evidence for Btk directly modifying transcription factors such as STAT5 (Mahajan et al., 2001) and TFII-I (Yang and Desiderio, 1997; Novina et al., 1999; Egloff and Desiderio, 2001) by tyrosine phosphorylation is one mode of control. The nuclear factor (NF)- $\kappa$ B transcription factor pathway has also been connected to Btk. BCR-induced activation of IKK and subsequent degradation of I- $\kappa$ B and activation of the NF- $\kappa$ B pathway is impaired in B cells lacking Btk, BLNK, or PLC $\gamma$ 2 (Bajpai et al., 2000; Petro et al., 2000; Petro and Khan, 2001; Tan et al., 2001). At least one transcription factor called Bright is reported to bind directly with Btk (Webb et al., 2000) and relocate as a complex within the nucleus. Such mechanisms could dramatically increase the range of actions for Btk within the nucleus (Mohamed et al., 2000).

### Mutation Analysis

#### Techniques for Mutation Analysis

Several techniques for mutation analysis exist, such as single-strand conformation polymorphism (SSCP), denaturing gradient gel electrophoresis (DGGE), and chemical cleavage of mismatch (CCM). Mutation detection has greatly improved over the years, and this development is likely to continue. Most of the techniques are highly reliable and identify the majority but rarely all of the mutations in affected genes. Thus, in selected patients alternative techniques may have to be employed. Knowledge of the genomic organization of the *BTK* gene now allows the use of DNA as a template (Conley et al., 1994; Hagemann et al., 1994; Ohta et al., 1994; Vorechovsky et al., 1995a, 1995b), whereas in the initial mutation reports reverse-transcribed RNA was applied. The use of DNA is advantageous, as it is more resistant to degradation than RNA, facilitating transport conditions. Furthermore, it allows the identification of splice-site mutations and other mutations, which are not encoded in the mRNA sequence.

Mutation analysis is often carried out on an international basis, and active laboratories can be found in the mutation database reports (Vihinen et al., 1995, 1998; Lindvall et al., 2005). It is advisable to contact the laboratory performing mutation determination prior to sampling as certain requirements may have to be fulfilled. Samples, frequently peripheral blood, may be sent as either a fresh, unprocessed specimen or as purified DNA. In some instances RNA and protein analysis may also be indicated.

In certain patients with an XLA phenotype a mutation will not be found. This may be due to an inability of the technique used to identify the mutation, but, as is the case in rare females, locus heterogeneity (other genes affected) is also expected to cause an XLA phenotype in certain males. Moreover, the selective absence of Btk RNA or protein should be regarded as XLA until proven otherwise.

#### Spectrum of Mutations in the *BTK* Gene

Although all DNA is subject to mutagenic alteration, gene-related patterns exist. Preferentially in diseases with an autosomal recessive inheritance pattern founder effects may be seen, resulting in

the overrepresentation of one or a few mutations. However, for sex-linked traits, representing about 10% of genetic disease in newborns (Baird et al., 1988), this is not the case, and in XLA patients mutations are spread out over the entire *BTK* gene. This pattern is reflected by the fact that the frequency of new mutations reported to the BTKbase (see below) has been only marginally reduced over time.

The first mutations identified resulted from amino acid substitutions in the kinase domain (Vetrie et al., 1993). However, mutations are scattered all over the gene, afflicting every domain of the protein. In 1994 an international study group for XLA was formed with the aim of collecting all mutations into a common database. This database is designated *BTKbase* and is continuously updated and available through the Internet (<http://bioinf.uta.fi/BTKbase/>). Investigators carrying out mutation analyses are encouraged to contact the study group and report new information. Instructions are available at the BTKbase Web site or through one of the authors (C.I.E.S.). For further information on immunodeficiency disease mutation databases, including instructions for data submission, see Chapter 45.

The first report contained 122 unique mutations (78%) from 157 families in Europe and the United States (Vihinen et al., 1995). The 1996 updates also include patients from Japan and Australia and list 175 unique mutations (74%) in 236 families (Vihinen et al., 1996a, 1996b). The last edition lists 554 unique molecular events (67%) in 823 unrelated families (Lindvall et al., 2005). Thus, the frequency of unique mutations among new cases is only slowly decreasing.

Various forms of genetic abnormalities have been found in the *BTK* gene, representing all major types of alterations (Vihinen et al., 1996a, 1996b, 1997a). These include missense (amino acid substitution) and nonsense (stop codon formation) mutations, deletions, and insertions. The majority of deletions and insertions are out of frame, resulting in stop codon formation, but in-frame variants have also been identified. Most of the mutations are located in exonic regions (affecting coding sequence), whereas about 16% affect splice sites (Table 21.4). Large deletions have also been found encompassing several exons and introns, some of which also extend into neighboring genes (Vetrie et al., 1993; Vorechovsky et al., 1994a; Richter et al., 2001). A single mutation confined to the promoter region has been found (Holinski-Feder et al., 1998), but these are normally very rare, typically corresponding to a few percent or less (Gianelli et al.,

1996). Gianelli et al. found 17 of 1380 patient entries (1.2%) to be caused by molecularly unique events in the promoter of the hemophilia B gene (*F9*), another X-linked disease.

Most mutations affect single base pairs and a predilection for certain sites exists. Thus, CpG sites are highly prone to mutagenic events. The 5-methylcytosine bases frequently spontaneously deaminate to thymine, causing transitions (Duncan and Miller, 1980). These sites are also the major mutational hot spots for the sex-linked primary immunodeficiencies, including XLA (Smith and Vihinen, 1996; Lindvall et al., 2005).

Figure 21.6 depicts the location of different mutations in relation to the amino acid sequence of the Btk protein. As can be seen, missense mutations are not uniformly distributed but are preferentially found in the kinase domain, and especially in the C-terminal portion of the kinase domain. A number of missense mutations also exist in the PH and SH2 domains, whereas the TH-SH3 region is much less affected. Conversely, mutations altering the reading frame, resulting in stop codon formation and frequent loss of protein expression due to unstable conformation, are, as expected, evenly distributed. Structural information has allowed the use of molecular modeling to interpret the consequences of mutations that are in-frame for all domains of Btk with the exception of the TH region, for which there is as yet no template (Lindvall et al., 2005).

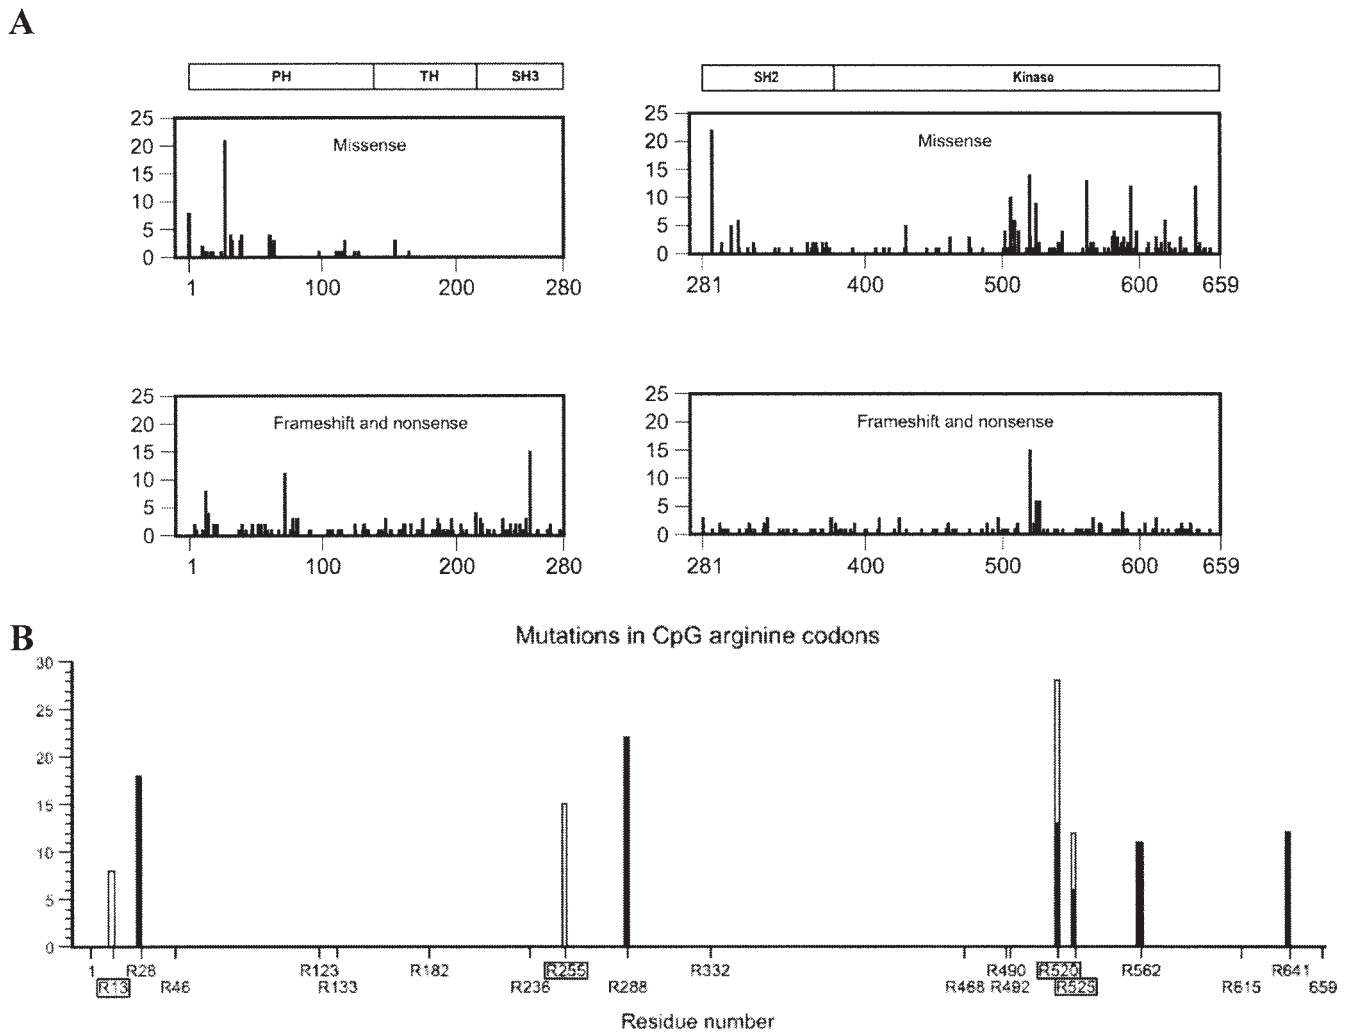

Genotype–phenotype analyses have been performed without initially establishing firm correlations (Vihinen et al., 1996a; Holinski-Feder et al., 1998). A modest number of mutations with mild phenotypes have been observed, most of which are caused by substitutions. However, in some patients frameshift mutations perturbing the expression of Btk protein were found to be compatible with mild disease. Especially splice site mutations yielding low levels of normal mRNA are expected to result in a mild phenotype, but this has so far not been documented (Noordzij et al., 2002b). Occasionally, the identical genetic change may cause both mild and severe disease. This phenomenon is of no surprise, as a phenotypic variation among family members, presumably carrying an identical genetic abnormality, was known in XLA many years prior to the disease gene cloning (Buckley and Sidbury, 1968; Goldblum et al., 1974; Wedgwood and Ochs, 1980) and has also been verified by mutation analysis (Bykowski et al., 1996; Kornfeld et al., 1997). This variation also demonstrates that confounding parameters exist, possibly of both genetic and environmental origin. Nevertheless, recent

**Figure 21.6.** Distribution of different mutations in the *BTK* gene. (A) Distribution of different codon mutations. The number of unrelated families with missense vs. frameshift + nonsense mutations in the different domains of Btk is shown. (B) Distribution of CpG-arginine codons in Btk and the location and number of mutations at these sites. Boxed

codons represent CGA sequences, which are prone to generate nonsense mutations. The Y axis denotes the number of unrelated families having mutations and the X axis, the codon number. Open bars represent nonsense and filled bars missense mutations. Reproduced with permission from Lindvall et al. (2005).

analysis conclusively demonstrates that many residues will not cause XLA when affected by missense mutations (Lindvall et al., 2005). Moreover, among the highly mutation-prone CpG sites, only some are sensitive to replacements, whereas stop codon formation without any known exception causes XLA (Lindvall et al., 2004).

#### Mutations Affecting *BTK* and *TIMM8A* Genes

Certain XLA patients have a mutation extending from the *BTK* gene into the adjacent *TIMM8A* gene causing sensory-neurologic manifestations (see Chromosomal Region Containing the *BTK* Gene, above).

#### Agammaglobulinemia with Growth Hormone Deficiency

Agammaglobulinemia with growth hormone deficiency (MIM number 307200) was originally reported in four males in an American family (Fleisher et al., 1980). In contrast to most pa-

tients with XLA, the affected individuals demonstrated the presence of some tonsillar tissue. Moreover, when mutation analysis was performed in the prototype family, sequencing of the complete cDNA did not reveal any mutation, and normal-sized Btk protein is expressed at a level comparable to that of healthy controls (Stewart et al., 1995). Recent findings implicate that the *ELF4* gene (E74-like factor 4; ets domain transcription factor; formerly MEF) located in Xq26 may be involved, although these findings should still be treated as nonconclusive (Stewart et al., 2005). At least five additional patients with agammaglobulinemia and growth hormone deficiency have been reported by different investigators (reviewed in Sideras and Smith, 1995), and in those patients undergoing mutation analysis alterations were confined to the *BTK* gene (Conley et al., 1994; Vihinen et al., 1994c). Furthermore, identical mutations have also been found in patients lacking evidence of growth hormone deficiency (Vihinen et al., 1996a, 1997a). The cause of the growth hormone deficiency in these patients remains elusive, and the criteria for establishing this form of hormone deficiency may vary.

### Females With an XLA Phenotype and Autosomal Recessive Inheritance

With a single reported exception, females carrying a mutation of the *BTK* gene on one of their X chromosomes are healthy and show no evidence of XLA. A strong selection of B lymphocytes expressing the nonaffected *BTK* gene has been reported in both mice (Nahm et al., 1983) and humans (Conley et al., 1986; Fearon et al., 1987). Thus, it is unlikely that females displaying even a highly skewed X-chromosome inactivation pattern would be affected, since the selective growth and differentiation advantage of B lineage cells using the X chromosome with a normal *BTK* gene would preclude disease. In the single reported female with XLA, the mutation is heterozygous and inherited from her father (Takada et al., 2004). Because of the unexpected phenotype and the finding of an exclusive inactivation of the maternal X chromosome in both hematopoietic and mucosal cells, basic mechanisms for lyonization were analyzed. Defects in the *XIST* gene regulating X-inactivation were not detected.

An array of other genetic abnormalities could, theoretically, result in female XLA, such as X-chromosome translocations, Turner's syndrome (females with a single X and no Y chromosome), and uniparental disomy (two copies of the same, affected X chromosome) (Conley and Sweinberg, 1992).

Over the past few years several autosomally recessive disorders causing B cell deficiency have been identified. Previously it was demonstrated in mice that mutations precluding the expression of surface IgM would result in the absence of B cells (Kitamura et al., 1991). Eight different mutations in the human IgH chain locus (*IGHM*) preventing expression of membrane protein were found to result in the virtual absence of B cells in 12 human families (Lopez Granados et al., 2002). Furthermore, mutations in the human 5/14.1 gene (*IGLL1*) encoding the pre-B cell receptor surrogate light chain, as well as in the Ig $\alpha$  gene (*CD79A*) and the linker protein *BLNK* gene result in B cell deficiency and agammaglobulinemia (see Chapter 22).

### Strategies for Diagnosis

An X-linked inheritance (only males having the disease) with more than one generation affected and laboratory findings demonstrating severely decreased B lymphocyte and Ig levels make the diagnosis of XLA highly probable. However, about one-third of XLA cases are sporadic and caused by de novo mutations. Diagnosis is confirmed by mutation analysis. In mild forms of XLA, B lymphocyte and Ig levels may be only partially decreased, thus resembling X-linked hyper-IgM syndrome and CVID. Another differential diagnosis may be X-linked lymphoproliferative syndrome.

The physical examination normally reveals markedly hypoplastic or absent tonsils, adenoids, and lymph nodes. In healthy newborns and infants peripheral lymphoid organs are hypoplastic, frequently preventing the inclusion of this diagnostic criterion. Untreated patients are generally infected once the maternally transferred Ig has been catabolized; the symptoms depend on the site and severity of the infection. Patients often get used to carrying infections, including having symptoms such as frequent coughing and rhinorrhea, and tiredness is a frequent complaint. A common finding is that adult patients perceive restrictions in several areas of their daily life (Gardulf et al., 1993).

In patients receiving adequate treatment, most of the time there will not be any firm evidence of overt infections; however, the lymphoid hypoplasia will persist. Growth and development

are generally age appropriate. However, infections may still occur even during optimal treatment, and many patients will continue to experience some restrictions in areas of their daily life.

### Mode of Inheritance, Carrier Detection, and Prenatal Diagnosis

X-linked agammaglobulinemia is a typical X-linked disease affecting males inheriting the defective gene, whereas females are healthy carriers. A defective gene in females can be detected at the level of X-chromosome usage. In females only one X chromosome is functional in each cell (Lyon, 1966; Migeon, 1994). Early during embryogenesis one of the two X chromosomes is inactivated in a random fashion in all mammals, providing a mechanism for gene dosage compensation. Thus, in an individual cell, or clone, the same X chromosome will be active, whereas in a cell lineage the X-chromosome usage is typically random. However, in females carrying a defective *BTK* gene, virtually all mature B cells use the normal X chromosome; in other lineages, such as the T lymphocyte, the inactivation is random (Conley et al., 1986). This demonstrates that Btk is essential for B lymphocyte differentiation or survival.

The technique of determining X chromosome inactivation was used for carrier detection prior to the cloning of the *BTK* gene. For prenatal diagnosis, measurement of fetal B lymphocytes was used prior to the cloning of the *BTK* gene (Journet et al., 1992). DNA markers linked to the disease locus were also employed (reviewed in Sideras and Smith, 1995) and may still be applied in families in whom a mutation in *BTK* has not been identified. Methods to identify inactivated vs. noninactivated X chromosomes via PCR-based techniques may be used for genetic counseling by assessing carrier status for mothers of isolated affected males (Allen et al., 1994). In families with known mutations in the *BTK* gene, unambiguous identification of carrier females and affected fetal males can be made. A protein-based flow-cytometric technique enabling the analysis of the majority of carriers, irrespective of knowledge of the exact mutation, has been developed (Futani et al., 1998). Flow cytometry and Western blotting with Btk-specific antisera will identify the majority of patients, since frameshifts, stop codons, and a large fraction of missense mutations will not yield a stable protein.

### Treatment and Prognosis

#### $\gamma$ -Globulin Replacement Therapy

##### Therapeutic effect of $\gamma$ -Globulin replacement

Substitution therapy with high-dose  $\gamma$ -globulin is essential in XLA as in other Ig deficiencies (Roifman et al., 1985) and is described in detail in Chapter 46. Normal serum IgG levels may be obtained using high-dose intravenous or subcutaneous treatment; intramuscular administration is insufficient. In a study comprising 29 patients with XLA, a beneficial effect of high-dose vs. low-dose IVIG therapy on the incidence of pneumonias and the number of days spent in the hospital was documented (Liese et al., 1992). Improvements in therapeutic outcome were particularly evident when replacement therapy was initiated before the age of 5 years. In a retrospective study of 31 XLA patients, Quartier et al. (1999) reported a significant decrease from 0.4 bacterial infections annually prior to IVIG to 0.06 during treatment. These authors also found that a residual serum IgG level of >8 g/l was significantly more protective than 5–8 g/l.

In a retrospective analysis of the incidence of pulmonary disease in hypogammaglobulinemia, it was found that XLA patients had on average only 0.1 pneumonias per treatment year compared to 0.18 in patients with CVID (Sweinberg et al., 1991). Seven of 10 patients with XLA had normal chest X-ray films 8–15 years after diagnosis, and none had bronchiectasies. Pulmonary disease was more common and more severe in CVID. In contrast, Curtin et al. (1991) reported that eight patients with XLA developed bronchiectasis at a significantly earlier age than those who had CVID. Since the mean age of patients reported by Sweinberg et al. (1991) was lower, these differences may either represent pathological changes developing over time or, more likely, reflect the improved therapy and improved diagnostic tools currently available. In a prospective study, Kainulainen et al. (1999) reported that IgG preinfusion levels of 5 g/l did not protect against silent progression of bronchiectasies in 5 of 14 patients with primary hypogammaglobulinemia receiving IVIG.

In a series of patients treated with high-dose subcutaneous  $\gamma$ -globulin, the majority of whom had CVID, only 0.2 patient days/year were spent in the hospital for respiratory tract infections (Gardulf et al., 1991). Furthermore, a significantly increased health-related function and improved self-rated health were reported (Gardulf et al., 1993, 1995). Subcutaneous delivery may also be in the form of express infusions, further decreasing the time (Hansen et al., 2002).

Because patients with normal IgG levels during replacement therapy may be resistant to acquiring fatal enteroviral disease (Liese et al., 1992; Misbah et al., 1992), it is important that XLA patients at all times receive appropriate doses of IgG. Once enteroviral meningoencephalitis has been contracted it is frequently therapy-resistant.

### Viral Hepatitis Transferred with Contaminated Immunoglobulin Batches

Hepatitis C infection has so far only occurred after treatment with IVIG and not following substitution with intramuscular preparations, the products also used for subcutaneous administration. Hepatitis C has been observed after the infusion of experimental IVIG preparations (Lever et al., 1984; Ochs et al., 1985; Yap et al., 1994) and commercial IVIG batches (Björkander et al., 1988; Bjørø et al., 1994; Healey et al., 1996).

Patients with PID seem to be unduly susceptible to this infection, possibly because they cannot mount a sufficient immune response against the virus. However, XLA patients with hepatitis C may develop a less fulminant hepatitis than that in CVID patients (Hermaszewski and Webster, 1993; Bjørø et al., 1994; J. Björkander, personal communication). In one series reported by Bjørø et al. (1994), all five infected CVID patients developed severe cirrhosis, including one with fatal outcome, whereas only one of six XLA patients developed cirrhosis and end-stage liver disease. This patient was coinfecting with hepatitis B and D viruses. However, in a study by Razvi et al. (2001), the outcome of a hepatitis C infection did not differ between CVID and XLA patients, whereas Quinti et al. (2002) reported a better prognosis in XLA than that in CVID.

### Antibiotics

Treatment of infections is essential in all forms of PIDs. The use of antibiotics to combat bacterial infections represents one of the cornerstones in the management of XLA, and prolonged administration is often necessary. However, as in CVID, it is frequently

not possible to eradicate an infectious agent completely. Thus, DNA fingerprinting and the use of antilipopolysaccharide monoclonal antibodies have revealed that the same strain of *H. influenzae* may colonize a patient for many years despite long-term therapy with adequate doses of different antibiotics (Samuelson et al., 1995). For a more detailed description of treatment with antibiotics, see Chapter 46.

### Bone Marrow Transplantation and Gene Therapy

Bone marrow transplantation is an option for XLA, as for other PIDs. However, transplantation is not a risk-free procedure, as graft-vs.-host reactions and severe infections may ensue. The stem cell grafting procedure may or may not be ablative. Thus, conditioning increases the chance for engraftment, whereas under nonablative conditions insufficient chimerism may develop. Howard et al. (2003) recently reported three patients receiving cord blood or bone marrow grafts from human leukocyte antigen (HLA)-matched siblings without receiving any preparative regimen or antirejection drugs, and another three who received treatment with cyclosporin A and mycophenolate mophetil. However, none of the patients showed an increase in serum IgM or peripheral B cell counts.

Gene therapy was suggested as a future treatment in both the original reports on cloning of the *BTk* gene (Tsukada et al., 1993; Vetrie et al., 1993). In theory, the defect underlying XLA makes this disease particularly suitable for gene therapy, since the differentiation defect would enable gene-corrected cells to selectively survive. This characteristic is seen also in adenosine deaminase (ADA) deficiency and SCID caused by mutations in the common  $\gamma$ -chain (*XSCID1*), mainly affecting T lineage development. For both these disorders, successful gene therapy has been conducted (see Chapter 48).

Because permanent correction of hematopoietic stem cells would be desirable and current retroviral delivery systems may cause tumor formation (Hacein-Bey-Abina et al., 2003; Dave et al., 2004), gene therapy for XLA may be more distant than previously thought. Thus, in contrast to ADA, the Btk protein could be hazardous if produced in excess amounts or expressed incorrectly in terms of lineage restriction or temporal control. Several other kinases have been implicated in tumor formation when mutated or overexpressed (Heisterkamp et al., 1990; Abraham et al., 1991). This phenomenon may necessitate the use of endogenous-control elements to ensure correct expression or, alternatively, techniques involving disease gene repair rather than the transfer of an intact copy of the defective gene. Nevertheless, retroviral vectors have been developed for the potential treatment of XLA (Islam et al., 1999; Yu et al., 2004).

Since only a single X chromosome is active in each cell, the potential dominant-negative effect of an abnormal Btk protein would not be seen in carriers. However, it could be inferred from other signaling pathways that mutated cytoplasmic tyrosine kinases may exert dominant-negative effects. Furthermore, the dominant-negative effect could be stronger than in the absence of a gene product, as exemplified by the Src family member Lck (Levin et al., 1993). The underlying mechanism may be that the abnormal protein could also affect other signaling pathways. This means that the transfer of a normal copy of the *BTk* gene to hematopoietic stem or progenitor cells might only have a therapeutic effect in the approximately 85% of XLA patients lacking Btk protein. In patients with a dominant-negative mutation, repair of the defective gene and gene transfer combined with

degradation of an abnormal transcript are potential treatment modalities. In several dominant-negative systems, a gene product needs to be overexpressed, as compared to the nonmutated, wild-type protein suggesting that the level of expression of the transferred gene is crucial.

Furthermore, the expression of Btk in early hematopoietic progenitors makes the Btk promoter (Himmelfmann et al., 1996; Müller et al., 1996, 1999) of potential interest in gene therapy for diseases other than XLA. Tissue-specific expression of other therapeutic genes might be provided by the use of this endogenous promoter.

### Prognosis

Prior to antibiotic therapy and  $\gamma$ -globulin substitution therapy, the prognosis was poor. Analysis of patients born before 1950 in a large Dutch pedigree revealed that there was a 90% probability of children with XLA dying between 2 months and 8 years of age (Mensink et al., 1984). With the advent of antibiotics and  $\gamma$ -globulin replacement therapy in the 1950s, the prognosis improved considerably (Lederman and Winkelstein, 1985), and this development seems to have continued (Hermaszewski and Webster, 1993; Ochs and Smith, 1996). This trend is also likely to continue because future therapies such as gene replacement have curative potential.

### Animal Models of Btk Loss of Function

#### Overview

The syntenic arrangement of mouse and human X chromosome regions suggests that murine Xid and human XLA are both caused by deficiencies of Btk expression or function. The Xid mutation is defined as a point mutation in the PH domain that leaves kinase activity intact (Rawlings et al., 1993; Thomas et al., 1993). Xid is a relatively mild immune deficiency with loss of some B cell subpopulations and humoral responses (Scher, 1982; Wicker and Scher, 1986). Allele-specific variation in disease severity seemed a plausible explanation until the phenotype of mice with null mutations of *Btk* were created and shown to have a mild Xid-like phenotype (Kerner et al., 1995; Khan et al., 1995; Hendriks et al., 1996), rather than the severe loss of B cells seen in XLA. This set of observations and other studies described below strongly support the concept that the penetrance of the B cell-immune deficit due to loss of Btk function is strongly influenced by genetic context.

#### Xid Affects Multiple Stages of B Cell Development and Function

The Xid mutation was first defined in the early 1970s by abnormal responses to polysaccharide antigens in the highly inbred CBA/N strain of mice, a defect that segregated in a sex-linked manner (Amsbaugh et al., 1972). This strain of mice and congenic derivatives of the Xid mutation on other backgrounds show normal fecundity and have minimal if any elevation of cancer risk. They also do not have to be housed in specialized animal facilities.

Detailed analysis of the immune defects in Xid show cell-autonomous defects only for the B cell lineage. These include the loss of specific cell subpopulations such as CD5<sup>+</sup> or B1 cells that normally accumulate in the peritoneum. The remaining B cells that emigrate from the marrow to peripheral sites show an

immature phenotype exemplified by a high IgM-to-IgD ratio, low major histocompatibility complex (MHC) class II antigen expression, and inability to secrete IgM or class switch for certain isotypes such as IgG3. In Xid mice, responses to type II T cell-independent antigens, exemplified by the trinitrophenyl-derivatized Ficoll, are absent, and B cells cannot form multicellular colonies in response to certain mitogens (Scher, 1982; Wicker and Scher, 1986).

Responses to T cell-dependent antigens are normal. If T cell help is removed through neonatal thymectomy or because of simultaneous presence of the nu/nu gene, B cell development in the bone marrow is blunted, and the immune deficit is severe (Wortis et al., 1982; Karagogeos et al., 1986). The presence of the Xid allele can relieve the systemic lupus-like autoimmune disease complex seen in mouse strains such as NZB/NZW (Taurog et al., 1979), reduce the susceptibility to *S. aureus*-induced arthritis (Zhao et al., 1995) and *M. pulmonis* pneumonia (Sandstedt et al., 1997), and modify the antibody production seen in the lymphoproliferative disorder caused by defects in the *Motheaten* tyrosine phosphatase (Scribner et al., 1987). All of these effects can be rationalized by the altered production of pathogenic antibodies associated with the Xid allele.

More subtle and complex genetic interactions are seen when the severity of the Xid allele is evaluated in the context of specific backcrosses or different congenic strains that do not harbor any obvious immune or developmental defect. The Xid allele on a C3H background is more severe than that of the original CBA/N strain (Bona et al., 1980; Mond et al., 1983a). Similar effects of strain background were noted in analysis of germ-line knockouts of the *Btk* gene, discussed below (Khan et al., 1995). The number and function of predicted modifier loci are not known.

#### Genetically Engineered Btk Knockout Strains Display a Phenotype Similar to Those of Xid Strains

Three groups have published analyses of lymphocyte development and function in the absence of Btk expression (Kerner et al., 1995; Khan et al., 1995; Hendriks et al., 1996). Null mutations of *Btk* created in embryonic stem cells by homologous recombination were passaged to the lymphocyte lineage by transfer into the blastocysts of immune-defective *Rag2* knockout mice and the germ line of otherwise immune-competent mice. Detailed analyses of the B cell developmental pathways and functional responses to a variety of cell surface cross-linking antibodies, mitogens, and chemical mediators showed a phenotype that is remarkably similar to that seen in Xid strains. Some minor variation in the subpopulations of early B cell precursors in the marrow and variation in immune responses according to strain background were described, but the overall picture strongly suggests that the point mutation in the PH domain found in Xid is as severe an allele as no expression of Btk at all. Recently it was demonstrated that there was no survival difference between cells carrying an active Xid allele and an active knockout allele in heterozygous females (Lindvall et al., 2005). This clearly demonstrates that there is no residual activity in Btk with an Xid alteration, nor is there any dominant negative effect on other signalling molecules. Moreover, expression profiling has been used to study the effect of the Xid mutation and of the Btk loss-of-function allele (Lindvall et al., 2004).

Development of wild-type levels of Btk by transgenesis experiments can reconstitute normal B cell function and development (Drabek et al., 1997). Transgenes that express less than endogenous levels of Btk show partial rescue and support

a dose-limiting role for Btk in Ig receptor signaling (Satterthwaite et al., 1997).

Some insight into the pathways Btk likely uses in connecting surface stimulation to the cellular responses comes from analyses of selected knockout strains of mice. A large number of genes involved in Ig gene structural rearrangement, components of the Ig receptor complex, and some downstream signal transduction components have been shown to be essential for normal B cell development. Many of these block B cell differentiation at an early stage in the marrow, and few B cells are available for detailed functional analyses. However, apart from the defect in the transition from small pre-B cells to immature B cells in the bone marrow, through replacement of the *Btk* gene by insertion of *lacZ*, Hendriks et al. (1996) demonstrated a second differentiation arrest during maturation from IgD<sup>low</sup>IgM<sup>high</sup> cells to IgD<sup>high</sup>-IgM<sup>low</sup> stages in the periphery.

Several studies have combined the Xid mutation with loss of function in a second gene to create more severe B cell phenotypes and help define pathways that are likely rate limiting for Btk function. A striking result is the severe block in B cell development at the pre-B cell stage observed when a loss of Btk function is combined with a loss of Tec function (Ellmeier et al., 2000). This can be most simply interpreted as Btk and Tec serving essential but redundant roles in the pathways connected to the pre-B cell Ig receptor. The phenotype of this mouse closely resembles the general changes seen in human XLA.

Other mutations can be combined with a loss of function of Btk to produce a severe XLA-like phenotype in the mouse. The transcription factor OBF1 regulates B cell-specific genes and germinal-center responses. When combined with the Xid mutation, the *OBF1* mutation results in agammaglobulinemia secondary to a block at the bone marrow stage of development (Schubart et al., 2000). Although both genes express cell-autonomous effects within the B cell lineage, the precise biochemical connection between their signal transduction pathways and the final phenotype of the whole mouse are not yet defined.

Even more difficult to understand is the dramatic effect of mutation at the nude locus when combined with Xid (Karageos et al., 1986). The nude gene encodes a transcription factor of the winged helix class that has an impact on T cell development and thymic function, but has no discernable phenotype within the B cell lineage as a single knockout. When combined with Xid, however, there is a severe block in B cell development at the pro-B to pre-B transition. The cellular and molecular circuitry of this strong genetic effect is not understood. These and other studies described below point out the importance of having whole-animal models to combine with biochemical and cellular tests of Btk function. They also suggest potential mechanisms for the difference in severity of Xid and XLA.

A most striking example of convergence toward a common function comes from genetic and phenotypic analysis of the collection of single gene knockouts that result in a Xid-like phenotype. Mutation affecting PLC $\gamma$ 2, the p85 form of PI3K, PKC $\beta$ , or the adaptor protein BLNK all show a very similar Xid-like phenotype with selective loss of B cells and antigen responses, defective activation from the Ig receptor, and loss of Ca<sup>2+</sup> flux in residual peripheral B cells (reviewed in Fruman et al., 2000; Leitges et al., 1996; Fruman et al., 1999; Hashimoto et al., 2000; Jumaa et al., 1999; Minegishi et al., 1999; Pappu et al., 1999; Suzuki et al., 1999; Wen et al., 2004). Much additional evidence, described below, suggests that these proteins all work in a complex or signalosome that mediates signals from cell membrane receptors including but not limited to the BCR (Fig. 21.5).

### Normal B cell Responses Require an Optimal Dose of Btk

Correction of the Xid phenotype can be accomplished by transgenic expression of a cDNA of the wild-type *Btk* gene controlled by an MHC class II region promoter (Drabek et al., 1997). Another transgenic strain used an Ig promoter and enhancer to express a Btk cDNA at about 25% of the normal level of Btk protein in peripheral B cells (Satterthwaite et al., 1997). These mice showed full correction of the numerical deficit in mature, IgM<sup>low</sup>IgD<sup>high</sup> peripheral B2 cells, but only partial recovery of signal response to BCR stimulation as measured with in vitro stimulation assays or in vivo immunizations (Satterthwaite et al., 1997; Pinschewer et al., 1999). Increasing the dose of Btk by creating mice homozygous for the transgene crossed over Xid or wild-type background demonstrated that Btk-dependent responses were optimal at the wild-type level of enzyme, with lower responses seen either below or above the wild-type level of expression.

This concept of an optimal dose of Btk is supported by the phenotype of a transgenic strain of mice expressing a mutant (E41K) form of the enzyme (Dingjan et al., 1998; Maas et al., 1999). This mutation was first isolated by random mutagenesis and selection for an allele of Btk that could transform fibroblast cells to grow suspended in agar. The mutation increases the ability of the enzyme to associate with membranes and the fraction of enzyme chronically modified by phosphotyrosine, indicating that it is an activated allele (Li et al., 1995). Surprisingly, the transgenic E41K strain did not overproduce B cells or have hyperactivated B cells, but rather produced a more severe block in B cell development at the pre-B cell stage similar to that in the human XLA phenotype. However, this phenotype was only seen in transgenic animals carrying several copies of the mutated gene fragment. This finding suggests that too much Btk activity can create negative signals as potently as loss-of-function mutations. Consistent with this model, we have observed that specific XLA patient mutations produce Btk enzymes with intact tyrosine kinase function and increased levels of activity for calcium flux after BCR stimulation in a reconstructed cell system (M. Wahl et al., unpublished observations). Strategies for defining genetic modifiers should help quantify genes and pathways that are most important for Btk function.

Unexpectedly, loss-of-function mutations in the *Btk* gene result in susceptibility to B lymphoma development. This is seen in mice homozygous for inactivating double mutations in *Blnk/Slp-65* and *Btk* genes (Kersseboom et al., 2003). Recently, the tumor-promoting effect was found to be independent of Btk kinase activity (Middendorp et al., 2005).

The availability of mouse strains with hemi- or homozygous loss-of-function mutations for numerous lymphocyte-specific or more generally expressed proteins allows the formal testing of pairwise combinations for genetic interaction and the modification of the Btk-defined Xid phenotype. Complete loss-of-function mutations of Btk or a transgenic strain expressing low levels of Btk have been used as genetic partners in such crosses. Strong evidence of such quantitatively important interactions have been defined for Btk and the transcription factor OBF-1 (Schubart et al., 2000), the Lyn tyrosine kinase (Satterthwaite et al., 1998, 2000; Takeshita et al., 1998), the nude winged-helix transcription factor (Karageos et al., 1986), the Motheaten SHP-1 phosphatase (Scribner et al., 1987), the Tec tyrosine kinase (Ellmeier et al., 2000), the CD19 coreceptor (Satterthwaite et al., 2000) and CD40 (Oka et al., 1996; Khan et al., 1997). Such genetic tests of function indicate that both components are important but require

biochemical analyses to unravel the potential mechanistic connections or parallel signals that may be involved.

Some help in expediting our understanding of the mechanisms of Btk action are likely to come from studies in *Drosophila*. Both the Src family and Tec family of kinases are found in flies and have already been connected genetically in pathways that influence structures like the ring canal of the fly oocyte, the structure of the male sexual organ, and longevity (Guarnieri et al., 1998; Roulier et al., 1998; Baba et al., 1999). It was recently demonstrated that the human *Btk* gene can partially substitute for the *Drosophila* Btk29A gene defect (Hamada et al., 2005). Our desire to understand the signal transduction pathways of B lymphocytes regulated by Btk, which may influence normal B cell function, autoimmune states, immune deficiencies in addition to XLA, and malignant lymphomas, should hopefully be moved forward by analysis of alternative genetic systems.

### Acknowledgments

## Autosomal Recessive Agammaglobulinemia

MARY ELLEN CONLEY

Normal development of the B cell lineage is dependent on appropriate expression and extinction of a panoply of genes, some of which are B cell-specific and some of which are more broadly expressed (Billips et al., 1995; Rajewsky, 1996; Yankee and Clark, 2000; Rolink et al., 2001). These genes encode B cell-specific transcription factors, proteins required for the rearrangement of the immunoglobulin gene segments, signal transduction molecules, receptors for growth factors and adhesion molecules, and many others. The immunoglobulin genes and proteins encoded by these genes obviously play a central role.

The classic disorder of B cell development, X-linked agammaglobulinemia (XLA), was first described in the 1950s (Bruton, 1952; Janeway et al., 1953; Good, 1954a, 1954b). It is characterized by the early onset of bacterial infections, profound hypogammaglobulinemia, and markedly reduced numbers of B cells (Ochs and Winkelstein, 1996; Conley et al., 2000a). The defective gene in this disorder encodes a cytoplasmic tyrosine kinase, Btk, that is involved in signal transduction (Tsukada et al., 1993; Vetrie et al., 1993). It is not yet clear, however, how defects in this protein result in impaired B cell proliferation, differentiation, or survival.

The incidence of other genetic disorders that result in a failure of B cell development is difficult to determine. Only about half of the males with the clinical features of XLA have a positive family history of the disease (Lederman and Winkelstein, 1985; Conley et al., 1998). The remaining patients may be the first members of their families to show manifestations of a new mutation in Btk or they may be patients with disorders that are clinically similar to XLA but caused by defects in different genes or by combinations of genetic and environmental factors. The frequency of XLA-like disorders in females provides some clues to the overall incidence; however, because physicians may be less likely to consider antibody deficiency in a girl, the

numbers calculated in this manner may represent an underestimate.

Defects in Btk are rarely responsible for immunodeficiency in females with an XLA phenotype. Studies using X chromosome inactivation analysis of B cells, T cells, neutrophils, and platelets of women who are heterozygous for mutations in Btk indicate that even a small number of B cell precursors that have the nonmutant X as the active X can provide normal B cell immunity because of the strong selective advantage conferred on these cells by a normal Btk (Conley et al., 1986; Fearon et al., 1987; Conley and Puck, 1988). However, it should be noted that an exception has been reported by Takada et al. (2004), who described a girl with XLA who had a mutation in Btk on one X chromosome and an inability to use the other X chromosome as the active X chromosome.

When techniques were developed to identify B cells in the early 1970s, it became clear that some of the patients with hypogammaglobulinemia and absent B cells were girls. In 1973 Aiuti et al. described three patients with infantile onset of hypogammaglobulinemia and absent B cells; one was a girl. Hoffman et al. reported two sisters with a disorder phenotypically identical to XLA in 1977; these authors postulated that their patients might have an autosomal recessive form of the disease. In a study on chronic enteroviral encephalitis that included 36 patients with agammaglobulinemia and absent B cells, McKinney et al. (1987) noted that 18 of the patients had a family history of disease consistent with XLA, and 18 had sporadic disease. Three of the latter 18 patients were females. In 1992 we reported two unrelated girls who were included in our patient population of 17 individuals with a disorder that was indistinguishable from XLA. Extensive evaluation of one of these girls indicated that it was highly unlikely that she had a defect in a gene at Xq22, the site of the XLA gene (Conley and Sweinberg, 1992). Both maternal and paternal alleles could be detected in this region and both X chromosomes could be used as the

active X chromosome. Because XLA is a relatively uncommon disorder, the probability of a new mutation in the Btk gene in both parental gametes was extremely small. Two more recent studies have examined early events in B cell differentiation in girls with an XLA phenotype (De La Morena et al., 1995; Meffre et al., 1996). On the basis of these observations, we have estimated that approximately 10% of patients with congenital hypogammaglobulinemia and markedly reduced numbers of B cells are females (Conley and Sweinberg, 1992; Conley et al., 1994). It can be assumed that there is a similar number of males with an XLA phenotype who do not have mutations in Btk.

### Approaches to Identification of Mutant Genes in Patients with Defects in B Cell Development

It cannot be concluded that all of the patients with an XLA phenotype who do not have mutations in Btk have an autosomal recessive disorder causing their disease. There may be environmental factors or combinations of susceptibility genes that result in immunodeficiency. We have evaluated several young adult males with the diagnosis of common variable immunodeficiency who have had markedly reduced numbers of B cells and no mutations in Btk or other genes associated with B cell development. Hypogammaglobulinemia and absent B cells may be the presenting findings in patients with myelodysplasia and monosomy 7 (Srivannaboon et al., 2001), trisomy 8, or dyskeratosis congenita. However, in families with more than one affected sibling or when there is parental consanguinity, the disease is very likely to be caused by an autosomal recessive disorder.

Several approaches could be used to identify candidate genes that might be responsible for autosomal recessive defects in B cell development. Murine models of immunodeficiency have been created by "knocking out" the function of a gene by homologous recombination (Loffert et al., 1994). In several of these models, the affected mice demonstrate hypogammaglobulinemia and a complete absence of B cells or a phenotype similar to that seen in Btk-deficient mice (Kitamura et al., 1991, 1992; Chen et al., 1993; Bain et al., 1994; Urbanek et al., 1994; Zhuang et al., 1994; Cheng et al., 1995; Lin and Grosschedl, 1995; Gong and Nussenzweig, 1996; Leitges et al., 1996; Nagasawa et al., 1996; Schilham et al., 1996; Torres et al., 1996; Jumaa et al., 1999; Pappu et al., 1999; Suzuki et al., 1999; Wang et al., 2000; Mundt et al., 2001; Tokimasa et al., 2001; Clayton et al., 2002; Jou et al., 2002; Yamazaki et al., 2002). Most of the genes that are targeted in these studies encode transcription factors important for B cell development, components of the B cell antigen receptor complex, or signal transduction molecules. There are several caveats to this approach. First, defects in the same gene may cause a different phenotype in mice and humans (Conley et al., 2000b). Abnormalities in the gene for Btk, which result in a severe B cell defect in humans and a much milder defect in mice, are an excellent example of this phenomenon. Second, spontaneously occurring mutations seen in patients may include amino acid substitutions in addition to the null phenotypes usually created in knockout mice. These more subtle mutations may have a wider range of consequences. Finally, it should be noted that while defects in several of the transcription factors, E2A, PAX5, EBF, and Sox4, result in abnormalities restricted to the B cell lineage in the immune system, they also caused runting, brain defects, or heart abnormalities (Bain et al., 1994; Urbanek et al., 1994; Zhuang et al., 1994; Lin and Grosschedl, 1995; Schilham et al., 1996), making it less likely that these genes are involved in

patients who have defects of B cell development but no additional morphologic defects.

Another approach to the identification of defective genes is based on the possibility that two different inherited disorders that result in the same clinical phenotype may involve genes that encode functionally related proteins (Conley and Sweinberg, 1992). For example, males with X-linked severe combined immunodeficiency (SCID) have absent T cells and natural killer (NK) cells but a normal or elevated number of B cells (Conley et al., 1990). Approximately 10% of the patients with SCID who have this laboratory profile are females, who were suspected to have an autosomal recessive form of the disease (Conley et al., 1990). After *IL2RG*, encoding the common  $\gamma$  chain, was identified as the abnormal gene in X-linked SCID, defects in the next protein involved in the common  $\gamma$ -chain signaling cascade, JAK3, were sought and found (Macchi et al., 1995; Russell et al., 1995). Although it is not clear that all of the crucial downstream targets of Btk have been identified, Btk is phosphorylated and activated by cross-linking of several cell surface receptors including IL-5R (Sato et al., 1994), IL-6R (Matsuda et al., 1995), the high-affinity receptor for IgE (Kawakami et al., 1994), the collagen receptor glycoprotein VI in platelets (Quek et al., 1998; Oda et al., 2000), and, perhaps most importantly, surface IgM on B cells (Aoki et al., 1994; de Weers et al., 1994; Saouaf et al., 1994).

To identify autosomal recessive disorders of B cell development, we have used an approach that combines evaluation of candidate genes with linkage analysis. Because it is likely that the most important role for Btk in B cell development relates to signaling through the B cell or pre-B cell receptor, we have focused on genes encoding proteins in this pathway. This includes the components of the B cell and pre-B cells receptor: the immunoglobulin heavy chain, the surrogate light chain, and the signal transduction molecules Ig $\alpha$  and Ig $\beta$ , as well as downstream signal transduction molecules such as Syk, PI3K, PLC $\gamma$ 2, and the adaptor protein BLNK. All of these genes have been mapped to specific sites within the human genome. This allows the selection of highly polymorphic markers linked to each gene. In a consanguineous family, the parents of a patient will share an allele (by common descent) at the correct locus and the affected patients will be homozygous for those polymorphic markers. In any family with more than one affected child, the affected siblings should have inherited the same polymorphic alleles near the gene of interest whereas the unaffected siblings should differ.

### Detection of Mutations in $\mu$ Heavy-Chain Gene

In our initial efforts to identify autosomal recessive causes of severe hypogammaglobulinemia and absent B cells, we studied two consanguineous families that included affected girls as well as boys (Fig. 22.1). Linkage studies using highly polymorphic markers near the immunoglobulin heavy-chain locus at chromosome 14q32.3 (Benger et al., 1991) showed that the affected children in each family were identical to each other and were homozygous for the polymorphic markers at this locus. Using a probe for the  $\mu$  constant region gene to analyze DNA by Southern blotting techniques, we identified a complete deletion of the  $\mu$  chain in the affected children in family 1, a Turkish family (Yel et al., 1996). Probes both proximal and distal to this portion of the heavy-chain locus demonstrated a 75 kb deletion that included most of the D region genes, the J region genes, the immunoglobulin enhancer region, and all of the coding regions of the  $\mu$  constant region gene but not the  $\delta$  constant region gene (Fig. 22.2).

**Figure 22.1.** Pedigrees for two families in which the affected individuals, shown as filled symbols, had early-onset hypogammaglobulinemia and absent B cells. Circles denote female family members and squares indicate male family members; symbols with a slash represent deceased family members. Figure adapted from Yel et al. (1996). Copyright 1996, Massachusetts Medical Society. All rights reserved.

Southern blot analysis of DNA from members of the second family, a family from Appalachia, did not demonstrate gross deletions or rearrangements of the immunoglobulin locus. However, because of the high probability of a mutation in this region indicated by the linkage studies, we screened genomic DNA from an affected child from this family by single-strand conformational polymorphism (SSCP; see Chapter 44) for alterations in the four constant region exons and two membrane exons of the  $\mu$  heavy-chain gene. The use of a screening evaluation allowed us to examine DNA from not only members of family 2 but also other patients who were thought to have sporadic XLA but in whom we had not found mutations in Btk. Analysis of exon 4 of the  $\mu$  constant-region gene, the exon that encodes the C-terminal immunoglobulin domain, demonstrated altered migrations of bands from the affected girl in family 2 and from a boy with presumed sporadic XLA (Yel et al., 1996) (Fig. 22.2). DNA from both samples showed the absence of bands seen in controls, indicating that the alterations were either homozygous or hemizygous (only one allele present).

Exon 4 from the affected girl in family 2 was sequenced and a single base pair substitution, a G-to-A transition at position 1831 (according to the numbering system of Friedlander et al. (1990), was identified. This substitution occurs at the -1 position for the

alternative splice site used to link the two membrane exons to the  $\mu$  constant region transcript so that the cell surface form of  $\mu$  chain can be produced, rather than the secreted form. This alteration causes the substitution of serine for glycine at codon 557 in the secreted form of  $\mu$  chain and the substitution of lysine for aspartic acid at the same codon in the membrane form of  $\mu$  chain. More importantly, the mutated splice site is expected to result in inefficient or absent production of the transcript for the membrane form of  $\mu$  heavy chain.

The sequence of exon 4 of the  $\mu$  heavy-chain gene in the boy with no family history of immunodeficiency demonstrated a T-to-G substitution at nucleotide 1768 in codon 536. This alteration causes a replacement of the wild-type cysteine with glycine. The cysteine at this position is the 3' cysteine involved in the intradomain disulfide bridge that is conserved in all immunoglobulin domains of all isotypes (Beale and Feinstein, 1976). The loss of this cysteine would be expected to make the immunoglobulin protein unstable. Because this patient's parents were from different ethnic backgrounds, it was thought to be unlikely that he was homozygous for this mutation. Therefore we sought evidence for a deletion on the other chromosome. When genomic DNA from the patient was analyzed by Southern blot, using a probe from the  $\mu$  constant region gene, there was a 50% decrease in the intensity

**Figure 22.2.** Mutations in  $\mu$  heavy-chain gene in patients with agammaglobulinemia. The approximate lengths of the five large deletions are shown below the drawing of the immunoglobulin heavy-chain locus. The sites of the frameshift mutations in exons 1 and 2 (triangle), the premature stop codon in exon 3 (square), the amino acid substitution

(diamond), and the alternative splice defects (circle) in exon 4 are shown in the magnified region of this locus at the top of the figure. The alternative splice site at the end of exon 4, which is marked by a dashed line, allows the constant region domains to be spliced to the membrane exons.

of the  $\mu$ -specific band. Probes from the  $V_H$ ,  $D_H$ ,  $J_H$ , and constant regions indicated that this deletion included part of the  $V_H$  region, all of the  $D_H$  and  $J_H$  regions, and all of the constant-region genes except for the IgA2 heavy-chain gene.

Since the original report of these mutations, 11 additional families with defects in  $\mu$  heavy chain have been reported (Lopez et al., 2002; Milili et al., 2002; Schiff et al., 2000) (Fig. 22.2). In five of the families, the affected patients were homozygous for the same single base pair substitution at the alternative splice site seen in family 2. Analysis of polymorphic markers within the immunoglobulin locus indicated that this mutation, a G-to-A substitution, occurred at least three separate times. This alteration is found at a vulnerable site, a CpG dinucleotide (Cooper and Youssoufian, 1988). Two unrelated Spanish families had a 2-base pair deletion, an AA deletion, at codon 168 within exon 2 of the constant region of  $\mu$  heavy chain. Immunoglobulin haplotype analysis in these families indicated that they shared an ancestor (Lopez et al., 2002). A premature stop codon at codon 258 in exon 3 was seen in a child from Argentina. A frameshift mutation, a C insertion at codon 23 in exon 1 of  $\mu$  heavy chain, was reported by Schiff et al. (2000). Five different large deletions within the  $\mu$  heavy-chain locus have been described (Lopez et al., 2002; Milili et al., 2002). All of these deletions remove the D and J regions as well as the  $\mu$  constant-region gene.

There are several factors that make the  $\mu$  heavy-chain locus susceptible to mutation. During normal B cell development, the 1000 kb immunoglobulin heavy-chain locus undergoes chromosomal breakage and rearrangement associated with both VDJ joining and isotype switching. The nature of the DNA structures that permits these rearrangements, including a high frequency of repeated or highly homologous sequences, may make this region susceptible to unequal crossover in meiosis resulting in deletions. Deletions within the V region (Cook et al., 1994) and within the region encoding the constant-region genes (Olsson et al., 1993; Chen et al., 1995) are well recognized.

Normal functioning of the  $\mu$  heavy-chain protein requires the ability to interact with many proteins, including the surrogate light chains, the classic light chains, and the immunoglobulin-associated chains, Ig $\alpha$  and Ig $\beta$ . The  $\mu$  heavy chain expressed on the cell surface must transmit signals to the cell interior and it must interact with other cell surface proteins, including the CD19/CD21 complex. These interactions place structural constraints throughout the  $\mu$  heavy-chain molecule and suggest that mutations at many sites may destroy the ability of the  $\mu$  heavy chain to function in B cell differentiation.

### Detection of Mutations in the $\lambda_{5/14.1}$ Gene

Because mutations in  $\mu$  heavy chain and Btk did not account for all of the patients with agammaglobulinemia and absent B cells, we tested the hypothesis that defects in other components of the B cell or pre-B cell receptor complex might result in an XLA phenotype. The genes for the surrogate light chain,  $V_{preB}$  and  $\lambda_{5/14.1}$ , were particularly attractive gene candidates because they are B cell-specific (Sakaguchi and Melchers, 1986; Kudo and Melchers, 1987; Melchers et al., 1993), they are functionally required at exactly the same point in B cell differentiation as the rearranged  $\mu$  heavy chain, and, as a practical point, they are small genes and therefore relatively easy to analyze (Kudo and Melchers, 1987).

The proteins encoded by the  $V_{preB}$  and  $\lambda_{5/14.1}$  genes assemble to produce a complex very similar to the  $\lambda$  light chain. The amino-terminal portion of  $V_{preB}$  has high homology to the variable region of an immunoglobulin molecule, and the carboxy-

terminal portion of  $\lambda_{5/14.1}$  has homology to the J region and constant region of  $\lambda$  light chain (Sakaguchi and Melchers, 1986; Kudo and Melchers, 1987). These two proteins are noncovalently linked to each other (Kerr et al., 1989; Minegishi et al., 1999b) and covalently linked to the  $\mu$  heavy chain via a cysteine residue in the carboxy-terminal portion of  $\lambda_{5/14.1}$  (Pillai and Baltimore, 1987; Kerr et al., 1989). Together,  $V_{preB}$  and  $\lambda_{5/14.1}$  form a surrogate light chain that escorts the rearranged  $\mu$  heavy chain to the cell surface prior to the rearrangement of the conventional light-chain genes. This allows the B cell precursor to test the integrity of the rearranged  $\mu$  heavy chain before investing in extensive proliferation or additional gene rearrangements.

To screen for mutations in the  $V_{preB}$  and  $\lambda_{5/14.1}$  genes, both of which are located within the  $\lambda$  light-chain locus at chromosome 22q11.2 (Erikson et al., 1981; Bossy et al., 1991; Bauer et al., 1993), polymerase chain reaction (PCR) primers were designed to flank the two exons of  $V_{preB}$  and the three exons of  $\lambda_{5/14.1}$ . Because there are two  $\lambda_5$  pseudogenes that have over 95% homology with exons 2 and 3 of  $\lambda_{5/14.1}$ , care was taken to develop primers for exon 2 that would amplify only the functional gene, and the PCR product for exon 3 was digested with BstUI, an enzyme that would be expected to cleave the functional sequence but not the sequence from the pseudogenes (Minegishi et al., 1998). The PCR products were separated on a nondenaturing gel and analyzed by SSCP. DNA from one patient, a 5-year-old boy with the clinical signs and symptoms of sporadic XLA, demonstrated both normal and abnormal bands for exon 1 and exon 3 of  $\lambda_{5/14.1}$  (Minegishi et al., 1998). Family studies and sequence analysis showed that the abnormality in exon 1, which was derived from the maternal allele, was due to a C-to-T transition in codon 22, resulting in the substitution of a premature stop codon for the wild-type glutamine. The alterations in exon 3, from the paternal allele, were caused by 3 base pair substitutions in codons 131, 140, and 142. The first two substitutions would not be expected to alter the coding sequence; however, the C-to-T transition at nucleotide 425 would be predicted to replace the invariant proline at codon 142 with a leucine. Protein-folding studies demonstrated that this alteration resulted in an inability of the  $\lambda_{5/14.1}$  protein to fold properly (Minegishi et al., 1998).

Of interest, the three base pair substitutions in the paternal allele of  $\lambda_{5/14.1}$  are the same as those found at the corresponding site in exon 3 of the  $\lambda_{5/14.1}$  pseudogene 16.1, a finding suggesting that this mutation was the result of a gene conversion event (Minegishi et al., 1998). To determine whether the alterations represented a normal polymorphic variant, we used SSCP to analyze genomic DNA from normal controls. Although an allele identical to that seen in the patient was not seen in controls, the  $\lambda_{5/14.1}$  locus was found to be highly polymorphic. Thirteen variant alleles of  $\lambda_{5/14.1}$ , the majority of which could be attributed to gene conversion events, were found in 134 unrelated individuals (Conley et al., 1999). Nine of these variants resulted in amino acid substitutions. Although gene conversion is an unusual mechanism of mutation, some species use gene conversion to generate diversity in the variable region of immunoglobulin loci (Reynaud et al., 1987; Thompson, 1992). Immunoglobulin and immunoglobulin-like genes may be unusually susceptible to gene conversion events.

### Detection of Mutations in the Ig $\alpha$ Gene

The signal transduction molecules Ig $\alpha$  and Ig $\beta$  (also called CD79a and CD79b or mb-1 and B29) are essential components of the pre-B cell and B cell receptor complex (Hombach et al., 1990). Both molecules are B cell-specific proteins with structural similarities to the CD3 $\gamma$ ,  $\delta$ , and  $\epsilon$  chains in T cells. Both have

a single extracellular immunoglobulin domain, a transmembrane domain, and an intracytoplasmic domain containing an immunoreceptor tyrosine-based activation motif (ITAM) characterized by the sequence YXXL(X)<sub>7</sub>YXXL, in which *Y* represents tyrosine, *L* represents leucine, and *X* denotes any amino acid. Ig $\alpha$  and Ig $\beta$  form a covalently linked heterodimer that masks the hydrophilic transmembrane domain of  $\mu$  heavy chain and escorts it to the cell surface. When the B cell receptor is cross-linked, a protein in the src family phosphorylates the tyrosines in the ITAM motif, converting this sequence into a docking site for the downstream tyrosine kinase, Syk.

SSCP analysis of genomic DNA has been used to screen patients for mutations in Ig $\alpha$ , a 5 exon gene at chromosome 19q13.2 (Ha et al., 1994), and Ig $\beta$ , a 6 exon gene at chromosome 17q23 (Wood et al., 1993). Three patients with defects in Ig $\alpha$  have been identified. The first, a Turkish girl, was found to have a homozygous A-to-G substitution at the invariant -2 position of the splice acceptor site for exon 3 (Minegishi et al., 1999a). Reverse transcription PCR analysis of cDNA derived from this patient's bone marrow showed that the majority of Ig $\alpha$  transcripts deleted exon 3. Because exon 3 contains 119 base pairs, this change results in a frameshift mutation. A small number of transcripts used a cryptic splice acceptor site within exon 3, resulting in a 13-base pair deletion. Exon 3 of Ig $\alpha$  encodes for the transmembrane domain; therefore, these frameshift mutations can be considered functional null mutations. A different splice defect, a G-to-A substitution at the +1 position of the splice donor site for exon 2, was identified in another Turkish child (Wang et al., 2002). The third mutation, a premature stop codon due to a G-to-T substitution in codon 48 in exon 2 in Ig $\alpha$ , was identified in a Mexican child (M.E. Conley, unpublished results).

To determine if a null defect in Ig $\alpha$  results in a block in B cell differentiation before V-to-DJ recombination, we used primers that could amplify members of the largest human V<sub>H</sub> families, VH1, VH3, and VH4, to analyze cDNA from the bone marrow of the first Ig $\alpha$ -deficient patient and the patient with an amino acid substitution in the CH4 domain of  $\mu$  heavy chain. The PCR products were separated on a sequencing gel to allow discrimination of transcripts with CDR3 regions of varying length. Both patients had markedly decreased transcripts for rearranged  $\mu$  heavy chains compared to controls; however, the amount and the diversity of the transcripts were approximately equal in the two patients (Minegishi et al., 1999a). These findings suggest that both defects block B cell differentiation at the same stage of maturation.

### Detection of Mutations in the BLNK Gene

Cross-linking of the B cell receptor complex initiates a cascade of tyrosine phosphorylation events. One of the first proteins to be phosphorylated is a 456-amino acid adaptor protein referred to as BLNK (Fu and Chan, 1997; Fu et al., 1998; Goitsuka et al., 1998; Wienands et al., 1998) (also called SLP-65 and BASH), which has significant homology to SLP-76, a protein expressed in T cells, myeloid cells, and platelets (Jackman et al., 1995; Clements et al., 1998a). Once BLNK is phosphorylated by Syk, it acts as a scaffold to assemble the downstream targets of B cell receptor-mediated activation including Grb2, Vav, Nck, and PLC $\gamma$ 2.

Several observations suggested that mutations in BLNK might result in a selective defect in B cell development. First, expression of BLNK is limited to B cells and myeloid cells (Fu et al., 1998). Second, absence of BLNK in a chicken B cell line, DT40, like absence of Btk, results in defective calcium mobilization (Ishiai et al., 1999; Kurosaki, 1999). Third, mice that are

null for the T cell homolog of BLNK, SLP-76, fail to develop T cells (Clements et al., 1998b; Pivniouk et al., 1998).

To determine whether mutations in BLNK might cause immunodeficiency, the gene was mapped to chromosome 10q23.22 using fluorescence in situ hybridization (FISH) and the genomic organization was determined (Minegishi et al., 1999c). PCR primers flanking each of the 17 exons were used to screen genomic DNA from patients with B cell defects of unknown etiology. One patient, a 20-year-old male from Appalachia who was previously thought to have XLA, was found to have a homozygous alteration in the first exon and associated flanking regions of BLNK. Sequencing of this region demonstrated two noncontiguous base pair substitutions. The first alteration, a C-to-A substitution at the third base pair in codon 10, does not change the proline encoded at this position and would not be expected to have functional consequences. The second alteration, an A-to-T substitution, was seen at the conserved +3 position of the splice donor site of intron 1, 20 base pairs downstream from the alteration in codon 10 (Minegishi et al., 1999c). Neither of the two base pair alterations seen in the patient were found in 100 normal controls. Analysis of cDNA from the bone marrow of this patient demonstrated a complete absence of BLNK transcripts.

### B Cell Differentiation in Patients with Proven Autosomal Recessive Agammaglobulinemia

Although patients with XLA have markedly reduced numbers of B cells, a small number of B cells with an immature phenotype are usually present in the peripheral circulation (patients have 0.01%–0.50% CD19<sup>+</sup> lymphocytes compared to 5%–20% in controls) in patients less than 15 years of age (Conley, 1985; Nomura et al., 2000). Older patients with XLA are less likely to have detectable B cells. Analysis of six patients with mutations in  $\mu$  heavy chain, or Ig $\alpha$ , all of whom were less than 15 years old at the time of the study, showed that these patients had less than 0.01% B cells in the blood (Yel et al., 1996; Minegishi et al., 1999a). This suggests a complete block in B cell development early in the B cell lineage in these patients. The patient with mutations in the  $\lambda_{5/14.1}$  gene has consistently had a small number of B cells (0.06%) in the peripheral circulation (Minegishi et al., 1998). The profound decrease in B cell numbers and antibody deficiency in the  $\lambda_{5/14.1}$ -deficient patient contrasts with findings in mice that fail to express  $\lambda_5$ . These mice have approximately 20% of the normal numbers of B cells by 4 months of age and they are able to make antibody to both T-dependent and T-independent antigens (Kitamura et al., 1992). The 20-year-old patient with BLNK deficiency was studied in parallel with an age-matched patient with XLA. There were fewer than 0.01% B cells in the peripheral circulation in either patient.

To compare the point in B cell differentiation at which the block occurs in patients with mutations in the genes for Btk,  $\mu$  heavy chain,  $\lambda_{5/14.1}$ , Ig $\alpha$ , or BLNK, we analyzed bone marrow samples from patients with each defect (Fig. 22.3) (Yel et al., 1996; Minegishi et al., 1998, 1999a, 1999c). In normal bone marrow, the earliest B cell precursors are identified by coexpression of surface CD34 and CD19 and cytoplasmic expression of terminal deoxynucleotidyl transferase (TdT) and RAG (Campana et al., 1990; Billips et al., 1995). At this stage in differentiation, the immunoglobulin genes are undergoing the first step in gene rearrangement, DJ joining. These pro-B cells give rise to a population of pre-B cells that are positive for CD19 but they have lost expression of CD34, TdT, and RAG. They have completed immunoglobulin heavy-chain gene rearrangement by joining a

**Figure 22.3.** Bone marrow cells from a control and from patients with immunodeficiency were stained with antibodies to CD19, CD34, and human light chains. Cells stained for CD19 were analyzed for expression of CD34 and surface immunoglobulin. An equal number of CD19<sup>+</sup> cells were evaluated in each sample. Figure is from Conley et al. (2000b). V gene to the DJ segment and they express cytoplasmic  $\mu$ . In the normal individual, the ratio of pro-B cells to pre-B cells declines with age; however, there are usually 2 to 5 times more pre-B cells than pro-B cells (Campana et al., 1990; Nunez et al., 1996).
